Park's Textbook of

PREVENTIVE AND SOCIAL MEDICINE

K. PARK

BHANOT

23rd EDITION

The Book is dedicated to the revered memory of my husband

DR. JOHN EVERETT PARK

B.A., M.D., D.P.H., F.I.P.H.A., F.A.M.S.

the founder of this title

PREFACE

It is indeed gratifying that this book has seen twenty two successful editions and is now entering the twenty-third edition with a brand new look. This new edition is in keeping with the tradition of release of new editions at regular intervals, with the objective to match the pace of everchanging subject matter. The book has been thoroughly updated and revised.

The Chapter on Communicable Diseases now contains the new treatment guidelines released by WHO (2013) for HIV/AIDS and December 2014 guidelines for post-exposure prophylaxis of HIV and use of cotrimoxazole in HIV cases. New treatment and diagnostic directives (2013) against malaria by Government of India have been incorporated. WHO has issued updated guidance on definitions of cases and treatment of tuberculosis to accomodate diagnosis using Xpert, MIB/ RIF and other WHO endorsed molecular tests. These definitions now replace the 2006 definitions. Extensive work is going on in MDR-TB investigations and treatment in different situations, e.g., adult tubercular cases, paediatric cases, TB with HIV/AIDS, during pregnancy etc. These regimens have been covered in detail. Ebola Virus Disease has been included in re-emerging Diseases. Soil transmitted helminthiasis contains new matter.

Chapter on Health Programmes in India now contains new plans introduced in 2013 and 2014 i.e., National Health Mission, National Urban Health Mission, RMNCH+A strategy (2013), India Newborn Action Plan (2014) etc. The chapter also contains details about NACP–IV, latest on RNTCP, malaria and leprosy.

The other topics of interest are Global Hunger Index, the current situation about Millennium Development Goals, revised classification of adverse events following immunization, the new and updated matter about child and maternal mortality, Mission Indradhanush (launched on 25th December 2014), and many more. 12th Five Year Plan replaces the 11th Plan.

In conclusion, I wish to express my gratitude to all those undergraduate and postgraduate students whose comments and encouragement has helped me to keep the book upto-date.

Lastly, I extend my appreciation to Mr. Brij Mohan Bhanot for the care bestowed in publication of this book.

CONTENTS

1 Man and Medicine : Towards Health for All

"Those who fail to read history are destined to suffer the repetition of its mistakes"

From time immemorial man has been interested in trying to control disease. The medicine man, the priest, the herbalist and the magician, all undertook in various ways to cure man's disease and/or to bring relief to the sick. In an almost complete absence of scientific medical knowledge, it would not be fair to say that the early practitioners of medicine contributed nothing to the alleviation of man's suffering from disease. Medical knowledge in fact has been derived, to a very great degree, from the intuitive and observational propositions and cumulative experiences gleaned from others. A history of medicine thus contributes a review of accomplishments and errors, false theories and misinformation and mistaken interpretations. It is also a study of the evolution of man and of human knowledge down the ages; of the biographies of eminent individuals who developed medicine; of the discoveries and inventions in different historical periods; and of the ever-changing concepts, goals and objectives of medicine. In the course of its evolution, which proceeded by stages, with advances and halts, medicine has drawn richly from the traditional cultures of which it is a part, and later from biological and natural sciences and more recently from social and behavioural sciences. Medicine is thus built on the best of the past. In the crucible of time, medicine has evolved itself into a social system heavily bureaucratized and politicized. The "explosion" of knowledge during the 20th century has made medicine more complex, and treatment more costly, but the benefits of modern medicine have not yet penetrated the social periphery in many countries. The glaring contrasts in the state of health between the developed and developing countries, between the rural and urban areas, and between the rich and poor have attracted worldwide criticism as "social injustice". The commitment of all countries, under the banner of the World Health Organization, is to wipe out the inequalities in the distribution of health resources and services, and attain the Millenium Development Goals. The goal of modern medicine is no longer merely treatment of sickness. The other and more important goals which have emerged are prevention of disease, promotion of health and improvement of the quality of life of individuals and groups or communities. In other words, the scope of medicine has considerably broadened during recent years. It is also regarded as an essential component of socio-economic development.

I. MEDICINE IN ANTIQUITY

In ancient times, health and illness were interpreted in a cosmological and anthropological perspective. Medicine was dominated by magical and religious beliefs which were an integral part of ancient cultures and civilizations. Henry Siegerist, the medical historian has stated that every culture had developed a system of medicine, and medical history is but one aspect of the history of culture *(1)*. Dubos goes one step further and says that ancient medicine was the mother of sciences and played a large role in the integration of early cultures *(2)*. Since there is an organic relationship between medicine and human advancement, any account of medicine at a given period should be viewed against the civilization and human advancement at that time, i.e. philosophy, religion, economic conditions, form of government, education, science and aspirations of the people.

Primitive medicine

It has been truly said that medicine was conceived in sympathy and born out of necessity; and that the first doctor was the first man, and the first woman, the first nurse. The prehistoric man, motivated by feelings of sympathy and kindness, was always at the behest of his kindred, trying to provide relief, in times of sickness and suffering.

Since his knowledge was limited, the primitive man attributed disease, and in fact all human suffering and other calamities, to the wrath of gods, the invasion of body by "evil spirits" and the malevolent influence of stars and planets. The concept of disease in which the ancient man believed is known as the "supernatural theory of disease". As a logical sequence, the medicine he practised consisted in appeasing gods by prayers, rituals and sacrifices, driving out "evil spirits" from the human body by witchcraft and other crude means and using charms and amulets to protect himself against the influence of evil spirits. The administration of certain herbs or drugs whose effect is doubtful or nil, but hopefully harmless, may also be likened to a kind of magic ritual associated with the need to "do something". There is also evidence that prehistoric man improvised stone and flint instruments with which he performed circumcisions, amputations and trephining of skulls. It is thus obvious that medicine in the prehistoric times (about 5000 B.C.) was intermingled with superstition, religion, magic and witchcraft.

Primitive medicine is timeless. If we look around the world, we find that the rudiments of primitive medicine still persist in many parts of the world – in Asia, Africa, South America, Australia and the Pacific islands. The supernatural theory of disease in which the primitive man believed is as new as today. For example, in India, one may still hear the talk of curing snake bites by "mantras". Diseases such as leprosy are interpreted as being punishment for one's past

sins in some cultures. Although primitive man may be extinct, his progeny – the so-called "traditional healers" are found everywhere. They live close to the people and their treatments are based on various combinations of religion, magic and empiricism.

Indian medicine *(3)*

The medical systems that are truly Indian in origin and development are the Ayurveda and the Siddha systems. Ayurveda is practised throughout India, but the Siddha system is practised in the Tamil-speaking areas of South India. These systems differ very little both in theory and practice *(4)*. Ayurveda by definition implies the "knowledge of life" or the knowledge by which life may be prolonged. Its origin is traced far back to the Vedic times, about 5000 B.C. During this period, medical history was associated with mythological figures, sages and seers. Dhanvantari, the Hindu god of medicine is said to have been born as a result of the churning of the oceans during a 'tug of war' between gods and demons. According to some authorities, the medical knowledge in the Atharvaveda (one of the four Vedas) gradually developed into the science of Ayurveda.

In ancient India, the celebrated authorities in Ayurvedic medicine were Atreya, Charaka, Susruta and Vaghbhatt. Atreya (about 800 B.C.) is acknowledged as the first great Indian physician and teacher. He lived in the ancient university of Takshashila, about 20 miles west of modern Rawalpindi *(5)*. Ayurveda witnessed tremendous growth and development during the Buddhist times. King Ashoka (226 B.C.) and the other Buddhist kings patronized Ayurveda as State medicine and established schools of medicine and public hospitals. Charaka (200 A.D.), the most popular name in Ayurvedic medicine, was a court physician to the Buddhist king Kanishka. Based on the teachings of Atreya, Charaka compiled his famous treatise on medicine, the "Charaka Samhita". Charaka mentions some 500 drugs. The Indian snakeroot (rauwolfia) was employed for centuries by the Indian physicians, before *reserpine* was extracted from the root and found spectacularly effective in the treatment of hypertension.

Among the many distinguished names in Hindu medicine, that of Susruta, the "father of Indian surgery" stands out in prominence. He compiled the surgical knowledge of his time in his classic "Susruta Samhita". It is believed that this classic was compiled between 800 B.C. and 400 A.D. Though this work is mainly devoted to surgery, it also includes medicine, pathology, anatomy, midwifery, ophthalmology, hygiene and bedside manners. The early Indians set fractures, performed amputations, excised tumours, repaired hernias and excelled in cataract operations and plastic surgery *(6)*. It is stated that the British physicians learned the art of rhinoplasty from Indian surgeons in the days of East India Company *(7)*. However, during Buddhist times, Indian surgery suffered a setback because of the doctrine of *ahimsa* (non-violence).

Of significance in Ayurveda is the "tridosha theory of disease". The *doshas* or humors are: *vata* (wind), pitta (gall) and kapha (mucus). Disease was explained as a disturbance in the equilibrium of the three humors; when these were in perfect balance and harmony, a person is said to be healthy *(8)*. This theory of disease is strikingly similar to the "theory of four humors" in Greek medicine. Medical historians admit that there was free exchange of thought and experience between the Hindu, Arab, Persian, Greek and Jewish scholars. The Samhitas of Charaka and Susruta were translated into Persian and Arabic in about 800 A.D.

Hygiene was given an important place in ancient Indian medicine. The laws of Manu were a code of personal hygiene. Archaeological excavations at Mohenjo-daro and Harappa in the Indus valley uncovered cities of over two thousand years old which revealed rather advanced knowledge of sanitation, water supply and engineering. The golden age of Indian medicine was between 800 B.C. and 600 A.D. During the Moghul period and subsequent years, Ayurveda declined due to lack of State support.

Medical historians admit that Indian medicine has played in Asia the same role as the Greek medicine in the west, for it has spread in Indochina, Indonesia, Tibet, Central Asia, and as far as Japan, exactly as the Greek medicine has done in Europe and Arab countries *(7)*.

Mention must be made of the other indigenous systems of medicine namely Unani-Tibb and Homoeopathy, which are not of Indian origin. The Unani-Tibb system of medicine, whose origin is traced to the ancient Greek medicine, was introduced into India by the Muslim rulers about the 10th century A.D. By the 13th century, the Unani system of medicine was firmly entrenched in certain towns and cities notably Delhi, Aligarh, Lucknow and Hyderabad *(5)*. It enjoyed State support under successive Muslim rulers in India, till the advent of the British in the 18th century. Homoeopathy, which was propounded by Samuel Hahnemann (1755–1843) of Germany gained foothold in India during 1810 and 1839 *(9)*. It is a system of pharmaco-dynamics based on "treatment of disease by the use of small amounts of a drug that, in healthy persons, produces symptoms similar to those of the disease being treated" *(10)*. Homoeopathy is practised in several countries, but India claims to have the largest number of practitioners of this system in the world *(9)*.

The Indian systems of medicine including Unani-Tibb and Homoeopathy are very much alive in India even today. In fact, they have become part of Indian culture, and they continue to be an important source of medical relief to the rural population.

Chinese medicine

Chinese medicine claims to be the world's first organized body of medical knowledge dating back to 2700 B.C. *(11)*. It is based on two principles – the yang and the yin. The yang is believed to be an active masculine principle and the yin a negative feminine principle. The balance of these two opposing forces meant good health. Hygiene, dietetics, hydrotherapy, massage, drugs were all used by the Chinese physicians.

The Chinese were early pioneers of immunization. They practised variolation to prevent smallpox. To a Chinese, "the great doctor is one who treats not someone who is already ill but someone not yet ill". The Chinese have great faith in their traditional medicine, which is fully integrated with modern medicine. The Chinese system of "barefoot doctors" and accupuncture have attracted worldwide attention in recent years *(12)*.

Egyptian medicine

Egypt had one of the oldest civilizations in about 2000 B.C. A lot is known about ancient Egypt because they invented picture writing and recorded their doings on papyrus. In Egyptian times, the art of medicine was mingled with religion. Egyptian physicians were co-equals of priests, trained in schools within the temples. They often helped

priests care for the sick who were brought to the temples for treatment. There were no practical demonstrations in anatomy, for Egyptian religion enjoined strict preservation of the human body. Egyptian medicine reached its peak in the days of Imhotep (2800 B.C.) who was famous as a statesman, architect, builder of the step pyramid at Saqqarah and physician. The Egyptians worshipped many gods. Imhotep was considered both a doctor and divinity. Specialization prevailed in Egyptian times. There were eye doctors, head doctors and tooth doctors. All these doctors were officials paid by the State. Homer speaking of the doctors of the ancient world considered the Egyptians to be the "the best of all" *(13)*.

Egyptian medicine was far from primitive. They believed that disease was due to absorption from the intestine of harmful substances which gave rise to putrefaction of blood and formation of pus. They believed that the pulse was "the speech of the heart". Diseases were treated with cathartics, enema, blood-letting and a wide range of drugs. The best known medical manuscripts belonging to the Egyptian times are the Edwin Smith papyrus (3000–2500 B.C.), and the Ebers papyrus (1150 B.C.). The Edwin Smith papyrus, the oldest treatise on surgery, accurately describes partial paralysis following cerebral lesions in skull fractures. The Ebers papyrus which was found with a mummy on the banks of the Nile, is a unique record of some 800 prescriptions based on some 700 drugs. Castor oil, tannic acid, opium, turpentine, gentian, senna, minerals and root drugs were all used by the Egyptian physicians. A great number of diseases are reported in the papyri such as worms, eye diseases, diabetes, rheumatism, polio and schistosomiasis. Unfortunately, these ailments are still present in modern Egypt *(7)*.

In the realm of public health also, the Egyptians excelled. They built planned cities, public baths and underground drains which even the modern might envy. They had also some knowledge of inoculation against smallpox, the value of mosquito nets and the association of plague with rats. Their god of health was Horus. Egyptian medicine occupied a dominant place in the ancient world for about 2,500 years when it was replaced by Greek medicine.

Mesopotamian medicine

Contemporary with ancient Egyptian civilization, there existed another civilization in the land which lies between the Euphrates and Tigris rivers, Mesopotamia (now part of Iraq), often called the "Cradle of Civilization", as long as 6,000 years ago.

In ancient Mesopotamia, the basic concepts of medicine were religious, and taught and practised by herb doctors, knife doctors and spell doctors – a classification that roughly parallels our own internists, surgeons and psychiatrists. Mesopotamia was the cradle of magic and necromancy. Medical students were busy in classifying "demons", the causes of diseases. Geomancy, the interpretation of dreams, and hepatoscopic divination (the liver was considered the seat of life) are characteristic of their medical lore. Sumerians, Babylonians and Assyrians were the authors of a medical astrology which flourished in the whole of Eurasia. Prescriptions were written on tablets, in cuneiform writing. The oldest medical prescription comes to us from Mesopotamia, dating back to 2100 B.C.

Hammurabi, a great king of Babylon who lived around 2000 B.C. formulated a set of drastic laws known as the Code of Hammurabi that governed the conduct of physicians and provided for health practices *(14)*. Doctors whose proposed therapy proved wrong, ran the risk of being killed. Laws relating to medical practice, including fees payable to physicians for satisfactory services and penalties for harmful therapy are contained in the Babylonian Code of Hammurabi, the very first codification of medical practice. While the code of Hammurabi reflected a high degree of social organization, the medicine of his time was devoid of any scientific foundation.

Greek medicine

The classic period of Greek medicine was the year 460–136 B.C. The Greeks enjoyed the reputation – the civilizers of the ancient world. They taught men to think in terms of 'why' and 'how'. An early leader in Greek medicine was Aesculapius (1200 B.C.). Aesculapius bore two daughters – Hygiea and Panacea. The medical historian, Douglas Guthrie *(17)* has reminded us of the legend that Hygiea was worshipped as the goddess of health, and Panacea as the goddess of medicine. Panacea and Hygiea gave rise to dynasties of healers (curative medicine) and hygienists (preventive medicine) with different philosophies. Thus the dichotomy between curative medicine and preventive medicine began early and we know it remains true today. Hygiea (prevention) is at present fashionable among the intellectuals; but Panacea (cure) gets the cash. Aesculapius is still cherished in medical circles – his staff, entwined by a serpent, continues to be the symbol of medicine.

By far the greatest physician in Greek medicine was Hippocrates (460–370 B.C.) who is often called the "Father of Medicine". He was born on the little island of Cos, in the Aegean sea, about 460 B.C. He studied and classified diseases based on observation and reasoning. He challenged the tradition of magic in medicine, and initiated a radically new approach to medicine i.e., application of clinical methods in medicine. Hippocrate's lectures and writings, as compiled later by Alexandrian scholars into the "Corpus Hippocraticum", encompassed all branches of medicine. This 72 volume work contains the first scientific clinical case histories. Some of the sayings of Hippocrates later became favourites with physicians, such as "Life is short, the art (of medicine) long, opportunity fleeting, experience treacherous and judgement difficult", and "where there is love for mankind, there is love for the art of healing". His famous oath, the "Hippocratic oath" has become the keystone of medical ethics. It sets a high moral standard for the medical profession and demands absolute integrity of doctors. Hippocrates will always be regarded as one of the masters of the medical art.

Hippocrates was also an epidemiologist. Since he distinguished between diseases which were epidemic and those which were endemic, he was, in fact, the first true epidemiologist. He was constantly seeking the causes of disease. He studied such things as climate, water, clothing diet, habits of eating and drinking and the effect they had in producing disease. His book "Airs, Water and Places" is considered a treatise on social medicine and hygiene. The Hippocratic concept of health and disease stressed the relation between man and his environment.

In short, the Greeks gave a new direction to medical thought. They rejected the supernatural theory of disease and looked upon disease as a natural process, not a visitation from a god of immolation. The Greeks believed that matter was made up of four elements – earth, air, fire and water. These elements had the corresponding qualities of being cold, dry, hot and moist and were represented in the body by the four humors – phlegm, yellow bile, blood

and black bile – similar to the "tridosha theory" in Ayurveda. The Greeks postulated that health prevailed when the four humors were in equilibrium and when the balance was disturbed, disease was the result. The human body was assumed to have powers of restoration of humoral equilibrium, and it was the physician's primary role to assist in this healing process. While the humoral theory of Hippocrates was based on incorrect foundations, the concept of the innate capacity of the body of responding to disturbances in the equilibrium that constitutes health is highly relevant to modern medicine *(15)*.

Outstanding amongst post-Hippocratic medical centres was Alexandria's huge museum, the first University in the world which sheltered a library containing over 70,000 books. To this house of learning came eminent men. Between 300 B.C. and 30 B.C., thousands of pupils matriculated in the school of Alexandria, which replaced Athens as the world's centre of learning. In short, the Hippocratic school inspired in turn the Alexandria school, and the Arabo-Persian medicine. The Hippocratic school changed the destiny of medicine by separating it from magic and raising it to the status of a science. They had scientific method, although not scientific knowledge. The glorious Greek civilization fell into decay and was succeeded by the Roman civilization.

Roman medicine

By the first Century B.C., the centre of civilization shifted to Rome. The Romans borrowed their medicine largely from the Greeks whom they had conquered. While the politics of the world became Roman, medicine remained Greek. In the political philosophy of the Romans, the State and not the individual was supreme.

The Romans were a more practical-minded people than the Greeks. They had a keen sense of sanitation. Public health was born in Rome with the development of baths, sewers and aqueducts. The Romans made fine roads throughout their empire, brought pure water to all their cities through aqueducts, drained marshes to combat malaria, built sewerage systems and established hospitals for the sick.

An outstanding figure among Roman medical teachers was Galen (130–205 A.D.) who was born in the Greek city of Pergamon in Asia Minor (now Turkey). He was physician to the Roman emperor, Marcus Aurelius. His important contributions were in the field of comparative anatomy and experimental physiology. Galen was far ahead of his time in his views about health and disease. About health he stated: "Since both in importance and in time, health precedes disease, so we ought to consider first how health may be preserved, and then how one may best cure disease" *(16)*. About disease, Galen observed that disease is due to three factors – predisposing, exciting and environmental factors, a truly modern idea. The doctrines of Hippocrates and Galen were often in conflict since their approaches were so different – one is synthetic, the other analytic. The author of some 500 treatises on medical subjects, Galen was literally a "medical dictator" in his time, and also for a long time thereafter. His writings influenced European medicine. They were accepted as standard textbooks in medicine for 14 centuries, till his teachings and views were challenged by the anatomist, Vesalius in 1543, and the physiologist, William Harvey in 1628, almost 1500 years after his death.

Middle ages

The period between 500 and 1500 A.D. is generally known as "Middle Ages". With the fall of the Roman empire, the medical schools established in Roman times also disappeared. Europe was ravaged by disease and pestilence: plague, smallpox, leprosy and tuberculosis. The practice of medicine reverted back to primitive medicine dominated by superstition and dogma. Rejection of the body and glorification of the spirit became the accepted pattern of behaviour. It was regarded as immoral to see one's body; consequently, people seldom bathed. Dissection of the human body was prohibited. Consequently there was no progress of medicine. The medieval period is therefore called the "Dark Ages of Medicine" – a time of great strife, of socio-political change, of regression and progression *(7)*.

When Europe was passing through the Dark Ages, the Arabs stole a march over the rest of the civilization. They translated the Graeco-Roman medical literature into Arabic and helped preserve the ancient knowledge. Borrowing largely from the Greeks and Romans, they developed their own system of medicine known as the Unani system of medicine. They founded schools of medicine and hospitals in Baghdad, Damascus, Cairo and other Muslim capitals. The Arabs lit a brilliant torch from Greecian lamps, said Osler. Leaders in Arabic medicine were the Persians, Abu Bécr (865–925) also known as Rhazes; and Ibn Sina (980–1037) known as Avicenna to the western world. Rhazes was a director of a large hospital in Baghdad and a court physician as well. Noted for keen observation and inventiveness, he was the first to observe pupillary reaction to light; to use mercurial purgatives; and to publish the first known book on Children's diseases *(7)*. However, the work most highly regarded today is his book on smallpox and measles which he distinguished clinically. Avicenna was an intellectual prodigy. He compiled a 21 volume encyclopaedia, the "Canon of Medicine", which was to leave its mark on medical theory and practice. He was responsible for elevating Islamic medicine to its zenith in the middle ages. The greatest contribution of Arabs, in general, was in the field of pharmacology. Seeking the "elixir of life", they developed pharmaceutical chemistry, introducing a large number of drugs, herbal and chemical. Pioneers in pharmacology, they invented the art of writing prescriptions, an art inherited by our modern pharmacists. They introduced a wide range of syrups, oils, poultices, plasters, pills, powders, alcoholates and aromatic waters. The words drug, alcohol, syrup and sugar are all Arabian *(17)*. The golden age of Arabic medicine was between 800–1300 A.D.

During the turbulent middle ages, Christianity exerted a wholesome influence. The spread of Christianity led to the establishment of hospitals. Early medieval hospitals rarely specialized in treatment of the sick. Usually the sick were received for the purpose of supplying their bodily wants and catering to their spiritual needs. The first hospital on record in England was built in York in 937 A.D. With the growth of medicine, a chain of hospitals sprang up from Persia to Spain– there were more than 60 in Baghdad and 33 in Cairo. Some hospitals, like Cairo's Al Mansur had separate departments for various diseases, wards for both sexes, fountains to cool fever patients, libraries, musicians and story tellers for the sleepless.

During the middle ages, religious institutions known as "monasteries" headed by monks, saints and abbotts also came up. These monasteries admitted men and women from all ranks including kings and queens. They not only helped preserve the ancient knowledge but also rendered active medical and nursing care to the sick.

II. DAWN OF SCIENTIFIC MEDICINE

The period following 1500 A.D. was marked by revolutions – political, industrial, religious and medical. Political revolutions took place in France and America, people claiming their just rights. The industrial revolution in the West brought great benefits leading to an improvement in the standard of living among people. With advancing degrees of civilization, medicine also evolved.

Revival of medicine

For many historians, the revival of medicine encompasses the period from 1453–1600 A.D. It was an age of individual scientific endeavour. The distinguished personalities during this period were: Paracelsus (1493–1541) who revived medicine. He was born at a time "when Europe stretched her limbs after a sleep of a thousand years in a bed of darkness". Labelled genius by some and quack by others, Swiss-born Paracelsus publicly burnt the works of Galen and Avicenna and attacked superstition and dogma and helped turn medicine towards rational research. Fracastorius (1483–1553), an Italian physician enunciated the "theory of contagion". He envisaged the transfer of infection *via* minute invisible particles and explained the cause of epidemics. Fracastorius recognized that syphilis was transmitted from person to person during sexual relations. He became the founder of epidemiology. Andreas Vasalius (1514–1564) of Brussels did lot of dissections on the human body and demonstrated some of Galen's errors. He raised the study of anatomy to a science, and has been called "the first man of modern science". Vesalius' great work Fabrica became a classic text in medical education. What Vesalius did for anatomy, Ambroise Pare (1510–1590), a French Army surgeon did for surgery and earned the title, "father of surgery". Pare advanced the art of surgery, but John Hunter (1728–1793) taught the science of it. In 1540, the United Company of Barber Surgeons was established in England, which later became the Royal College of Surgeons. Another great name in clinical medicine is that of Thomas Sydenham (1624–1689), the English Hippocrates who set the example of the true clinical method. He made a differential diagnosis of scarlet fever, malaria, dysentery and cholera. Sydenham is also regarded as the first distinguished epidemiologist.

The 17th and 18th centuries were full of even more exciting discoveries, e.g., Harvey's discovery of the circulation of blood (1628), Leeuwenhoek's microscope (1670) and Jenner's vaccination against smallpox (1796). However, the progress in medicine as well as surgery, during the 19th century would not have been possible but for Morgagni (1682–1771) who founded a new branch of medical science, pathologic anatomy.

Sanitary awakening

Another historic milestone in the evolution of medicine is the "great sanitary awakening" which took place in England in the mid-nineteenth century and gradually spread to other countries. It had a tremendous impact in modifying the behaviour of people and ushering an era of public health. The industrial revolution of the 18th century sparked off numerous problems – creation of slums, overcrowding with all its ill-effects, accumulation of filth in cities and towns, high sickness and death rates especially among women and children, infectious diseases like tuberculosis, industrial and social problems – which deteriorated the health of the people to the lowest ebb. The mean age at death in London was reported to be 44 years for the gentry and professionals, and 22 years for the working class, in 1842 *(14)*. Add to this, the frequent visitations of cholera compounded the misery of the people. The great cholera epidemic of 1832 led Edwin Chadwick (1800–1890), a lawyer in England to investigate the health of the inhabitants of the large towns with a view to improve the conditions under which they lived *(18)*. Chadwick's report on "The Sanitary Conditions of the Labouring Population in Great Britain", a landmark in the history of public health, set London and other cities slowly on the way to improve housing and working conditions. Chadwick's report focussed the attention of the people and government on the urgent need to improve public health. Filth was recognized as man's greatest enemy and with this began an anti-filth crusade, the "great sanitary awakening" which led to the enactment of the Public Health Act of 1848 in England. A new thinking began to take shape i.e., the State has a direct responsibility for the health of the people.

Rise of public health

The above events led to the birth of public health concept in England around 1840. Earlier, Johanna Peter Frank (1745–1821) a health philosopher of his time, conceived public health as good health laws enforced by the police and enunciated the principle that the State is responsible for the health of its people. The Public Health Act of 1848 was a fulfilment of his dream about the State's responsibility for the health of its people.

Cholera which is often called the "father of public health" appeared time and again in the western world during the 19th century. An English epidemiologist, John Snow, studied the epidemiology of cholera in London from 1848 to 1854 and established the role of polluted drinking water in the spread of cholera. In 1856, William Budd, another pioneer, by careful observations of an outbreak of typhoid fever in the rural north of England concluded that the spread was by drinking water, not by miasma and sewer gas. These two discoveries were all the more remarkable when one considers that the causative agents of cholera and typhoid fever were not identified. Then came the demand from people for clean water. At that time the Thames was both a source of drinking water and the depository for sewage. A comprehensive piece of legislation was brought into force in England, the Public Health Act of 1875 for the control of man's physical environment. The torch was already lit by Chadwick, but the man who was actually responsible more than any other for sanitary reforms was Sir John Simon (1816–1904), the first medical officer of health of London. He built up a system of public health in England which became the admiration of the rest of the world *(18)*. This early phase of public health (1880–1920) is often called the "disease control phase". Efforts were directed entirely towards general cleanliness, garbage and refuse disposal. Quarantine conventions were held to contain disease.

The development of the public health movement in Amercia follows closely the English pattern. In 1850, Lemuel Shattuck (1793–1859), a bookseller and publisher, published his report on the health conditions in Massachusetts. Like Chadwick's report it stirred the conscience of the American people to the improvement of public health. France, Spain, Australia, Germany, Italy, Belgium and the Scandinavian countries all developed their public health. By the beginning of the 20th century, the broad foundations of public health – clean water, clean surroundings, wholesome condition of houses, control of offensive trades, etc were laid in all the countries of the

western world. After the First World War, there were three particular newcomers to the public health scene – Yugoslavia, Turkey and Russia *(19)*. These three countries in 1920 presented the typical picture of the underdeveloped world. Today they are quite advanced in public health.

While public health made rapid strides in the western world, its progress has been slow in the developing countries such as India where the main health problems continue to be those faced by the western world 100 years ago. The establishment of the WHO providing a Health Charter for all people provided a great fillip to the public health movement in these countries.

Germ theory of disease

For long, man was groping in darkness about the causation of disease. Several theories were advanced from time to time to explain disease causation such as the supernatural theory of disease, the theory of humors by Greeks and Indians, the theory of contagion, the miasmatic theory which attributed disease to noxious air and vapours, the theory of spontaneous generation, etc. The breakthrough came in 1860, when the French bacteriologist Louis Pasteur (1822–1895) demonstrated the presence of bacteria in air. He disproved the theory of "spontaneous generation". In 1873, Pasteur advanced the "germ theory of disease". In 1877, Robert Koch (1843–1910) showed that anthrax was caused by a bacteria. The discoveries of Pasteur and Koch confirmed the germ theory of disease. It was the golden age of bacteriology. Microbe after microbe was discovered in quick succession – gonococcus in 1847; typhoid bacillus, pneumococcus in 1880; tubercle bacillus in 1882; cholera vibrio in 1883; diphtheria bacillus in 1884, and so on. These discoveries and a host of others at the turn of the century marked a turning point in our aetiological concepts. All attention was focussed on microbes and their role in disease causation. The germ theory of disease came to the forefront, supplanting the earlier theories of disease causation. Medicine finally shed the rags of dogma and superstition and put on the robes of scientific knowledge.

Birth of preventive medicine

Preventive medicine really dates back to the 18th century. It developed as a branch of medicine distinct from public health. Curiously, it came into existence even before the causative agents of disease were known. James Lind (1716–1794), a naval surgeon advocated the intake of fresh fruit and vegetables for the prevention of scurvy in 1753. Edward Jenner (1749–1823) of Great Britain, a pupil of John Hunter, discovered vaccination against smallpox in 1796. These two discoveries marked the beginning of a new era, the era of disease prevention by specific measures.

Preventive medicine got a firm foundation only after the discovery of causative agents of disease and the establishment of the germ theory of disease. The latter part of the 19th century was marked by such discoveries in preventive medicine as Pasteur's anti-rabies treatment (1883), cholera vaccine (1892), diphtheria antitoxin (1894), anti-typhoid vaccine (1898), antiseptics and disinfectants (1827–1912), etc. A further advance was the elucidation of the modes of disease transmission. For example, in 1896, Bruce, a British Army surgeon, demonstrated that the African sleeping sickness was transmitted by tsetse fly. In 1898, Ross demonstrated that malaria was transmitted by the Anopheles. In 1900, Walter Reed and his colleagues demonstrated that yellow fever was transmitted by the Aedes mosquito. With the knowledge derived from bacteriology, it became possible to control disease by specific measures such as blocking the channels of transmission, e.g., quarantine, water purification, pasteurization of milk, protection of foods, proper disposal of sewage, destruction of insects and disinfection. The development of laboratory methods for the early detection of disease was a further advance. In its early years, preventive medicine was equated with the control of infectious diseases. The modern concepts of primary, secondary and tertiary prevention were not known.

III. MODERN MEDICINE

The dichotomy of medicine into two major branches namely curative medicine, and public health/preventive medicine was evident at the close of the 19th century. After 1900, medicine moved faster towards specialization, and a rational, scientific approach to disease. The pattern of disease began to change. With the control of acute infectious diseases, the so-called modern diseases such as cancer, diabetes, cardiovascular disease, mental illness and accidents came into prominence and have become the leading causes of death in industrialized countries. These diseases could not be explained on the basis of the germ theory of disease, nor treated with "magic bullets". The realization began to dawn that there are other factors or causes in the aetiology of diseases, namely social, economic, genetic, environmental and psychological factors which are equally important. Most of these factors are linked to man's lifestyle and behaviour. The germ theory of disease gave place to a newer concept of disease – "multifactorial causation". In fact, it was Pettenkofer of Munich (1819–1901) who first mooted the concept of multifactorial causation of disease but his ideas were lost in the bacteriological era. The concept of multifactorial causation was revived by epidemiologists who have contributed significantly to our present-day understanding of multifactorial causation of disease and "risk-factors" in the aetiology of disease. The developments in modern medicine may be reviewed broadly under the following heads:

1. Curative medicine

Although curative medicine is thousands of years old, modern medicine, as we know today, is hardly 100 years old. Its primary objective is the removal of disease from the patient (rather than from the mass). It employs various modalities to accomplish this objective, e.g., diagnostic techniques, treatment. Over the years, the tools of diagnosis have become refined, sophisticated and numerous; the armamentarium for treatment more specific and potent. In the middle of the 20th century a profound revolution was brought in "allopathic medicine" which has been defined as "treatment of disease by the use of a drug which produces a reaction that itself neutralizes the disease" *(10)*, by the introduction of antibacterial and antibiotic agents. These discoveries, if they were to be recorded, would fill volumes. Suffice it to say that curative medicine, over the years, has accumulated a vast body of scientific knowledge, technical skills, medicaments and machinery – highly organized – not merely to treat disease but to preserve life itself as far as it could be possible.

In reviewing the history of medicine during the past 100 years, one cannot fail to note the tremendous growth of specialization that has taken place in response to advances in medical technology due to changes in the nature and

distribution of health and disease pattern in the community, and to the changing emphasis placed by society upon age and sex groups. Some specialities have emerged, based on clearly defined skills such as surgery, radiology, and anaesthesia; some based on parts of the body such as ENT, ophthalmology, cardiology, gynaecology; and, some based on particular age or sex groups such as paediatrics, geriatrics and obstetrics. Again, within each speciality, there has been a growth of sub-specialities, as for example, neonatology, perinatology, paediatric cardiology, paediatric neurology and paediatric surgery – all in paediatrics. One wonders whether such microspecialization is needed.

Specialization has no doubt raised the standards of medical care, but it has escalated the cost of medical care and placed specialist medical care beyond the means of an average citizen, without outside aid or charity. It has infringed upon the basic tenets of socialism (i.e., the greatest good of the greatest number) and paved the way to varying degrees of social control over medicine. Specialization has also contributed to the decline of general practice and the isolation of medical practitioners at the periphery of the medical care system *(20)*.

2. Preventive medicine

Preventive medicine developed as a branch of medicine distinct from public health. By definition, preventive medicine is applied to "healthy" people, customarily by actions affecting large numbers or populations. Its primary objective is prevention of disease and promotion of health.

The early triumphs of preventive medicine were in the field of bacterial vaccines and antisera at the turn of the century which led to the conquest of a wide spectrum of specific diseases. Declines took place in the morbidity and mortality from diphtheria, tetanus, typhoid fever and others. Later, the introduction of tissue culture of viruses led to the development of anti-viral vaccines, e.g., polio vaccines (1955, 1960). The eradication of smallpox (the last case of smallpox occurred in Somalia in 1977) is one of the greatest triumphs of preventive medicine in recent times. The search for better and newer vaccines (e.g., against malaria, leprosy, syphilis and other parasitic diseases and even cancer) continues.

Preventive medicine did not confine itself to vaccination and quarantine. Discoveries in the field of nutrition have added a new dimension to preventive medicine. New strategies have been developed for combating specific deficiencies as for example, nutritional blindness and iodine deficiency disorders. The recognition of the role of vitamins, minerals, proteins and other nutrients, and more recently dietary fibre emphasize the nutrition component of preventive medicine.

Another glorious chapter in the history of preventive medicine is the discovery of synthetic insecticides such as DDT, HCH, malathion and others. They have brought about fundamental changes in the strategy in the control of vector-borne diseases (e.g., malaria, leishmaniasis, plague, rickettsial diseases) which have been among the most important world-wide health problems for many years. Despite insecticide resistance and environmental pollution mishaps (e.g., Bhopal tragedy in India in 1984), some of the chemical insecticides such as DDT still remain unchallenged in the control of disease.

The discovery of sulpha drugs, anti-malarials, antibiotics, anti-tubercular and anti-leprosy drugs have all enriched preventive medicine. Chemoprophylaxis and mass drug treatment have become important tools of preventive medicine. The pattern of disease in the community began to change with improved control of infectious diseases through both prevention and treatment, and people are now living for longer years, especially those in developing countries.

A new concept – concept of disease eradication – began to take shape. This concept found ready application in the eradication of smallpox. Eradication of certain other diseases (e.g., measles, tetanus, guineaworm and endemic goitre) are on the anvil.

Another notable development in the 20th century is the development of "screening" for the diagnosis of disease in its presymptomatic stage *(21)*. In the 1930s, the two most commonly used tests were the serologic blood test for syphilis, and the chest X-ray for tuberculosis. As the number of screening tests increased, the concept of screening for individual diseases entered the multiphasic epoch in early 1950s. In spite of the fact that the utility of screening has been increasingly debated in recent years, screening for disease among apparently healthy people has remained an important part of preventive medicine. An offshoot of the screening is screening for "risk-factors" of disease and identification of "high-risk groups". Since we do not have specific weapons against chronic diseases, screening and regular health–checkups have acquired an important place in the early detection of cancer, diabetes, rheumatism and cardiovascular disease, the so-called "diseases of civilization".

Preventive medicine is currently faced with the problem of "population explosion" in developing countries where population overgrowth is causing social, economic, political and environmental problems. This is another kind of prevention – prevention of a problem that demands a mass attack, if its benefits are to accrue in the present and succeeding generations. Consequently, research in human fertility and contraceptive technology has gained momentum. Genetic counselling is another aspect of the population problem that is receiving attention.

Preventive medicine has become a growing point in medicine *(21)*. Advances in the field of treatment in no way has diminished the need for preventive care nor its usefulness. Preventive measures are already being applied not only to the chronic, degenerative and hereditary diseases but also to the special problems of old age. In fact, as medical science advances, it will become more and more preventive medical practice in nature. The emergence of preventive paediatrics, geriatrics and preventive cardiology reflect newer trends in the scope of preventive medicine.

Scientific advances, improved living standards and fuller education of the public have opened up a number of new avenues to prevention. Three levels of prevention are now recognized: primary, intended to prevent disease among healthy people; secondary, directed towards those in whom the disease has already developed; and tertiary, to reduce the prevalence of chronic disability consequent to disease. Preventive medicine ranges far beyond the medical field in the narrow sense of the word. Besides communicable diseases, it is concerned with the environmental, social, economic and more general aspects of prevention. Modern preventive medicine has been defined as "the art and science of health promotion, disease prevention, disability limitation and rehabilitation". It implies a more personal encounter between the individual and health professional than public health. In sum, preventive medicine is a kind of anticipatory medicine *(22)*.

3. Social medicine

Social medicine has been primarily a European speciality. The seeds that medicine is a social science were sown late in the 19th century by pioneers such as Neumann (1847) and Virchow (1848). But their ideas were far too ahead of their time. The germ theory of disease and discoveries in microbiology checked the development of these ideas.

In 1911, the concept of social medicine was revived by Alfred Grotjahn (1869–1931) of Berlin who stressed the importance of social factors in the aetiology of disease, which he called "social pathology". Others called it geographical pathology and population pathology. In 1912 Rene Sand had founded the Belgian Social Medicine Association. Developments in the field of social sciences (e.g., sociology, psychology, anthropology) rediscovered that man is not only a biological animal, but also a social being, and disease has social causes, social consequences and social therapy. The ideas of social medicine spread to other countries. John Ryle and his group in England were influenced by these ideas and visualized social medicine as an evolution of medicine. They promoted the concept of social medicine in England. A Chair of social medicine was set up at Oxford in 1942 followed by similar others in other Universities in England.

Social medicine has varying meanings attached to its label. By derivation, social medicine is the study of man as a social being in his total environment. Its focus is on the health of the community as a whole. Professor Crew *(23)* had ably stated that social medicine stands on two pillars – medicine and sociology. Others stated that the maiden sociology married public health and became social medicine *(24)*. McKeown *(25)* has this to say: "In contemporary usage social medicine has two meanings, one broad and ill-defined, the other more restricted and precise. In the broad sense, social medicine is an expression of the humanitarian tradition in medicine and people read into it any interpretation consistent with their own aspirations and interests. Thus it may be identified with care of patients, prevention of disease, administration of medical services; indeed with almost any subject in the extensive field of health and welfare. But in the more restricted sense, social medicine is concerned with a body of knowledge embodied in epidemiology and the study of the medical needs or medical care of society". In short, social medicine is not a new branch of medicine but rather a new orientation of medicine to the changing needs of man and society. It emphasizes the strong relationship between medicine and social sciences. The pre-eminent concern of social medicine has unquestionably been the development of epidemiological methods and their application to the investigation of disease. It has entered into a productive relationship with social sciences and statistics to be able to elucidate the role of social factors in disease aetiology *(26)*. These developments represent a forceful bid for the expanding concept of medicine. However, social medicine was criticized because it was virtually isolated from the service world and confined mostly to academic study of health services and chronic disease *(27)*.

Changing concepts in public health

In the history of public health, four distinct phases may be demarcated:

a. Disease control phase (1880–1920)

Public health during the 19th century was largely a matter of sanitary legislation and sanitary reforms aimed at the control of man's physical environment, e.g., water supply, sewage disposal, etc. Clearly these measures were not aimed at the control of any specific disease, for want of the needed technical knowledge. However, these measures vastly improved the health of the people due to disease and death control.

b. Health promotional phase (1920–1960)

At the beginning of the 20th century, a new concept, the concept of "health promotion" began to take shape. It was realized that public health had neglected the citizen as an individual, and that the State had a direct responsibility for the health of the individual. Consequently, in addition to disease control activities, one more goal was added to public health, that is, health promotion of individuals. It was initiated as personal health services such as mother and child health services, school health services, industrial health services, mental health and rehabilitation services. Public health nursing was a direct offshoot of this concept. Public health departments began expanding their programmes towards health promotional activities. C.E.A. Winslow, one of the leading figures in the history of public health, in 1920, defined public health as "the science and art of preventing disease, prolonging life and promoting health and efficiency through organized community effort". This definition summarizes the philosophy of public health, which remains largely true even today.

Since the State had assumed direct responsibility for the health of the individual, two great movements were initiated for human development during the first half of the present century, namely (a) provision of "basic health services" through the medium of primary health centres and subcentres for rural and urban areas. The evolution of health centres is an important development in the history of public health *(28)*. The concept of the health centre was first mooted in 1920 by Lord Dawson in England. In 1931, the League of Nations Health Organization called for the establishment of health centres. The Bhore Committee (1946) in India had also recommended the establishment of health centres for providing integrated curative and preventive services. Many developing countries have given the highest priority to the establishment of health centres for providing basic health services. (b) The second great movement was the Community Development Programme to promote village development through the active participation of the whole community and on the initiative of the community. This programme tried to do too much too quickly with inadequate resources. It was a great opportunity lost, because it failed to survive. However, the establishment of primary health centres and subcentres provided the much-needed infrastructure of health services, especially in the rural areas *(29)*.

c. Social engineering phase (1960–1980)

With the advances in preventive medicine and practice of public health, the pattern of disease began to change in the developed world. Many of the acute illness problems have been brought under control. However, as old problems were solved, new health problems in the form of chronic diseases began to emerge, e.g., cancer, diabetes, cardiovascular diseases, alcoholism and drug addiction etc. especially in the affluent societies. These problems could not be tackled by the traditional approaches to public health such as isolation, immunization and disinfection nor could these be explained on the basis of the germ theory of disease. A new concept, the concept of "risk factors" as determinants of these diseases

came into existence. The consequences of these diseases, unlike the swift death brought by the acute infectious diseases, was to place a chronic burden on the society that created them. These problems brought new challenges to public health which needed reorientation more towards social objectives. Public health entered a new phase in the 1960s, described as the "social engineering" phase *(14)*. Social and behavioural aspects of disease and health were given a new priority. Public health moved into the preventive and rehabilitative aspects of chronic diseases and behavioural problems. In this process, the goals of public health and preventive medicine which had already considerable overlapping became identical, namely prevention of disease, promotion of health and prolongation of life. In short, although the term "public health" is still used, its original meaning has changed. In view of its changed meaning and scope, the term "community health" has been preferred by some leaders in public health. Community health incorporates services to the population at large as opposed to preventive or social medicine.

d. "Health for All" phase (1981–2000 A.D.)

As the centuries have unfolded, the glaring contrasts in the picture of health in the developed and developing countries came into a sharper focus, despite advances in medicine. Most people in the developed countries, and the elite of the developing countries, enjoy all the determinants of good health – adequate income, nutrition, education, sanitation, safe drinking water and comprehensive health care. In contrast, only 10 to 20 per cent of the population in developing countries enjoy ready access to health services of any kind *(30)*. Death claims 60–250 of every 1000 live births within the first year of life, and the life expectancy is 30 per cent lower than in the developed countries *(30)*. John Bryant in the introduction to his book: "Health and the Developing World" presented a gloomy picture and a challenge of inequalities in health by saying: "Large numbers of the world's people, perhaps more than half, have no access to health care at all, and for many of the rest, the care they receive does not answer the problems they have". The global conscience was stirred leading to a new awakening that the health gap between rich and poor within countries and between countries should be narrowed and ultimately eliminated. It was conceded that the neglected 80 per cent of the world's population too have an equal claim to health care, to protection from the killer diseases of childhood, to primary health care for mothers and children, to treatment for those ills that mankind has long ago learnt to control, if not to cure *(31)*. Against this background, in 1981, the members of the WHO pledged themselves to an ambitious target to provide "Health for All" by the year 2000, that is attainment of a level of health that will permit all people "to lead a socially and economically productive life" *(32)*. Currently public health, along with other medical sciences and other health-related sectors is engaged in this broad field of effort.

IV. MEDICAL REVOLUTION

State of the art

Medicine has moved from the organism to organ, and from the organ to the cell, and from the cell to molecular properties. The discovery of the biological role of nucleic acids, the uncovering of the genetic code and its role in regulating life processes are marvellous discoveries in recent years. Medicine has acquired a vast body of knowledge and has become highly technical. It has acquired new capabilities to modify and perhaps control the capacities and activities of men by direct intervention into and manipulation of their bodies and minds, viz. genetic counselling, genetic engineering, prenatal diagnosis of sex, prenatal diagnosis of genetic diseases, *in vitro* fertilization, the prospect of cloning (the asexual reproduction of unlimited number of genetically identical individuals from a single parent), organ transplantation, the use of artificial kidney machine, the development of an artificial heart, the practice of psychosurgery, etc. The data presented show that modern medicine has entered a new evolutionary stage with the promise of continued improvements in medical capabilities to preserve life, if not merely to solve problems of sickness.

Failure of medicine

Despite spectacular biomedical advances and massive expenditures, death rates in the developed countries have remained unchanged; and also life expectancy. Today, a great scepticism surrounds medical care *(33)*. Like so many other institutions in contemporary society medicine has come under heavy fire. Medicine, as practised today, has begun to be questioned and criticized. Some critics have even described modern medicine as a threat to health. Their arguments have been based on certain facts such as: (a) with increased medical costs has not come increased benefits in terms of health (b) despite spectacular advances in medicine, the threat posed by certain major diseases such as malaria, schistosomiasis, leprosy, filaria, trypanosomiasis and leishmaniasis either has not lessened or has actually increased (c) the expectation of life has remained low and infant and child mortality rates high in many developing countries, despite advances in medicine (d) historical epidemiological studies showed that significant improvements in longevity had been achieved through improved food supplies and sanitation long before the advent of modern drugs and high technology, *(34)*. (e) there is no equity in the distribution of health services, resulting in limited access to health care for large segments of the world's population, and (f) modern medicine is also attacked for its elitist orientation even in health systems adapted to overcome social disparities *(35)*.

High-technology medicine seems to be getting out of hand and leading health systems in the wrong direction i.e., away from the health promotion for the many and towards expensive treatment for the few. For example, in the developing countries, the tendency has been to follow the Western models of medical education and favour high cost, low coverage, elite-oriented health services. Not only is there an increasing concern about the cost and allocation of health resources, but the efficacy of modern medicine is fundamentally questioned from various points of view *(35)*. It has given rise to the notion that limits had been reached on the health impact of medical care and research *(36,37)*. This has been labelled as a "failure of success" *(38)*.

Social control of medicine

When Virchow wrote in 1849 that "Medicine is a social science and politics is medicine on a large scale", he anticipated probably the social (political) control of medicine. Indeed, as medicine advanced, it became a highly personalized and institutionalized service. This generated a feeling that medicine was not rendering its full service to humanity. As the cost of medical care increased, two kinds of medical care came into existence – one for the rich and the other for the poor. The gap was bridged to a small extent by

charitable and voluntary agencies providing free medical care to the poor. An attitude developed that charity was worthy of man and that the benefits of modern medicine should be available to all people. A solution was to be found – it was "socialization of medicine".

Social medicine should not be confused with state medicine or socialized medicine. State medicine implies provision of free medical service to the people at government expense. Socialized medicine envisages provision of medical service and professional education by the State as in state medicine, but the programme is operated and regulated by professional groups rather than by the government.

Germany led the way by instituting compulsory sickness insurance in 1883. Other countries followed suit – England in 1911, France in 1928 and so on. Great Britain nationalized its health services in 1946. A few other countries notably the socialist nations in Europe, New Zealand and Cuba took steps to socialize their health services. However, Russia was the first country to socialize medicine completely and to give its citizens a constitutional right to all health services. From a private ownership, medicine became a social institution, one more link in the chain of welfare institutions *(39)*.

Socialization is a noble idea. It eliminates the competition among physicians in search of clients. It ensures social equity, that is universal coverage by health services. Medical care becomes free for the patient, which is supported by the State. However, the varying degrees of social control over medicine, has resulted in a variety of health systems, each system having its own merits and demerits. It is now recognized that mere socialization was not sufficient to ensure utilization of health services. What is required is "community participation", which, as envisaged by WHO and UNICEF is "the process by which individuals and families assume responsibility for their own health and welfare and for those of the community, and develop the capacity to contribute to their and the community's development *(32)*. It also implies community participation in the planning, organization and management of their own health services. This is called simply "Health by the People" *(40)*. This is what Virchow had prophesied that medicine is nothing but politics on a large scale.

Family and community medicine

Way back in 1923, Dr. Francis Peabody, professor of medicine at Harvard, commented that specialization in medicine had already reached its apex and that modern medicine had fragmented the health care delivery system to too great a degree. He called for a rapid return of the general physician (family physician) who would give comprehensive and personalized care. In 1966, two reports (i.e., Millis Commission Report, Willard Committee Report) in United States made similar recommendations. In 1971, the American Academy of General Practice (which began in 1947) changed its name to "American Academy of Family Physicians" to place increased emphasis upon family-oriented health care and to gain academic acceptance for the new speciality.

The emergence of Family and Community Medicine represents a counterforce to the direction which medical science has taken during the past 20 years or so. The field of specialization of family and community medicine is neither an organ system nor a disease syndrome, but rather in both instances, a designation of social categories namely family and community. Family and community medicine overlap and strengthen each other.

Family medicine

The emergence of family medicine has been hailed as a rediscovery of the human, social and cultural aspects of health and disease, and of the recognition of family as a focal point of health care and the right place for integrating preventive, promotive and curative services. Family medicine has been defined as "a field of specialization in medicine which is neither disease nor organ oriented. It is family oriented medicine or health care centred on the family as the unit – from first contact to the ongoing care of chronic problems (from prevention to rehabilitation). When family medicine is applied to the care of patients and their families, it becomes the speciality of *family* practice. Family practice is a horizontal speciality, which, like paediatrics and internal medicine, shares large areas of content with other clinical disciplines. The speciality of family practice is specially designed to deliver "primary care" *(41)*.

Community medicine

Like family medicine, community medicine is a newcomer. It is the successor of what was previously known as public health, community health, preventive and social medicine. All these share common ground, i.e., prevention of disease and promotion of health. The appearance of community medicine has caused confusion. The Faculty of Community Medicine of the Royal College of Physicians has defined community medicine as "that speciality which deals with populations..... and comprises those doctors who try to measure the needs of the population, both sick and well, who plan and administer services to meet those needs, and those who are engaged in research and teaching in the field" *(27)*. Besides this, there are at least four other definitions of community medicine *(42)*. To make matters worse, a WHO study group *(43)* stated that since health problems vary from country to country, each country should formulate its own definition of community medicine in the light of its traditions, geography and resources. There is still confusion and conflict about roles, tasks and professional identities in the service as well as the academic worlds of community medicine *(27)*.

V. HEALTH CARE REVOLUTION

Background

It was recognized that in both developed and developing countries, the standard of health services the public expected was not being provided *(44)*. The services do not cover the whole population. There is lack of services in some areas and unnecessary duplication in others. A very high proportion of the population in many developing countries, and especially in rural areas does not have ready access to health services. The health services favoured only the privileged few and urban dwellers. Although there was the recognition that health is a fundamental human right, there is a denial of this right to millions of people who are caught in the vicious circle of poverty and illhealth. There are marked differences in health status between people in different countries as well as between different groups in the same country; the cost of health care is rising without much improvement in their quality. In short, there has been a growing dissatisfaction with the existing health services and a clear demand for better health care.

Health for All

The spate of new ideas and concepts, e.g., increasing importance given to social justice and equity, recognition of the crucial role of community participation, changing ideas about the nature of health and development, the importance of political will called for new approaches to make medicine in the service of humanity more effective.

Against the above background, the 30th World Health Assembly resolved in May 1977, that "the main social target of governments and WHO in the coming decades should be the attainment by all citizens of the world by the year 2000 of a level of health that will permit them to lead a socially and economically productive life." This culminated in the international objective of HEALTH FOR ALL by the year 2000 as the social goal of all governments.

The goal of Health for All has two perspectives. Viewed in the long-term context, it simply means the realization of the WHO's objective of "attainment by all peoples of the highest possible level of health". But, what is of immediate relevance is the meaning that, as a minimum, all people in all countries should have at least such a level of health that they are capable of working productively and of participating actively in the social life of the community in which they live.

Health for All means that health is to be brought within the reach of every one in a given community. It implies the removal of obstacles to health – that is to say, the elimination of malnutrition, ignorance, disease, contaminated water supply, unhygienic housing, etc. It depends on continued progress in medicine and public health.

Health for All was a holistic concept calling for efforts in agriculture, industry, education, housing and communications, just as much as in medicine and public health. The attainment of Health for All by 2000 A.D. was the central issue and official target of WHO and its member countries. It symbolized the determination of the countries of the world to provide an acceptable level of health to all people. Health for All has been described as a revolutionary concept and a historic movement – a movement in terms of its own evolutionary process.

Primary health care *(45)*

With increasing recognition of the failure of existing health services to provide health care, alternative ideas and methods to provide health care have been considered and tried *(40,46)*. Discussing these issues at the Joint WHO–UNICEF international conference in 1978 at Alma-Ata (USSR), the governments of 134 countries and many voluntary agencies called for a **revolutionary approach** to health care. Declaring that "The existing gross inequality in the health status of people particularly between developed and developing countries as well as within countries is politically, socially and economically unacceptable", the Alma-Ata conference called for acceptance of the WHO goal of Health for All by 2000 A.D. and proclaimed primary health care as way to achieving "Health for All".

Primary health care is a new approach to health care, which integrates at the community level all the factors required for improving the health status of the population. It consists of at least eight elements (see page 30) described as "essential health care". This presupposes services that are both simple and efficient with regard to cost, techniques, and organization, that are readily accessible to those concerned, and that contribute to improving the living conditions of individuals, families and the community as a whole. Primary health care is available to all people at the first level of health care. It is based on principles of equity, wider coverage, individual and community involvement and intersectoral coordination. Viewed in these terms, primary health care is a radical departure from the conventional health care systems of the past. While it integrates promotive, preventive and curative services, it is also conceived as an integral part of the country's plan for socio-economic development.

The Alma-Ata Declaration called on all governments to formulate national policies, strategies and plans of action to launch and sustain primary health care as part of a national health system. It is left to each country to innovate, according to its own circumstances to provide primary health care. This was followed by the formulation and adoption of the **Global strategy** for Health for All by the 34th World Health Assembly in 1981. Primary health care got off to a good start in many countries with the theme "Health for All by 2000 A.D.". It presented a challenge so formidable that its implications boggle the bravest minds. The challenge brought us face-to-face with the Declaration of Alma-Ata.

Deprofessionalization of medicine

The practice of primary health care involves a good deal of "deprofessionalizaion" of medicine. Laymen have come to play a prominent role in the delivery of health care. While the physician still holds his unique position in the field of health care in general, the participation of a new cadre of health workers (e.g., community health workers, anganwadi workers, multipurpose workers, practitioners of indigenous medicine, social workers) with relatively little training and support have been considered and tried to provide health care. They now comprise part of the "health teams". The medical man can no longer restrict himself to his traditional role as diagnoser of ailments, prescriber of pills and potions, and exciser of lumps. He has acquired new roles – being an educator, case-finder, preventer, counsellor and an agent of social change.

The Millennium Development Goals

In September 2000, representatives from 189 countries met at the Millennium Summit in New York to adopt the United Nations Millennium Declaration. The leaders made specific commitments in seven areas : peace, security and disarmament; development and poverty eradication; protecting our common environment, human rights, democracy and good governance; protecting the vulnerable; meeting the special needs of Africa; and strengthening the United Nations. The Road Map established goals and targets to be reached by the year 2015 in each of seven areas. The goals in the area of development and poverty eradication are now widely referred to as *"Millennium Development Goals" (47, 48)*.

The Millennium Development Goals, place health at the heart of development and represent commitments by governments throughout the world to do more to reduce poverty and hunger, and to tackle ill-health, gender inequality, lack of education, access to clean water; and environmental degradation. Thus three of the eight goals are directly health related and all of other goals have important indirect effects on health; three of the 8 goals, 8 of the 18 targets required to achieve these goals, and 18 of the 48 indicators of progress, are health related.

Conclusion

Contemporary medicine is no longer solely an art and science for the diagnosis and treatment of diseases. It is also the science for the prevention of disease and the promotion of health. The scope of medicine has expanded during the last few decades to include not only health problems of individuals, but those of communities as well. This expansion of the scope of medicine has required a reformulation of its goals and objectives. Systems should integrate health promotion and disease prevention on the one hand, and treatment for acute illness and chronic care on the other. This should be done across all levels of the health care system, with the aim of delivering quality services equitably and efficiently to the whole population. The real progress in health depends vitally on stronger health system based on primary health care.

It is left to the posterity to review our errors and accomplishments. This is how medicine has evolved down the centuries. Medicine will continue to evolve so long as man's quest for better health continues.

2 Concept of Health and Disease

"Health is NOT mainly an issue of doctors, social services and hospitals. It is an issue of social justice."

CONCEPT OF HEALTH

Health is a common theme in most cultures. In fact, all communities have their concepts of health, as part of their culture. Among definitions still used, probably the oldest is that health is the "absence of disease". In some cultures, health and harmony are considered equivalent, harmony being defined as "being at peace with the self, the community, god and cosmos". The ancient Indians and Greeks shared this concept and attributed disease to disturbances in bodily equilibrium of what they called "humors".

Modern medicine is often accused for its preoccupation with the study of disease, and neglect of the study of health. Consequently, our ignorance about health continues to be profound, as for example, the determinants of health are not yet clear; the current definitions of health are elusive; and there is no single yardstick for measuring health. There is thus a great scope for the study of the "epidemiology" of health.

However, during the past few decades, there has been a reawakening that health is a fundamental human right and a worldwide social goal; that it is essential to the satisfaction of basic human needs and to an improved quality of life; and, that it is to be attained by all people. In 1977, the 30th World Health Assembly decided that the main social target of governments and WHO in the coming decades should be "the attainment by all citizens of the world by the year 2000 of a level of health that will permit them to lead a socially and economically productive life", for brevity, called "Health for All" *(1)*. With the adoption of health as an integral part of socio-economic development by the United Nations in 1979 *(2)*, health, while being an end in itself, has also become a major instrument of overall socio-economic development and the creation of a new social order.

CHANGING CONCEPTS

An understanding of health is the basis of all health care. Health is not perceived the same way by all members of a community including various professional groups (e.g., biomedical scientists, social science specialists, health administrators, ecologists, etc) giving rise to confusion about the concept of health. In a world of continuous change, new concepts are bound to emerge based on new patterns of thought. Health has evolved over the centuries as a concept from an individual concern to a worldwide social goal and encompasses the whole quality of life. A brief account of the changing concepts of health is given below:

1. Biomedical concept

Traditionally, health has been viewed as an "absence of disease", and if one was free from disease, then the person was considered healthy. This concept, known as the "biomedical concept" has the basis in the "germ theory of disease" which dominated medical thought at the turn of the 20th century. The medical profession viewed the human body as a machine, disease as a consequence of the breakdown of the machine and one of the doctor's task as repair of the machine *(3)*. Thus health, in this narrow view, became the ultimate goal of medicine.

The criticism that is levelled against the biomedical concept is that it has minimized the role of the environmental, social, psychological and cultural determinants of health. The biomedical model, for all its spectacular success in treating disease, was found inadequate to solve some of the major health problems of mankind (e.g., malnutrition, chronic diseases, accidents, drug abuse, mental illness, environmental pollution, population explosion) by elaborating the medical technologies. Developments in medical and social sciences led to the conclusion that the biomedical concept of health was inadequate.

2. Ecological concept

Deficiencies in the biomedical concept gave rise to other concepts. The ecologists put forward an attractive hypothesis which viewed health as a dynamic equilibrium between man and his environment, and disease a maladjustment of the human organism to environment. Dubos *(4)* defined health saying : "Health implies the relative absence of pain and discomfort and a continuous adaptation and adjustment to the environment to ensure optimal function". Human, ecological and cultural adaptations do determine not only the occurrence of disease but also the availability of food and the population explosion. The ecological concept raises two issues, viz. imperfect man and imperfect environment. History argues strongly that improvement in human adaptation to natural environments can lead to longer life expectancies and a better quality of life – even in the absence of modern health delivery services *(5)*.

3. Psychosocial concept

Contemporary developments in social sciences revealed that health is not only a biomedical phenomenon, but one which is influenced by social, psychological, cultural, economic and political factors of the people concerned *(5)*. These factors must be taken into consideration in defining and measuring health. Thus health is both a biological and social phenomenon.

4. Holistic concept

The holistic model is a synthesis of all the above concepts. It recognizes the strength of social, economic, political and environmental influences on health. It has been variously described as a unified or multidimensional process involving the well-being of the whole person in the context of his environment. This view corresponds to the view held by the ancients that health implies a sound mind, in a sound body, in a sound family, in a sound environment. The holistic approach implies that all sectors of society have an effect on health, in particular, agriculture, animal husbandry, food, industry, education, housing, public works, communications and other sectors *(6)*. The emphasis is on the promotion and protection of health.

DEFINITION OF HEALTH

"Health" is one of those terms which most people find it difficult to define, although they are confident of its meaning. Therefore, many definitions of health have been offered from time to time.

WHO definition

The widely accepted definition of health is that given by the World Health Organization (1948) in the preamble to its constitution, which is as follows :

> *"Health is a state of complete physical, mental and social well-being and not merely an absence of disease or infirmity"*

In recent years, this statement has been amplified to include the ability to lead a "socially and economically productive life" *(6)*.

The WHO definition of health has been criticized as being too broad. Some argue that health cannot be defined as a "state" at all, but must be seen as a process of continuous adjustment to the changing demands of living and of the changing meanings we give to life. It is a dynamic concept. It helps people live well, work well and enjoy themselves.

Inspite of the above limitations, the concept of health as defined by WHO is broad and positive in its implications; it sets out the standard, the standard of "positive" health. It symbolizes the aspirations of people and represents an overall objective or goal towards which nations should strive.

Operational definition of health

The WHO definition of health is not an "operational" definition, i.e., it does not lend itself to direct measurement. Studies of epidemiology of health have been hampered because of our inability to measure health and well-being directly. In this connection an "operational definition" has been devised by a WHO study group *(7)*. In this definition, the concept of health is viewed as being of two orders. In a broad sense, health can be seen as "a condition or quality of the human organism expressing the adequate functioning of the organism in given conditions, genetic or environmental".

In a narrow sense – one more useful for measuring purposes – health means: (a) there is no obvious evidence of disease, and that a person is functioning normally, i.e., conforming within normal limits of variation to the standards of health criteria generally accepted for one's age, sex, community, and geographic region; and (b) the several organs of the body are functioning adequately in themselves and in relation to one another, which implies a kind of equilibrium or homeostasis – a condition relatively stable but which may vary as human beings adapt to internal and external stimuli.

New philosophy of health

In recent years, we have acquired a new philosophy of health, which may be stated as below :

- health is a fundamental human right
- health is the essence of productive life, and not the result of ever increasing expenditure on medical care
- health is intersectoral
- health is an integral part of development
- health is central to the concept of quality of life
- health involves individuals, state and international responsibility
- health and its maintenance is a major social investment
- health is a worldwide social goal.

DIMENSIONS OF HEALTH

Health is multidimensional. The WHO definition envisages three specific dimensions – the physical, the mental and the social. Many more may be cited, viz. spiritual, emotional, vocational and political dimensions. As the knowledge base grows, the list may be expanding. Although these dimensions function and interact with one another, each has its own nature, and for descriptive purposes will be treated separately.

1. Physical dimension

The physical dimension of health is probably the easiest to understand. The state of physical health implies the notion of "perfect functioning" of the body. It conceptualizes health biologically as a state in which every cell and every organ is functioning at optimum capacity and in perfect harmony with the rest of the body. However, the term "optimum" is not definable.

The signs of physical health in an individual are: "a good complexion, a clean skin, bright eyes, lustrous hair with a body well clothed with firm flesh, not too fat, a sweet breath, a good appetite, sound sleep, regular activity of bowels and bladder and smooth, easy, coordinated bodily movements. All the organs of the body are of unexceptional size and function normally; all the special senses are intact; the resting pulse rate, blood pressure and exercise tolerance are all within the range of "normality" for the individual's age and sex. In the young and growing individual there is a steady gain in weight and in the future this weight remains more or less constant at a point about 5 lbs (2.3 kg) more or less than the individual's weight at the age of 25 years *(8)*. This state of normality has fairly wide limits. These limits are set by observation of a large number of "normal" people, who are free from evident disease.

Evaluation of physical health

Modern medicine has evolved tools and techniques which may be used in various combinations for the assessment of physical health. They include :

- self assessment of overall health
- inquiry into symptoms of ill-health and risk factors
- inquiry into medications
- inquiry into levels of activity (e.g., number of days of restricted activity within a specified time, degree of fitness)

- inquiry into use of medical services (e.g., the number of visits to a physician, number of hospitalizations) in the recent past
- standardized questionnaires for cardiovascular diseases
- standardized questionnaires for respiratory diseases
- clinical examination
- nutrition and dietary assessment, and
- biochemical and laboratory investigations.

At the community level, the state of health may be assessed by such indicators as death rate, infant mortality rate and expectation of life. Ideally, each piece of information should be individually useful and when combined should permit a more complete health profile of individuals and communities.

2. Mental dimension

Mental health is not mere absence of mental illness. Good mental health is the ability to respond to the many varied experiences of life with flexibility and a sense of purpose. More recently, mental health has been defined as "a state of balance between the individual and the surrounding world, a state of harmony between oneself and others, a coexistence between the realities of the self and that of other people and that of the environment" *(9)*.

Some decades ago, the mind and body were considered independent entities. However, researchers have discovered that psychological factors can induce all kinds of illness, not simply mental ones. They include conditions such as essential hypertension, peptic ulcer and bronchial asthma. Some major mental illnesses such as depression and schizophrenia have a biological component. The underlying inference is that there is a behavioural, psychological or biological dysfunction and that the disturbance in the mental equilibrium is not merely in the relationship between the individual and the society *(10)*.

Although mental health is an essential component of health, the scientific foundations of mental health are not yet clear. Therefore, we do not have precise tools to assess the state of mental health unlike physical health. Psychologists have mentioned the following characteristics as attributes of a mentally healthy person:

a. a mentally healthy person is free from internal conflicts; he is not at "war" with himself.
b. he is well-adjusted, i.e., he is able to get along well with others. He accepts criticism and is not easily upset.
c. he searches for identity.
d. he has a strong sense of self-esteem.
e. he knows himself: his needs, problems and goals (this is known as self-actualization).
f. he has good self-control-balances rationality and emotionality.
g. he faces problems and tries to solve them intelligently, i.e., coping with stress and anxiety.

Assessment of mental health at the population level may be made by administering mental status questionnaires by trained interviewers. The most commonly used questionnaires seek to determine the presence and extent of "organic disease" and of symptoms that could indicate psychiatric disorder; some personal assessment of mental well-being is also made. The most basic decision to be made in assessing mental health is whether to assess mental functioning, i.e., the extent to which cognitive or affective impairments impede role performance and subjective life quality, or psychiatric diagnosis *(10)*.

One of the keys to good health is a positive mental health. Unfortunately, our knowledge about mental health is far from complete.

3. Social dimension

Social well-being implies harmony and integration within the individual, between each individual and other members of society and between individuals and the world in which they live *(11)*. It has been defined as the "quantity and quality of an individual's interpersonal ties and the extent of involvement with the community" *(12)*.

The social dimension of health includes the levels of social skills one possesses, social functioning and the ability to see oneself as a member of a larger society. In general, social health takes into account that every individual is part of a family and of wider community and focuses on social and economic conditions and well-being of the "whole person" in the context of his social network. Social health is rooted in "positive material environment" (focussing on financial and residential matters), and "positive human environment" which is concerned with the social network of the individual *(10)*.

4. Spiritual dimension

Proponents of holistic health believe that the time has come to give serious consideration to the spiritual dimension and to the role this plays in health and disease. Spiritual health in this context, refers to that part of the individual which reaches out and strives for meaning and purpose in life. It is the intangible "something" that transcends physiology and psychology. As a relatively new concept, it seems to defy concrete definition. It includes integrity, principles and ethics, the purpose in life, commitment to some higher being and belief in concepts that are not subject to "state of the art" explanation *(13)*.

5. Emotional dimension

Historically the mental and emotional dimensions have been seen as one element or as two closely related elements. However, as more research becomes available a definite difference is emerging. Mental health can be seen as "knowing" or "cognition" while emotional health relates to "feeling". Experts in psychobiology have been relatively successful in isolating these two separate dimensions. With this new data, the mental and emotional aspects of humanness may have to be viewed as two separate dimensions of human health *(13)*.

6. Vocational dimension

The vocational aspect of life is a new dimension. It is part of human existence. When work is fully adapted to human goals, capacities and limitations, work often plays a role in promoting both physical and mental health. Physical work is usually associated with an improvement in physical capacity, while goal achievement and self-realization in work are a source of satisfaction and enhanced self-esteem *(14)*.

The importance of this dimension is exposed when individuals suddenly lose their jobs or are faced with mandatory retirement. For many individuals, the vocational dimension may be merely a source of income. To others, this dimension represents the culmination of the efforts of other dimensions as they function together to produce what the individual considers life "success" *(13)*.

7. Others

A few other dimensions have also been suggested such as *(15)*:

- philosophical dimension
- cultural dimension
- socio-economic dimension
- environmental dimension
- educational dimension
- nutritional dimension
- curative dimension
- preventive dimension.

A glance at the above dimensions shows that there are many "non-medical" dimensions of health, e.g., social, cultural, educational, etc. These symbolize a huge range of factors to which other sectors besides health must contribute if all people are indeed to attain a level of health that will permit them to lead a socially and economically productive life.

POSITIVE HEALTH

Health in the broad sense of the world does not merely mean the absence of disease or provision of diagnostic, curative and preventive services. It also includes as embodied in the WHO definition, a state of physical, mental and social well-being. The harmonious balance of this state of the human individual integrated into his environment, constitutes health, as defined by WHO.

The state of positive health implies the notion of "perfect functioning" of the body and mind. It conceptualizes health **biologically**, as a state in which every cell and every organ is functioning at optimum capacity and in perfect harmony with the rest of the body; **psychologically**, as a state in which the individual feels a sense of perfect well-being and of mastery over his environment, and **socially**, as a state in which the individual's capacities for participation in the social system are optimal *(16)*. These ideas were widely ventilated some years ago but now appear slightly ridiculous *(17)*.

Dubos *(4)* said, "The concept of perfect positive health cannot become a reality because man will never be so perfectly adapted to his environment that his life will not involve struggles, failures and sufferings". Positive health will, therefore, always remain a mirage, because everything in our life is subject to change. Health in this context has been described as a potentiality – the ability of an individual or a social group to modify himself or itself continually, in the face of changing conditions of life. In working for positive health the doctor and the community health expert are in the same position as the gardener or farmer faced with insects, moulds and weeds. Their work is never done *(18)*.

A broader concept of health has been emerging – that of improving the quality of life of which health is an essential component. This at once brings to focus that positive health depends not only on medical action, but on all the other economic, cultural and social factors operating in the community.

HEALTH – A RELATIVE CONCEPT

An alternative approach to positive health conceptualizes health not as an ideal state, but as a biologically "normal" state, based on statistical averages *(3)*. For example, a newborn baby in India weighs 2.8 kg on an average compared to 3.5 kg in the developed countries, and yet compares favourably in health. The height and weight standards vary from country to country, and also between socio-economic groups. Many normal people show heart murmurs, enlarged tonsils and X-ray shadows in the chest and yet do not show signs of ill-health. Thus health is a relative concept *(7)* and health standards vary among cultures, social classes and age-groups. This implies that health in any society should be defined in terms of prevailing ecological conditions. That is, instead of setting universal health standards, each country will decide on its own norms for a given set of prevailing conditions and then look into ways to achieve that level *(19)*.

CONCEPT OF WELL-BEING

The WHO definition of health introduces the concept of "well-being". The question then arises: what is meant by well-being? In point of fact, there is no satisfactory definition of the term "well-being *(8)*.

Psychologists have pointed out that the "well-being" of an individual or group of individuals have objective and subjective components. The objective components relate to such concerns as are generally known by the term "standard of living" or "level of living". The subjective component of well-being (as expressed by each individual) is referred to as "quality of life" *(20)*. Let us consider these concepts separately.

1. Standard of living

The term "standard of living" refers to the usual scale of our expenditure, the goods we consume and the services we enjoy. It includes the level of education, employment status, food, dress, house, amusements and comforts of modern living *(20)*.

A similar definition, corresponding to the above, was proposed by WHO: "Income and occupation, standards of housing, sanitation and nutrition, the level of provision of health, educational, recreational and other services may all be used individually as measures of socio-economic status, and collectively as an index of the "standard of living" *(21)*.

There are vast inequalities in the standards of living of the people in different countries of the world. The extent of these differences are usually measured through the comparison of per capita GNP on which the standard of living primarily depends.

2. Level of living

The parallel term for standard of living used in United Nations documents is "level of living" *(22)*. It consists of nine components: health, food consumption, education, occupation and working conditions, housing, social security, clothing, recreation and leisure, and human rights. These objective characteristics are believed to influence human well-being. It is considered that health is the most important component of the level of living because its impairment always means impairment of the level of living.

3. Quality of life

Much has been said and written on the quality of life in recent years. It is the "subjective" component of well-being. "Quality of life" was defined by WHO *(23)* as: "the condition of life resulting from the combination of the effects of the complete range of factors such as those determining health, happiness (including comfort in the physical environment and a satisfying occupation), education, social and intellectual attainments, freedom of action, justice and freedom of expression".

A recent definition of quality of life is as follows *(20)*: "a composite measure of physical, mental and social well-being as **perceived** by each individual or by group of individuals – that is to say, happiness, satisfaction and gratification as it is experienced in such life concerns as health, marriage, family work, financial situation, educational opportunities, self-esteem, creativity, belongingness, and trust in others".

Thus, a distinction is drawn between the concept of "level of living" consisting of objective criteria and of "quality of life" comprising the individual's own subjective evaluation of these. The quality of life can be evaluated by assessing a person's subjective feelings of happiness or unhappiness about the various life concerns.

People are now demanding a better quality of life. Therefore, governments all over the world are increasingly concerned about improving the quality of life of their people by reducing morbidity and mortality, providing primary health care and enhancing physical, mental and social well-being. It is conceded that a rise in the standard of living of the people is not enough to achieve satisfaction or happiness. Improvement of quality of life must also be added, and this means increased emphasis on social policy and on reformulation of societal goals to make life more liveable for all.

Physical quality of life index (PQLI)

As things stand at present, this important concept of quality of life is difficult to define and even more difficult to measure. Various attempts have been made to reach one composite index from a number of health indicators. The "Physical quality of life index" is one such index. It consolidates three indicators, viz. infant mortality, life expectancy at age one, and literacy. These three components measure the results rather than inputs. As such they lend themselves to international and national comparison.

For each component, the performance of individual countries is placed on a scale of 0 to 100, where 0 represents an absolutely defined "worst" performance, and 100 represents an absolutely defined "best" performance. The composite index is calculated by averaging the three indicators, giving equal weight to each of them. The resulting PQLI thus also is scaled 0 to 100.

It may be mentioned that PQLI has not taken per capita GNP into consideration, showing thereby that "money is not everything". For example, the oil-rich countries of Middle East with high per capita incomes have in fact not very high PQLIs. At the other extreme, Sri Lanka and Kerala state in India have low per capita incomes with high PQLIs. In short, PQLI does not measure economic growth; it measures the results of social, economic and political policies. It is intended to complement, not replace GNP *(24)*. The ultimate objective is to attain a PQLI of 100.

Human Development Index (HDI) *(25)*

Human development index (HDI) is defined as "a composite index combining indicators representing three dimensions – longevity (life expectancy at birth); knowledge (mean years of schooling and expected years of schooling. Before the year 2009, the indicators used were adult literacy rate and gross enrolment ratio) and income (GNI per capita in purchasing power parity in US dollars)". Fig. 1 summarizes how the human development index is constructed.

Thus the concept of HDI reflects achievements in the most basic human capabilities, viz, leading a long life, being knowledgeable and enjoying a decent standard of living. Hence, these three variables have been chosen to represent those dimensions. The HDI is a more comprehensive measure than per capita income. Income is only a means to human development, not an end. Nor is it a sum total of human lives. Thus by focussing on areas beyond income and treating income as a proxy for a decent standard of living, the HDI provides a more comprehensive picture of human life than income does.

The HDI values range between 0 to 1. The HDI value for a country shows the distance that it has already travelled towards maximum possible value to 1, and also allows comparisons with other countries.

STEPS TO ESTIMATE THE HUMAN DEVELOPMENT INDEX *(26)*

There are two steps to calculating the HDI.

Step 1. Creating the dimension indices

Minimum and maximum values (goalposts) are set in order to transform the indicators into indices between 0 and 1. The maximums are the highest observed values in the time series (1980–2011). The minimum values can be appropriately conceived of as subsistence values. The minimum values are set at 20 years for expectancy, at 0 years for both education variables and at $100 for per capita gross national income (GNI).

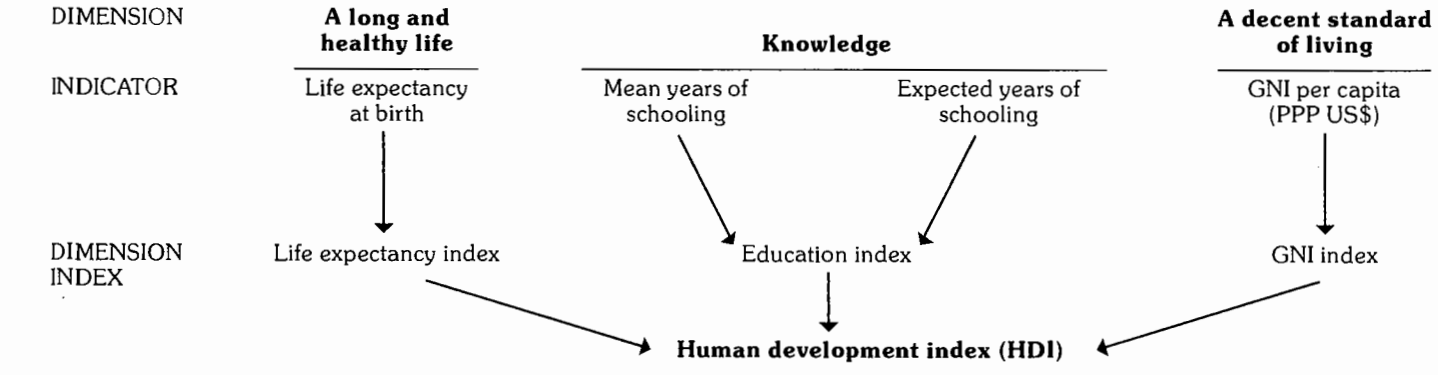

FIG. 1
Calculating the Human Development Index

Source : *(26)*

Goalposts for the Human Development Index

DIMENSION	OBSERVED MAXIMUM	MINIMUM
Life expectancy	83.4 (Japan, 2011)	20.0
Mean years of schooling	13.1 (Czech Republic, 2005)	0
Expected years of schooling	18.0 (capped at)	0
Combined education index	0.978 (New Zealand, 2010)	0
Per capita income (PPP $)	107,721 (Qatar, 2011)	100

Having defined the minimum and maximum values, the subindices are calculated as follows:

$$\text{Dimension index} = \frac{\text{Actual value} - \text{Minimum value}}{\text{Maximum value} - \text{Minimum value}} \quad (1)$$

For education, equation 1 is applied to each of the two subcomponents, then a geometric mean of the resulting indices is created and finally, equation 1 is reapplied to the geometric mean of the indices using 0 as the minimum and the highest geometric mean of the resulting indices for the time period under consideration, as the maximum. This is equivalent to applying equation 1 directly to the geometric mean of the two subcomponents.

Step 2. Aggregating the subindices to produce the Human Development Index

The HDI is the geometric mean of the three dimension indices:

$$(I_{Life}^{1/3} \times I_{Education}^{1/3} \times I_{Income}^{1/3}) \quad (2)$$

The construction of HDI methodology can be illustrated with the example of India for the year 2010.

Indicator	Value
Life expectancy at birth (years)	65.4
Mean years of schooling (years)	4.4
Expected years of schooling (years)	10.3
GNI per capita (PPP $)	3,468

$$\text{Life expectancy index} = \frac{65.4 - 20}{83.4 - 20} = \frac{45.4}{63.4} = 0.716$$

$$\text{Mean years of schooling index} = \frac{4.4 - 0}{13.1 - 0} = 0.335$$

$$\text{Expected years of schooling index} = \frac{10.3 - 0}{18 - 0} = 0.572$$

$$\text{Education index} = \frac{\sqrt{0.335 \times 0.572} - 0}{0.978 - 0} = 0.447$$

$$\text{Income index} = \frac{\ln(3468) - \ln(100)}{\ln(107{,}721) - \ln(100)} = 0.508$$

$$\text{Human development index} = \sqrt[3]{0.716 \times 0.447 \times 0.508}$$

$$= 0.547$$

HDI classification for the year 2012 are relative – based on quartiles of HDI distribution across 187 countries, denoted a very high, high, medium (each with 47 countries), and low (with 46 countries).

Norway, Australia and USA are at the top of HDI ranking and D.R. of Congo, Niger are at the bottom. India comes in the medium human development category, ranking at number 136 *(27)*.

Disparities between regions can be significant with some regions having more ground to cover in making the shortfall than others. The link between the economic prosperity and human development is neither automatic nor obvious. Two countries with similar income per capita can have very different HDI values, and countries having similar HDI can have very different income levels.

SPECTRUM OF HEALTH

Health and disease lie along a continuum, and there is no single cut-off point. The lowest point on the health–disease spectrum is death and the highest point corresponds to the WHO definition of positive health (Fig. 2). It is thus obvious that health fluctuates within a range of optimum well-being to various levels of dysfunction, including the state of total dysfunction, namely the death. The transition from optimum health to ill-health is often gradual, and where one state ends and the other begins is a matter of judgment.

The spectral concept of health emphasizes that the health of an individual is not static; it is a dynamic phenomenon and a process of continuous change, subject to frequent subtle variations. What is considered maximum health today may be minimum tomorrow. That is, a person may function at maximum levels of health today, and diminished levels of health tomorrow. It implies that health is a state not to be attained once and for all, but ever to be renewed. There are degrees or "levels of health" as there are degrees or severity of illness. As long as we are alive there is some degree of health in us.

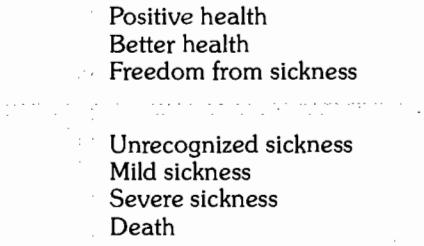

FIG. 2
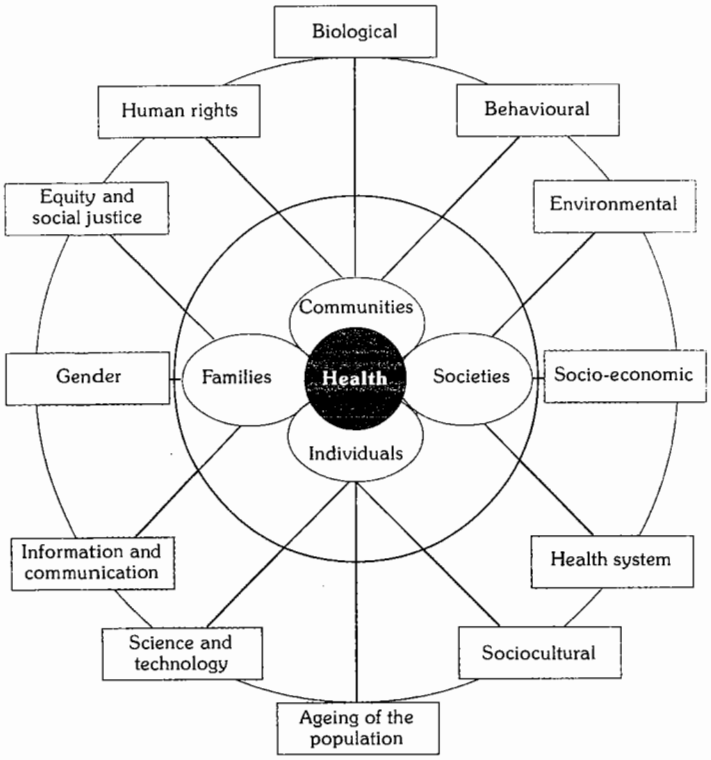
The health sickness spectrum

DETERMINANTS OF HEALTH

Health is multifactorial. The factors which influence health lie both within the individual and externally in the society in which he or she lives. It is a truism to say that what man is and to what diseases he may fall victim depends on a combination of two sets of factors – his genetic factors and the environmental factors to which he is exposed. These factors interact and these interactions may be health-promoting or deleterious. Thus, conceptually, the health of individuals and whole communities may be considered to be the result of many interactions. Only a brief indication of the more important determinants or variables are shown in Fig. 3.



Source : *(28)*

FIG. 3
Determinants of health

1. Biological determinants

The physical and mental traits of every human being are to some extent determined by the nature of his genes at the moment of conception. The genetic make-up is unique in that it cannot be altered after conception. A number of diseases are now known to be of genetic origin, e.g., chromosomal anomalies, errors of metabolism, mental retardation, some types of diabetes, etc. The state of health, therefore depends partly on the genetic constitution of man. Nowadays, medical genetics offers hope for prevention and treatment of a wide spectrum of diseases, thus the prospect of better medicine and longer, healthier life. A vast field of knowledge has yet to be exploited. It plays a particularly important role in genetic screening and gene therapy.

Thus, from the genetic stand-point, health may be defined as that "state of the individual which is based upon the absence from the genetic constitution of such genes as correspond to characters that take the form of serious defect and derangement and to the absence of any aberration in respect of the total amount of chromosome material in the karyotype or stated in positive terms, from the presence in the genetic constitution of the genes that correspond to the normal characterization and to the presence of a normal karyotype" *(8)*.

The "positive health" advocated by WHO implies that a person should be able to express as completely as possible the potentialities of his genetic heritage. This is possible only when the person is allowed to live in healthy relationship with his environment – an environment that transforms genetic potentialities into phenotypic realities *(18)*.

2. Behavioural and socio-cultural conditions

The term "lifestyle" is rather a diffuse concept often used to denote "the way people live", reflecting a whole range of social values, attitudes and activities *(29)*. It is composed of cultural and behavioural patterns and lifelong personal habits (e.g., smoking, alcoholism) that have developed through processes of socialization. Lifestyles are learnt through social interaction with parents, peer groups, friends and siblings and through school and mass media.

Health requires the promotion of healthy lifestyle. A considerable body of evidence has accumulated which indicates that there is an association between health and lifestyle of individuals *(30)*. Many current-day health problems especially in the developed countries (e.g., coronary heart disease, obesity, lung cancer, drug addiction) are associated with lifestyle changes. In developing countries such as India where traditional lifestyles still persist, risks of illness and death are connected with lack of sanitation, poor nutrition, personal hygiene, elementary human habits, customs and cultural patterns.

It may be noted that not all lifestyle factors are harmful. There are many that can actually promote health. Examples include adequate nutrition, enough sleep, sufficient physical activity, etc. In short, the achievement of optimum health demands adoption of healthy lifestyles. Health is both a consequence of an individual's lifestyle and a factor in determining it *(29)*.

3. Environment

It was Hippocrates who first related disease to environment, e.g., climate, water, air, etc. Centuries later, Pettenkofer in Germany revived the concept of disease–environment association.

Environment is classified as "internal" and "external". The **internal** environment of man pertains to "each and every component part, every tissue, organ and organ–system and their harmonious functioning within the system". Internal environment is the domain of internal medicine. The **external** or macro-environment consists of those things to which man is exposed after conception. It is defined as "all that which is external to the individual human host" *(31)*. It can be divided into physical, biological and psychosocial components, any or all of which can affect the health of man and his susceptibility to illness. Some epidemiologists have used the term "micro-environment" (or domestic environment) to personal environment which includes the individual's way of living and lifestyle, e.g., eating habits, other personal habits (e.g., smoking or drinking), use of drugs, etc. It is also customary to speak about occupational environment, socio-economic environment and moral environment.

It is an established fact that environment has a direct impact on the physical, mental and social well-being of those living in it. The environmental factors range from housing, water supply, psychosocial stress and family structure through social and economic support systems, to the organization of health and social welfare services in the community.

The environmental components (physical, biological and psychological) are not water-tight compartments. They are so inextricably linked with one another that it is realistic and fruitful to view the human environment in toto when we consider the influence of environment on the health status of the population. If the environment is favourable to the individual, he can make full use of his physical and mental capabilities. Protection and promotion of family and environmental health is one of the major issues in the world today.

4. Socio-economic conditions

Socio-economic conditions have long been known to influence human health. For the majority of the world's people, health status is determined primarily by their level of socio-economic development, e.g., per capita GNP, education, nutrition, employment, housing, the political system of the country, etc. Those of major importance are :

(i) *Economic status* : The per capita GNP is the most widely accepted measure of general economic performance. There can be no doubt that in many developing countries, it is the economic progress that has been the major factor in reducing morbidity, increasing life expectancy and improving the quality of life (Table 4). The economic status determines the purchasing power, standard of living, quality of life, family size and the pattern of disease and deviant behaviour in the community. It is also an important factor in seeking health care. Ironically, affluence may also be a contributory cause of illness as exemplified by the high rates of coronary heart disease, diabetes and obesity in the upper socio-economic groups.

(ii) *Education* : A second major factor influencing health status is education (especially female education). The world map of illiteracy closely coincides with the maps of poverty, malnutrition, illhealth, high infant and child mortality rates. Studies indicate that education, to some extent, compensates the effects of poverty on health, irrespective of the availability of health facilities. The small state of Kerala in India is a striking example *(32)*. Kerala has an estimated infant mortality rate of 12 compared to 42 for all-India in 2012. A major factor in the low infant mortality of Kerala is its high female literacy rate of 91.98 per cent as compared to 65.46 per cent for all-India *(34)*.

(iii) *Occupation* : The very state of being employed in productive work promotes health, because the unemployed usually show a higher incidence of illhealth and death. For many, loss of work may mean loss of income and status. It can cause psychological and social damage.

(iv) *Political system* : Health is also related to the country's political system. Often the main obstacles to the implementation of health technologies are not technical, but rather political. Decisions concerning resource allocation, manpower policy, choice of technology and the degree to which health services are made available and accessible to different segments of the society are examples of the manner in which the political system can shape community health services *(35)*. The percentage of GNP spent on health is a quantitative indicator of political commitment. The WHO has set the target of at least 5 per cent expenditure of each country's GNP on health care. However India spends about 2 per cent of its GNP on health and family welfare *(36)*. What is needed is political commitment and leadership which is oriented towards social development, and not merely economic development. If poor health patterns are to be changed, then changes must be made in the entire socio-political system in any given community. Social, economic and political actions are required to eliminate health hazards in people's working and living environments.

5. Health services

The term health and family welfare services cover a wide spectrum of personal and community services for treatment of disease, prevention of illness and promotion of health. The purpose of health services is to improve the health status of population. For example, immunization of children can influence the incidence/prevalence of particular diseases. Provision of safe water can prevent mortality and morbidity from water-borne diseases. The care of pregnant women and children would contribute to the reduction of maternal and child morbidity and mortality. To be effective, the health services must reach the social periphery, equitably distributed, accessible at a cost the country and community can afford, and socially acceptable *(6)*. All these are ingredients of what is now termed "primary health care", which is seen as the way to better health.

Health services can also be seen as essential for social and economic development. It is well to remind ourselves that "health care does not produce good health" *(37)*. Whereas, there is a strong correlation between GNP and expectation of life at birth, there is no significant correlation between medical density and expectation of life at birth *(38)*. The most we can expect from an effective health service is good care *(37)*. The epidemiological perspective emphasizes that health services, no matter how technically elegant or cost-effective, are ultimately pertinent only if they improve health *(39)*.

6. Ageing of the population

By the year 2020, the world will have more than one billion people aged 60 and over, and more than two-thirds of them living in developing countries. Although the elderly in many countries enjoy better health than hitherto, a major concern of rapid population ageing is the increased prevalence of chronic diseases and disabilities, both being conditions that tend to accompany the ageing process and deserve special attention.

7. Gender

The 1990s have witnessed an increased concentration on women's issues. In 1993, the Global Commission on Women's Health was established. The commission drew up an agenda for action on women's health covering nutrition, reproductive health, the health consequences of violence, ageing, lifestyle related conditions and the occupational environment. It has brought about an increased awareness among policy–makers of women's health issues and encourages their inclusion in all development plans as a priority.

8. Other factors

We are witnessing the transition from post industrial age to an information age and experiencing the early days of two interconnected revolutions, in information and in communication. The development of these technologies offers tremendous opportunities in providing an easy and instant access to medical information once difficult to retrieve. It contributes to dissemination of information worldwide, serving the needs of many physicians, health professionals, biomedical scientists and researchers, the mass media and the public.

Other contributions to the health of population derive from systems outside the formal health care system, i.e., health related systems (e.g., food and agriculture, education, industry, social welfare, rural development), as well as adoption of policies in the economic and social fields that would assist in raising the standard of living. This would include employment opportunities, increased wages, prepaid medical programmes and family support systems.

In short, medicine is not the sole contributor to the health and well-being of population. The potential of intersectoral contributions to the health of communities is increasingly recognized.

ECOLOGY OF HEALTH

Ecology is a key word in present-day health philosophy. It comes from the Greek "Oikos" meaning a house. Ecology is defined as the science of mutual relationship between living organisms and their environments. Human ecology is a subset of more general science of ecology.

A full understanding of health requires that humanity be seen as part of an ecosystem. The human ecosystem includes in addition to the natural environment, all the dimensions of the man-made environment – physical, chemical, biological, psychological: in short, our culture and all its products *(40)*. Disease is embedded in the ecosystem of man. Health, according to ecological concepts, is visualized as a state of dynamic equilibrium between man and his environment.

By constantly altering his environment or ecosystem by such activities as urbanization, industrialization, deforestation, land reclamation, construction of irrigation canals and dams, man has created for himself new health problems. For example, the greatest threat to human health in India today is the ever-increasing, unplanned urbanization, growth of slums and deterioration of environment. As a result, diseases at one time thought to be primarily "rural" (e.g., filariasis) have acquired serious urban dimensions. The agents of a number of diseases, for example, malaria and chikungunya fever, which were effectively controlled have shown a recrudescence. The reasons for this must be sought in changes in the human ecology. Man's intrusion into ecological cycles of disease has resulted in zoonotic diseases such as kyasanur forest disease, rabies, yellow fever, monkeypox, lassa fever, etc. The Bhopal gas tragedy in 1984 highlights the danger of locating industries in urban areas. The nuclear disaster in Soviet Russia in April 1986 is another grim reminder of environmental pollution. Construction of irrigation systems and artificial lakes has created ecological niches favouring the breeding of mosquitoes and snails. In fact, ecological factors are at the root of the geographic distribution of disease. Therefore it has been said that good public health is basically good ecology.

Some have equated ecology with epidemiology. The main distinction between epidemiology and ecology is that while epidemiology is the study of the relationship between variations in man's environment and his state of health (or disease), ecology embraces the interrelationship of all living things. In this regard, epidemiology constitutes a special application of human ecology or that part of ecology relating to the state of human health *(41)*.

It is now being increasingly recognized that environmental factors and ecological considerations must be built into the total planning process to prevent degradation of ecosystems. Prevention of disease through ecological or environmental manipulations or interventions is much safer, cheaper and a more effective rational approach than all the other means of control. It is through environmental manipulations that diseases such as cholera and other diarrhoeal diseases, typhoid, malaria and other vector borne diseases, and hookworm disease could be brought under control or eliminated. The greatest improvement in human health thus may be expected from an understanding and modification of the factors that favour disease occurrence in the human ecosystem. Professor Rene Dubos believes that man's capacity to adapt himself to ecological changes is not unlimited. Man can adapt himself only in so far as the mechanisms of adaptations are potentially present in his genetic code *(18)*.

RIGHT TO HEALTH

Historically, the right to health was one of the last to be proclaimed in the Constitutions of most countries of the world *(42)*. At the international level, the Universal Declaration of Human Rights established a breakthrough in 1948, by stating in Article 25: "Everyone has the right to a standard of living adequate for the health and well-being of himself and his family.....". The Preamble to the WHO Constitution also affirms that it is one of the fundamental rights of every human being to enjoy "the highest attainable standard of health". Inherent in the right to health is the right to health or medical care. Some countries have used the term "right to health protection" which is assured by a comprehensive system of social insurance that provides material security in cases of illness or accident, and free medical education, medicaments and other necessary materials and the right to be cared for by society in old age and invalidity *(42)*.

In an increasing number of societies, health is no longer accepted as a charity or the privilege of the few, but demanded as a right for all. However, when resources are limited (as in most developing countries), the governments cannot provide all the needed health services. Under these circumstances the aspirations of the people should be satisfied by giving them equal right to available health care services *(43)*.

The concept of "right to health" has generated so many questions, viz. right to medical care, right to responsibility for health, right to a healthy environment, right to food, right to procreate (artificial insemination included), the right not to procreate (family planning, sterilization, legal abortion), rights of the deceased persons (determination of death, autopsies, organ removal) and the right to die (suicide, hunger strike, discontinuation of life support measures), etc. Many of these issues have been the subject of debate. It is left to the lawyers, ethicists and physicians to formulate a general outline of what is acceptable and what is unacceptable in human society.

RESPONSIBILITY FOR HEALTH

Health is on one hand a highly personal responsibility and on the other hand a major public concern. It thus involves the joint efforts of the whole social fabric, viz. the individual, the community and the state to protect and promote health.

1. Individual responsibility

Although health is now recognized a fundamental human right, it is essentially an individual responsibility. It is not a commodity that one individual can bestow on another. No community or state programme of health services can give health. In large measure, it has to be earned and maintained by the individual himself, who must accept a broad spectrum of responsibilities, now known as "self care".

Self care in health

A recent trend in health care is self care *(44)*. It is defined as "those health-generating activities that are undertaken by the persons themselves" *(45)*. It refers to those activities individuals undertake in promoting their own health, preventing their own disease, limiting their own illness, and restoring their own health. These activities are undertaken without professional assistance, although individuals are informed by technical knowledge and skills. The generic attribute of self care is its non-professional, non-bureaucratic, non-industrial character; its natural place in social life *(46)*.

Self care activities comprise observance of simple rules of behaviour relating to diet, sleep, exercise, weight, alcohol, smoking and drugs. Others include attention to personal hygiene, cultivation of healthful habits and lifestyle, submitting oneself to selective medical examinations and screening; accepting immunization and carrying out other specific disease–prevention measures, reporting early when sick and accepting treatment, undertaking measures for the prevention of a relapse or of the spread of the disease to others. To these must be added family planning which is essentially an individual responsibility.

The shift in disease patterns from acute to chronic disease makes self care both a logical necessity and an appropriate strategy. For example, by teaching patients self care (e.g., recording one's own blood pressure, examination of urine for sugar), the burden on the official health services would be considerably reduced. In other words, health must begin with the individual.

2. Community responsibility

Health can never be adequately protected by health services without the active understanding and involvement of communities whose health is at stake. Until quite recently, throughout the world, people were neglected as a health resource; they were merely looked upon as sources of pathology or victims of pathology and consequently as a "target" for preventive and therapeutic services. This negative view of people's role in health has changed because of the realization that there are many things which the individual cannot do for himself except through united community effort. The individual and community responsibility are complementary, not antithetical. The current trend is to "demedicalize" health and involve the communities in a meaningful way. This implies a more active involvement of families and communities in health matters, viz. planning, implementation, utilization, operation and evaluation of health services. In other words, the emphasis has shifted from **health care for the people to health care by the people.** The concept of primary health care centres round people's participation in their own activities. The Village Health Guides' scheme in India, launched in 1977, is an example of community participation.

There are three ways in which a community can participate *(47)*: (i) the community can provide in the shape of facilities, manpower, logistic support, and possibly funds (ii) it also means the community can be actively involved in planning, management, and evaluation, and (iii) an equally important contribution that people can make is by joining in and using the health services. This is particularly true of preventive and protective measures. Further, no standard pattern of community participation can be recommended since there is a wide range of economic and social problems, as well as political and cultural traits among and within the communities. What is essential is flexibility of approach.

However, community involvement is not easy to obtain as extensive experience has indicated *(48)*. The traditional Indian society is cut across on rigid religion and caste lines, and appropriate role for each caste group has been a serious obstacle in securing complete community participation *(49)*. And in the health sector, the greatest resistance to health guide's involvement in primary health care came from the medical profession than the lay public *(50)*. Community participation has become an aphorism that is still awaiting genuine realization in many countries of the world.

Long ago, Henry Sigerist, the medical historian stated that "The people's health ought to be the concern of the people themselves. They must struggle for it and plan for it. The war against disease and for health cannot be fought by physicians alone. It is a people's war in which the entire population must be mobilized permanently" *(51)*.

3. State responsibility

The responsibility for health does not end with the individual and community effort. In all civilized societies, the State assumes responsibility for the health and welfare of its citizens. The Constitution of India provides that health is a State responsibility. The relevant portions are to be found in the Directive Principles of State Policy, which are as below :

The State shall, in particular, direct the policy towards securing–

....that the health and strength of workers, men and women and the tender age of children are not abused and that citizens are not forced by economic necessity to enter avocations unsuited to their age or strength.

....that childhood and youth are protected against exploitation and against moral and material abandonment.

The State shall, within the limits of its economic capacity and development, make effective provision for securing the right to work, to education and to public assistance in cases of unemployment, old age, sickness and disablement, and in other cases of undeserved want.

The State shall make provision for securing just and humane conditions of work and maternity relief.

The State shall regard the raising of the level of nutrition and standard of living of its people and the improvement of public health as among its primary duties.

– The Constitution of India; Part IV

India is a signatory to the Alma-Ata Declaration of 1978 and the Millennium Development Goals of 2000. The National Health Policy, approved by Parliament in 1983 and later on in 2002 have resulted in a greater degree of state involvement in the management of health services, and the establishment of nation-wide systems of health services with emphasis on primary health care approach.

4. International responsibility

The health of mankind requires the cooperation of governments, the people, national and international organizations both within and outside the United Nations system in achieving our health goals. This cooperation covers such subjects as exchange of experts, provision of drugs and supplies, border meetings with regard to control of communicable diseases. The TCDC (Technical Cooperation in Developing Countries), ASEAN (Association of South–East Asian Nations) and SAARC (South Asia Association for Regional Cooperation) are important regional mechanisms for such cooperation *(49)*.

The eradication of smallpox, the pursuit of "Health for All" and the campaign against smoking and AIDS are a few recent examples of international responsibility for the control of disease and promotion of health. Today, more than ever before, there is a wider international understanding on matters relating to health and "social injustices" in the distribution of health services. The WHO is a major factor in fostering international cooperation in health. In keeping with its constitutional mandate, WHO acts as a directing and coordinating authority on international health work.

HEALTH AND DEVELOPMENT

"Health is essential to socio-economic development" has gained increasing recognition. It was commonly thought in the 1960s that socio-economic progress was not essential for improving the health status of people in developing countries, and that substantial and rapid progress could be made through introduction of modern public health measures alone. According to this way of thinking, the role of human beings in the developing process was grossly underestimated.

The period 1973–1977 witnessed considerable rethinking on this subject *(49)*. There was profound modification of the economic theory. It became increasingly clear that economic development alone cannot solve the major problems of poverty, hunger, malnutrition and disease. In its place, "non-economic" issues (e.g., education, productive employment, housing, equity, freedom and dignity, human welfare) have emerged as major objectives in development strategies.

The experiences of a few developing countries (e.g., Sri Lanka, Costa Rica, and the state of Kerala in India) illustrate dramatically the way in which health forms part of development. This was because the efforts in the health field were simultaneously reinforced by developments in other sectors such as education, social welfare and land reforms *(52)*. The link between health and development has been clearly established, the one being the starting point for the other and vice versa.

Since health is an integral part of development, all sectors of society have an effect on health. In other words, health services are no longer considered merely as a complex of solely medical measures but a "subsystem" of an overall socio-economic system. In the final analysis, human health and well-being are the ultimate goal of development.

Lessons from Kerala State

Kerala is the southern-most state of India. With a population of 33.36 million, and a population density of 858 per sq.km, the state of Kerala is extremely crowded, perhaps more than Bangladesh. Its annual *per capita* income of Rs. 83,725 (2011–12) is more than the national average of Rs. 60,603. Kerala has surpassed all the Indian states in certain important measures of health and social development, as shown in Table 1.

TABLE 1

Comparison of Kerala and all-India Health Statistics

	Kerala	All India
Death rate/1000 (2012)	6.9	7.0
Rural birth rate (2012)	15.1	23.1
Infant mortality rate (2012)	12.0	42
Annual growth rate, per cent (2012)	0.8	1.45
Life expectancy at birth 2011–2015 (Projection)		
Male	73.2	67.3
Female	77.6	69.1
Literacy rate, per cent (2011)	90.92	74.04
Female literacy rate (2011)	91.98	65.46
Mean age at marriage, females (2012)	22.9	21.2
Per capita income (2011–12)	Rs. 83,725	Rs. 60,603

Kerala has demonstrated that, in a democratic system with a strong political commitment to equitable socio-economic development, high levels of health can be achieved even on modest levels of income. Kerala can therefore be considered a **yardstick** for judging health status in the country.

Studies have shown that the efforts in the health field were simultaneously reinforced by developments in other sectors. Literacy (especially female literacy) has played a key role in improving the health situation. This was probably responsible for the high rate of utilization of health facilities. Long-standing programmes directed at social welfare raised not only educational levels of the population but also developed a social infrastructure, including a transport network which provided easy access to services. An effective programme of land reform had given poor people access to land resources for food production at the household level. Kerala has demonstrated that good health at low cost is attainable by poor countries, but requires major political and social commitment.

HEALTH DEVELOPMENT

Health development is defined as "the process of continuous progressive improvement of the health status of a population" *(53)*. Its product is rising level of human well-being, marked not only by reduction in the burden of disease, but also by the attainment of positive physical and mental health related to satisfactory economic functioning and social integration *(54)*.

The concept of **health development** as distinct from the provision of medical care is a product of recent policy thinking. It is based on the fundamental principle that governments have a responsibility for the health of their people and at the same time people should have the right as well as the duty, individually and collectively to participate in the development of their own health.

Health development contributes to and results from social and economic development. Therefore, health development has been given increasing emphasis in the policies and programmes of the United Nations system. One example is that of World Bank which is providing funds for the health component of economic development programmes. The UNDP has also shown a growing interest in health development, as has the World Bank.

INDICATORS OF HEALTH

A question that is often raised is: How healthy is a given community ? Indicators are required not only to measure the health status of a community, but also to compare the health status of one country with that of another; for assessment of health care needs; for allocation of scarce resources; and for monitoring and evaluation of health services, activities, and programmes. Indicators help to measure the extent to which the objectives and targets of a programme are being attained.

As the name suggests, indicators are only an indication of a given situation or a reflection of that situation. In WHO's guidelines for health programme evaluation *(55)* they are defined as **variables** which help to measure changes. Often they are used particularly when these changes cannot be measured directly, as for example health or nutritional status *(54)*. If measured sequentially over time, they can indicate direction and speed of change and serve to compare different areas or groups of people at the same moment in time *(55)*.

There has been some confusion over terminology: **health indicator** as compared to **health index** (plural: indices or indexes). It has been suggested that in relation to health trends, the term **indicator** is to be preferred to **index**, whereas **health index** is generally considered to be an amalgamation of health indicators *(56)*.

Characteristics of indicators

Indicators have been given scientific respectability; for example **ideal** indicators

a. should be **valid**, i.e., they should actually measure what they are supposed to measure;
b. should be **reliable** and objective, i.e., the answers should be the same if measured by different people in similar circumstances;
c. should be **sensitive**, i.e., they should be sensitive to changes in the situation concerned,
d. should be **specific**, i.e., they should reflect changes only in the situation concerned,
e. should be **feasible**, i.e., they should have the ability to obtain data needed, and;
f. should be **relevant**, i.e., they should contribute to the understanding of the phenomenon of interest.

But in real life there are few indicators that comply with all these criteria. Measurement of health is far from simple. No existing definition (including the WHO definition) contains criteria for measuring health. This is because health, like happiness, cannot be defined in exact measurable terms. Its presence or absence is so largely a matter of subjective judgement. Since we have problems in defining health, we also have problems in measuring health and the question is largely unresolved. Therefore, measurements of health have been framed in terms of illness (or lack of health), the consequences of ill-health (e.g., morbidity, disability) and economic, occupational and domestic factors that promote ill-health – all the antitheses of health.

Further, health is multidimensional, and each dimension is influenced by numerous factors, some known and many unknown. This means we must measure health multidimensionally. Thus the subject of health measurement is a complicated one even for professionals. Our understanding of health, therefore, cannot be in terms of a single indicator; it must be conceived in terms of a profile, employing many indicators, which may be classified as:

1. Mortality indicators
2. Morbidity indicators
3. Disability rates
4. Nutritional status indicators
5. Health care delivery indicators
6. Utilization rates
7. Indicators of social and mental health
8. Environmental indicators
9. Socio-economic indicators
10. Health policy indicators
11. Indicators of quality of life, and
12. Other indicators.

1. Mortality indicators

(a) *Crude death rate:* This is considered a fair indicator of the comparative health of the people. It is defined as the number of deaths per 1000 population per year in a given community. It indicates the rate at which people are dying. Strictly speaking, health should not be measured by the number of deaths that occur in a community. But in many countries, the crude death rate is the only available indicator of health. When used for international comparison, the usefulness of the crude death rate is restricted because it is influenced by the age–sex composition of the population. Although not a perfect measure of health status, a decrease in death rate provides a good tool for assessing the overall health improvement in a population. Reducing the number of deaths in the population is an obvious goal of medicine and health care, and success or failure to do so is a measure of a nation's commitment to better health.

(b) *Expectation of life :* Life expectancy at birth is "the average number of years that will be lived by those born alive into a population if the current age-specific mortality rates persist". Life expectancy at birth is highly influenced by the infant mortality rate where that is high. Life expectancy at the age of 1 excludes the influence of infant mortality, and life expectancy at the age of 5 excludes the influence of child mortality. Life expectancy at birth is used most frequently *(57)*. It is estimated for both sexes separately. An increase in the expectation of life is regarded, inferentially, as an improvement in health status.

Life expectancy is a good indicator of socio-economic development in general. As an indicator of long-term survival, it can be considered as a positive health indicator. It has been adopted as a global health indicator.

(c) *Age-specific death rates :* Death rates can be expressed for specific age groups in a population which are defined by age. An age-specific death rate is defined as total number of deaths occurring in a specific age group of the population (e.g. 20–24 years) in a defined area during a specific period per 1000 estimated total population of the same age group of the population in the same area during the same period.

(d) *Infant mortality rate :* Infant mortality rate is the ratio of deaths under 1 year of age in a given year to the total number of live births in the same year; usually expressed as a rate per 1000 live births *(56)*. It is one of the most universally accepted indicators of health status not only of infants, but also of whole population and of the socio-economic conditions under which they live. In addition, the infant mortality rate is a sensitive indicator of the availability, utilization and effectiveness of health care, particularly perinatal care.

(e) *Child mortality rate :* Another indicator related to the overall health status is the early childhood (1–4 years) mortality rate. It is defined as the number of deaths at ages 1–4 years in a given year, per 1000 children in that age group at the mid-point of the year concerned. It thus excludes infant mortality.

Apart from its correlation with inadequate MCH services, it is also related to insufficient nutrition, low coverage by immunization and adverse environmental exposure and other exogenous agents. Whereas the IMR may be more than 10 times higher in the least developed countries than in the developed countries, the child mortality rate may be as much as 25 times higher. This indicates the magnitude of the gap and the room for improvement.

(f) *Under–5 proportionate mortality rate :* It is the proportion of total deaths occurring in the under–5 age group. This rate can be used to reflect both infant and child mortality rates. In communities with poor hygiene, the proportion may

exceed 60 per 1000 live births. In some European countries, the proportion is less than 2 per 1000 live births. High rate reflects high birth rates, high child mortality rates and shorter life expectancy *(26)*.

(g) *Adult mortality rate* : The adult mortality rate is defined as the probability of dying between the age of 15 and 60 years per 1000 population. The adult mortality rate offers a way to analyze health gaps between countries in the main working groups. The probability of dying in adulthood is greater for men than for women in almost all countries, but the variations between countries is very large. In Japan, less than 1 in 10 men (and 1 in 20 women) die in these productive age group, compared to almost 2–3 in 10 men (and 1–2 women) in Angola *(58)*.

(h) *Maternal (puerperal) mortality rate* : Maternal (puerperal) mortality accounts for the greatest proportion of deaths among women of reproductive age in most of the developing world. There are enormous variations in maternal mortality rate according to country's level of socio-economic status.

(i) *Disease-specific mortality rate* : Mortality rates can be computed for specific diseases. As countries begin to extricate themselves from the burden of communicable diseases, a number of other indicators such as deaths from cancer, cardiovascular diseases, accidents, diabetes, etc have emerged as measures of specific disease problems.

(j) *Proportional mortality rate* : The simplest measure of estimating the burden of a disease in the community is proportional mortality rate, i.e., the proportion of all deaths currently attributed to it. For example, coronary heart disease is the cause of 25 to 30 per cent of all deaths in most western countries. The proportional mortality rate from communicable diseases has been suggested as a useful health status indicator; it indicates the magnitude of preventable mortality.

(k) *Case fatality rate* : Case fatality rate measures the risk of persons dying from a certain disease within a given time period. Case fatality rate is calculated as number of deaths from a specific disease during a specific time period divided by number of cases of the disease during the same time period, usually expressed as per 100. The case fatality rate is used to link mortality to morbidity. One function of the case fatality rate is to measure various aspects or properties of a disease such as its pathogenicity, severity or virulence *(59)*. It can also be used in poisonings, chemical exposures or other short-term non-disease cause of death.

(l) *Years of potential life lost (YPLL)* : Years of potential life lost is based on the years of life lost through premature death. It is defined as one that occurs before the age to which a dying person could have expected to survive (before an arbitrary determined age, usually taken age 75 years). A 30 year old who dies in a road accident could theoretically have lived to an average life expectancy of 75 years of age; thus 45 years of life are lost.

Mortality indicators represent the traditional measures of health status. Even today they are probably the most often used indirect indicators of health. As infectious diseases have been brought under control, mortality rates have declined to very low levels in many countries. Consequently mortality indicators are losing their sensitivity as health indicators in developed countries. However, mortality indicators continue to be used as the starting point in health status evaluation.

2. Morbidity indicators

To describe health in terms of mortality rates only is misleading. This is because, mortality indicators do not reveal the burden of ill-health in a community, as for example mental illness and rheumatoid arthritis. Therefore, morbidity indicators are used to supplement mortality data to describe the health status of a population. Morbidity statistics have also their own drawback; they tend to overlook a large number of conditions which are subclinical or inapparent, that is, the hidden part of the iceberg of disease.

The following morbidity rates are used for assessing ill-health in the community *(60)*.

a. incidence and prevalence
b. notification rates
c. attendance rates at out-patient departments, health centres, etc.
d. admission, readmission and discharge rates
e. duration of stay in hospital, and
f. spells of sickness or absence from work or school.

3. Disability rates

Since death rates have not changed markedly in recent years, despite massive health expenditures, disability rates related to illness and injury have come into use to supplement mortality and morbidity indicators. The disability rates are based on the premise or notion that health implies a full range of daily activities. The commonly used disability rates fall into two groups: (a) Event–type indicators and (b) person–type indicators *(10, 61)*.

(a) *Event–type indicators*

i) Number of days of restricted activity
ii) Bed disability days
iii) Work-loss days (or school-loss days) within a specified period

(b) *Person–type indicators*

i) *Limitation of mobility*: For example, confined to bed, confined to the house, special aid in getting around either inside or outside the house.
ii) *Limitation of activity*: For example, limitation to perform the basic activities of daily living (ADL)–e.g., eating, washing, dressing, going to toilet, moving about, etc; limitation in major activity, e.g., ability to work at a job, ability to housework, etc.

HALE (Health-Adjusted Life Expectancy) : The name of the indicator used to measure healthy life expectancy has been changed from disability–adjusted life expectancy (DALE) to health–adjusted life expectancy (HALE). HALE is based on life expectancy at birth but includes an adjustment for *time spent in poor health*. It is most easily understood as the equivalent number of years in full health that a newborn can expect to live based on current rates of ill-health and mortality.

Quality-adjusted life years (QALY) : QALY is a measure of disease burden including both the quality and quantity of life lived. It is used in assessing the value for money of a medical intervention. The QALY is based on the number of years of life that would be added by intervention. Each year in perfect health is assigned a value of 1.0 down to a value of 0.0 for death, i.e. 1 QALY (1 year of life × 1 utility value = 1 QALY) is a year of life lived in perfect health. Half a year lived in perfect health is equivalent to 0.5 QALY (1 year × 0.5 utility value).

Disability-free life expectancy (Syn : active life expectancy) : Disability-free life expectancy (DFLE) is the average number of years an individual is expected to live free of disability if current pattern of mortality and disability continue to apply *(62)*.

Disability-adjusted life years (DALY) : DALY is a measure of overall disease burden, expressed as a number of years lost due to ill-health, disability or early death. Originally developed by Harvard University for the World Bank in 1990, the WHO subsequently adopted the method in the year 2000. The DALY is becoming increasingly common in the field of public health and health impact assessment. The Global Burden of Disease project combines the impact of premature mortality with that of disability. It captures the population impact of important fatal and non-fatal disabling conditions through a single measure. The major measure used is disability–adjusted life years (DALYs) which combines *(58)* :

- years of lost life (YLL) – calculated from the number of deaths at each age multiplied by the expected remaining years of life according to a global standard life expectancy
- years lost to disability (YLD) where the number of incident cases due to injury and illness is multiplied by the average duration of the disease and a weighting factor reflecting the severity of the disease on a scale from 0 (perfect health) to 1 (dead).

It is calculated by formula : DALY = YLL + YLD

The DALY relies on an acceptance that the most appropriate measure of the effects of the chronic illness is time. One DALY, therefore, is equal to one year of healthy life lost. Japanese life expectancy statistics are used as a standard for measuring premature death, as Japanese have the longest life expectancy.

DALY can reveal surprising things about a population's health. For example, the 1990 WHO report indicated that 5 out of 10 leading causes of disability were psychiatric conditions. Psychiatric and neurological conditions account for about 28 per cent of years lived with disability, but accounts for only 1.4 per cent of all deaths and 1.1 per cent of years of life lost. Thus they have a huge impact on population. A crucial distinction among DALY studies is the use of "social weighting", in which the value of each year of life depends on age. Commonly, years lived as a young adult are valued more highly than years spent as a young child or older adults. This weighting system reflects societie's interest in productivity and receiving a return on its investment in upbringing of the children. The effects of the interplay between life expectancy and years lost, discounting, and social weighting are complex, depending on the severity and duration of illness.

4. Nutritional status indicators

Nutritional status is a positive health indicator. Three nutritional status indicators are considered important as indicators of health status. They are *(57)* :

a. anthropometric measurements of preschool children, e.g., weight and height, mid-arm circumference;
b. heights (and sometimes weights) of children at school entry; and
c. prevalence of low birth weight (less than 2.5 kg).

5. Health care delivery indicators

The frequently used indicators of health care delivery are:

a. Doctor–population ratio
b. Doctor–nurse ratio
c. Population–bed ratio
d. Population per health/subcentre, and
e. Population per traditional birth attendant.

These indicators reflect the equity of distribution of health resources in different parts of the country, and of the provision of health care.

6. Utilization rates

In order to obtain additional information on health status, the extent of use of health services is often investigated. Utilization of services – or actual coverage – is expressed as the proportion of people in need of a service who actually receive it in a given period, usually a year *(57)*. It is argued that utilization rates give some indication of the care needed by a population, and therefore, the health status of the population. In other words, a relationship exists between utilization of health care services and health needs and status. Health care utilization is also affected by factors such as availability and accessibility of health services and the attitude of an individual towards his health and the health care system. A few examples of utilization rates are cited below:

a. proportion of infants who are "fully immunized" against the 6 EPI diseases.
b. proportion of pregnant women who receive antenatal care, or have their deliveries supervised by a trained birth attendant.
c. percentage of the population using the various methods of family planning.
d. bed–occupancy rate (i.e., average daily in-patient census/average number of beds).
e. average length of stay (i.e., days of care rendered/ discharges), and
f. bed turnover ratio (i.e., discharges/average beds).

The above list is neither exhaustive nor all–inclusive. The list can be expanded depending upon the services provided. These indicators direct attention away from the biological aspects of disease in a population towards the discharge of social responsibility for the organization in delivery of health care services.

7. Indicators of social and mental health

As long as valid positive indicators of social and mental health are scarce, it is necessary to use indirect measures, viz. *indicators of social and mental pathology.* These include suicide, homicide, other acts of violence and other crime; road traffic accidents, juvenile delinquency; alcohol and drug abuse; smoking; consumption of tranquillizers; obesity, etc *(57)*. To these may be added family violence, battered–baby and battered–wife syndromes and neglected and abandoned youth in the neighbourhood. These social indicators provide a guide to social action for improving the health of the people.

8. Environmental indicators

Environmental indicators reflect the quality of physical and biological environment in which diseases occur and in which the people live. They include indicators relating to

pollution of air and water, radiation, solid wastes, noise, exposure to toxic substances in food or drink. Among these, the most useful indicators are those measuring the proportion of population having access to safe water and sanitation facilities, as for example, percentage of households with safe water in the home or within 15 minutes' walking distance from a water standpoint or protected well; adequate sanitary facilities in the home or immediate vicinity *(57)*.

9. Socio-economic indicators

These indicators do not directly measure health. Nevertheless, they are of great importance in the interpretation of the indicators of health care. These include :

a. rate of population increase
b. per capita GNP
c. level of unemployment
d. dependency ratio
e. literacy rates, especially female literacy rates
f. family size
g. housing: the number of persons per room, and
h. per capita "calorie" availability.

10. Health policy indicators

The single most important indicator of political commitment is "allocation of adequate resources". The relevant indicators are: (i) proportion of GNP spent on health services (ii) proportion of GNP spent on health–related activities (including water supply and sanitation, housing and nutrition, community development), and (iii) proportion of total health resources devoted to primary health care.

11. Indicators of quality of life

Increasingly, mortality and morbidity data have been questioned as to whether they fully reflect the health status of a population. The previous emphasis on using increased life expectancy as an indicator of health is no longer considered adequate, especially in developed countries, and attention has shifted more towards concern about the quality of life enjoyed by individuals and communities. Quality of life is difficult to define and even more difficult to measure (see page 16). Various attempts have been made to reach one composite index from a number of health indicators. The physical quality of life index is one such index (see page 17). It consolidates three indicators, viz. infant mortality, life expectancy at age one, and literacy. Obviously more work is needed to develop indicators of quality of life.

12. Other indicators series

(a) *Social indicators* : Social indicators, as defined by the United Nations Statistical Office, have been divided into 12 categories:– population; family formation, families and households; learning and educational services; earning activities; distribution of income, consumption, and accumulation; social security and welfare services; health services and nutrition; housing and its environment; public order and safety; time use; leisure and culture; social stratification and mobility *(63)*.

(b) *Basic needs indicators* : Basic needs indicators are used by ILO. Those mentioned in "Basic needs performance" *(64)* include calorie consumption; access to water; life expectancy; deaths due to disease; illiteracy, doctors and nurses per population; rooms per person; GNP per capita.

(c) *"Health for All" indicators* : For monitoring progress towards the goal of Health for All by 2000 AD, the WHO has listed the following four categories of indicators (Table 2).

TABLE 2
Indicators selected for monitoring progress towards "Health for All"

(1) Health policy indicators:
- political commitment to "Health for All"
- resource allocation
- the degree of equity of distribution of health services
- community involvement
- organizational framework and managerial process

(2) Social and economic indicators related to health:
- rate of population increase
- GNP or GDP
- income distribution
- work conditions
- adult literacy rate
- housing
- food availability

(3) Indicators for the provision of health care:
- availability
- accessibility
- utilization
- quality of care

(4) Health status indicators:
- low birth weight (percentage)
- nutritional status and psychosocial development of children
- infant mortality rate
- child mortality rate (1–4 years)
- life expectancy at birth
- maternal mortality rate
- disease specific mortality
- morbidity – incidence and prevalence
- disability prevalence

Source : *(57)*

(d) *Millennium Development Goal Indicators* : The Millennium Development Goals adopted by the United Nations in the year 2000 provide an opportunity for concerted action to improve global health. The health related goals and their indicators of progress are listed in Table 3.

The search for indicators associated with or casually related to health continues. It will be seen from the above that there is no single comprehensive indicator of a nation's health. Each available indicator reflects an aspect of health. The ideal index which combines the effect of a number of components measured independently is yet to be developed. While the search for a single global index of health status continues, the use of multiple indicators arranged in profiles or patterns should make comparisons between areas, regions and nations possible *(66)*. In the last few decades, attention has shifted from reliance on economic performance (e.g., GNP or GDP) towards other ways of measuring a society's performance and quality of life.

TABLE 3

Health-related Millennium Development Goals, and Indicators

Goal: 1. Eradicate extreme poverty and hunger	
Indicator:	4. Prevalence of underweight children under five years of age
	5. Proportion of population below minimum level of dietary energy consumption
Goal: 4. Reduce child mortality	
Indicator:	13. Under-five mortality rate
	14. Infant mortality rate
	15. Proportion of 1-year-old children immunized against measles
Goal: 5. Improve maternal health	
Indicator:	16. Maternal mortality ratio
	17. Proportion of births attended by skilled health personnel
Goal: 6. Combat HIV/AIDS, malaria and other diseases	
Indicator:	18. HIV prevalence among young people aged 15 to 24 years
	19. Condom use rate of the contraceptive prevalence rate
	20. Number of children orphaned by HIV/AIDS
	21. Prevalence and death rates associated with malaria
	22. Proportion of population in malaria-risk areas using effective malaria prevention and treatment measures
	23. Prevalence and death rates associated with tuberculosis
	24. Proportion of tuberculosis cases detected and cured under Directly Observed Treatment, Short-course (DOTS)
Goal: 7. Ensure environmental sustainability	
Indicator:	29. Proportion of population using solid fuel
Indicator:	30. Proportion of population with sustainable access to an improved water source, urban and rural
Indicator:	31. Proportion of urban population with access to improved sanitation
Goal: 8. Develop a global partnership for development	
Indicator:	46. Proportion of population with access to affordable essential drugs on a sustainable basis

DEVELOPED AND DEVELOPING REGIONS

The world today is divided into developed and developing regions on the basis of some common features shared by them. The former is represented by countries such as USA and UK, and the latter by countries such as India. If one defined development as the organization of society to provide adequate housing, food, health services, education and employment for the majority of people, then many developing countries are wide of the mark. Social medicine is concerned with disparities that exist among countries. This is because socio-economic factors and health problems are interlinked. An account of these disparities is given below:

1. Social and economic characteristics

Most people in the developing countries live in rural areas and urban slums. There is a rigid hierarchy and class structure moulded by tradition and long–standing customs. The family, often a joint family, is a strong binding force. People depend mainly on agriculture and there is a lack of alternative employment opportunities. The GNP *per capita* ranges from US $ 200 to 6000 in most developing countries. The production and consumption per capita are low. They have an economic potential which is not fully realized; this refers to unemployed labour, natural resources and fertility of the soil. Science and technology are not fully applied. The level of literacy is low – it averages only 63 per cent in the least developed countries. The quality of life is poor because of the scarcity of essential goods, facilities and money. There is isolation caused by distance, poor communication and transport facilities. The environment is unfavourable predisposing to communicable diseases and malnutrition. The vast majority of people are not able to pay for medical services. There is a long tradition of free medical services provided by the State.

In the developed countries, most people (8 out of 10) are urban residents. Urban life differs from that in the villages by being more impersonal. Women are economically employed. Agriculture is second to industry. Great use is made of scientific disciplines. The standard of living and quality of life are high. The GNP per capita ranges from US $ 5000 to 40,600 in most developed countries. The adult literacy is almost universal.

2. Demographic characteristics

Population growth and changes have always been a central issue in community medicine. These changes have an impact on economic and social conditions and therefore on health and health care needs. The population of the world was 6.856 billion in the year 2010. About 93 per cent of the world population lives in developing countries.

The annual global rate of population growth is estimated to be 1.2 per cent. The advanced countries are failing to reproduce themselves, with growth rates less than 0.6 per cent, and some have already achieved zero population growth rate (e.g., Austria, Belgium, Federal Republic of Germany and the UK). The rest of the world continues to reproduce at a prodigious rate. Rates over 2.4 per cent have occurred in some African (e.g., Nigeria, Zambia, Congo) and Middle East (e.g., UAE, Libya, Saudi Arabia, Iraq) countries. In India, the current growth rate is about 1.45 per cent. These countries are now facing the population problem.

The population in developing countries is a "young" population; the proportion of persons under 15 years of age in the year 2011 was about 39 per cent in the least developed countries and 22 in other developing countries, compared to about 17 per cent in developed countries. The proportion of people over 60 years of age in developing countries is about 6 per cent, compared to 22 per cent in the developed countries. The social and economic backlashes of this age distribution are being felt in both the developing and developed countries – the former having to bear the heavy burden of providing for a population which is mainly young; and the latter having to deal with the problems of ageing.

3. Contrasts in health (Health gap)

While accurate statistical data are difficult to obtain, even perfunctory glance at available data (Table 4) are sufficient to illustrate the wide health gap between population in the developed and developing countries.

Table 4 shows that the present gap in life expectancy at birth between developed and developing countries is 15–20 years. Developed countries are characterized by longer life expectancy and lower infant and child mortality rates, and the opposite is true of developing countries.

TABLE 4
Selected health and socio-economic indicators

Indicator	Low income countries	Lower middle income countries	Upper middle income countries	High income countries
1. Life expectancy at birth (2011)	60	66	74	80
2. IMR (per 1000 live births) (2011)	63	46	76	5
3. Under 5 mortality per 1000 live births (2011)	95	62	20	6
4. Maternal mortality per 100,000 live births (2010)	410	260	53	14
5. Doctor–population ratio per 10,000 (2005–12)	5.1	7.8	17.8	27.1
6. Nurse–population ratio per 10,000 (2005–12)	14.9	13.4	35.4	72.4
7. GNI, per capita (US $ PPP) (2011)	1,313	3,666	10,566	38,690
8. Per capita public expenditure on health, US $ at average exchange rate (2010)	28	72	384	4,828
9. Adult literacy rate (%) (2005–2011)	63	71	93	97
10. Access to safe water % population (2011)	67	87	93	99
11. Access to adequate sanitation % population (2011)	37	42	74	100

Source : *(67)*

The burden of disease pattern of developed, developing high mortality, and developing low mortality countries in the world differ substantially. This phenomenon reflects what is known as the "epidemiological transition". As life expectancy increases, the major causes of death and disability in general shift from communicable, maternal and perinatal causes to chronic, non-communicable ones.

To sum up, the world health situation leaves much to be desired. Millions of people in the developing countries have incomes too low to ensure basic nutrition and have little access to essential health services. In a number of industrialized countries, rapid increases in health cost have called into question the relationship between health care and health indicators. A search for alternative approaches has led to the view that primary health care is the most important means, whereby, the health sector, with intersectoral coordination, can close the health gap and improve the health status of the population.

HEALTH SERVICE PHILOSOPHIES

Health care

Health care is an expression of concern for fellow human beings. It is defined as a "multitude of services rendered to individuals, families or communities by the agents of the health services or professions, for the purpose of promoting, maintaining, monitoring or restoring health" *(31)*. Such services might be staffed, organized, administered and financed in every imaginable way, but they all have one thing in common: people are being "served", that is, diagnosed, helped, cured, educated and rehabilitated by health personnel *(21)*. In many countries, health care is completely or largely a government function.

Health care includes "medical care". Many people mistakenly believe that both are synonymous. Medical care is a subset of a health care system. The term "medical care (which ranges from domiciliary care to resident hospital care) refers chiefly to those personal services that are provided directly by physicians or rendered as a result of the physician's instructions" *(68)*.

Health care has many characteristics; they include:

i. **appropriateness** (relevance), i.e., whether the service is needed at all in relation to essential human needs, priorities and policies;

ii. **comprehensiveness** i.e., whether there is an optimum mix of preventive, curative and promotional services;

iii. **adequacy**, i.e., if the service is proportionate to requirement;

iv. **availability**, i.e., ratio between the population of an administrative unit and the health facility (e.g., population per centre; doctor–population ratio);

v. **accessibility**, i.e., this may be geographic accessibility, economic accessibility or cultural accessibility;

vi. **affordability**, i.e., the cost of health care should be within the means of the individual and the state; and

vii. **feasibility**, i.e., operational efficiency of certain procedures, logistic support, manpower and material resources.

Health system

The "health system" is intended to deliver health services; in other words, it constitutes the management sector and involves organizational matters, e.g., planning, determining priorities, mobilizing and allocating resources, translating policies into services, evaluation and health education *(69)*.

The components of the health system include: **concepts** (e.g., health and disease); **ideas** (e.g., equity, coverage, effectiveness, efficiency, impact); **objects** (e.g., hospitals, health centres, health programmes) and **persons** (e.g., providers and consumers). Together, these form a whole in which all the components interact to support or control one another *(70)*. The aim of a health system is **health development** – a process of continuous and progressive improvement of the health status of a population.

Levels of health care

Health services are usually organized at three levels, each level supported by a higher level to which the patient is referred. These levels are:

(a) **Primary health care :** This is the first level of contact between the individual and the health system where "essential" health care (primary health care) is provided. A majority of prevailing health complaints and problems can be satisfactorily dealt with at this level. This level of care is closest to the people. In the Indian context, this care is provided by the primary health centres and their subcentres, with community participation.

(b) **Secondary health care** : At this level, more complex problems are dealt with. This care comprises essentially curative services and is provided by the district hospitals and community health centres. This level serves as the first referral level in the health system.

(c) **Tertiary health care** : This level offers super-specialist care. This care is provided by the regional/central level institutions. These institutions provide not only highly specialized care, but also planning and managerial skills and teaching for specialized staff. In addition, the tertiary level supports and complements the actions carried out at the primary level.

Health team concept

It is recognized that the physician of today is overworked professionally. It is also recognized that many of the functions of the physician can be performed by auxiliaries, given suitable training. An auxiliary worker has been defined as one "who has less than full professional qualifications in a particular field and is supervised by a professional worker". The WHO no longer uses the term "paramedical" for the various health professions allied with medicine *(53)*.

The practice of modern medicine has become a joint effort of many groups of workers, both medical and non-medical, viz. physicians, nurses, social workers, health assistants, trained dais, village health guides and a host of others. The composition of the team varies. The hospital team is different from the team that works in the community. Whether it is a hospital team or community health work team, it is important for each team member to have a specific and recognized function in the team and to have freedom to exercise his or her particular skills. In this context, a **health team** has been defined as "a group of persons who share a common health goal and common objectives, determined by community needs and towards the achievement of which each member of the team contributes in accordance with her/his competence and skills, and respecting the functions of the other" *(71)*. The auxiliary is an essential member of the team. The team must have a leader. The leader should be able to evaluate the team adequately and should know the motivations of each member in order to stimulate and enhance their potentialities. The health team concept has taken a firm root in the delivery of health services both in the developed and developing countries. The health team approach aims to produce the right "mix" of health personnel for providing full health coverage of the entire population. The mere presence of a variety of health professionals is not sufficient to establish teamwork; it is the proper division and combination of their operations from which the benefits of divided labour will be derived *(72)*.

Health for All

After three decades of trial and error and dissatisfaction in meeting people's basic health needs, the World Health Assembly, in May 1977, decided that the main social goal of governments and WHO in the coming years should be the "attainment by all the people of the world by the year 2000 AD of a level of health that will permit them to lead a socially and economically productive life". This goal has come to be popularly known as "Health for All by the year 2000" (HFA). The background to this "new" philosophy was the growing concern about the unacceptably low levels of health status of the majority of the world's population especially the rural poor and the gross disparities in health between the rich and poor, urban and rural population, both between and within countries. The essential principle of "HFA" is the concept of "equity in health", that is, all people should have an opportunity to enjoy good health.

Primary health care

The concept of primary health care came into lime-light in 1978 following an international conference in Alma-Ata, USSR. It has been defined as:

> *"Essential health care based on practical, scientifically sound and socially acceptable methods and technology made universally accessible to individuals and families in the community through their full participation and at a cost that the community and the country can afford to maintain at every stage of their development in the spirit of self-determination"*

The primary health care approach is based on principles of social equity, nation-wide coverage, self-reliance, intersectoral coordination, and people's involvement in the planning and implementation of health programmes in pursuit of common health goals. This approach has been described as "Health by the people" and "placing people's health in people's hands". Primary health care was accepted by the member countries of WHO as the key to achieving the goal of HFA by the year 2000 AD.

The **Declaration of Alma-Ata** *(6)* stated that primary health care includes at least:

- education about prevailing health problems and methods of preventing and controlling them;
- promotion of food supply and proper nutrition;
- an adequate supply of safe water and basic sanitation;
- maternal and child health care, including family planning;
- immunization against infectious diseases;
- prevention and control of endemic diseases;
- appropriate treatment of common diseases and injuries; and
- provision of essential drugs.

The concept of primary health care involves a concerted effort to provide the rural population of developing countries with at least the bare minimum of health services. The list can be modified to fit local circumstances. For example, some countries have specifically included mental health, physical handicaps, and the health and social care of the elderly. The primary health care approach integrates at the community level all the factors required for improving the health status of the population. As a signatory to the Alma-Ata Declaration, the Government of India, has pledged itself to provide primary health care. Obstacles to the implementation of primary health care in India include shortage of health manpower, entrenchment of a curative culture within the existing health system, and a high concentration of health services and health personnel in urban areas *(49)*.

Health promotion *(73)*

The first international conference on health promotion was held in Ottawa in November 1986, primarily in response to growing expectation for a new public health movement around the world. It was built on progress made through Declaration on Primary Health Care at Alma-Ata, and the debate at the World Health Assembly on intersectoral action for health. The conference resulted in proclamation of the **Ottawa Charter for Health**

Promotion, which has been a source of guidance and inspiration for health promotion since that time.

Health is a basic human right and is essential for social and economic development. Increasingly health promotion is being recognized as an essential element of health development. Health promotion, through investment and action, has a marked impact on the determinants of health so as to create the greatest health gain for people, to contribute significantly to the reduction of inequities of health, and to further human rights. The ultimate goal is to increase health expectancy.

The **Jakarta Declaration on Health Promotion** (the fourth conference held in July 1997) offered a vision and focus for health promotion into the 21st century. The determinants of health; new challenges in the 21st century; and the fundamental conditions and resources for health are peace, shelter, education, social security, social relations, food, income, the empowerment of women, a stable ecosystem, sustainable resource use, social justice, respect for human rights, and equity. Above all, poverty is the greatest threat to health.

Demographic trends such as urbanization, an increase in the number of older people and the high prevalence of chronic diseases pose new problems in all countries. Other social, behavioural and biological changes such as increased sedentary behaviour, resistance to antibiotics and other commonly available drugs, increased drug abuse, and civil and domestic violence threaten the health and well-being of hundreds of millions of people. New and re-emerging infectious diseases, and the greater recognition of mental health problems, require an urgent response. It is vital that approaches to health promotion evolve to meet changes in the determinants of health. To address emerging threats to health, new forms of action are needed. The challenges for the coming years will be to unlock the potential for health promotion inherent in many sectors of society, among local communities, and within families.

The Ottawa charter incorporates five key action areas in health promotion. They are :

a. build healthy public policy,
b. create supportive environment for health,
c. strenghthen community action for health,
d. develop personal skills, and
e. re-orient health services

a. *Build healthy public policy :* Health promotion goes beyond health care. It puts health on the agenda of policy makers in all sectors and at all levels, directing them to be aware of the health consequences of their decisions and to accept their responsibilities for health.

b. *Create supportive environment :* Systematic assessment of the health impact of a rapidly changing environment – particularly in areas of technology, work, energy production and urbanization – is essential and must be followed by action to ensure positive benefit to the health of the public. The protection of the natural and built environments and the conservation of natural resources must be addressed in any health promotion strategy.

c. *Strengthen community actions* : Health promotion works through concrete and effective community action in setting priorities, making decisions, planning strategies and implementing them to achieve better health. At the heart of this process is the empowerment of communities – their ownership and control of their own endeavours and destinies.

d. *Develop personal skills :* Health promotion supports personal and social development through providing information, education for health, and enhancing life skills. By so doing, it increases the options available to people to exercise more control over their own health and over their environment, and to make choices conducive to health.

e. *Reorient health servies :* The responsibility for health promotion in health services is shared among individuals, community groups, health professionals, health service institutions and governments. They must work together towards a health care system which contributes to the pursuit of health. The role of the health sector must move increasingly in a health promotion direction, beyond its responsibility for providing clinical and curative services. Health services need to embrace an expanded mandate which is sensitive and respects cultural needs. This mandate should support the needs of individuals and communities for a healthier life, and open channels between the health sector and broader social, political, economic and physical environmental components.

It also incorporates three basic strategies for health promotion, "enabling, mediating and advocacy", which are needed and applied to all health promotion action areas. They are briefly described below:

Advocate : Good health is a major resource for social, economic and personal development, and an important dimension of quality of life. Political economic, social, cultural, environmental, behavioural and biological factors can all favour health, or be harmful to it. Health promotion action aims at making these conditions favourable through advocacy for health.

Enable : Health promotion focusses on acheiving equity in health. Health promotion action aims at reducing differences in current health status and ensuring equal opportunities and resources to enable all people to achieve their fullest health potential. This includes a secure foundation in a supportive environment, access to information, life skills and opportunities for making healthy choices. People cannot achieve their fullest potential unless they are able to take control of those things which determine their health. This must apply equally to women and men.

Mediate : The prerequisities and prospects for health cannot be ensured by the health sector alone. More importantly, health promotion demands coordinated action by all concerned: by governments, by health and other social and economic sectors, by non-governmental and voluntary organizations, by local authorities, by industry and by the media. People in all walks of life are involved as individuals, families and communities. Professional and social groups and health personnel have a major responsibility to mediate between differing interests in society for the pursuit of health.

A Logo was created for Ottawa conference. Since then, WHO kept this symbol as the **Health Promotion Logo,** as it stands for the approaches to health promotion as outlined in Ottawa Charter. The Logo represents a circle with 3 wings. It incorporates five key action areas in health promotion and three basic health promotion strategies.

Health promotion strategies and programmes should be adapted to the local needs and possibilities of individual countries and regions to take into account differing social, cultural and economic systems.

Millennium Development Goals

In the Millennium Declaration of September 2000, Member States of the United Nations made a most passionate committment to address the crippling poverty and multiplying misery that grip many areas of the world. Governments had set a date of 2015 by which they would meet the Millennium Development Goals: eradicate extreme poverty and hunger, achieve universal primary education, promote gender equality and empower women, reduce child mortality, improve maternal health, combat HIV/AIDS, malaria and other diseases, ensure environmental sustainability and develop a global partnership for development.

Health policy

Policies are general statements based on human aspirations, set of values, commitments, assessment of current situation and an image of a desired future situation *(53)*. A national health policy is an expression of goals for improving the health situation, the priorities among these goals, and the main directions for attaining them *(74)*. Health policy is often defined at the national level.

Each country will have to develop a health policy of its own aimed at defined goals, for improving the people's health, in the light of its own problems, particular circumstances, social and economic structures, and political and administrative mechanisms. Among the crucial factors affecting realization of these goals are: a political commitment; financial implications; administrative reforms; community participation and basic legislation *(75)*.

A landmark in the development of health policy was the worldwide adoption of the goal of HFA by 2000 A.D. A further landmark was the Alma-Ata Declaration (1978) calling on all governments to develop and implement primary health care strategies to attain the target of "HFA" by 2000 A.D. and more recently, Millennium Development Goals.

Health services research

Health research has several ramifications. It may include (a) **Biomedical research**, to elucidate outstanding health problems and develop new or better ways of dealing with them; (b) **Intersectoral research**, for which relationships would have to be established with the institutions concerned with the other sectors, and (c) **Health services research** or health practice research (now called "health systems research").

The concept of health services research (HSR) was developed during 1981–1982. It has been defined as "the systematic study of the means by which biomedical and other relevant knowledge is brought to bear on the health of individuals and communities under a given set of conditions" *(76)*. HSR is wide in scope. It deals with all aspects of management of health services, viz. prioritization of health problems, planning, management, logistics and delivery of health care services. It deals with such topics as manpower, organization, the utilization of facilities, the quality of health care, cost-benefit and cost-effectiveness *(77)*.

Thousands of people suffer morbidity, mortality and disability not because of deficiencies in biomedical knowledge but as a result of the failure to apply this knowledge effectively. Health services research aims to correct this failure *(78)*.

The concept of HSR is holistic and multidisciplinary. The prime purpose of HSR is to improve the health of the people through improvement not only of conventional health services but also of other services that have a bearing on health. HSR is essential for the continuous evolution and refinement of health services *(76)*.

CONCEPT OF DISEASE

There have been many attempts to define disease. Webster defines disease as "a condition in which body health is impaired, a departure from a state of health, an alteration of the human body interrupting the performance of vital functions". The Oxford English Dictionary defines disease as "a condition of the body or some part or organ of the body in which its functions are disrupted or deranged". From an **ecological** point of view, disease is defined as "a maladjustment of the human organism to the environment" *(79)*. From a **sociological** point of view, disease is considered a social phenomenon, occurring in all societies *(80)* and defined and fought in terms of the particular cultural forces prevalent in the society. The simplest definition is, of course, that disease is just the opposite of health – i.e., any deviation from normal functioning or state of complete physical or mental well-being – since health and disease are mutually exclusive. These definitions are considered inadequate because they do not give a criterion by which to decide when a disease state begins, nor do they lend themselves to measurement of disease.

The WHO has defined health but not disease. This is because disease has many shades ("spectrum of disease") ranging from inapparent (subclinical) cases to severe manifest illness. Some diseases commence acutely (e.g., food poisoning), and some insidiously (e.g., mental illness, rheumatoid arthritis). In some diseases, a "carrier" state occurs in which the individual remains outwardly healthy, and is able to infect others (e.g., typhoid fever). In some instances, the same organism may cause more than one clinical manifestation (e.g., streptococcus). In some cases, the same disease may be caused by more than one organism (e.g., diarrhoea). Some diseases have a short course, and some a prolonged course. It is easy to determine illness when the signs and symptoms are manifest, but in many diseases the border line between normal and abnormal is indistinct as in the case of diabetes, hypertension and mental illness. The end-point or final outcome of disease is variable – recovery, disability or death of the host.

Distinction is also made between the words disease, illness and sickness which are not wholly synonymous. The term "disease" literally means "without ease" (uneasiness) – disease, the opposite of ease – when something is wrong with bodily function. "Illness" refers not only to the presence of a specific disease, but also to the individual's perceptions and behaviour in response to the disease, as well as the impact of that disease on the psychosocial environment *(81)*. "Sickness" refers to a state of social dysfunction. Susser *(82)* has suggested the following usage:

> Disease is a physiological/psychological dysfunction;
>
> Illness is a subjective state of the person who feels aware of not being well;
>
> Sickness is a state of social dysfunction, i.e., a role that the individual assumes when ill ("sickness role").

The clinician sees people who are ill rather than the diseases which he must diagnose and treat *(83)*. However, it

is possible to be victim of disease without feeling ill, and to be ill without signs of physical impairment. In short, an adequate definition of disease is yet to be found – a definition that is satisfactory or acceptable to the epidemiologist, clinician, sociologist and the statistician.

CONCEPT OF CAUSATION

Upto the time of Louis Pasteur (1922–1895), various concepts of disease causation were in vogue, e.g., the supernatural theory of disease, the theory of humors, the concept of contagion, miasmatic theory of disease, the theory of spontaneous generation, etc. Discoveries in microbiology marked a turning point in our aetiological concepts .

Germ theory of disease

Mention has already been made about the germ theory of disease in chapter 1. This concept gained momentum during the 19th and the early part of 20th century. The emphasis had shifted from empirical causes (e.g., bad air) to microbes as the sole cause of disease. The concept of cause embodied in the germ theory of disease is generally referred to as a **one-to-one** relationship between causal agent and disease. The disease model accordingly is :

Disease agent → Man → Disease

The germ theory of disease, though it was a revolutionary concept, led many epidemiologists to take one–sided view of disease causation. That is, they could not think beyond the germ theory of disease. It is now recognized that a disease is rarely caused by a single agent alone, but rather depends upon a number of factors which contribute to its occurrence. Therefore, modern medicine has moved away from the strict adherence to the germ theory of disease.

Epidemiological triad

The germ theory of disease has many limitations. For example, it is well-known, that not everyone exposed to tuberculosis develops tuberculosis. The same exposure, however, in an undernourished or otherwise susceptible person may result in clinical disease. Similarly, not everyone exposed to beta-haemolytic streptococci develops acute rheumatic fever. There are other factors relating to the host and environment which are equally important to determine whether or not disease will occur in the exposed host. This demanded a broader concept of disease causation that synthesized the basic factors of agent, host and environment (Fig. 4).

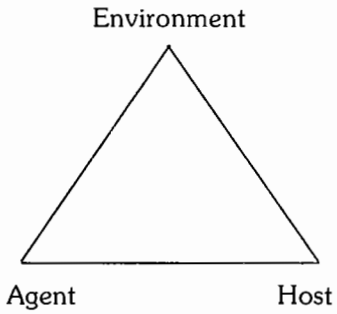

FIG. 4
Epidemiological triad

The above model – agent, host and environment – has been in use for many years. It helped epidemiologists to focus on different classes of factors, especially with regard to infectious diseases *(84)*.

The triangle of epidemiology *(59)*

The traditional triangle of epidemiology is shown in Figure 5. This triangle is based on the communicable disease model and is useful in showing the interaction and interdependence of agent, host, environment, and time as used in the investigation of diseases and epidemics. The agent is the cause of disease; the host is an organism, usually a human or an animal, that harbours the disease, the environment is those surroundings and conditions external to the human or animal that cause or allow disease transmission; and time accounts for incubation periods, life expectancy of the host or the pathogen, and duration of the course of illness or condition.

Agents of infectious diseases include bacteria, viruses, parasites, fungi, and molds. With regard to non-infectious disease, disability, injury, or death, agents can include chemicals from dietary foods, tobacco smoke, solvents, radiation or heat, nutritional deficiencies, or other substances, such as poison. One or several agents may contribute to an illness.

A host offers subsistence and lodging for a pathogen and may or may not develop the disease. The level of immunity, genetic makeup, level of exposure, state of health, and overall fitness of the host can determine the effect a disease organism will have on it. The makeup of the host and the ability of the pathogen to accept the new environment can also be a determining factor because some pathogens thrive only under limited ideal conditions. For example, many infectious disease agents can exist only in a limited temperature range.

Environmental factors can include the biological aspects as well as social, cultural, and physical aspects of the environment. The surroundings in which a pathogen lives and the effect the surroundings have on it are a part of the environment. Environment can be within a host or external to it in the community. Finally, time includes severity of illness in relation to how long a person is infected or until the condition causes death or passes the threshold of danger towards recovery. Delays in time from infection to when symptoms develop, duration of illness, and threshold of an epidemic in a population are time elements with which the epidemiologist is concerned.

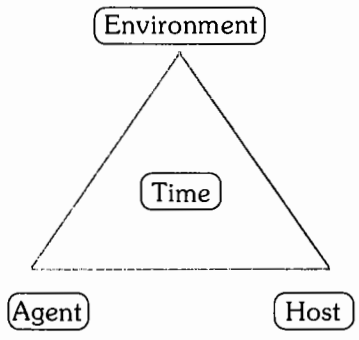

FIG. 5
The Triangle of Epidemiology

Source : *(59)*

The primary mission of epidemiology is to provide information that results in breaking one of the legs of the triangle, thereby disrupting the connection among environment, host, and agent, and stopping the outbreak.

Multifactorial causation

The concept that disease is due to multiple factors is not a new one. Pettenkofer of Munich (1819–1901) was an early proponent of this concept. But the "germ theory of disease" or "single cause idea" in the late 19th century overshadowed the multiple cause theory.

As a result of advances in public health, chemotherapy, antibiotics and vector control communicable diseases began to decline – only to be replaced by new types of diseases, the so-called "modern" diseases of civilization, e.g., lung cancer, coronary heart disease, chronic bronchitis, mental illness, etc. These diseases could not be explained on the basis of the germ theory of disease nor could they be prevented by the traditional methods of isolation, immunization or improvements in sanitation. The realization began to dawn that the "single cause idea" was an oversimplification and that there are other factors in the aetiology of diseases – social, economic, cultural, genetic and psychological which are equally important. As already mentioned, tuberculosis is not merely due to tubercle bacilli; factors such as poverty, overcrowding and malnutrition contribute to its occurrence. The doctrine of one-to-one relationship between cause and disease has been shown to be untenable, even for microbial diseases, e.g., tuberculosis, leprosy.

It is now known that diseases such as coronary heart disease and cancer are due to multiple factors. For example, excess of fat intake, smoking, lack of physical exercise and obesity are all involved in the pathogenesis of coronary heart disease. Most of these factors are linked to lifestyle and human behaviour. Epidemiology has contributed significantly to our present day understanding of multifactorial causation of disease. Medical men are looking "beyond the "germ theory" of disease into the total life situation of the patient and the community in search of multiple (or risk) factors of disease. Fig. 6 presents an adapted and ***advanced model of the triangle of epidemiology***. This new model includes all facets of the communicable disease model, and to make it more relevant and useful with regard to today's diseases, conditions, disorders, defects, injuries, and deaths; it also reflects the causes of current illnesses and conditions. Behaviour, lifestyle factors, environmental causes, ecologic elements, physical factors, and chronic diseases must also be taken into account. The term ***agent*** is replaced by ***causative factors***, which implies the need to identify multiple causes or a aetiologic factors of disease, disability, injury and death *(59)*.

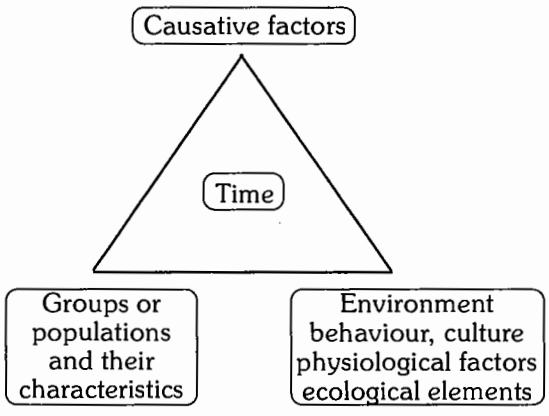

FIG. 6
Advanced model of the triangle of epidemiology

Source : *(59)*

The purpose of knowing the multiple factors of disease is to quantify and arrange them in priority sequence (prioritization) for modification or amelioration to prevent or control disease. The multifactorial concept offers multiple approaches for the prevention/control of disease.

Web of causation

This model of disease causation was suggested by MacMahon and Pugh in their book: "Epidemiologic Principles and Methods" *(85)*. This model is ideally suited in the study of chronic disease, where the disease agent is often not known, but is the outcome of interaction of multiple factors.

The "web of causation" considers all the predisposing factors of any type and their complex interrelationship with each other. Fig. 7 illustrates the complexities of a causal web of myocardial infarction (which is by no means complete). The basic tenet of epidemiology is to study the clusters of causes and combinations of effects and how they relate to each other *(86)*. It can be visualized that the causal web (Fig. 7) provides a model which shows a variety of possible interventions that could be taken which might reduce the occurrence of myocardial infarction.

The web of causation does not imply that the disease cannot be controlled unless all the multiple causes or chains of causation or at least a number of them are appropriately controlled or removed. This is not the case. Sometimes removal or elimination of just only one link or chain may be sufficient to control disease, provided that link is sufficiently important in the pathogenetic process. In a multifactorial event, therefore, individual factors are by no means all of equal weight. The relative importance of these factors may be expressed in terms of "relative risk" (see page 73).

NATURAL HISTORY OF DISEASE

Disease results from a complex interaction between man, an agent (or cause of disease) and the environment. The term ***natural history of disease*** is a key concept in epidemiology. It signifies the way in which a disease evolves over time from the earliest stage of its prepathogenesis phase to its termination as recovery, disability or death, in the absence of treatment or prevention. Each disease has its own unique natural history, which is not necessarily the same in all individuals, so much so, any general formulation of the natural history of disease is necessarily arbitrary.

The natural history of disease is best established by cohort studies (see page 75). As these studies are costly and laborious, our understanding of the natural history of disease is largely based on other epidemiological studies, such as cross-sectional and retrospective studies, undertaken in different population settings, both national and international. What the physician sees in the hospital is just an "episode" in the natural history of disease. The epidemiologist, by studying the natural history of disease in the community setting, is in a unique position to fill the gaps in our knowledge about the natural history of disease.

A schematic diagram of the natural history of disease is shown in Fig. 8. It is a necessary framework to understand the pathogenetic chain of events for a particular disease, and for the application of preventive measures. It is customary to describe the natural history of disease as consisting of two phases: prepathogenesis (i.e., the process in the environment) and pathogenesis (i.e., the process in man). Let us consider the events that take place in the natural history of disease, using infectious disease as a principal model *(87)*.

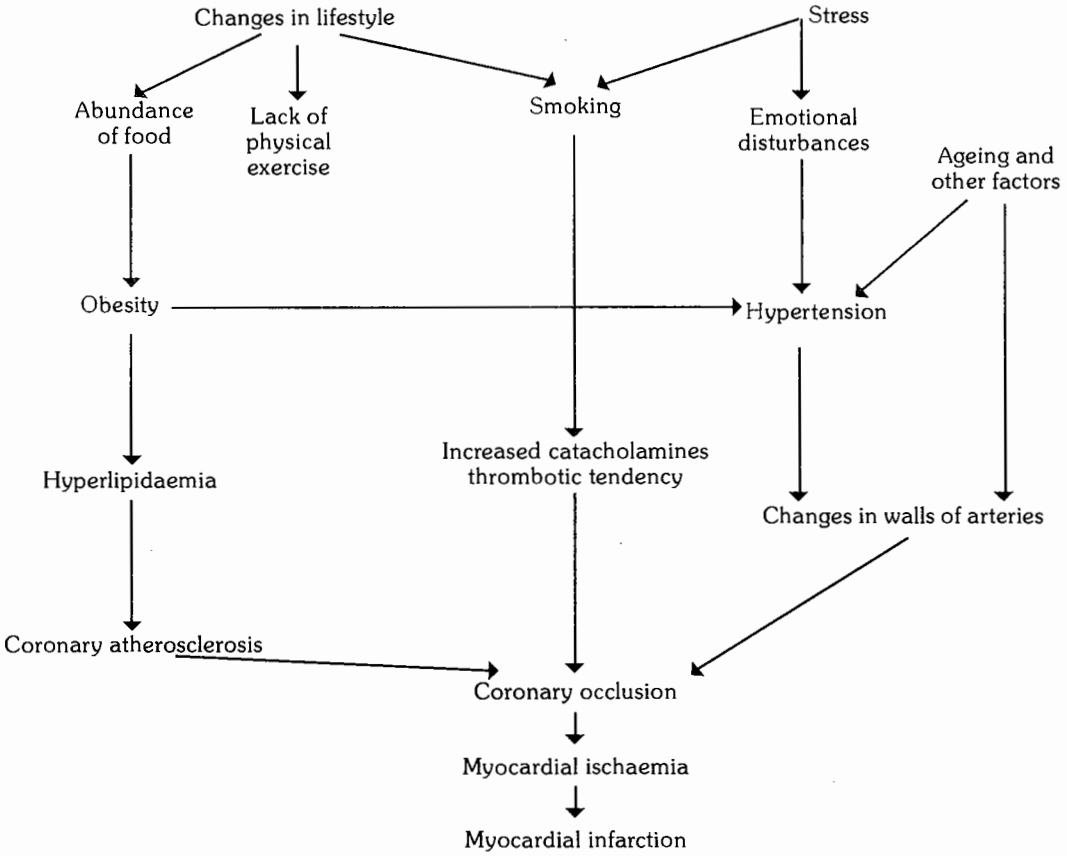

FIG. 7
Web of casuation for myocardial infarction

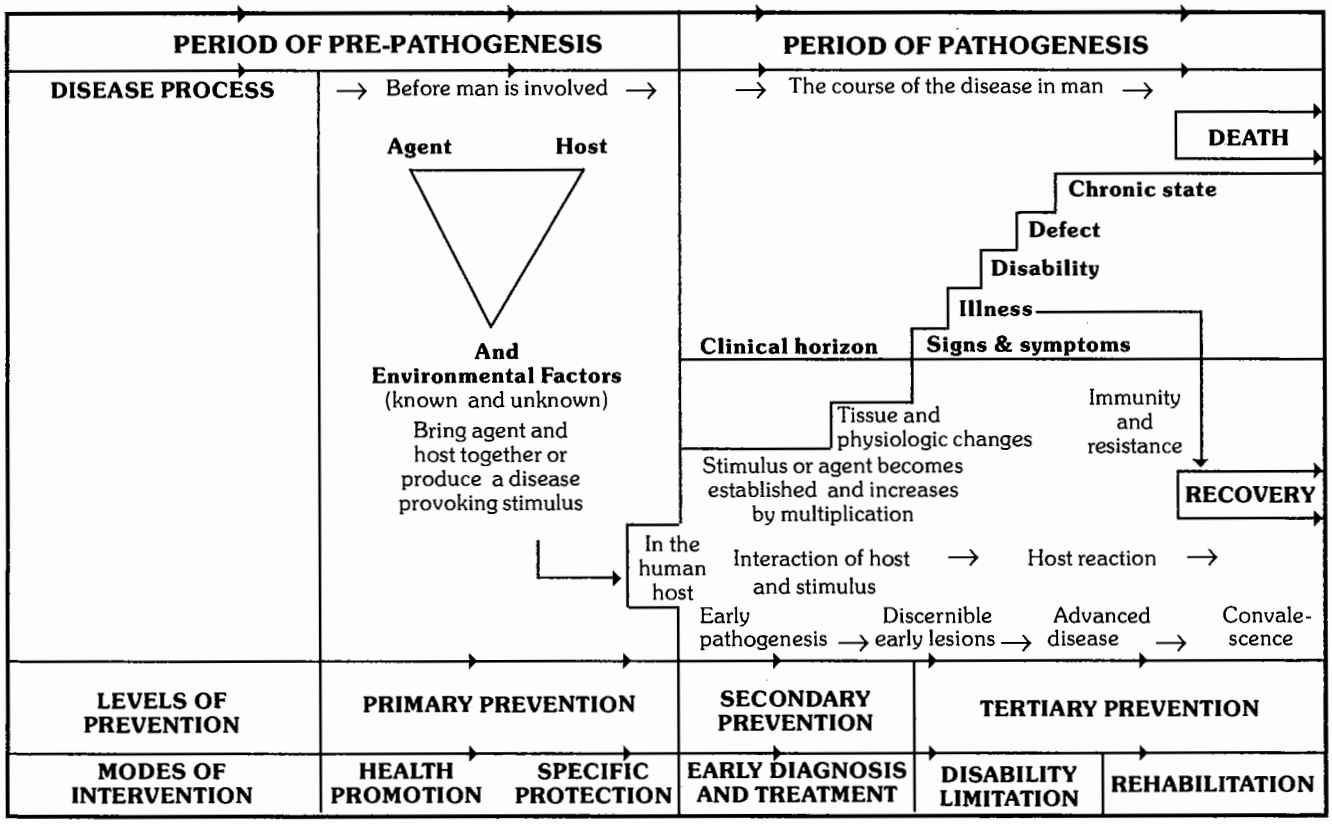

FIG. 8
Natural history of disease
(From Preventive Medicine for the Doctor in His Community, by Leavell & Clark with permission of McGraw-Hill Book Co.)

1. Prepathogenesis phase

This refers to the period preliminary to the onset of disease in man. The disease agent has not yet entered man, but the factors which favour its interaction with the human host are already existing in the environment. This situation is frequently referred to as "man in the midst of disease" or "man exposed to the risk of disease". Potentially we are all in the prepathogenesis phase of many diseases, both communicable and non-communicable.

The causative factors of disease may be classified as AGENT, HOST and ENVIRONMENT. These three factors are referred to as **epidemiological triad**. The mere presence of agent, host and favourable environmental factors in the prepathogenesis period is not sufficient to start the disease in man. What is required is an **interaction** of these three factors to initiate the disease process in man. The agent, host and environment operating in combination determine not only the onset of disease which may range from a single case to epidemics (as depicted in Fig. 9's black area) but also the distribution of disease in the community.

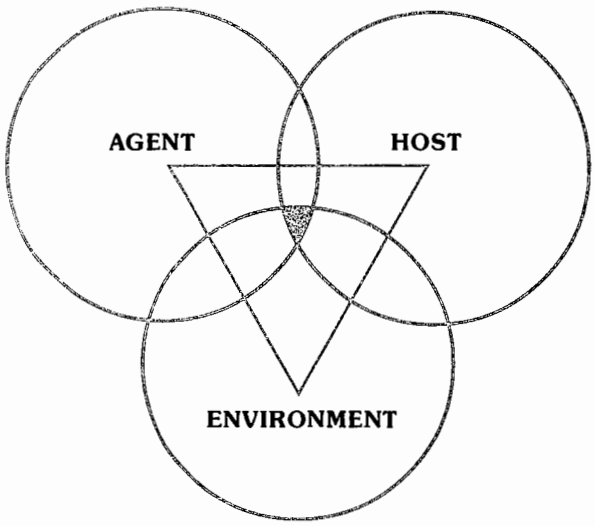

FIG. 9
Epidemiologic concept of interactions of Agent, Host and Environment
(Adapted from Health Services Reports, Vol. 87, page 672)

2. Pathogenesis phase

The pathogenesis phase begins with the entry of the disease "agent" in the susceptible human host. The further events in the pathogenesis phase are clear-cut in infectious diseases, i.e., the disease agent multiplies and induces tissue and physiological changes, the disease progresses through a period of incubation and later through early and late pathogenesis. The final outcome of the disease may be recovery, disability or death. The pathogenesis phase may be modified by intervention measures such as immunization and chemotherapy.

It is useful to remember at this stage that the host's reaction to infection with a disease agent is not predictable. That is, the infection may be clinical or subclinical; typical or atypical or the host may become a carrier with or without having developed clinical disease as in the case of diphtheria and hepatitis B.

In chronic diseases (e.g., coronary heart disease, hypertension, cancer), the early pathogenesis phase is less dramatic. This phase in chronic diseases is referred to as presymptomatic phase. During the presymptomatic stage, there is no manifest disease. The pathological changes are essentially below the level of the "clinical horizon". The clinical stage begins when recognizable signs or symptoms appear. By the time signs and symptoms appear, the disease phase is already well advanced into the late pathogenesis phase. In many chronic diseases, the agent-host-environmental interactions are not yet well understood.

Agent factors

The first link in the chain of disease transmission is a disease agent. The disease "agent" is defined as a substance, living or non-living, or a force, tangible or intangible, the excessive presence or relative lack of which may initiate or perpetuate a disease process. A disease may have a single agent, a number of independent alternative agents or a complex of two or more factors whose combined presence is essential for the development of the disease *(31)*.

Disease agents may be classified broadly into the following groups :

1. Biological agents

These are living agents of disease, viz, viruses, rickettsiae, fungi, bacteria, protozoa and metazoa. These agents exhibit certain "host–related" biological properties such as: (i) **infectivity**: this is the ability of an infectious agent to invade and multiply (produce infection) in a host; (ii) **pathogenicity**: this is the ability to induce clinically apparent illness, and (iii) **virulence**: this is defined as the proportion of clinical cases resulting in severe clinical manifestations (including sequelae). The case fatality rate is one way of measuring virulence *(84)*.

2. Nutrient agents

These are proteins, fats, carbohydrates, vitamins, minerals and water. Any excess or deficiency of the intake of nutritive elements may result in nutritional disorders. Protein energy malnutrition (PEM), anaemia, goitre, obesity and vitamin deficiencies are some of the current nutritional problems in many countries.

3. Physical agents

Exposure to excessive heat, cold, humidity, pressure, radiation, electricity, sound, etc may result in illness.

4. Chemical agents

(i) Endogenous: Some of the chemicals may be produced in the body as a result of derangement of function, e.g., urea (ureamia), serum bilirubin (jaundice), ketones (ketosis), uric acid (gout), calcium carbonate (kidney stones), etc.

(ii) Exogenous: Agents arising outside of human host, e.g., allergens, metals, fumes, dust, gases, insecticides, etc. These may be acquired by inhalation, ingestion or inoculation.

5. Mechanical agents

Exposure to chronic friction and other mechanical forces may result in crushing, tearing, sprains, dislocations and even death.

6. Absence or insufficiency or excess of a factor necessary to health

These may be (i) Chemical factors: e.g., hormones (insulin, oestrogens, enzymes) (ii) Nutrient factors: given under no. (2) above (iii) Lack of structure: e.g., thymus (iv) Lack of part of structure, e.g., cardiac defects (v) Chromosomal factors, e.g.,

mongolism, turner's syndrome, and (vi) Immunological factors, e.g., agammaglobulinaemia.

7. Social agents

It is also necessary to consider social agents of disease. These are poverty, smoking, abuse of drugs and alcohol, unhealthy lifestyles, social isolation, maternal deprivation, etc.

Thus the modern concept of disease "agent" is a very broad one; it includes both living and non-living agents.

Host factors (intrinsic)

In epidemiological terminology, the human host is referred to as "soil" and the disease agent as "seed". In some situations, host factors play a major role in determining the outcome of an individual's exposure to infection (e.g., tuberculosis).

The host factors may be classified as (i) Demographic characteristics such as age, sex, ethnicity; (ii) Biological characteristics such as genetic factors; biochemical levels of the blood (e.g., cholesterol); blood groups and enzymes; cellular constituents of the blood; immunological factors; and physiological function of different organ systems of the body (e.g., blood pressure, forced expiratory ventilation). etc. (iii) Social and economic characteristics such as socio-economic status, education, occupation, stress, marital status, housing, etc. and (iv) Lifestyle factors such as personality traits, living habits, nutrition, physical exercise, use of alcohol, drugs and smoking, behavioural patterns, etc. The association of a particular disease with a specific set of host factors frequently provides an insight into the cause of disease. The host factors of importance are further discussed in chapter 3.

Environmental factors (extrinsic)

The study of disease is really the study of man and his environment. Hundreds of millions of people are affected by preventable diseases originating in the environment in which they live. For human beings the environment is not limited, as it normally is for plants and animals, to a set of climatic factors. For example, for man, social and economic conditions are more important than the mean annual temperature. Thus the concept of environment is complex and all-embracing. The external or **macro-environment** is defined as "all that which is external to the individual human host, living and non-living, and with which he is in constant interaction". This includes all of man's external surroundings such as air, water, food, housing, etc.

For descriptive purposes, the environment of man has been divided into three components – physical, biological and psychosocial. It should be emphasized that this separation is artificial. They are closely related to each other and with host factors.

a. Physical environment

The term "physical environment" is applied to non-living things and physical factors (e.g., air, water, soil, housing, climate, geography, heat, light, noise, debris, radiation, etc) with which man is in constant interaction. Man's victory over his physical environment has been responsible for most of the improvement in health during the past century. In most developing countries, defective environment (e.g., lack of sanitation) continues to be the main health problem. Man has altered practically everything in his physical environment to his advantage. In doing so, he has created for himself a host of new health problems such as air pollution, water pollution, noise pollution, urbanization, radiation hazards, etc. The increasing use of electrical and electronic devices, including the rapid growth of telecommunication system (e.g., satellite systems), radio-broadcasting, television transmitters and radar installations have increased the possibility of human exposure to electromagnetic energy.

Man is living today in a highly complicated environment which is getting more complicated as man is becoming more ingenious. If these trends continue, it is feared that the very "quality of life" we cherish may soon be in danger.

b. Biological environment

The biological environment is the universe of living things which surrounds man, including man himself. The living things are the viruses and other microbial agents, insects, rodents, animals and plants. These are constantly working for their survival, and in this process, some of them act as disease–producing agents, reservoirs of infection, intermediate hosts and vectors of disease. Between the members of the ecological system (which includes man) there is constant adjustment and readjustment. For the most part, the parties manage to effect a harmonious inter-relationship, to achieve a state of peaceful co-existence, even though this may not be always enduring. When for any reason, this harmonious relationship is disturbed, ill-health results. In the area of biological environment also, preventive medicine has been highly successful in protecting the health of the individual and of the community.

c. Psychosocial environment

It is difficult to define "psychosocial environment" against the background of the highly varied social, economic and cultural contexts of different countries and their social standards and value systems. It includes a complex of psychosocial factors which are defined as "those factors affecting personal health, health care and community well-being that stem from the psychosocial make-up of individuals and the structure and functions of social groups" *(60)*. They include cultural values, customs, habits, beliefs, attitudes, morals, religion, education, lifestyles, community life, health services, social and political organization.

In addition to this broad aspect of psychosocial environment, man is in constant interaction with that part of the social environment known as "people". He is a member of a social group, the member of a family, of a caste, of a community and of a nation. Between the individual and other members of the group, there can be harmony or disharmony, interests and points of view that are shared or that are in conflict. The behaviour of one individual can affect others more or less directly; conflict and tension between the individual and the group as a whole or between the individual and other members of the group can yield great distress. The law of the land, customs, attitudes, beliefs, traditions, all regulate the interactions among groups of individuals and families.

The impact of social environment has both positive and negative aspects on the health of individuals and communities. A favourable social environment can improve health, provide opportunities for man to achieve a sense of fulfilment, and add to the quality of life. Therefore, customs and traditions favouring health must be preserved. Beneficial social behaviour (e.g., community participation) should be restored where it has disappeared due to social changes.

Psychosocial factors can also affect negatively man's health and well-being. For example, poverty, urbanization, migration and exposure to stressful situations such as bereavement, desertion, loss of employment, birth of a handicapped child may produce feelings of anxiety, depression, anger, frustration, and so forth; and these feelings may be accompanied by physical symptoms such as headache, palpitation and sweating. But these emotional states also produce changes in the endocrine, autonomic and motor systems, which, if prolonged and in interaction with genetic and personality factors, may lead to structural changes in various bodily organs. The resulting psychosomatic disorders include conditions such as duodenal ulcer, bronchial asthma, hypertension, coronary heart disease, mental disorders and socially deviant behaviour (e.g., suicide, crime, violence, drug abuse). Of primary concern is coronary heart disease which may be related to lifestyle and psychosocial stress. In many countries, road accidents are now the principal cause of death in young people. It is related to psychosocial states such as boredom, anxiety, frustration and other pre-occupations that can impair attention.

Man today is viewed as an "agent" of his own diseases; his state of health is determined more by what he does to himself than what some outside germ or infectious agent does to him. For example, the medical cause of lung cancer may be a chemical substance in cigarettes, but the psychosocial cause is behaviour – smoking. From a psychosocial point of view, disease may be viewed as a maladjustment of the human organism to his psychosocial environment resulting from misperception, misinterpretation and misbehaviour *(88)*. The epidemiologists today are as much concerned with psychosocial environment, as with physical or biological environment, in search for aetiological causes of disease.

Because of the fact that man exists concurrently in so many environmental contexts, it has become customary to speak of man in his "total environment". The social environment is so inextricably linked with the physical and biological environments that it is realistic and necessary to view the human environment in toto to promote health. A stable and harmonious equilibrium between man and his environment is needed to reduce man's vulnerability to disease and to permit him to lead a more productive and satisfying life.

Risk factors

For many diseases, the disease "agent" is still unidentified, e.g. coronary heart disease, cancer, peptic ulcer, mental illness, etc. Where the disease agent is not firmly established, the aetiology is generally discussed in terms of "risk factors".

The term "risk factor" is used by different authors with at least two meanings *(31)*:

a. an attribute or exposure that is significantly associated with the development of a disease *(89)*;
b. a determinant that can be modified by intervention, thereby reducing the possibility of occurrence of disease or other specified outcomes *(31)*;

Risk factors are often suggestive, but absolute proof of cause and effect between a risk factor and disease is usually lacking. That is, the presence of a risk factor does not imply that the disease will occur, and in its absence, the disease will not occur. The important thing about risk factors is that they are observable or identifiable prior to the event they predict. It is also recognized that combination of risk factors in the same individual may be purely additive or synergistic (multiplicative). For example, smoking and occupational exposure (shoe, leather, rubber, dye and chemical industries) were found to have an additive effect as risk factors for bladder cancer *(85)*. On the other hand, smoking was found to be synergistic with other risk factors such as hypertension and high blood cholesterol *(90)*. That is, the effects are more than additive.

Risk factors may be truly causative (e.g., smoking for lung cancer); they may be merely contributory to the undesired outcome (e.g., lack of physical exercise is a risk factor for coronary heart disease), or they may be predictive only in a statistical sense (e.g., illiteracy for perinatal mortality).

Some risk factors can be modified; others cannot be modified. The modifiable factors include smoking, hypertension, elevated serum cholesterol, physical activity, obesity, etc. They are amenable to intervention and are useful in the care of the individual. The unmodifiable or immutable risk factors such as age, sex, race, family history and genetic factors are not subject to change. They act more as signals in alerting health professionals and other personnel to the possible outcome *(91)*.

Risk factors may characterize the individual, the family, the group, the community or the environment. For example, some of the individual risk factors include age, sex, smoking, hypertension, etc. But there are also collective community risks – for example, from the presence of malaria, from air pollution, from substandard housing, or a poor water supply or poor health care services. The degree of risk in these cases is indirectly an expression of **need**. Therefore it is stated that a risk factor is a proxy for need – indicating the need for promotive and preventive health services.

Epidemiological methods (e.g., case control and cohort studies) are needed to identify risk factors and estimate the degree of risk. These studies are carried out in population groups among whom certain diseases occur much more frequently than other groups. By such comparative studies, epidemiologists have been able to identify smoking as a risk for lung cancer; high serum cholesterol and high blood pressure as risk factors for coronary heart disease. The contribution of epidemiology in the identification of risk factors has been highly significant. Risk factors associated with some major disease groups are as shown in Table 5.

TABLE 5
Prominent risk factors

Disease	Risk factors
Heart disease	Smoking, high blood pressure, elevated serum cholesterol, diabetes, obesity, lack of exercise, type A personality
Cancer	Smoking, alcohol, solar radiation, ionizing radiation, work-site hazards, environmental pollution, medications, infectious agents, dietary factors
Stroke	High blood pressure, elevated cholesterol, smoking
Motor vehicle accidents	Alcohol, non-use of seat belts, speed, automobile design, roadway design
Diabetes	Obesity, diet
Cirrhosis of liver	Alcohol

Source : *(92)*

The detection of risk factors should be considered a prelude to prevention or intervention. For each risk factor ascertained, the question has to be asked whether it can be reduced in a cost-effective way and whether its reduction will prevent or delay the unwanted outcome *(93)*. Since the detection procedure usually involves whole population, it bears some similarity to presymptomatic screening for disease *(91)*.

Risk groups

Another approach developed and promoted by WHO is to identify precisely the "risk groups" or "target groups" (e.g., at-risk mothers, at-risk infants, at-risk families, chronically ill, handicapped, elderly) in the population by certain defined criteria and direct appropriate action to them first. This is known as the "risk approach". It has been summed up as "something for all, but more for those in need – in proportion to the need" *(53)*. In essence, the risk approach is a managerial device for increasing the efficiency of health care services within the limits of existing resources *(94)*. WHO has been using the risk approach in MCH services since a long time (Table 6).

TABLE 6
Guidelines for defining "at-risk" groups

a. Biological situation:
- age group, e.g., infants (low birth weight), toddlers, elderly
- sex, e.g., females in the reproductive age period
- physiological state, e.g., pregnancy, cholesterol level, high blood pressure
- genetic factors, e.g. family history of genetic disorders
- other health conditions (disease, physical functioning, unhealthy behaviour)

b. Physical situation:
- rural, urban slums
- living conditions, overcrowding
- environment: water supply, proximity to industries

c. Sociocultural and cultural situation:
- social class
- ethnic and cultural group
- family disruption, education, housing
- customs, habits and behaviour (e.g., smoking, lack of exercise, over-eating, drug addicts)
- access to health services
- lifestyles and attitudes

Source : *(95)*

Modern epidemiology is concerned with the identification of risk factors and high-risk groups in the population. Since resources are scarce, identification of those at risk is imperative. It helps to define priorities and points to those most in need of attention. The knowledge of risk factors and risk groups can be used to prevent disease in so far as we are able to remove or minimize the risk.

Spectrum of disease

The term "spectrum of disease" is a graphic representation of variations in the manifestations of disease. It is akin to the spectrum of light where the colours vary from one end to the other, but difficult to determine where one colour ends and the other begins. At one end of the disease spectrum are subclinical infections which are not ordinarily identified, and at the other end are fatal illnesses. In the middle of the spectrum lie illnesses ranging in severity from mild to severe. These different manifestations are simply reflections of individuals' different states of immunity and receptivity. Leprosy is an excellent example of the spectral concept of disease. For almost every disease there exists a spectrum of severity, with few exceptions such as rabies. In infectious diseases, the spectrum of disease is also referred to as the "gradient of infection".

The sequence of events in the spectrum of disease can be interrupted by early diagnosis and treatment or by preventive measures which if introduced at a particular point will prevent or retard the further development of the disease. The concept of spectrum of disease provides for inclusion of all cases, both subclinical and clinical, in the study of disease.

Iceberg of disease

A concept closely related to the spectrum of disease is the concept of the iceberg phenomenon of disease. According to this concept, disease in a community may be compared with an iceberg (Fig. 10). The floating tip of the iceberg represents what the physician sees in the community, i.e., clinical cases. The vast submerged portion of the iceberg represents the hidden mass of disease, i.e., latent, inapparent, presymptomatic and undiagnosed cases and carriers in the community. The "waterline" represents the demarcation between apparent and inapparent disease.

In some diseases (e.g., hypertension, diabetes, anaemia, malnutrition, mental illness) the unknown morbidity (i.e., the submerged portion of the iceberg) far exceeds the known morbidity. The hidden part of the iceberg thus constitutes an important, undiagnosed reservoir of infection or disease in the community, and its detection and control is a challenge to modern techniques in preventive medicine. One of the major deterrents in the study of chronic diseases of unknown aetiology is the absence of methods to detect the subclinical state – the bottom of the iceberg *(96)*.

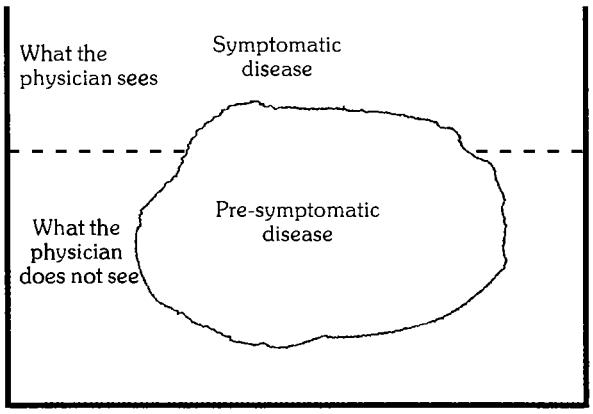

FIG. 10
The Iceberg of disease

CONCEPTS OF CONTROL

Disease control

The term "disease control" describes (ongoing) operations aimed at reducing:

i. the incidence of disease
ii. the duration of disease, and consequently the risk of transmission
iii. the effects of infection, including both the physical and psychosocial complications; and
iv. the financial burden to the community.

Control activities may focus on primary prevention or secondary prevention, most control programmes combine the two. The concept of tertiary prevention is comparatively less relevant to control efforts.

In disease control, the disease "agent" is permitted to persist in the community at a level where it ceases to be a public health problem according to the tolerance of the local population. A state of equilibrium becomes established between the disease agent, host and environment components of the disease process. An excellent embodiment of this concept is malaria control, which is distinct from malaria eradication.

Disease elimination

Between control and eradication, an intermediate goal has been described, called "regional elimination" *(97)*. The term "elimination" is used to describe interruption of transmission of disease, as for example, elimination of measles, polio and diphtheria from large geographic regions or areas *(31)*. Regional elimination is now seen as an important precursor of eradication *(97)*.

Disease eradication

Eradication literally means to "tear out by roots". Eradication of disease implies termination of all transmission of infection by extermination of the infectious agent *(31)*. As the name implies, eradication is an absolute process, and not a relative goal. It is "all or none phenomenon". The word eradication is reserved to cessation of infection and disease from the whole world *(97)*.

Today, smallpox is the only disease that has been eradicated globally. Every disease like every human being is unique with its own epidemiological characteristics and specific strategies for control.

During recent years, three diseases have been seriously advanced as candidates for global eradication within the foreseeable future: polio, measles and dracunculiasis. The feasibility of eradicating polio appears to be greater than that of others and the goal is in sight.

Experience gained from eradication programmes (e.g., malaria, yaws) has shown that once the morbidity of a disease reaches a very low level, a "residual" infection usually persists in the population leading to a state of equilibrium between the agent, host and environmental components of the disease process. In this situation, there are always hidden foci of infection, unrecognized methods of transmission, resistance of the vector or organism, all of which may again flare up when the agent–host–environment equilibrium is disturbed *(98)*. Failure to understand this led to disappointment in the eradication programmes mounted against malaria, yaws, plague, kala-azar and yellow fever.

Monitoring and surveillance

According to standard dictionaries, the words monitoring and surveillance are almost synonymous. But in public health practice they have taken on rather specific and somewhat different meanings *(99)*:

i) Monitoring

Monitoring is "the performance and analysis of routine measurements aimed at detecting changes in the environment or health status of population" *(31)*. Thus we have monitoring of air pollution, water quality, growth and nutritional status, etc. It also refers to on-going measurement of performance of a health service or a health professional, or of the extent to which patients comply with or adhere to advice from health professionals.

In management, monitoring refers to "the continuous oversight of activities to ensure that they are proceeding according to plan. It keeps track of achievements, staff movements and utilization, supplies and equipment, and the money spent in relation to the resources available so that if anything goes wrong, immediate corrective measures can be taken" *(53)*.

ii) Surveillance

Surveillance is defined in many ways. According to one interpretation, surveillance means to watch over with great attention, authority and often with suspicion *(95)*. According to another, surveillance is defined as "the continuous scrutiny of the factors that determine the occurrence and distribution of disease and other conditions of ill-health" *(100)*. Surveillance programmes can assume any character and dimension – thus we have epidemiological surveillance *(101)*, demographic surveillance, nutritional surveillance *(102)*, etc.

The main objectives of surveillance are: (a) to provide information about new and changing trends in the health status of a population, e.g., morbidity, mortality, nutritional status or other indicators and environmental hazards, health practices and other factors that may affect health *(103)*; (b) to provide feed-back which may be expected to modify the policy and the system itself and lead to redefinition of objectives, and (c) provide timely warning of public health disasters so that interventions can be mobilized.

According to the above definitions, monitoring becomes one specific and essential part of the broader concept embraced by surveillance. Monitoring requires careful planning and the use of standardized procedures and methods of data collection, and can then be carried out over extended periods of time by technicians and automated instrumentation. Surveillance, in contrast, requires professional analysis and sophisticated judgement of data leading to recommendations for control activities.

Sentinel surveillance

No routine notification system can identify all cases of infection or disease. A method for identifying the missing cases and thereby supplementing the notified cases is required. This is known as "sentinel surveillance." The sentinel data is extrapolated to the entire population to estimate the disease prevalence in the total population. The advantages of such a system are that the reporting biases are minimized, and feed-back of information to the providers is simplified.

Sentinel surveillance agencies could be interested and competent physicians (or institutions) in selected areas to report the cases of disease in their areas. This system would provide more valuable and detailed information than could be obtained from the traditional notification system *(104)*. Finally, these sentinel sites could be developed into a notification system for providing more detailed information, which, in some settings, may be less costly than developing and maintaining an ongoing notification system.

Evaluation of control

Evaluation is the process by which results are compared with the intended objectives, or more simply the assessment of how well a programme is performing. Evaluation should always be considered during the planning and implementation stages of a programme or activity.

Evaluation may be crucial in identifying the health benefits derived (impact on morbidity, mortality, sequelae, patient satisfaction). Evaluation can be useful in identifying performance difficulties. Evaluation studies may also be carried out to generate information for other purposes, e.g., to attract attention to a problem, extension of control activities, training and patient management, etc. The principles of evaluation are discussed in chapter 20.

CONCEPTS OF PREVENTION

The goals of medicine are to promote health, to preserve health, to restore health when it is impaired, and to minimize suffering and distress. These goals are embodied in the word "prevention" *(31)*. Successful prevention depends upon a knowledge of causation, dynamics of transmission, identification of risk factors and risk groups, availability of prophylactic or early detection and treatment measures, an organization for applying these measures to appropriate persons or groups, and continuous evaluation of and development of procedures applied *(105)*.

It is not necessary (although desirable) to know everything about the natural history of a disease to initiate preventive measures. Often times, removal or elimination of a single known essential cause may be sufficient to prevent a disease. The objective of preventive medicine is to intercept or oppose the "cause" and thereby the disease process. This epidemiological concept permits the inclusion of treatment as one of the modes of intervention *(87)*.

Levels of prevention

In modern day, the concept of prevention has become broad–based. It has become customary to define prevention in terms of four level:

1. primordial prevention
2. primary prevention
3. secondary prevention
4. tertiary prevention

These levels of prevention are shown in Fig.10 in relation to the natural history of disease. Authorities on preventive medicine do not agree on the precise boundaries between these levels, but that does not minimize their importance. For example, the supply of food supplements to a family could be primary prevention for some members, and secondary prevention (curative) for others. These differences of opinion are more semantic than substantive *(31)*. A general discussion of these concepts is given below:

1. Primordial prevention

Primordial prevention, a new concept, is receiving special attention in the prevention of chronic diseases. This is primary prevention in its purest sense, that is, prevention of the emergence or development of risk factors in countries or population groups in which they have not yet appeared. For example, many adult health problems (e.g., obesity, hypertension) have their early origins in childhood, because this is the time when lifestyles are formed (for example, smoking, eating patterns, physical exercise). In primordial prevention, efforts are directed towards discouraging children from adopting harmful lifestyles. The main intervention in primordial prevention is through individual and mass education.

2. Primary prevention

Primary prevention can be defined as "action taken prior to the onset of disease, which removes the possibility that a disease will ever occur". It signifies intervention in the pre-pathogenesis phase of a disease or health problem (e.g., low birth weight) or other departure from health. Primary prevention may be accomplished by measures designed to promote general health and well-being, and quality of life of people or by specific protective measures. These are discussed in detail elsewhere under "Mode of Intervention".

Primary prevention is far more than averting the occurrence of a disease and prolonging life. It includes the concept of "positive health", a concept that encourages achievement and maintenance of "an acceptable level of health that will enable every individual to lead a socially and economically productive life". It concerns an individual's attitude towards life and health and the initiative he takes about positive and responsible measures for himself, his family and his community.

The concept of primary prevention is now being applied to the prevention of chronic diseases such as coronary heart disease, hypertension and cancer based on elimination or modification of "risk-factors" of disease. The WHO has recommended the following approaches for the primary prevention of chronic diseases where the risk factors are established *(106)* :

a. population (mass) strategy

b. high-risk strategy

a. Population (mass) strategy

Another preventive approach is "population strategy" which is directed at the whole population irrespective of individual risk levels. For example, studies have shown that even a small reduction in the average blood pressure or serum cholesterol of a population would produce a large reduction in the incidence of cardiovascular disease *(107)*. The population approach is directed towards socio-economic, behavioural and lifestyle changes *(107)*.

b. High-risk strategy

The high-risk strategy aims to bring preventive care to individuals at special risk. This requires detection of individuals at high risk by the optimum use of clinical methods.

Primary prevention is a desirable goal. It is worthwhile to recall the fact that the industrialized countries succeeded in eliminating a number of communicable diseases like cholera, typhoid and dysentery and controlling several others like plague, leprosy and tuberculosis, not by medical interventions but mainly by raising the standard of living (primary prevention). And much of this success came even before immunization became universal routine. The application of primary prevention to the prevention of chronic disease is a recent development. To have an impact on the population, all the above three approaches (primordial prevention, population strategy and high-risk strategy) should be implemented as they are usually complementary.

In summary, primary prevention is a "holistic" approach. It relies on measures designed to promote health or to protect against specific disease "agents" and hazards in the environment. It utilizes knowledge of the prepathogenesis phase of disease, embracing the agent, host and environment. Fundamental public health measures and activities such as sanitation; infection control; immunization; protection of food, milk, and water supplies; environmental

protection; and protection against occupational hazards and accidents are all basic to primary prevention. Basic personal hygiene and public health measures have had a major impact on halting communicable disease epidemics. Immunization, infection control (eg, hand washing), refrigeration of foods, garbage collection, solid and liquid waste management, water supply protection and treatment, and general sanitation have reduced infectious disease threats to populations. The safety and low cost of primary prevention justifies its wider application. Primary prevention has become increasingly identified with "health education" and the concept of individual and community responsibility for health *(108)*.

3. Secondary prevention

Secondary prevention can be defined as "action which halts the progress of a disease at its incipient stage and prevents complications". The specific interventions are early diagnosis (e.g., screening tests, case finding programmes) and adequate treatment. By early diagnosis and adequate treatment, secondary prevention attempts to arrest the disease process; restore health by seeking out unrecognized disease and treating it before irreversible pathological changes have taken place; and reverse communicability of infectious diseases. It may also protect others in the community from acquiring the infection and thus provide, at once, secondary prevention for the infected individuals and primary prevention for their potential contacts *(84)*.

Secondary prevention is largely the domain of clinical medicine. The health programmes initiated by governments are usually at the level of secondary prevention. The drawback of secondary prevention is that the patient has already been subject to mental anguish, physical pain; and the community to loss of productivity. These situations are not encountered in primary prevention.

Secondary prevention is an imperfect tool in the control of transmission of disease. It is often more expensive and less effective than primary prevention. In the long run, human health, happiness and useful longevity will be achieved at far less expense with less suffering through primary prevention than through secondary prevention *(109)*.

4. Tertiary prevention

When the disease process has advanced beyond its early stages, it is still possible to accomplish prevention by what might be called "tertiary prevention" *(87)*. It signifies intervention in the late pathogenesis phase. Tertiary prevention can be defined as "all measures available to reduce or limit impairments and disabilities, minimize suffering caused by existing departures from good health and to promote the patient's adjustment to irremediable conditions" *(31)*. For example, treatment, even if undertaken late in the natural history of disease may prevent sequelae and limit disability. When defect and disability are more or less stabilized, rehabilitation may play a preventable role. Modern rehabilitation includes psychosocial, vocational, and medical components based on team work from a variety of professions. Tertiary prevention extends the concept of prevention into fields of rehabilitation.

Table 7 summarizes the levels of prevention.

MODES OF INTERVENTION

"Intervention" can be defined as any attempt to intervene or interrupt the usual sequence in the development of disease in man. This may be by the provision of treatment, education, help or social support. Five modes of intervention have been described which form a continuum corresponding to the natural history of any disease. These levels are related to agent, host and environment and are shown in Fig. 9. They are:

1. Health promotion
2. Specific protection
3. Early diagnosis and treatment
4. Disability limitation
5. Rehabilitation

TABLE 7

Levels of prevention

Level	Phase of disease	Aim	Actions	Target
Primordial	Underlying economic, social, and environmental conditions leading to causation	Establish and maintain conditions that minimize hazards to health	Measures that inhibit the emergence of environmental, economic, social and behavioural conditions.	Total population or selected groups; achieved through public health policy and health promotion.
Primary	Specific causal factors	Reduce the incidence of disease	Protection of health by personal and community efforts, such as enhancing nutritional status, providing immunizations, and eliminating environmental risks.	Total population, selected groups and individuals at high-risk; achieved through public health programmes
Secondary	Early stage of disease	Reduce the prevalence of disease by shortening its duration	Measures available to individuals and communities for early detection and prompt intervention to control disease and minimize disability (e.g. through screening programmes).	Individuals with established disease; achieved through early diagnosis and treatment.
Tertiary	Late stage of disease (treatment, rehabilitation)	Reduce the number and/or impact of complications	Measures aimed at softening the impact of long-term disease and disability; minimizing suffering; maximizing potential years of useful life.	Patients; achieved through rehabilitation.

Source : *(58)*

1. Health promotion

Health promotion is "the process of enabling people to increase control over, and to improve health " *(110)*. It is not directed against any particular disease, but is intended to strengthen the host through a variety of approaches (interventions). The well–known interventions in this area are:

i. health education
ii. environmental modifications
iii. nutritional interventions
iv. lifestyle and behavioural changes

(i) **Health education**: This is one of the most cost–effective interventions. A large number of diseases could be prevented with little or no medical intervention if people were adequately informed about them and if they were encouraged to take necessary precautions in time. Recognizing this truth, the WHO's constitution states that "the extension to all people of the benefits of medical, psychological and related knowledge is essential to the fullest attainment of health". The targets for educational efforts may include the general public, patients, priority groups, health providers, community leaders and decision–makers.

(ii) **Environmental modifications**: A comprehensive approach to health promotion requires environmental modifications, such as provision of safe water; installation of sanitary latrines; control of insects and rodents; improvement of housing, etc. The history of medicine has shown that many infectious diseases have been successfully controlled in western countries through environmental modifications, even prior to the development of specific vaccines or chemotherapeutic drugs. Environmental interventions are non-clinical and do not involve the physician.

(iii) **Nutritional interventions**: These comprise food distribution and nutrition improvement of vulnerable groups; child feeding programmes; food fortification; nutrition education, etc.

(iv) **Lifestyle and behavioural changes**: The conventional public health measures or interventions have not been successful in making inroads into lifestyle reforms. The action of prevention in this case, is one of individual and community responsibility for health (see page 19), the physician and in fact each health worker acting as an educator than a therapist. Health education is a basic element of all health activity. It is of paramount importance in changing the views, behaviour and habits of people.

Since health promotion comprises a broad spectrum of activities, a well-conceived health promotion programme would first attempt to identify the "target groups" or at-risk individuals in a population and then direct more appropriate message to them *(111)*. Goals must be defined. Means and alternative means of accomplishing them must be explored. It involves "organizational, political, social and economic interventions designed to facilitate environmental and behavioural adaptations that will improve or protect health" *(112)*.

2. Specific protection

To avoid disease altogether is the ideal but this is possible only in a limited number of cases. The following are some of the currently available interventions aimed at specific protection: (a) immunization (b) use of specific nutrients (c) chemoprophylaxis (d) protection against occupational hazards (e) protection against accidents (f) protection from carcinogens (g) avoidance of allergens (h) the control of specific hazards in the general environment, e.g., air pollution, noise control (i) control of consumer product quality and safety of foods, drugs, cosmetics, etc.

Health protection

The term "health protection" which is quite often used, is not synonymous with specific protection. Health protection is defined as "The provision of conditions for normal mental and physical functioning of the human being individually and in the group. It includes the promotion of health, the prevention of sickness and curative and restorative medicine in all its aspects" *(56)*. In fact, health protection is conceived as an integral part of an overall community development programme, associated with activities such as literacy campaigns, education and food production *(113)*. Thus health protection covers a much wider field of health activities than specific protection.

3. Early diagnosis and treatment

A WHO Expert Committee *(114)* defined early detection of health impairment as "the detection of disturbances of homoeostatic and compensatory mechanism while biochemical, morphological, and functional changes are still reversible." Thus, in order to prevent overt disease or disablement, the criteria of diagnosis should, if possible, be based on early biochemical, morphological and functional changes that precede the occurrence of manifest signs and symptoms. This is of particular importance in chronic diseases.

Early detection and treatment are the main interventions of disease control. The earlier a disease is diagnosed and treated the better it is from the point of view of prognosis and preventing the occurrence of further cases (secondary cases) or any long-term disability. It is like stamping out the "spark" rather than calling the fire brigade to put out the fire.

Strictly speaking, early diagnosis and treatment cannot be called prevention because the disease has already commenced in the host. However, since early diagnosis and treatment intercepts the disease process, it has been included in the schema of prevention, in as much as the goal of prevention is "to oppose or intercept a cause to prevent or dissipate its effect." *(87)*.

Early diagnosis and treatment though not as effective and economical as "primary prevention" may be critically important in reducing the high morbidity and mortality in certain diseases such as essential hypertension, cancer cervix and breast cancer. For many others such as tuberculosis, leprosy and STD, early diagnosis and treatment are the only effective mode of intervention. Early effective therapy has made it possible to shorten considerably the period of communicability and reduce the mortality from acute communicable diseases.

Mass treatment: A mass treatment approach is used in the control of certain diseases, viz. yaws, pinta, bejel, trachoma and filaria, The rationale for a mass treatment programme is the existence of at least 4–5 cases of latent infection for each clinical case of active disease in the community. Patients with a latent (incubating) infection may develop disease at any time. In such cases, mass treatment is a critical factor in the interruption of disease transmission. There are many variants of mass treatment – total mass treatment, juvenile mass treatment, selective mass treatment, depending upon the nature and prevalence of disease in the community *(104)*.

4. Disability limitation

When a patient reports late in the pathogenesis phase, the mode of intervention is disability limitation. The objective of this intervention is to prevent or halt the transition of the disease process from impairment to handicap.

Concept of disability

The sequence of events leading to disability and handicap have been stated as follows *(115)*:

Disease → impairment → disability → handicap

The WHO *(115)* has defined these terms as follows:

(i) **Impairment** : An impairment is defined as "any loss or abnormality of psychological, physiological or anatomical structure or function", e.g., loss of foot, defective vision or mental retardation. An impairment may be visible or invisible, temporary or permanent, progressive or regressive. Further, one impairment may lead to the development of "secondary" impairments as in the case of leprosy where damage to nerves (primary impairment) may lead to plantar ulcers (secondary impairment).

(ii) **Disability** : Because of an impairment, the affected person may be unable to carry out certain activities considered normal for his age, sex, etc. This inability to carry out certain activities is termed "disability". A disability has been defined as "any restriction or lack of ability to perform an activity in the manner or within the range considered normal for a human being".

(iii) **Handicap** : As a result of disability, the person experiences certain disadvantages in life and is not able to discharge the obligations required of him and play the role expected of him in the society. This is termed "handicap", and is defined as "a disadvantage for a given individual, resulting from an impairment or a disability, that limits or prevents the fulfilment of a role that is normal (depending on age, sex, and social and cultural factors) for that individual".

Taking accidents as an example, the above terms can be explained further as follows *(93)*:

Accident.....	Disease (or disorder)
Loss of foot	Impairment (extrinsic or intrinsic)
Cannot walk	Disability (objectified)
Unemployed	Handicap (socialized)

FIG. 11
Concept of disability

The intervention in disability will often be social or environmental as well as medical. While impairment which is the earliest stage has a large medical component, disability and handicap which are later stages have large social and environmental components in terms of dependence and social cost *(93)*.

Disability prevention

Another concept is "disability prevention". It relates to all the levels of prevention: (a) reducing the occurrence of impairment, viz. immunization against polio (primary prevention); (b) disability limitation by appropriate treatment (secondary prevention); and, (c) preventing the transition of disability into handicap (tertiary prevention) *(116)*.

The major causes of disabling impairments in the developing countries are communicable diseases, malnutrition, low quality of perinatal care and accidents. These are responsible for about 70 per cent of cases of disability in developing countries. Primary prevention is the most effective way of dealing with the disability problem in developing countries *(116)*.

5. Rehabilitation

Rehabilitation has been defined as "the combined and coordinated use of medical, social, educational and vocational measures for training and retraining the individual to the highest possible level of functional ability" *(117)*. It includes all measures aimed at reducing the impact of disabling and handicapping conditions and at enabling the disabled and handicapped to achieve social integration *(116)*. Social integration has been defined as the active participation of disabled and handicapped people in the mainstream of community life *(118)*.

Rehabilitation medicine has emerged in recent years as a medical speciality. It involves disciplines such as physical medicine or physiotherapy, occupational therapy, speech therapy, audiology, psychology, education, social work, vocational guidance and placement services. The following areas of concern in rehabilitation have been identified:

(a) Medical rehabilitation – restoration of function.

(b) Vocational rehabilitation – restoration of the capacity to earn a livelihood.

(c) Social rehabilitation – restoration of family and social relationships.

(d) Psychological rehabilitation – restoration of personal dignity and confidence.

Rehabilitation is no longer looked upon as an extra-curricular activity of the physician. The current view is that the responsibility of the doctor does not end when the "temperature touches normal and stitches are removed". The patient must be restored and retrained "to live and work within the limits of his disability but to the hilt of his capacity". As such medical rehabilitation should start very early in the process of medical treatment.

Examples of rehabilitation are: establishing schools for the blind, provision of aids for the crippled, reconstructive surgery in leprosy, muscle re-education and graded exercises in neurological disorders, change of profession for a more suitable one and modification of life in general in the case of tuberculosis, cardiac patients and others. The purpose of rehabilitation is to make productive people out of non–productive people.

It is now recognized that rehabilitation is a difficult and demanding task that seldom gives totally satisfactory results; but needs enthusiastic cooperation from different segments of society as well as expertise, equipment and funds not readily available for this purpose even in affluent societies. It is further recognized that interventions at earlier stages are more feasible, will yield results, and are less demanding of scarce resources.

CHANGING PATTERN OF DISEASE

Although diseases have not changed significantly through human history, their patterns have. It is said that every decade produces its own pattern of disease. The truth of this will be obvious when one compares the leading causes of death globally for the year 2000 and 2011 (Fig. 12).

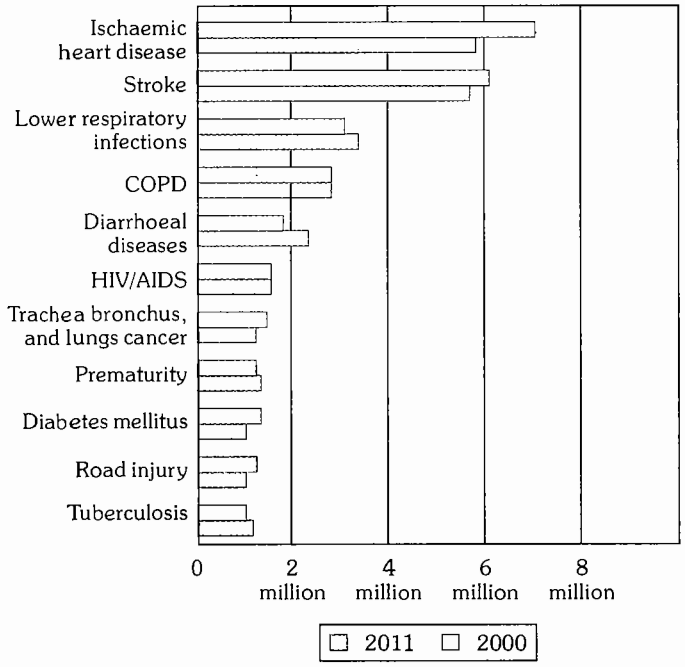

FIG. 12
Comparison of leading causes of death worldwide over the past decade, 2000 and 2011

Source : *(119)*

Worldwide, during 2011, about 7 million persons died of IHD, 6.2 million due to stroke, 3.2 million due to lower respiratory infections, 3 million due to COPD (chronic obstructive pulmonary disease), 1.9 million due to diarrhoeal disesaes, 1.5 million due to HIV/AIDS, 1.5 million due to lung, trachea and bronchus cancer, 1.4 million due to diabetes mellitus, 1.3 million due to road injury and 1.2 million due to prematurity *(119)*.

Developed countries

During the past decades, the developed world has experienced a dramatic change in the pattern of disease. By far the greatest part of this development has been the decline of many of the infectious diseases (e.g., tuberculosis, typhoid fever, polio, diphtheria). However problems of a different nature have achieved ascendancy, e.g., coronary heart disease, cancer, accident, dementia, COPD and diabetes. Lower respiratory infection remains the leading infectious cause of death. Only one in every 100 deaths is among children under 15 years. Table 8 shows the top 10 causes of death in high income, upper middle income and other countries.

The morbidity pattern has also changed. In recent years, there has been a steady increase in mental disorders. Alzheimer's disease described as the "silent epidemic" of the century, is an important cause of morbidity and mortality. There has been a steady increase in social pathology due to alcohol and drug abuse. Lung cancer as well as other chronic lung diseases due to smoking, and obesity due to overeating have become common. Environmental health problems connected with toxic, carcinogenic and mutagenic material in the external environment due to industrialization and growing urbanization are assuming growing importance.

The microbial diseases that are now becoming prominent are often caused by organisms previously regarded as being innocuous such as the coliforms and the other gram-negative bacilli, the non-haemolytic streptococci, campylobacters, legionella, chlamydia, rotaviruses and AIDS virus.

TABLE 8
Top 10 causes of death in developed and developing countries, 2011

Deaths per lac population

Cause	High income countries	Upper middle income countries	Lower middle income countries	Low income countries
Ischaemic heart disease	119	120	93	47
Stroke	69	126	75	56
Trachea, bronchus and lung cancer	51	28	–	–
Alzheimer's disease	48	–	–	–
COPD	32	45	51	–
Lower respiratory infections	32	22	60	98
Colon and rectum cancer	27	–	–	–
Diabetes mellitus	21	20	20	–
Hypertensive heart disease	20	18	–	–
Breast cancer	16	–	–	–
Road injury	–	21	19	–
Liver cancer	–	19	–	–
Stomach cancer	–	18	–	–
Diarrhoeal diseases	–	–	47	69
Prematurity	–	–	27	43
HIV/AIDS	–	–	24	70
Tuberculosis	–	–	22	32
Malaria	–	–	–	38
Protein energy malnutrition	–	–	–	32
Birth asphyxia and birth trauma	–	–	–	30

Developing countries

The pattern of diseases in developing countries is very different. In a typical developing country, about 40 per cent of deaths are among children under 15 years of age. People predominantly die of infectious diseases like lower respiratory infections, HIV/AIDS, diarrhoeal diseases, malaria and tuberculosis. These diseases collectively account for almost one-third of all deaths in these countries. Complications of childbirth due to prematurity, birth asphyxia and birth trauma are among leading causes of death as shown in Table 8.

In India, as in other developing countries, most deaths result from infectious and parasitic diseases, abetted by malnutrition. Diarrhoeal diseases are widespread. Cholera has shown a declining trend. Malaria which showed a decline in the 1960s have staged a comeback. Japanese encephalitis, dengue and meningococcal meningitis have shown an increasing trend. There is appreciable change in the prevalence of tuberculosis, filariasis, but little change in the prevalence of viral hepatitis, diarrhoea and dysentery and disorders of malnutrition and undernutrition. On the other hand, an increase in the frequency of "new" health problems such as coronary heart disease, hypertension, cancer, diabetes and accidents has been noted. Along with the development of industries, various occupational diseases, e.g., pneumoconiosis are on the increase. The emerging picture is a mixture of the old and "modern" diseases.

The factors which play a role in the changing patterns of disease are multiple. They include changing lifestyles and

living standards, demographic factors, urbanization and industrialization, medical interventions, maintenance of people with transmissible genetic defects, and the widespread effects of technology on ecology.

The changing pattern of disease in both developed and developing countries and the emergence of new problems emphasize the need for forward-looking approaches in health planning and management.

POPULATION MEDICINE

Knowledge about human health and disease is sum of the contributions of a large number of disciplines, classified as (a) basic sciences (b) clinical sciences, and (c) population medicine. The basic sciences (e.g., biochemistry, physiology, microbiology) are primarily sited in laboratories; clinical activities are carried out in hospitals, and population medicine in the community. Tuberculosis provides a good illustration of the three different approaches to the same disease. The basic sciences are concerned with tubercle bacilli; the clinical sciences with the treatment of tuberculosis in the individual, and population medicine with prevention and control of tuberculosis in the community *(84)*. All these approaches are highly interrelated.

In different settings, **population medicine** is referred to as hygiene, public health, preventive medicine, social medicine or community medicine. All these share common ground in their concern for promotion of health and prevention of disease. Each has originated at a different time, and each has introduced a new direction or emphasis. So there should be little expectation that definitions can be other than arbitrary and imprecise *(120)*. It has been truly said that every definition is dangerous.

Hygiene

The world "hygiene" is derived from **Hygeia**, the goddess of health in Greek mythology. She is represented as a beautiful woman holding in her hand a bowl from which a serpent is drinking. In Greek mythology, the serpent testifies the art of healing which symbol is retained even today. Hygiene is defined as "the science of health and embraces all factors which contribute to healthful living".

Public health

The term "public health" came into general use around 1840. It arose from the need to protect "the public" from the spread of communicable diseases. Later, it appeared in 1848 in the name of a law, the Public Health Act in England to crystallize the efforts organized by society to protect, promote, and restore the people's health.

In 1920, C.E.A. Winslow, a former professor of public health at Yale University, gave the oft-quoted definition of public health. The WHO Expert Committee on Public Health Administration, adapting Winslow's earlier definition, has defined it as *(121)*:

> *"the science and art of preventing disease, prolonging life, and promoting health and efficiency through organized community efforts for the sanitation of the environment, the control of communicable infections, the education of the individual in personal hygiene, the organization of medical and nursing services for early diagnosis and preventive treatment of disease, and the development of social machinery to ensure for every individual a standard of living adequate for the maintenance of health, so organizing these benefits as to enable every citizen to realize his birthright of health and longevity".*

Whereas in developing countries, public health has not made much headway in terms of sanitary reforms and control of communicable diseases, it has made tremendous strides in the industrialized western countries resulting in longer expectation of life and significant decline in death rates. As a result of improvements in public health during the past 50 or 60 years, public health in the developed countries has moved from sanitation and control of communicable diseases (which have been largely controlled) to preventive, therapeutic and rehabilitative aspects of chronic diseases and behavioural disorders.

A EURO symposium in 1966 *(56)* suggested that the definition of public health should be expanded to include the organization of medical care services. This was endorsed by another Expert Committee of WHO in 1973 *(122)*. Thus modern public health also includes organization of medical care, as a means of protecting and improving the health of people *(123)*. Since the organization of public health tends to be determined by cultural, political and administrative patterns of the countries, there is a wide mosaic of organizational arrangements.

Public health, in its present form, is a combination of scientific disciplines (e.g., epidemiology, biostatistics, laboratory sciences, social sciences, demography) and skills and strategies (e.g., epidemiological investigations, planning and management, interventions, surveillance, evaluation) that are directed to the maintenance and improvement of the health of the people *(123)*.

With the adoption of the goal of "Health for All", a new public health was evident worldwide, which may be defined as:

> *"the organized application of local, state, national and international resources to achieve "Health for All", i.e., attainment by all people of the world by the year 2000 of a level of health that will permit them to lead a socially and economically productive life".*

Although the term "public health" has lost its original meaning, the term is still widely used. Terms like preventive medicine, social medicine and community medicine are used as synonyms for public health. Public health is not only a discipline but has become a "social institution" *(31)* created and maintained by society to do something about the death rate and sanitary conditions and many other matters relating to life and death *(124)*. In this sense public health is both a body of knowledge and also a means to apply that knowledge.

Preventive medicine

Preventive medicine developed as a branch of medicine distinct from public health, based on aetiology. It is, by definition, applied to "healthy" people. It scored several successes in the prevention of communicable diseases based on immunization, so much so, in its early years, preventive medicine was equated with the control of infectious diseases. A brief account of the advances made in preventive medicine is given in chapter 1.

As concepts of the aetiology of disease changed through time, so too have the techniques and activities of preventive medicine. Preventive medicine is no longer concerned, as it used to be, with immunization, important though it may be. The concept of preventive medicine has broadened to include health promotion, treatment, and prevention of disability as well as specific protection *(88)*. Preventive medicine has thus come to include both specific medical measures (e.g., immunization), as well as general health

promotional measures (e.g., health education). Within this change in the definition and scope of preventive medicine, it has become clear that promoting health and preventing illness involve responsibilities and decisions at many levels – individual, public and private; and that these efforts are applied to whole population or to segments. In this, preventive medicine has become akin to public health.

Preventive medicine has become a growing point in medicine *(125)*. It has branched into newer areas such as screening for disease, population control, environmental control, genetic counselling and prevention of chronic diseases. Community prevention and primordial prevention (see page 41) are relatively new concepts which are being applied in the community control of coronary heart disease, hypertension and cancer with palpable success *(107)*. The emergence of preventive paediatrics, preventive geriatrics and preventive cardiology are relatively new dimensions of prevention.

Since preventive medicine has increasingly tended to be applied to the organized health activities of the community *(56)*, the term "preventive medicine" is regarded as synonymous with public health. Both terms often appear in combination (e.g., Maxcy–Rosenau Textbook of "Public Health and Preventive Medicine").

Associated with the concept of public health, preventive medicine has been defined as meaning "not only the organized activities of the community to prevent occurrence as well as progression of disease and disability, mental and physical, but also the timely application of all means to promote the health of individuals, and of the community as a whole, including prophylaxis, health education and similar work done by a good doctor in looking after individuals and families" *(56)*. In this the goals of preventive medicine and public health have become identical, i.e., Health for All. In line with this extension of the scope of preventive medicine, it is now customary to speak of primary, secondary and tertiary levels of prevention *(56)*. The cornerstone of preventive medicine is, however, "primary prevention".

Community health

The term "community health" has replaced in some countries, the terms public health, preventive medicine and social medicine. A EURO symposium in 1966 *(56)* defined community health as including "all the personal health and environmental services in any human community, irrespective of whether such services were public or private ones". In some instances, community health is used as a synonym for "environmental health". It is also used to refer to "community health care". Therefore, a WHO Expert Committee in 1973 *(122)* observed that without further qualification, the term "community health" is ambiguous, and suggested caution in the use of the term.

Social medicine

The term "social medicine" was first introduced by Jules Guerin, a French physician in 1848. In 1911, the concept of social medicine was revived by Alfred Grotjahn of Berlin who stressed the importance of social factors as determinants of health and disease. These ideas of social medicine spread throughout Europe and England after the First World War (see page 8).

By derivation, social medicine is "the study of man as a social being in his total environment". It is concerned with all the factors affecting the distribution of health and illhealth in population, including the use of health services *(126)*. Social medicine is not a new branch of medicine, but rather an extension of the public health idea reflecting the strong relationship between medicine and social sciences.

Professor Crew of Edinburgh defined social medicine as follows: "Social medicine stands upon two pillars, medicine and sociology. Social medicine, by derivation is concerned with the health of groups of individuals and individuals within these groups with a view to create, promote, preserve, and maintain optimum health. The laboratory to practice social medicine is the whole community; the tools for diagnosing community ills are epidemiology and biostatistics; and social therapy does not consist in administration of drugs, but social and political action for the betterment of conditions of life of man. Social medicine is one more link in the chain of social organizations of a civilized community". Terms such as social anatomy, social physiology, social pathology and social therapy came into vogue to describe the various aspects of social medicine.

Although the term "social medicine" was introduced more than 150 years ago, the characteristic aspect was its repeated advent and disappearance. It never came to be generally accepted. There was no unanimity in its objectives or subject matter. This is reflected in more than 50 definitions given to social medicine.

Social medicine had achieved academic respectability in England when John Ryle was appointed as professor of social medicine at Oxford, and Crew at Edinburgh. The post–war period (1945–1967) saw considerable expansion of social medicine as an academic discipline *(126)*.

With the development of epidemiology as a new discipline and a practical tool in the planning, provision and evaluation of health services, interest in social medicine began to wane. In 1968, the Report of the Royal Commission on Medical Education (Todd Report) for the first time referred to "community medicine" instead of social medicine, and defined it in terms which embraced social medicine, but went beyond it, by giving greater emphasis to the organizational and administrative aspects than had academic social medicine in the past *(126)*. This gave a blow to the further development of social medicine which had tended in many countries to be displaced by the newer term "community medicine" *(56)*.

Community medicine

The term "community medicine" is a newcomer. It is the successor of what has been previously known as public health, preventive medicine, social medicine and community health. Since community medicine is a recent introduction, it has borrowed heavily from the concepts, approaches and methods of public health, preventive medicine and social medicine.

The history of community medicine in England is interesting. It was instituted by Ordinance and by Act of Parliament *(127)*. The Todd Commission (1968) forcibly recommended that every medical school in England should have a department of community medicine. The Royal College of Physicians of Edinburgh and London and the Royal College of Physicians and Surgeons of Glasgow established the Faculty of community medicine, which came into being in March 1972 as the central body with a responsibility of setting standards and overseeing the quality of postgraduate education and training in the field *(128)*. On the night of 31 March 1974, the traditional medical officer of health passed into the pages of the history book, and was thereafter designated as the "community physician".

The term community medicine means different things in different countries *(56)*. For example, in most European countries various aspects of community medicine are taught at medical universities, though under different names, such as general practice, family medicine, community medicine or social medicine *(129)*. Even in the same country and region, the variation in the amount and range of teaching remains remarkable *(128)*. These variations are reflected in the definitions quoted below *(56)*.

(a) The field concerned with the study of health and disease in the population of a defined community or group. Its goal is to identify the health problems and needs of defined population (community diagnosis) and to plan, implement and evaluate the extent to which health measures effectively meet these needs.

(b) The practice of medicine concerned with groups or population rather than with individual patients. This includes the elements listed in definition (a), together with the organization and provision of health care at a community or group level.

(c) The term is also used to describe the practice of medicine in the community, e.g., by a family physician. Some writers equate the terms "family medicine" and "community medicine"; others confine its use to public health practice.

(d) Community oriented primary health care is an integration of community medicine with the primary health care of individuals in the community. In this form of practice, the community practitioner or community health team has responsibility for health care at a community or at an individual level.

It will be seen that a common thread runs through all the above definitions. Diagnosis of the state of health of a community is an important foundation of community medicine. As used in the present context, community medicine is a practice which focuses on the health needs of the community as a whole. The combination of community medicine with "primary health care" extends the functioning of both elements to a health care system which aims to change the state of health of the community by intervention both at the individual and group level. The foundations of community medicine are in no way different from those of modern public health and social medicine, viz. epidemiology, biostatistics, social sciences and organization of health care which includes planning, implementation and evaluation *(130)*.

It is anomalous that in England and United States where the term community medicine is freely used, their standard textbooks on the subject are still titled **Public Health** (e.g., Oxford "Textbook of Public Health;" Maxcy-Rosenau: "Public Health and Preventive Medicine").

HOSPITALS AND COMMUNITY

The hospital is a unique institution of man. A WHO Expert Committee in 1963 *(131)* proposed the following working definition of a hospital: "A hospital is a residential establishment which provides short-term and long-term medical care consisting of observational, diagnostic, therapeutic and rehabilitative services for persons suffering or suspected to be suffering from a disease or injury and for parturients. It may or may not also provide services for ambulatory patients on an out-patient basis".

The criticism levelled against the hospital is that it exists in splendid isolation in the community, acquiring the euphemism "an ivory tower of disease"; it absorbs vast proportion (50 to 80 per cent) of health budget; it is not people-oriented; its procedures and styles are inflexible; it overlooks the cultural aspects of illness (treating the disease without treating the patient); the treatment is expensive; it is intrinsically resistant to change, and so on. The relative isolation of hospitals from the broader health problems of the community which has its roots in the historical development of health services has contributed to the dominance of hospital model of health care.

In 1957, an Expert Committee of WHO *(132)* emphasized that the general hospital cannot work in isolation; it must be a part of a social and medical system that provides complete health care for the population. Subsequent years witnessed the efforts of WHO, UNICEF and non-governmental agencies to involve hospitals in providing basic and referral services. The establishment of primary health centres was a step forward to integrate preventive and curative services.

The community hospital should be a flexible institution, capable of adapting its resources to the total health care needs of the community. This adaptation requires hospital administration that is both a science and art. Dr. Rene Sand has said that the right patient should receive the right care at the right time in the right place at the right cost *(133)*. This ideal, seemingly simple, is perhaps never achieved, like all other ideals because of a complex set of interacting and often conflicting social forces operating both within and outside the hospital system.

With the acceptance of the goal of "Health for All", there is involvement of hospitals in primary health care activities. Member countries of WHO have enunciated in their national policies to reorient and restructure their health care systems on the basis of primary health care. Primary health care cannot work unless there is effective hospital support to deal with referred patients, and to refer patients who do not require hospital attention to one of the other primary health care services. Without hospital support primary health care could not achieve its full potential. The trend is now set to redefine the role of the hospital as a community health oriented institution, which means that it is not only disease oriented but has responsibilities in the field of preventive medicine and health promotion *(134)*.

Functions of a physician

The object of medical education is to prepare a doctor (physician) for the tasks he is likely to be given. In view of the fact that there is no internationally accepted definition of the word "physician", the WHO has adopted the following definition *(135)*.

> *"A physician is a person who, having been regularly admitted to a medical school, duly recognized in the country in which it is located, has successfully completed the prescribed courses of studies in medicine and has acquired the requisite qualification to be legally licensed to practise medicine (comprising prevention, diagnosis, treatment and rehabilitation) using independent judgement to promote community and individual health".*

In India, at present, a doctor soon after graduation, has often to take charge of a health centre (population 30,000) which is usually in a rural area. He is called upon to provide promotive, preventive, curative, rehabilitative and emergency care services appropriate to meet the main health problems in the community, with special attention to vulnerable groups.

The functions of the health centre are discussed elsewhere. The functions of a doctor (physician) may be summarized as follows:

(a) *The care of the individual*: A physician must be able to assess the state of health of the individual. This would include a clinical diagnosis, a simple laboratory diagnosis as well as an assessment of the individual's state of nutrition, level of development, social and emotional state and the health needs. He must then be able to take any further measures necessary for treatment, prevention and referral to higher levels of health care. He must be particularly expert in common conditions, in first-aid and in the management of acute emergencies. Because of the large numbers involved, he must know how to delegate work to his auxiliaries.

(b) *The care of community*: The care of the community centres round the eight essential elements of primary health care as stated in the Alma-Ata Declaration (see page 30). The physician is the leader of the "health team". He provides primary health care through the health team at the grass-root level. He should be familiar with community diagnosis, prioritization of health problems and community treatment.

(c) *The physician as a teacher*: The term "doctor" by derivation means to teach. Therefore the physician has a major responsibility as a teacher and educator. In his practice, in his professional associations and in his community activities, the physician has wide educational opportunities. But unfortunately, the physician's role as a teacher is a neglected one. Many physicians are reluctant to capitalize on their role as educators. As a teacher, the physician can play an effective role in community health education so that individuals, families and communities assume greater responsibility for their own health and welfare, including self-care. He can also generate and mobilize community participation in health programmes through effective propagation of relevant information.

Community diagnosis

The diagnosis of disease in an individual patient is a fundamental idea in medicine. It is based on signs and symptoms and the making of inferences from them. When this is applied to a community, it is known as community diagnosis. The community diagnosis may be defined as the pattern of disease in a community described in terms of the important factors which influence this pattern *(136)*.

The community diagnosis is based on collection and interpretation of the relevant data such as (a) the age and sex distribution of a population; the distribution of population by social groups; (b) vital statistical rates such as the birth rate, and the death rate; (c) the incidence and prevalence of the important diseases of the area. In addition, a doctor must be able to find information on a wide variety of social and economic factors that may assist him in making a community diagnosis. The focus is on the identification of the basic health needs and health problems of the community. The needs **as felt** by the community (some of which may have no connection at all with health) should be next investigated and listed according to priority for community treatment.

Community treatment

Community treatment or community health action is the sum of steps decided upon to meet the health needs of the community taking into account the resources available and the wishes of the people, as revealed by community diagnosis. Improvement of water supplies, immunization, health education, control of specific diseases, health legislation are examples of community health action or interventions. Action may be taken at three levels: at the level of the individual, at the level of the family and at the level of the community *(136)*.

A programme of community action must have the following characteristics: (a) it must effectively utilize all the available resources, (b) it must coordinate the efforts of all other agencies in the community, now termed as "intersectoral coordination", and (c) it must encourage the full participation of the community in the programme. These are the principles on which primary health care, as defined in the Alma-Ata Declaration, is based. This approach is a significant departure from the earlier basic services approach.

DISEASE CLASSIFICATION

There is a wide variation among countries in the criteria and standards adopted for diagnosis of diseases and their notification, making it difficult to compare national statistics. A system of classification was needed whereby diseases could be grouped according to certain common characteristics, that would facilitate the statistical study of disease phenomena. Over the years, many approaches were tried to classify diseases. John Graunt in the 17th century in his study of Bills of Mortality, arranged diseases in an alphabetical order. Later, a more scientific approach was adopted in classifying diseases according to certain characteristics of the disease or injuries such as (a) the part of the body affected (b) the aetiologic agent (c) the kind of morbid change produced by the disease, and (d) the kind of disturbance of function produced by the disease or injury. Thus there are many axes of classification, and the particular axis selected will depend on the interest of the investigator *(137)*.

International classification of diseases

All the above criteria formed the basis of the International classification of diseases (ICD) produced by WHO and accepted for national and international use. Since its inception, ICD has been revised about once every 10 years; the latest revision, the 10th revision, came into effect on January 1, 1993. Earlier, the scope of ICD was expanded in the sixth revision in 1948 to cover morbidity from illness and injury. The ICD also provides a basis that can be adapted for use in other fields e.g., dentistry, oncology and ophthalmology.

As in previous revisions, the ICD-10 is arranged in 21 major chapters.

I. Certain infectious and parasitic diseases (A00 – B99)
II. Neoplasms (C00 – D48)
III. Diseases of the blood and blood forming organs and certain disorders involving the immune mechanism (D50 – D89)
IV. Endocrine, nutritional and metabolic diseases (E00 – E90)
V. Mental and behavioural disorders (F00 – F99)
VI. Diseases of the nervous system (G00 – G99)
VII. Diseases of the eye and adnexa (H00 – H59)
VIII. Diseases of the ear and mastoid process (H60 – H95)
IX. Diseases of the circulatory system (I00 – I99)

X. Diseases of the respiratory system (J00 – J99)
XI. Diseases of the digestive system (K00 – K93)
XII. Diseases of the skin and subcutaneous tissue (L00 –L99)
XIII. Diseases of the musculosketetal system and connective tissue (M00 – M99)
XIV. Diseases of the genitourinary system (N00 – N99)
XV. Pregnancy, childbirth and puerperium (O00–O99)
XVI. Certain conditions originating in perinatal period (P00 –P96)
XVII. Congenital malformations, deformations and chromosomal abnormalities (Q00 – Q99)
XVIII. Symptoms, signs and abnormal clinical and laboratory findings, not elsewhere classified (R00 – R99)
XIX. Injury, poisoning and certain other consequences of external causes (S00 – T98)
XX. External causes of morbidity and mortality (V01 – Y98)
XXI. Factors influencing health status and contact with health services (Z00 – Z99).

The coding system

The first character of the ICD–10 code is a letter and each letter is associated with a particular chapter, except for the letter D, which is used in chapter II and chapter III, and letter H which is used in chapter VII and chapter VIII. Chapter I, II, XIX and XX use more than one letter in the first position of their codes.

Each chapter contains sufficient three–character categories to cover its contents. Not all the available codes are used, allowing space for future revision and expansion. The range of categories is given in parentheses after each block title.

Although not mandatory for reporting at the international level, most of the three–character categories are subdivided by means of a fourth numeric character after a decimal point, allowing upto 10 subcategories. Where a three - character category is not subdivided, it is recommended that the letter "X" be used to fill the fourth position so that the codes are of a standard length for data-processing.

Examples :

Chapter XXI – Factors influencing health status and contact with health services (Z 00 – Z 99)

Z 72 - Problems relating to lifestyle
Z 72.0 Tobacco use
Z 72.1 Alcohol use
Z 72.2 Drug use
Z 72.3 Lack of physical exercise
Z 72.4 Inappropriate diet and eating habits
Z 72.5 High-risk sexual behaviour

The unused "U" code : Codes U 00 – U 49 are to be used for provisional assignment of new diseases of uncertain aetiology. Codes U 50-U 99 may be used in research, e.g., when testing an alternative sub–classification for a special project *(138)*.

ICD–10 consists of three volumes. Volume 1 contains the report of the International conference for the Tenth Revision, the classification itself at the three–and four character levels, the classification of the morphology of neoplasms, special tabulation lists for mortality and morbidity, definitions, and the nomenclature regulations. Volume 2 is instruction manual and volume 3 contains alphabetical index.

The ultimate purpose of ICD is to contribute to a uniform classification that can be used throughout the world to make accurate comparisons of morbidity and mortality data for decision–making in prevention, in management of health care and in facilitating research on particular health problems. The reader is referred to the Tenth Revision of the ICD for general principles and description of the ICD classification.

3 Principles of Epidemiology and Epidemiologic Methods

"I keep six honest serving men; they taught me all I know.
Their names are what, why, when, how, where and who."

Epidemiology is the basic science of preventive and social medicine. Although of ancient lineage, it made only slow progress upto the start of 20th century. Epidemiology has evolved rapidly during the past few decades. Its ramifications cover not only study of disease distribution and causation (and thereby prevention), but also health and health-related events occurring in human population. Modern epidemiology has entered the most exciting phase of its evolution. By identifying risk factors of chronic disease, evaluating treatment modalities and health services, it has provided new opportunities for prevention, treatment, planning and improving the effectiveness and efficiency of health services. The current interest of medical sciences in epidemiology has given rise to newer off-shoots such as infectious disease epidemiology, chronic disease epidemiology, clinical epidemiology, serological epidemiology, cancer epidemiology, malaria epidemiology, neuro epidemiology, genetic epidemiology, occupational epidemiology, psychosocial epidemiology, and so on. This trend is bound to increase in view of the increasing importance given to the pursuit of epidemiological studies. That these studies have added substantially to the advancement of medical knowledge is indisputable. This Chapter studies the basic concepts and principles of epidemiology as an introduction to the subject.

History

Epidemiology began with Adam and Eve, both trying to investigate the qualities of the "forbidden fruit". Epidemiology is derived from the word epidemic (epi=among; demos=people; logos=study), which is a very old word dating back to the 3rd century B.C. The foundation of epidemiology was laid in the 19th century, when a few classic studies made a major contribution to the saving of life. Mention is made of an Epidemiological Society in London in 1850s under the presidency of the Earl of Shaftesbury *(1)*. The Society's main concern was the investigation of infectious diseases. The sudden growth of bacteriology had smothered the development of epidemiology in the Universities.

In the United States, Winslow and Sedgwick both lectured in epidemiology in the early 1920s, although the subject was not given departmental status. In 1927, W.H. Frost became the first professor of epidemiology in US. Later Major Greenwood became the first professor of epidemiology and medical statistics in the University of London *(1)*. Epidemiology has grown rapidly during the past few decades. It has now become firmly established in medical education.

There appears to be almost as many definitions of epidemiology as there are authors who have written on the subject, ranging from Hippocrates to those of the present day. A short list is given below *(2, 3)* :

1. That branch of medical science which treats epidemics (Parkin, 1873).
2. The science of the mass phenomena of infectious diseases (Frost, 1927).
3. The study of disease, any disease, as a mass phenomenon (Greenwood, 1934), and
4. The study of the distribution and determinants of disease frequency in man (MacMahon, 1960).

Definition

Epidemiology has been defined by John M. Last in 1988 as:–

> *"The study of the distribution and determinants of health-related states or events in specified populations, and the application of this study to the control of health problems".*

The wide variety of meanings attached to epidemiology is the expression of the wide ranging subject–matter. The diseases included in the subject–matter have increased from those which occur in epidemics to include those infectious diseases which are endemic in nature, and more recently chronic diseases, accidents and mental health. Modern epidemiology has also taken within its scope the study of health-related states, events and "facts of life" occurring in human population. This includes study of the health services used by the population, and to measure their impact. Epidemiology, like public health itself, is often more concerned with the well-being of society as a whole, than with the well-being of individuals.

Although there is no single definition to which all epidemiologists subscribe, three components are common to most of them. First, studies of disease frequency; second, studies of the distribution; and third, studies of the determinants. Each of these components confers an important message.

1. Disease frequency

Inherent in the definition of epidemiology is measurement of frequency of disease, disability or death, and summarizing this information in the form of rates and ratios (e.g., prevalence rate, incidence rate, death rate, etc). Thus the basic measure of disease frequency is a rate or ratio. These

rates are essential for comparing disease frequency in different populations or subgroups of the same population in relation to suspected causal factors. Such comparisons may yield important clues to disease aetiology. This is a vital step in the development of strategies for prevention or control of health problems.

Equally, epidemiology is also concerned with the measurement of health-related events and states in the community (e.g., health needs, demands, activities, tasks, health care utilization) and variables such as blood pressure, serum cholesterol, height, weight, etc. In this respect, epidemiology has the features of a quantitative science. Much of the subject matter of measurement of disease and health-related events falls in the domain of biostatistics, which is a basic tool of epidemiology.

2. Distribution of disease

It is well-known that disease, or for that matter health, is not uniformly distributed in human populations. The basic tenet of epidemiology is that the distribution of disease occurs in *patterns* in a community *(3)* and that the patterns may lead to the generation of hypotheses about causative (or risk) factors. An important function of epidemiology is to study these distribution patterns in the various subgroups of the population by time, place and person. That is, the epidemiologist examines whether there has been an increase or decrease of disease over time span; whether there is a higher concentration of disease in one geographic area than in others; whether the disease occurs more often in men or in a particular age-group, and whether most characteristics or behaviour of those affected are different from those not affected *(4)*. Epidemiology addresses itself to a study of these variations or patterns, which may suggest or lead to measures to control or prevent the disease. An important outcome of this study is formulation of aetiological hypothesis. This aspect of epidemiology is known as "descriptive epidemiology".

3. Determinants of disease

A unique feature of epidemiology is to test aetiological hypotheses and identify the underlying causes (or risk factors) of disease. This requires the use of epidemiological principles and methods. This is the real substance of epidemiology. This aspect of epidemiology is known as "analytical epidemiology". Analytical strategies help in developing scientifically sound health programmes, interventions and policies. In recent years, analytical studies have contributed vastly to our understanding of the determinants of chronic diseases, e.g., lung cancer and cardiovascular diseases.

Aims of epidemiology

According to the International Epidemiological Association (IEA), epidemiology has three main aims *(5)*:

a. to describe the distribution and magnitude of health and disease problems in human populations
b. to identify aetiological factors (risk factors) in the pathogenesis of disease; and
c. to provide the data essential to the planning, implementation and evaluation of services for the prevention, control and treatment of disease and to the setting up of priorities among those services.

In order to fulfil these aims, three rather different classes of epidemiological studies may be mentioned: descriptive studies, analytical studies, and experimental or intervention studies *(6)*. These studies are described in the following pages.

The ultimate aim of epidemiology is to lead to effective action :

a. to eliminate or reduce the health problem or its consequences; and
b. to promote the health and well-being of society as a whole.

Epidemiology and clinical medicine

The basic difference between epidemiology and clinical medicine is that in epidemiology, the unit of study is a "defined population" or "population at-risk"; in clinical medicine, the unit of study is a "case" or "cases". In clinical medicine, the physician is concerned with disease in the individual patient, whereas the epidemiologist is concerned with disease patterns in the entire population. Epidemiology is thus concerned with both the sick and healthy. It has been stated that clinicians are interested in cases with the disease, the statistician with the population from which the cases are derived, and the epidemiologist is interested in the relationship between cases and the population in the form of a rate *(7)*.

In clinical medicine, the physician seeks a diagnosis from which he derives a prognosis and prescribes specific treatment. In epidemiology, an analogous situation exists. The epidemiologist is confronted with relevant data derived from a particular epidemiological study. He seeks to identify a particular source of infection, a mode of spread or an aetiological factor in order to determine a future trend and recommend specific control measures *(8)*. The epidemiologist also evaluates the outcome of preventive and therapeutic measures instituted which provides the necessary guidance and feed-back to the health care administrator for effective management of public health programmes.

In clinical medicine, the patient comes to the doctor; in epidemiology, the investigator goes out into the community to find persons who have the disease or experience of the suspected causal factor in question. Clinical medicine is based on biomedical concepts with an ever-increasing concern for refining the technique of diagnosis and treatment at the individual level. The subject matter of clinical medicine is easily "perceived" by such techniques as clinical and laboratory examinations including postmortem reports. In contrast, the subject matter of epidemiology is "conceptual" and can only be symbolized in the form of tables and graphs *(9)*.

Finally, it may be stated that clinical medicine and epidemiology are not antagonistic. Both are closely related, co-existent and mutually helpful. Most epidemiological enquiries could never be established without appropriate clinical consideration as to how the disease in question can be identified among individuals comprising the group under scrutiny. Likewise, a knowledge of prevalence, aetiology and prognosis derived from epidemiological research is important to the clinician for the diagnosis and management of individual patients and their families *(9)*.

Epidemiological approach

The epidemiological approach to problems of health and disease is based on two major foundations:

a. Asking questions
b. Making comparisons.

a. *Asking questions*

Epidemiology has been defined as "a means of learning or asking questions....and getting answers that lead to further questions" *(10)*. For example, the following questions could be asked *(11)* :

RELATED TO HEALTH EVENTS

a. What is the event ? (the problem)
b. What is its magnitude?
c. Where did it happen?
d. When did it happen?
e. Who are affected?
f. Why did it happen?

RELATED TO HEALTH ACTION

a. What can be done to reduce this problem and its consequences ?
b. How can it be prevented in the future ?
c. What action should be taken by the community ? By the health services? By other sectors ? Where and for whom these activities be carried out ?
d. What resources are required ? How are the activities to be organized ?
e. What difficulties may arise, and how might they be overcome ?

Answer to the above questions may provide clues to disease aetiology, and help the epidemiologist to guide planning and evaluation.

b. *Making comparisons*

The basic approach in epidemiology is to make comparisons and draw inferences. This may be comparison of two (or more groups) – one group having the disease (or exposed to risk factor) and the other group(s) not having the disease (or not exposed to risk factor), or comparison between individuals. By making comparisons, the epidemiologist tries to find out the crucial differences in the host and environmental factors between those affected and not affected. In short the epidemiologist weighs, balances and contrasts. Clues to aetiology come from such comparisons.

One of the first considerations before making comparisons is to ensure what is known as "comparability" between the study and control groups. In other words, both the groups should be similar so that "like can be compared with like". For facts to be comparable, they must be accurate, and they must be gathered in a uniform way. For example, the study and control groups should be similar with regard to their age and sex composition, and similar other pertinent variables. The best method of ensuring comparability, in such cases, is by randomization or random allocation (see page 82). Where random allocation is not possible (as in case control and cohort studies) what is known as "matching" is done for selected characteristics that might confound the interpretation of results. Another alternative is standardization which usually has a limited application to a few characteristics such as age, sex and parity. These biostatistical concepts are elaborated in the following pages. It may be mentioned that international comparisons may be difficult because of differences in terminology. It requires standardization of definitions, classifications, criteria and nomenclature.

BASIC MEASUREMENTS IN EPIDEMIOLOGY

Epidemiology focuses, among other things, on measurement of mortality and morbidity in human populations. The first requirement is therefore definition of what is to be measured and establishment of criteria or standards by which it can be measured. This is not only a prerequisite of epidemiological studies, but also one of its goals *(12)*. The clinician may not require a precise definition of disease (e.g., migraine) for immediate patient care, but the epidemiologist needs a definition (a) that is acceptable and applicable to its use in large populations; and (b) that is precise and valid, to enable him to identify those who have the disease from those who do not *(9)*. Clear definitions help to minimize errors in classification of data. Standardized methods of observation and recording are therefore essential before commencing any epidemiological study.

Measurements in Epidemiology

The scope of measurements in epidemiology is very broad and unlimited and includes the following : *(13)*

a. Measurement of mortality
b. Measurement of morbidity
c. Measurement of disability
d. Measurement of natality
e. Measurement of the presence, absence or distribution of the characteristic or attributes of the disease
f. Measurement of medical needs, health care facilities, utilization of health services and other health-related events
g. Measurement of the presence, absence or distribution of the environmental and other factors suspected of causing the disease, and
h. Measurement of demographic variables.

Inspite of a wide range of presently available measurements, there are many areas which are not fully covered. As for example, measurement of the psycho-social aspects of health and disease. The components of well-being need to be better identified.

The basic requirements of measurements are validity, reliability, accuracy, sensitivity and specificity. These are discussed in the next chapter. Finally, measurement errors are unavoidable, no matter where and by whom measurements are taken. The purpose of quality control in measurement is, therefore, not to eliminate errors, but to reduce them as much as possible or at least to an acceptable level.

In the above connection, the following terminology needs explanation: (a) *Variate*: Any piece of information referring to the patient or his disease is called a variate. A variate can be discrete, that is it can be present or absent, e.g., cancer lung, broken leg, or rash in measles or it can be *continuously distributed,* e.g., blood pressure, serum cholesterol, height, etc. (b) *Circumstance*: Any factor in the environment that might be suspected of causing a disease, e.g., air pollution, polluted water, etc *(9)*.

The frequency of a discrete variable or circumstance can be expressed as a rate in relation to population. The frequency of continuously distributed variables or circumstances is expressed in the form of a *frequency distribution* using the summarizing indices of mean, centiles, standard deviations, etc.

Tools of measurement

The epidemiologist usually expresses disease magnitude as a rate, ratio or proportion. A clear understanding of the term is required for proper interpretation of epidemiological data. The basic tools of measurement in epidemiology are :

1. Rates
2. Ratios, and
3. Proportions

1. RATE

When we say there were 500 deaths from motor vehicle accidents in City A during 2010, it is just nothing more than counting deaths in that city during that particular year. Such a statement might be sufficient for the municipal administrator to provide necessary health services. But it conveys no meaning to an epidemiologist who is interested in comparing the frequency of accidents in City A with that in City B. To allow such comparisons, the frequency must be expressed as a rate.

A rate measures the occurrence of some particular event (development of disease or the occurrence of death) in a population during a given time period. It is a statement of the risk of developing a condition. It indicates the change in some event that takes place in a population over a period of time. An example of a typical rate is the death rate. It is written as below:

$$\text{Death rate} = \frac{\text{Number of deaths in one year}}{\text{Mid-year population}} \times 1000$$

A rate comprises the following elements – numerator, denominator, time specification and multiplier. The time dimension is usually a calendar year. The rate is expressed per 1000 or some other round figure (10,000; 100,000) selected according to the convenience or convention to avoid fractions.

The various categories of rates are :

(1) Crude rates: These are the actual observed rates such as the birth and death rates. Crude rates are also known as unstandardized rates.

(2) Specific rates: These are the actual observed rates due to specific causes (e.g., tuberculosis); or occurring in specific groups (e.g., age-sex groups) or during specific time periods (e.g., annual, monthly or weekly rates).

(3) Standardized rates: These are obtained by direct or indirect method of standardization or adjustment, e.g., age and sex standardized rates (see page 58, 59).

2. RATIO

Another measure of disease frequency is a ratio. It expresses a relation in size between two random quantities. The numerator is not a component of the denominator. The numerator and denominator may involve an interval of time or may be instantaneous in time. Broadly, ratio is the result of dividing one quantity by another. It is expressed in the form of:

$$x : y \quad \text{or} \quad \frac{x}{y}$$

Example 1:

The ratio of white blood cells relative to red cells is 1:600 or 1/600, meaning that for each white cell, there are 600 red cells.

Example 2:

$$\frac{\text{The number of children with scabies at a certain time}}{\text{The number of children with malnutrition at a certain time}}$$

Other examples include: sex–ratio, doctor–population ratio, child–woman ratio, etc.

3. PROPORTION

A proportion is a ratio which indicates the relation in magnitude of a part of the whole. The numerator is always included in the denominator. A proportion is usually expressed as a percentage.

$$\text{Example : } \frac{\text{The number of childern with scabies at a certain time}}{\text{The total number of children in the village at the same time}} \times 100$$

CONCEPT OF NUMERATOR AND DENOMINATOR

1. Numerator

Numerator refers to the number of times an event (e.g., sickness, birth, death, episodes of sickness) has occurred in a population, during a specified time–period. The numerator is a component of the denominator in calculating a rate, but not in a ratio.

2. Denominator

Numerator has little meaning unless it is related to the denominator, The epidemiologist has to choose an appropriate denominator while calculating a rate. It may be (a) related to the population, or (b) related to the total events.

a. Related to the population

The denominators related to the population comprise the following: (i) *MID-YEAR POPULATION:* Because the population size changes daily due to births, deaths and migration, the mid-year population is commonly chosen as a denominator. The mid-point refers to the population estimated as on the first of July of an year. (ii) *POPULATION AT-RISK:* This is an important concept in epidemiology because it focuses on groups at risk of disease rather than on individuals. The term is applied to all those to whom an event could have happened whether it did or not. For example, if we are determining the rate of accidents for a town, the population at risk is all the people in the town. But sometimes, it may be necessary to exclude people because they are not at risk, as for example, in food poisoning, only those who ate the food are at risk of becoming ill. Similarly in calculating "general fertility rate", the denominator is restricted to women of child-bearing age (i.e., 15–49 years); older women and little girls are excluded because they are not "at risk" of becoming pregnant. In short, "population at risk" is restricted solely to those who are capable of having or acquiring the disease or condition in question. (iii) *PERSON–TIME:* In some epidemiological studies (e.g., cohort studies), persons may enter the study at different times. Consequently, they are under observation for varying time periods. In such cases, the denominator is a combination of persons and time. The most frequently used person–time is person–years. Sometimes, this may be person–months, person–weeks or man-hours. For example, if 10 persons remain in the study for 10 years, there are said to be 100 person–years of observation. The same figure would be derived if 100 persons were under observation for one year. These denominators have the advantage of summarizing the experience of persons with different

durations of observation or exposure. (iv) *PERSON–DISTANCE:* A variant of person–time is person–distance, as for example passenger–miles. (v) *SUB-GROUPS OF THE POPULATION:* The denominator may be subgroups of a population, e.g., age, sex, occupation, social class, etc.

b. Related to total events

In some instances, the denominator may be related to total events instead of the total population, as in the case of infant mortality rate and case fatality rate. In the case of accidents, the number of accidents "per 1000 vehicles" or "per million vehicle–miles" will be a more useful denominator than the total population, many of them may not be using vehicles.

MEASUREMENT OF MORTALITY

Traditionally and universally, most epidemiological studies begin with mortality data. Mortality data are relatively easy to obtain, and, in many countries, reasonably accurate. Many countries have routine systems for collecting mortality data. Each year, information on deaths is analyzed and the resulting tabulations are made available by each government. Mortality data provide the starting point for many epidemiological studies. In fact, they are the major resource for the epidemiologist.

International Death Certificate

The basis of mortality data is the Death Certificate. So we first look at death certification for ascertaining the frequency of disease in a population. For ensuring national and international comparability, it is very necessary to have a uniform and standardized system of recording and classifying deaths. The death certificate recommended by WHO for international use is given in Fig. 1.

It will be seen from Fig. 1 that the international death certificate is in two parts. Part I deals with the immediate cause, and the underlying cause which started the whole trend of events leading to death. The underlying cause of death is recorded on line (c). In the example cited, the underlying cause of death is strangulated hernia. After operation, the patient developed bronchopneumonia as a complication which ended in death. The concept of "underlying cause" is the essence of the international death certificate. It is defined as (a) the disease or injury which initiated the train of morbid events leading directly to death or (b) the circumstances of the accident or violence which produced the fatal injury. In Part II is recorded any significant associated diseases that contributed to the death but did not directly lead to it.

Death Certificate used in India

In order to improve the quality of maternal mortality and infant mortality data and to provide alternative method of collecting data on deaths during pregnancy and infancy, a set of questions are added to the basic structure of international death certificate for use in India.

Limitations of mortality data

Mortality data are not without limitations. Problems are posed by (a) *Incomplete reporting of deaths.* This is not a problem in developed countries, but in India and other developing countries, this may be considerable. (b) *Lack of accuracy:* That is inaccuracies in the recording of age and cause of death. The practice of medical certification of death is not widespread. If it does exist, the cause of death is often inaccurate or incomplete due to such difficulties as lack of diagnostic evidence, inexperience on the part of the certifying doctor and absence of postmortem which may be important in deciding the cause of death. (c) *Lack of uniformity:* There is no uniform and standardized method of collection of data. This hampers national and international comparability (d) *Choosing a single cause of death:* Most countries tabulate mortality data only according to the underlying cause of death. Other diseases (or risk factors) and conditions which contribute to the patient's death are not tabulated, and valuable information is thereby lost. (e) *Changing:* Changing coding systems and changing fashions in diagnosis may affect the validity. We also need uniform definitions and nomenclature. (f) *Diseases with low fatality:* Lastly, mortality statistics are virtually useless, if the disease is associated with low fatality (e.g., mental diseases, arthritis).

CAUSE OF DEATH		Approximate interval between onset and death
I		
*Disease or condition directly leading to death**	(a) Bronchopneumonia	
	due to (or as a consequence of)	
Antecedent causes Morbid conditions, if any, giving rise to the above cause, stating the underlying condition last	(b)	
	due to (or as a consequence of)	
	(c) Strangulated Hernia	
II		
Other significant conditions contributing to the death, but not related to the disease or condition causing it	Diabetes	

This does not mean the mode of dying e.g., heart failure, asthenia, etc. It means the disease, injury, or complication which caused death

FIG. 1
International form of Death Certificate

Uses of mortality data

Statistics on causes of death are important and widely used for a number of purposes. They may be employed in explaining trends and differentials in overall mortality, indicating priorities for health action and the allocation of resources, in designing intervention programmes, and in the assessment and monitoring of public health problems and programmes – moreover, they give important clues for epidemiological research.

MORTALITY RATES AND RATIOS

The commonly used measures are described below :

1. Crude death rate

The simplest measure of mortality is the 'crude death rate'. It is defined as "the number of deaths (from all causes) per 1000 estimated mid-year population in one year, in a given place". It measures the rate at which deaths are occurring from various causes in a given population, during a specified period. The crude death rate is calculated from the formula:

$$\frac{\text{Number of deaths during the year}}{\text{Mid-year population}} \times 1000$$

It is important to recognize that the crude death rate summarizes the effect of two factors:

a. population composition
b. age-specific death rates (which reflect the probability of dying)

Table 1 shows the crude death rates of two populations, A and B. The crude death rate for population A is 15.2 per 1000. The crude death rate for population B is 9.9 per 1000. Apparently, population B appears healthier, than population A.

The limitation of the crude death rate is exposed, when we compare the age-specific rates between the two populations as shown in Table 1. It can be seen that population B has higher age-specific rates in all age groups. This seeming contradiction is due to differences in the age-composition of the population. The higher crude death rate in population A is due to its older population compared with population B which has a relatively younger population. Currently, this is the prevailing situation in most developing countries with low crude death rates, but high age-specific death rates.

TABLE 1
Crude and age-specific death rates

Popula-tion	Crude death rate	Age-specific death rates per 1000 population					
		0–1	1–4	5–7	8–44	45–64	65+
A	15.2	13.5	0.6	0.4	1.5	10.7	59.7
B	9.9	22.6	1.0	0.5	3.6	18.8	61.1

In summary, the crude death rates have a major disadvantage, that is, they lack comparability for communities with populations that differ by age, sex, race, etc. However, they should always be examined first, and later the age-specific death rates which are the most useful single measures of mortality. By moving away from the crude death rate to the more detailed age-specific rates, an attractive feature of the crude death rate, that is, its ability to portray an impression in a single figure is lost.

2. Specific death rates

When analysis is planned to throw light on aetiology, it is essential to use specific death rates. The specific death rates may be – (a) cause or disease specific – e.g., tuberculosis, cancer, accident; (b) related to specific groups – e.g., age-specific, sex-specific, age and sex specific, etc. Rates can also be made specific for many other variables such as income, religion, race, housing, etc. Specific death rates can help us to identify particular groups or groups "at-risk", for preventive action. They permit comparisons between different causes within the same population. Specific death rates are obtained mainly in countries in which a satisfactory civil registration system operates and in which a high proportion of deaths is certified medically.

Table 2 illustrates how some specific death rates in common use are computed :

TABLE 2
Specific death rates

1. Specific death rate due to tuberculosis $= \dfrac{\text{Number of deaths from tuberculosis during a calendar year}}{\text{Mid-year population}} \times 1{,}000$

2. Specific death rate for males $= \dfrac{\text{Number of deaths among males during a calendar year}}{\text{Mid-year population of males}} \times 1{,}000$

3. Specific death rate in age group 15-20 years $= \dfrac{\text{Number of deaths of persons aged 15–20 during a calendar year}}{\text{Mid-year population of persons aged 15–20}} \times 1{,}000$

4. Death rate for January (Note: The deaths are multiplied by 12 in order to make the monthly death rate comparable with the annual death rate) $= \dfrac{\text{Deaths in January} \times 12}{\text{Mid-year population}} \times 1{,}000$

5. Weekly death rate $= \dfrac{\text{Deaths in the week} \times 52}{\text{Mid-year population}} \times 1{,}000$

3. Case fatality rate (Ratio)

$$= \frac{\text{Total number of deaths due to a particular disease}}{\text{Total number of cases due to the same disease}} \times 100$$

Case fatality rate represents the killing power of a disease. It is simply the ratio of deaths to cases. The time interval is not specified. Case fatality rate is typically used in acute infectious diseases (e.g., food poisoning, cholera, measles). Its usefulness for chronic diseases is limited, because the period from onset to death is long and variable. The case fatality rate for the same disease may vary in different epidemics because of changes in the agent, host and environmental factors. Case fatality is closely related to virulence.

4. Proportional mortality rate (Ratio)

It is sometimes useful to know what proportion of total deaths are due to a particular cause (e.g., cancer) or what proportion of deaths are occurring in a particular age group (e.g., above the age of 50 years). Proportional mortality rate expresses the "number of deaths due to a particular cause (or in a specific age group) per 100 (or 1000) total deaths". Thus we have:

(a) *Proportional mortality from a specific disease*

$$= \frac{\text{Number of deaths from the specific disease in a year}}{\text{Total deaths from all causes in that year}} \times 100$$

(b) *Under-5 proportionate mortality rate*

$$= \frac{\text{Number of deaths under 5 years of age in the given year}}{\text{Total number of deaths during the same period}} \times 100$$

(c) *Proportional mortality rate for aged 50 years and above*

$$= \frac{\text{Number of deaths of persons aged 50 years and above}}{\text{Total deaths of all age groups in that year}} \times 100$$

Proportional mortality rate is computed usually for a broad disease group (such as communicable diseases as a whole) and for a specific disease of major public health importance, such as cancer or coronary heart disease in industrialized countries *(14)*.

Proportional rates are used when population data are not available. Since proportional mortality rate depends upon two variables, both of which may differ, it is of limited value in making comparison between population groups or different time periods. However, proportional rates are useful indicators within any population group of the relative importance of the specific disease or disease group, as a cause of death. Mortality from communicable diseases is especially important as it relates mostly to preventable conditions. Since the prevailing causes of death vary according to age and sex, it is desirable to compute proportionate mortality separately for each age and sex group in order to determine measures directed to particular age–sex groups for the reduction of preventable mortality *(14)*. Proportional mortality rate does not indicate the risk of members of the population contracting or dying from the disease.

5. Survival rate

It is the proportion of survivors in a group, (e.g., of patients) studied and followed over a period (e.g., a 5–year period). It is a method of describing prognosis in certain disease conditions. Survival experience can be used as a yardstick for the assessment of standards of therapy. The survival period is usually reckoned from the date of diagnosis or start of the treatment. Survival rates have received special attention in cancer studies.

$$\text{Survival rate} = \frac{\text{Total number of patients alive after 5 years}}{\text{Total number of patients diagnosed or treated}} \times 100$$

6. Adjusted or standardized rates

If we want to compare the death rates of two populations with different age–composition, the crude death rate is not the right yardstick. This is because, rates are only comparable if the populations upon which they are based are comparable. And it is cumbersome to use a series of age specific death rates. The answer is "age adjustment" or "age standardization", which removes the confounding effect of different age structures and yields a single standardized or adjusted rate, by which the mortality experience can be compared directly. The adjustment can be made not only for age but also sex, race, parity, etc. Thus one can generate age–sex, and race-adjusted rates.

Standardization is carried out by one of two methods – direct or indirect standardization. Both the methods begin by choosing a "standard population", not the age–structures of the populations.

DIRECT STANDARDIZATION

Two examples of direct standardization are given. In the first, a "standard population" is selected. A standard population is defined as one for which the numbers in each age and sex group are known. A frequently used standard age-composition *(14)* is shown in Table 3. The standard population may also be "created" by combining 2 populations; this is shown in the second example.

The next step is to apply to the standard population, the age-specific rates of the population whose crude death rate is to be adjusted or standardized. As a result, for each age group, an "expected" number of deaths (or events) in the standard population is obtained; these are added together for all the age groups, to give the total expected deaths. The final operation is to divide the "expected" total number of deaths by the total of the standard population, which yields the standardized or age-adjusted rate.

Example 1

Example 1 shows: (a) the computation of age-specific death rates per 1000 population for city X (Table 3); and (b) application of these rates to a standard population to obtain the "expected deaths" and the standardized or age-adjusted death rate (Table 4).

TABLE 3

Calculation of age-specific death rates for City "X"

Age	Mid-year population	Deaths in the year	Age-specific death rates
0	4,000	60	15.0
1–4	4,500	20	4.4
5–14	4,000	12	3.0
15–19	5,000	15	3.0
20–24	4,000	16	4.0
25–34	8,000	25	3.1
35–44	9,000	48	5.3
45–54	8,000	100	12.5
55–64	7,000	150	21.4
	53,500	446	

Crude death rate per 1000 = **8.3**

TABLE 4

Calculation of the standardized death rate for City "X"

Age	Standard population	Age-specific death rates per 1000	Expected deaths
0	2,400	15.0	36
1–4	9,600	4.4	42.24
5–14	19,000	3.0	57
15–19	9,000	3.0	27
20–24	8,000	4.0	32
25–34	14,000	3.1	43.4
35–44	12,000	5.3	63.6
45–54	11,000	12.5	137.5
55–64	8,000	21.4	171.2
	93,000		609.94

Standardized death rate per 1000 $= \frac{609.94}{93,000} \times 1000 =$ **6.56**

It can be seen from Tables 3 and 4 that standardizing for age distribution has reduced the crude death rate from 8.3 to 6.56. The choice of the standard population is, to some extent, arbitrary. Clearly, use of a different standard population will give rise to a different value for the standardized death rate, but it must be remembered that these standardized rates have been calculated so that they can be compared between themselves – they have no intrinsic meaning other than for this purpose *(15)*.

It is usual to use the national population as standard when inter-regional comparisons between cities within a range are made. In order that comparisons can be made over a period of years, a 'standard population' can be maintained for that period *(15)*. The standard population used in Table 4 is given by WHO in its publication "Health for All" Series No. 4, on page 77 *(14)*.

Example 2

Table 5 shows that in a study of lung cancer and smoking, 42 per cent of cases and 18 per cent of controls were heavy smokers.

TABLE 5

Proportion of heavy smokers in cases and controls (lung cancer)

Age	Total subjects	CASES No.	CASES Heavy smokers	CASES %	CONTROLS No.	CONTROLS Heavy smokers	CONTROLS %
40–49	500	400	200	50	100	50	50
50–59	500	100	10	10	400	40	10
Total	1,000	500	210	42	500	90	18

Source : *(5)*

Age adjustments were carried out (a) first, by combining the number of subjects in both the age groups (500+500=1,000) to create a standard population, and (b) applying the observed age-specific proportions of heavy smokers (i.e., 50% and 10% in both cases and controls) to the same standard population. The results (or "expected" values) are shown in Table 6, which shows that the age adjusted proportions of heavy smokers are identical (30%) for cases and controls. The previously observed difference is explained entirely by the difference in age composition.

TABLE 6

Age-adjusted proportions

Age	Subjects	Expected number of heavy smokers: CASES	CONTROLS
40–49	500	$\frac{500 \times 50}{100} = 250$	$\frac{500 \times 50}{100} = 250$
50–59	500	$\frac{500 \times 10}{100} = 50$	$\frac{500 \times 10}{100} = 50$
Total	1000	300	300
Standardized rates		$\frac{300}{1000} \times 100 = 30$	$\frac{300}{1000} \times 100 = 30$

The direct method of standardization is feasible only if the actual specific rates in subgroups of the observed population are available, along with the number of individuals in each subgroup.

INDIRECT AGE STANDARDIZATION

1. Standardized mortality ratio (SMR)

The simplest and most useful form of indirect standardization is the Standardized Mortality Ratio (SMR). In England, it is the basis for the allocation of government money to the health regions of the country. The concept is that the regions with higher mortality also have the higher morbidity, and should therefore receive proportionately higher funding to combat ill-health *(15)*.

Standard mortality ratio is a ratio (usually expressed as a percentage) of the total number of deaths that occur in the study group to the number of deaths that would have been expected to occur if that study group had experienced the death rates of a standard population (or other reference population). In other words. SMR compares the mortality in a study group (e.g., an occupational group) with the mortality that the occupational group would have had if they had experienced national mortality rates. In this method, the more stable rates of the larger population are

applied to the smaller study group. It gives a measure of the likely excess risk of mortality due to the occupation.

$$*SMR = \frac{\text{Observed deaths}}{\text{Expected deaths}} \times 100$$

If the ratio had value greater than 100, then the occupation would appear to carry a greater mortality risk than that of the whole population. If the ratio had value less than 100, then the occupation risks of mortality would seem to be proportionately less than that for the whole population.

Table 7 shows that the mortality experience of coal workers was 129 per cent, which meant that their mortality was 29 per cent more than that experienced by the national population. Values over 100 per cent represent an unfavourable mortality experience and those below 100 per cent relatively favourable mortality experience. Table 7 displays the calculations.

TABLE 7
Calculation of the SMR for coal workers

Age	National population death rates per 1000	Coal workers population	Observed deaths	Expected deaths
25–34	3.0	300	*	0.9
35–44	5.0	400	*	2.0
45–54	8.0	200	*	1.6
55–64	25.0	100	*	2.5
		1,000	9	7.0

SMR = 9/7 × 100=129

* It is not necessary to know these values; only the total for the whole age–range is required

The SMR has the advantage over the direct method of age adjustment in that it permits adjustment for age and other factors where age-specific rates are not available or are unstable because of small numbers. One needs to know only the number of persons in each age group in the study population and the age-specific rates of the national population (or other reference population). It is possible to use SMR if the event of interest is occurrence of disease rather than death.

2. Other standardization techniques

(a) A more complicated method of indirect adjustment which yields absolute age adjusted rate, involves the calculation of an index death rate and a standardizing factor for each population of interest. The reader is referred to A.B. Hill's "Principles of Medical Statistics". (b) *Life* table is an age-adjusted summary of current all-causes mortality. (c) *Regression techniques:* These are an efficient means of standardization. (d) *Multivariate analysis:* A computer, using regression or similar methods, can standardize for many variables simultaneously *(16)*.

MEASUREMENT OF MORBIDITY

Morbidity has been defined as "any departure, subjective or objective, from a state of physiological well-being" *(17,18)*. The term is used equivalent to such terms as sickness, illness, disability etc. The WHO Expert Committee on Health Statistics noted in its 6th Report *(17)* that morbidity could be measured in terms of 3 units – (a) persons who were ill; (b) the illnesses (periods or spells of illness) that these persons experienced; and (c) the duration (days, weeks, etc) of these illnesses.

Three aspects of morbidity are commonly measured by *morbidity rates* or *morbidity ratios*, namely frequency, duration and severity. Disease frequency is measured by *incidence* and prevalence rates. The average duration per case or the disability rate, which is the average number of days of *disability* per person, may serve as a measure of the duration of illnesses. The case fatality rate may be used as an index of severity *(19)*. This section focuses on incidence and prevalence rates, which are widely used to describe disease occurrence in a community.

The value of morbidity data may be summarized as follows:

a. they describe the extent and nature of the disease load in the community, and thus assist in the establishment of priorities.
b. they usually provide more comprehensive and more accurate and clinically relevant information on patient characteristics, than can be obtained from mortality data, and are therefore essential for basic research.
c. they serve as starting point for aetiological studies, and thus play a crucial role in disease prevention.
d. they are needed for monitoring and evaluation of disease control activities.

INCIDENCE

Incidence rate is defined as "the number of NEW cases occurring in a defined population during a specified period of time". It is given by the formula :

$$\text{Incidence} = \frac{\text{Number of new cases of specific disease during a given time period}}{\text{Population at-risk during that period}} \times 1000$$

For example, if there had been 500 new cases of an illness in a population of 30,000 in a year, the incidence rate would be:

$$= 500/30{,}000 \times 1000$$

$$= 16.7 \text{ per } 1000 \text{ per year}$$

Note: Incidence rate must include the unit of time used in the final expression. If you write 16.7 per 1000, this would be inadequate. The correct expression is 16.7 per 1000 per year *(20)*.

It will be seen from the above definition that incidence rate refers

a. only to new cases
b. during a given period (usually one year)
c. in a specified population or "population at risk", unless other denominators are chosen.
d. it can also refer to new spells or episodes of disease arising in a given period of time, per 1000 population. For example, a person may suffer from common cold more than once a year. If he had suffered twice, he would contribute 2 spells of sickness in that year. The formula in this case would be:

$$\text{Incidence rate (spells)} = \frac{\text{Number of spells of sickness starting in a defined period}}{\text{Mean number of persons exposed to risk in that period}} \times 1000$$

Incidence measures the rate at which new cases are occurring in a population. It is not influenced by the duration of the disease. The use of incidence is generally restricted to acute conditions.

Special incidence rates

Examples include: Attack rate (case rate), Secondary attack rate, Hospital admission rate, etc.

a. *Attack rate*

An attack rate is an incidence rate (usually expressed as a per cent), used only when the population is exposed to risk for a limited period of time such as during an epidemic. It relates the number of cases in the population at risk and reflects the extent of the epidemic. Attack rate is given by the formula:

$$\text{Attack rate} = \frac{\text{Number of new cases of a specified disease during a specified time interval}}{\text{Total population at risk during the same interval}} \times 100$$

b. *Secondary attack rate*

It is defined as the number of exposed persons developing the disease within the range of the incubation period following exposure to a primary case. (see page 100).

USES OF INCIDENCE RATE

The incidence rate, as a health status indicator, is useful for taking action (a) to control disease, and (b) for research into aetiology and pathogenesis, distribution of diseases, and efficacy of preventive and therapeutic measures *(14)*.

For instance, if the incidence rate is increasing, it might indicate failure or ineffectiveness of the current control programmes. Rising incidence rates might suggest the need for a new disease control or preventive programme, or that reporting practices had improved. A change or fluctuation in the incidence of disease may also mean a change in the aetiology of disease, e.g., change in the agent, host and environmental characteristics. Analysis of differences in incidence rates reported from various socio-economic groups and geographical areas may provide useful insights into the effectiveness of the health services provided *(14)*.

PREVALENCE

The term "disease prevalence" refers specifically to all current cases (old and new) existing at a given point in time, or over a period of time in a given population. A broader definition of prevalence is as follows: "the total number of all individuals who have an attribute or disease at a particular time (or during a particular period) divided by the population at risk of having the attribute or disease at this point in time or midway through the period *(2)*". Although referred to as a rate, prevalence rate is really a ratio.

Prevalence is of two types :

(a) Point prevalence

(b) Period prevalence

(a) Point prevalence

Point prevalence of a disease is defined as the number of all current cases (old and new) of a disease at one point of time, in relation to a defined population. The "point" in point prevalence, may for all practical purposes consist of a day, several days, or even a few weeks, depending upon the time it takes to examine the population sample *(20)*.

Point prevalence is given by the formula:

$$= \frac{\text{Number of all current cases (old and new) of a specified disease existing at a given point in time}}{\text{Estimated population at the same point in time}} \times 100$$

When the term "prevalence rate" is used, without any further qualification, it is taken to mean "point prevalence" *(17)*.

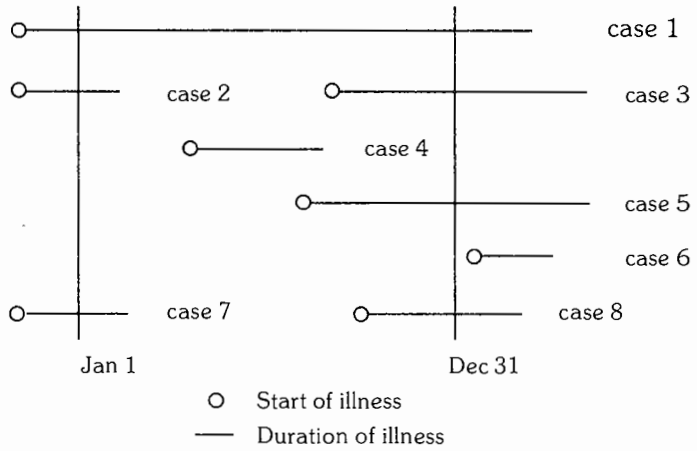
Point prevalence can be made specific for age, sex and other relevant factors or attributes.

(b) Period prevalence

A less commonly used measure of prevalence is period prevalence. It measures the frequency of all current cases (old and new) existing during a defined period of time (e.g., annual prevalence) expressed in relation to a defined population. It includes cases arising before but extending into or through to the year as well as those cases arising during the year (Fig. 2). Period prevalence is given by the formula:

$$= \frac{\text{Number of existing cases (old and new) of a specified disease during a given period of time interval}}{\text{Estimated mid-interval population at-risk}} \times 100$$

The terms incidence and prevalence are illustrated in Fig. 2



Incidence would include cases – 3,4,5, and 8
Point prevalence (Jan 1) cases – 1,2, and 7
Point prevalence (Dec.31) cases – 1,3,5 and 8
Period prevalence (Jan–Dec) cases – 1,2,3,4,5,7, and 8

FIG. 2
Number of cases of a disease beginning, developing and ending during a period of time

Relationship between prevalence and incidence

Prevalence depends upon 2 factors, the incidence and duration of illness. Given the assumption that the population is stable, and incidence and duration are unchanging, the relationship between incidence and prevalence can be expressed as :

$$P = I \times D$$

= incidence × mean duration

Example (for a stable condition)
Incidence = 10 cases per 1000 population per year
Mean duration of disease = 5 years
Prevalence = $10 \times 5 = 50$ per 1000 population

Conversely, it is possible to derive incidence and duration as follows:

Incidence = P/D

Duration = P/I

The above equation ($P = I \times D$) shows that the longer the duration of the disease, the greater its prevalence. For example, tuberculosis has a high prevalence rate relative to incidence. This is because new cases of tuberculosis keep cropping up throughout the year, while the old ones may persist for months or years. On the other hand, if the disease is acute and of short duration either because of rapid recovery or death, the prevalence rate will be relatively low compared with the incidence rate. In some diseases (e.g., food poisoning), the disease is so short–lived, there are no "old" cases. The same is true of conditions which are rapidly fatal, such as homicides. Strictly speaking, these events have no prevalence. In other words, decrease in prevalence may take place not only from a decrease in incidence, but also from a decrease of the duration of illness through either more rapid recovery or more rapid death.

When we see a change in prevalence from one time period to another, this can result from changes in incidence, changes in duration of disease or both. For example, improvements in treatment may decrease the duration of illness and thereby decrease prevalence of a disease. But if the treatment is such that by preventing death, and at the same time not producing recovery, may give rise to the apparently paradoxical effect of an increase in prevalence. Further, if duration is decreased sufficiently, a decrease in prevalence could take place despite an increase in incidence.

Prevalence has been compared with a photograph, an instantaneous record; and incidence with a film, a continuous record. Both the terms may perhaps be better understood by taking into consideration a coffee house. After the coffee house opens in the morning, people keep entering and leaving, each one remaining inside the coffee house for a short while. At any point of time, say 10 AM, we could go into the coffee house and count people over there. This corresponds to estimating the *prevalence*. The rate at which people enter the coffee house, say 10 people per hour, is equivalent to the incidence. The relationship between incidence and prevalence is shown in Fig. 3 *(21)*.

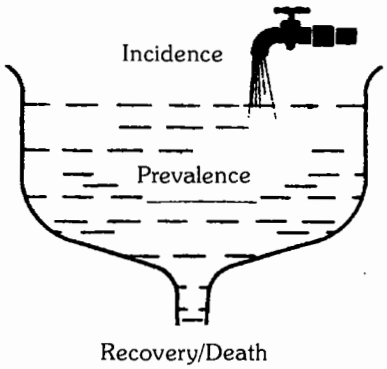


FIG. 3
Relationship between incidence and prevalence

It is important to note the limitations of prevalence rate. It is not the ideal measure for studying disease aetiology or causation. We have seen that two factors determine prevalence, namely incidence and duration. Incidence is related to the occurrence of disease and duration to factors which affect the course of the disease. In other words, the element of *duration* reflects the prognostic factors, and incidence reflects the causal factors. Therefore, incidence rates should be optimally used in the formulation and testing of aetiological hypotheses. When incidence rates are not available, prevalence rates (which are readily obtainable) may have to be used, but the contribution of duration element always has to be assessed.

Uses of prevalence

(a) Prevalence helps to estimate the magnitude of health/disease problems in the community, and identify potential high-risk populations (b) Prevalence rates are especially useful for administrative and planning purposes, e.g., hospital beds, manpower needs, rehabilitation facilities, etc.

EPIDEMIOLOGIC METHODS

The primary concern of the epidemiologist is to study disease occurrence in people, who during the course of their lives are exposed to numerous factors and circumstances, some of which may have a role in disease aetiology. Unlike the clinician or the laboratory investigator, who is able to study disease conditions more precisely, the epidemiologist employs carefully designed research strategies to explore disease aetiology.

Epidemiological studies can be classified as observational studies and experimental studies with further subdivisions :

1. *Observational studies*

a. Descriptive studies

b. Analytical studies

(i) Ecological	or	Correlational,	with populations as unit of study
(ii) Cross-sectional	or	Prevalence,	with individuals as unit of study
(iii) Case-control	or	Case-reference,	with individuals as unit of study
(iv) Cohort	or	Follow-up,	with individuals as unit of study

2. Experimental studies Intervention studies

a. Randomized controlled trials	or	Clinical trials	with patients as unit of study
b. Field trials			with healthy people as unit of study
c. Community trials	or	Community intervention studies	with communities as unit of study

These studies or methods cannot be regarded as watertight compartments; they complement one another. Observational studies allow nature to take its own course; the investigator measures but does not intervene. Descriptive study is limited to a description of the occurrence of a disease in a population. An analytical study goes further by analyzing relationship between health status and other variables. Experimental or intervention studies involve an active attempt to change a disease determinant or the progress of a disease, and are similar in design to experiments in other sciences. However, they are subject to extra constraints, since the health of the people in the study group may be at stake. The major experimental design is the randomized controlled trial using patients as subjects. Field

trials and community trials are other experimental studies in which the participants are healthy people and community respectively *(22)*.

In all epidemiological studies, it is essential to have a clear definition of a case of the disease being investigated and of an exposed person. In absence of clear definitions of disease and exposure, great difficulties are likely to be experienced in interpreting the data.

DESCRIPTIVE EPIDEMIOLOGY

The best study of mankind is man. This statement emphasizes the importance of making the best use of observations on individuals or populations exposed to suspected factors of disease. Meticulous observations made in Africa by Burkitt led to the eventual incrimination of Epstein-Barr virus (EBV) as the aetiological factor (possibly conditioned by other factors such as malarial infection) of the type of cancer known as Burkitt's lymphoma. It was the epidemiological study in New Guinea of "Kuru", a hereditary neurological disorder, that led to the discovery of slow virus infections as the cause of chronic degenerative neurological disorders in human beings. The list is endless.

Descriptive studies are usually the first phase of an epidemiological investigation. These studies are concerned with observing the distribution of disease or health-related characteristics in human populations and identifying the characteristics with which the disease in question seems to be associated. Such studies basically ask the questions.

a. When is the disease occurring ?
   – time distribution
b. Where is it occurring ?
   – place distribution
c. Who is getting the disease?
   – person distribution

The various procedures involved in descriptive studies may be outlined as below (Table 8).

TABLE 8

Procedures in descriptive studies

1. Defining the population to be studied
2. Defining the disease under study
3. Describing the disease by
   a. time
   b. place
   c. person
4. Measurement of disease
5. Comparing with known indices
6. Formulation of an aetiological hypothesis

1. Defining the population

Descriptive studies are investigations of populations, not individuals. The first step is, therefore, to define the "population base" not only in terms of the total number, but also its composition in terms of age, sex, occupation, cultural characters and similar information needed for the study.

The "defined population" can be the whole population in a geographic area, or more often a representative sample taken from it. The defined population can also be a specially selected group such as age and sex groups, occupational groups, hospital patients, school children, small communities as well as wider groupings – in fact, wherever a group of people can be fairly accurately counted.

The defined population needs to be large enough so that age, sex and other specific rates are meaningful. The community chosen should be stable, without migration into or out of the area. It should be clear who does and who does not belong to the population, as for example, visitors and relations. Perhaps the most essential ingredient is community participation, which must be forthcoming. Furthermore, the population should not be overtly different from other communities in the region. Finally, a health facility should be close enough to provide relatively easy access for patients requiring medical services. In the famous Framingham Heart Study in US, all the above criteria were taken into consideration in choosing the study population.

The concept of 'defined population' (or population at risk) is crucial in epidemiological studies. It provides the denominator for calculating rates which are essential to measure the frequency of disease and study its distribution and determinants. Epidemiologists therefore have been labelled as men in search of a denominator *(23)*.

2. Defining the disease under study

Once the population to be studied is defined or specified, one must then define the disease or condition being investigated. Here the needs of the clinician and epidemiologist may diverge. The clinician may not need a precise definition of disease (e.g., migraine) for immediate patient care. If the diagnosis is wrong, he can revise it subsequently. But the epidemiologist, whose main concern is to obtain an accurate estimate of disease in a population, needs a definition that is both precise and valid to enable him (or observers working in field conditions) to identify those who have the disease from those who do not *(9)*. The diagnostic methods for use in epidemiological studies must be acceptable to the population to be studied, and applicable to their use in large populations.

In other words, the epidemiologist looks out for an "operational definition", i.e., a definition by which the disease or condition can be identified and measured in the defined population with a degree of accuracy. For example, tonsillitis might be defined clinically as an inflammation of the tonsils caused by infection, usually with *streptococcus pyogenes*. This definition, like many other clinical definitions (and the WHO definition of 'health') serves to convey particular information, but cannot be used to measure disease in the community. On the other hand, an "operational definition" spells out clearly the criteria by which the disease can be measured. Such criteria in the case of tonsillitis would include the presence of enlarged, red tonsils with white exudate, which on throat swab culture grow predominantly *S. pyogenes*. If the definition is not valid, it would be a powerful source of error in the presentation and comparability of measurements from different sources. With regard to certain diseases (e.g., neurological diseases) which often do not have pathognomonic signs and symptoms, disease definition is a crucial concern for the epidemiologist. In such cases, the epidemiologist frames his own definition keeping the objectives of his study in view and aiming at the same time a degree of accuracy sufficient for his purpose. Once established, the case definition must be adhered to throughout the study.

3. Describing the disease

The primary objective of descriptive epidemiology is to describe the occurrence and distribution of disease (or

health-related events or characteristics within populations) by time, place and person, and identifying those characteristics associated with presence or absence of disease in individuals. This involves systematic collection and analysis of data. Some of the characteristics most frequently examined by epidemiologists in descriptive studies are given in Table 9. It is only an initial separation or grouping of variables according to time, place and person and NOT a classification of causal factors.

TABLE 9

Characteristics frequently examined in descriptive studies

Time	Place	Person	
Year, season	Climatic zones	Age	Birth order
Month, week	Country, region	Sex	Family size
Day, hour of onset,	Urban/rural Local community	Marital state	Height Weight
Duration	Towns Cities Institutions	Occupation Social status Education	Blood pressure Blood cholesterol Personal habits

TIME DISTRIBUTION

The pattern of disease may be described by the time of its occurrence, i.e., by week, month, year, the day of the week, hour of onset, etc. It raises questions whether the disease is seasonal in occurrence; whether it shows periodic increase or decrease; or whether it follows a consistent time trend. Such studies may yield important clues about the source or aetiology of the disease, thereby suggesting potential preventive measures. Epidemiologists have identified three kinds of time trends or fluctuations in disease occurrence.

I. Short-term fluctuations
II. Periodic fluctuations, and
III. Long-term or secular trends

I. Short-term fluctuations

The best known short-term fluctuation in the occurrence of a disease is an epidemic. According to modern concepts an epidemic is defined as "the occurrence in a community or region of cases of an illness or other health-related events clearly in excess of normal expectancy". The community or region, and the time period in which the cases occur, are specified precisely. Epidemicity is thus relative to usual frequency of the disease in the same area, among the specified population, at the same season of the year *(2)*. The data in Table 10 illustrates this point.

Types of epidemics

Three major types of epidemics may be distinguished.

A. Common-source epidemics
   (a) Single exposure or "point-source" epidemics.
   (b) Continuous or multiple exposure epidemics
B. Propagated epidemics
   (a) Person-to-person
   (b) Arthropod vector
   (c) Animal reservoir
C. Slow (modern) epidemics.

A graph of the time distribution of epidemic cases is called the "epidemic curve" (Fig. 4). The epidemic curve may suggest : (1) a time relationship with exposure to a suspected source, (2) a cyclical or seasonal pattern suggestive of a particular infection, and common source or propagated spread of the disease.

A. *Common-source epidemics*

(a) Common-source, single exposure epidemics

These are also known as "point-source" epidemics. The exposure to the disease agent is brief and essentially simultaneous, the resultant cases all develop within one incubation period of the disease (e.g., an epidemic of food poisoning). Fig. 4 illustrates a common-source, single exposure epidemic. The curve has usually one peak. One point of interest is the "median incubation period", it is the time required for 50 per cent of the cases to occur following exposure.

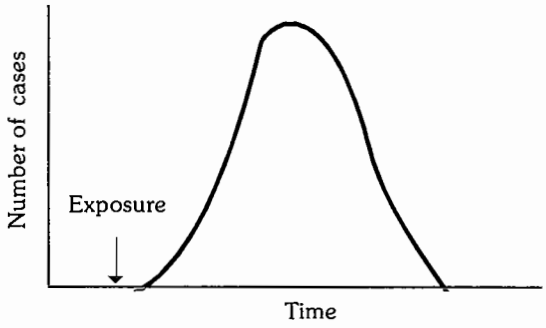

FIG. 4
Epidemic curve

Source : *(3)*

The main features of a "point-source" epidemic are : (i) the epidemic curve rises and falls rapidly, with no secondary waves (ii) the epidemic tends to be explosive, there is clustering of cases within a narrow interval of time, and (iii) more importantly, all the cases develop within one incubation period of disease.

Common-source epidemics are frequently, but not always, due to exposure to an infectious agent. They can result from contamination of the environment (air, water, food, soil) by industrial chemicals or pollutants, e.g., Bhopal gas tragedy in India and Minamata disease in Japan resulting from consumption of fish containing high concentration of methyl mercury.

If the epidemic continues over more than one incubation period, there is either a continuous or multiple exposure to a common source, or a propagated spread.

(b) Common-source, continuous or repeated exposure

Sometimes the exposure from the same source may be prolonged – continuous, repeated or intermittent – not necessarily at the same time or place. A prostitute may be a common source in a gonorrhoea outbreak, but since she will infect her clients over a period of time there may be no explosive rise in the number of cases. A well of contaminated water, or a nationally distributed brand of vaccine (e.g. polio vaccine), or food, could result in similar outbreaks. In these instances, the resulting epidemics tend to be more extended or irregular. The outbreak of respiratory illness, the Legionnaire's disease, in the summer of 1976 in Philadelphia (USA) was a common-source, continuous or repeated exposure outbreak. This outbreak, as in other outbreaks of this type, continued beyond the range of one incubation period. There was no evidence of secondary cases among persons who had contact with ill persons *(24)*.

A variation to the above model is that an epidemic may

be initiated from a common source and then continue as a propagated epidemic. Water-borne cholera is a familiar example, the epidemic reaches a sharp peak, but tails off gradually over a longer period of time.

B. *Propagated epidemics*

A propagated epidemic is most often of infectious origin and results from person-to-person transmission of an infectious agent (e.g., epidemics of hepatitis A and polio). The epidemic usually shows a gradual rise and tails off over a much longer period of time. Transmission continues until the number of susceptibles is depleted or susceptible individuals are no longer exposed to infected persons or intermediary vectors. The speed of spread depends upon herd immunity, opportunities for contact and secondary attack rate. Propagated epidemics are more likely to occur where large number of susceptibles are aggregated, or where there is a regular supply of new susceptible individuals (e.g., birth, immigrants) lowering herd immunity. Fig. 5 illustrates the course of a typical propagated epidemic in which the agent is transmitted by contact between individuals.

II. Periodic fluctuations

(i) *Seasonal trend* : Seasonal variation is a well-known characteristic of many communicable diseases, e.g., measles, varicella, cerebro-spinal meningitis, upper respiratory infections, malaria, etc. For example, measles is usually at its height in early spring and so is varicella. Upper respiratory infections frequently show a seasonal rise during winter months. Bacterial gastrointestinal infections are prominent in summer months because of warm weather and rapid multiplication of flies. The seasonal variations of disease occurrence may be related to environmental conditions (e.g., temperature, humidity, rainfall, overcrowding, life cycle of vectors, etc.) which directly or indirectly favour disease transmission. However, in many infectious diseases (e.g., polio), the basis for seasonal variation is unknown. Non-infectious diseases and conditions may sometimes exhibit seasonal variation, e.g., sunstroke, hay fever, snakebite. Some epidemiologists would regard seasonal trend as a form of cyclic trend. Table 10 shows a typical pattern of seasonal trend, – the outbreaks of dengue/DF starting by month of July and peaking in September, October and November, coinciding with late summer and rain.

TABLE 10

Seasonal trend of dengue/DHF in India 2005-2007

Month	2005	2006	2007
January	151	281	83
February	80	193	64
March	59	178	46
April	68	166	50
May	172	181	127
June	130	269	175
July	742	478	487
August	946	577	487
September	4,852	1,275	974
October	2,482	5,880	1,507
November	1,507	1,934	802
December	801	905	221
Total	11,990	12,317	5,023

Source : *(25)*

(ii) *Cyclic trend* : Some diseases occur in cycles spread over short periods of time which may be days, weeks, months or years. For example, measles in the pre-vaccination era appeared in cycles with major peaks every 2–3 years and rubella every 6–9 years. This was due to naturally occurring variations in herd immunity. A build-up of susceptibles is again required in the "herd" before there can be another attack. Influenza pandemics are known to occur at intervals of 7–10 years, due to antigenic variations. Non-infectious conditions may also show periodic fluctuations, e.g., automobile accidents in US are more frequent on week-ends, especially Saturdays. A knowledge of cyclicity of disease is useful in that it may enable communities to defend themselves.

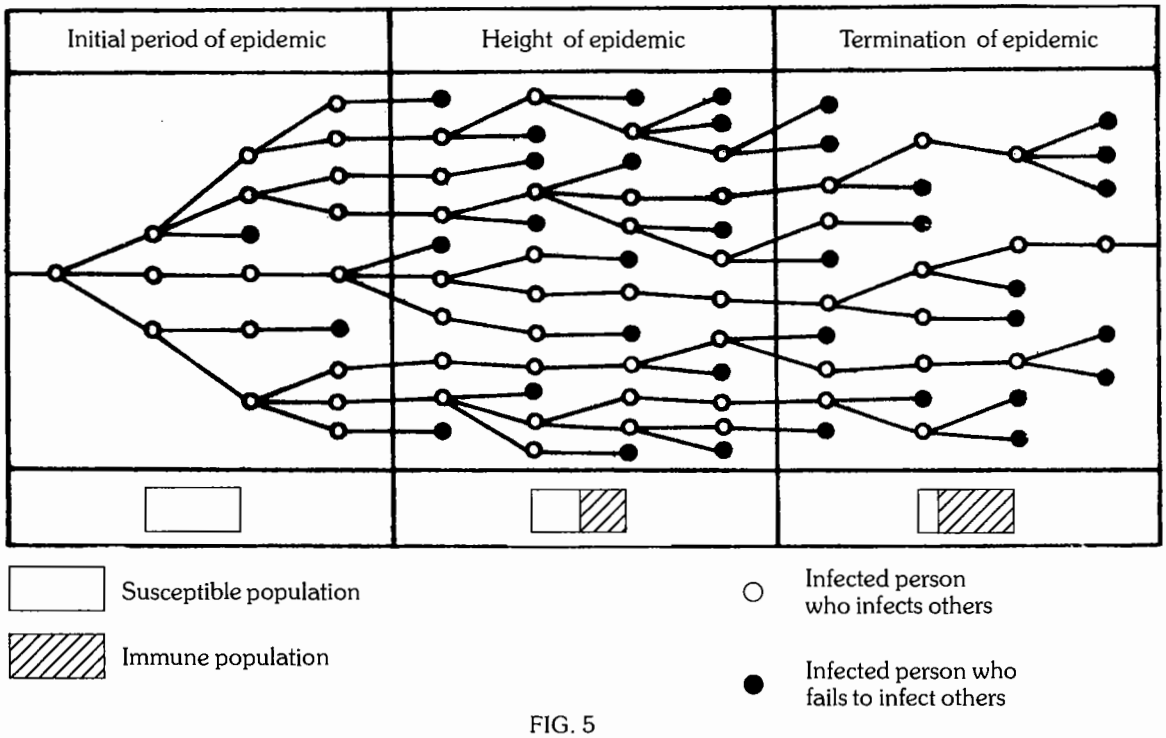

FIG. 5
Course of typical propagated epidemic (Source 4)

III. Long-term or secular trends

The term "secular trend" implies changes in the occurrence of disease (i.e., a progressive increase or decrease) over a long period of time, generally several years or decades. Although it may have short-term fluctuations imposed on it, a secular trend implies a consistent tendency to change in a particular direction or a definite movement in one direction. Examples include coronary heart disease, lung cancer and diabetes which have shown a consistent upward trend in the developed countries during the past 50 years or so, followed by a decline of such diseases as tuberculosis, typhoid fever, diphtheria and polio.

Interpretation of time-trends

By surveillance or monitoring of time-trends, the epidemiologist seeks which diseases are increasing, which decreasing, and which are the emerging health problems and of the effectiveness of measures to control old ones *(16)*. He tries to formulate aetiological hypotheses, and seeks explanations whether these changes were due to changes in the aetiological agent or variations in diagnosis, reporting, case fatality or changes in age distribution, or some other determinants, specific and non-specific (e.g., changes in quality of life, socio-economic status and personal habits). For example the "time-clustering" of cases of adenocarcinoma of vagina in young women led to the incrimination of its cause, viz. *in utero* exposure to diethylstilbestrol *(26)*. Even changes taking place over several years or decades can be productive of hypotheses, as in the cases of lung cancer. By studying time trends, the epidemiologist seeks to provide guidelines to the health administrator in matters of prevention or control of disease.

PLACE DISTRIBUTION

(Geographical comparisons)

Studies of the geography of disease (or geographical pathology) is one of the important dimensions of descriptive epidemiology. By studying the distribution of disease in different populations we gain perspective on the fascinating differences (or variations) in disease patterns not only between countries, but also within countries. The relative importance of genes versus environment; changes with migration; and the possible roles of diet and other aetiological factors. In short geographical studies have profoundly influenced our understanding of disease, its nature, its detriments and its relation to subsequent pathology. The geographic variation in disease occurrence has been one of the stimulants to national and international studies.

The world is not a uniform unit. Cultures, standard of living and external environments vary greatly. The use of migrant studies is one way of distinguishing genetic and environmental factors. The study of the geography of diseases has developed its own special techniques, which sometimes involve complex statistical analysis. The SMR is one of them.

Geographic patterns provide an important source of clues about the causes of the disease. The range of geographic studies include those concerned with local variations. At a broader level, international comparisons may examine mortality and morbidity in relation to socio-economic factors, dietary differences and the differences in culture and behaviour. These variations may be classified as :

a. International variations
b. National variations
c. Rural–urban variations
d. Local distributions

International variations

Descriptive studies by place have shown that the pattern of disease is not the same everywhere. For example, we know that cancer exists all over the world. There is, however, a marked difference between the incidence of each cancer in different parts of the world. Thus cancer of the stomach is very common in Japan, but unusual in US. Cancers of the oral cavity and uterine cervix are exceedingly common in India as compared to industrialized countries. An international study of breast cancer showed that rates differ widely from country to country with the lowest prevalence in Japan and the highest in the western countries. Similarly, there are marked international differences in the occurrence of cardiovascular diseases. These variations have stimulated epidemiologists to search for cause–effect relationships between the environmental factors and disease. The aim is to identify factors which are crucial in the cause and prevention of disease.

National variations

It is obvious that variations in disease occurrence must also exist within countries or national boundaries. For example the distribution of endemic goitre, lathyrism, fluorosis, leprosy, malaria, nutritional deficiency diseases have all shown variations in their distribution in India, with some parts of the country more affected and others less affected or not affected at all. Such situations exist in every country. One of the functions of descriptive epidemiology is to provide data regarding the type of disease problems and their magnitude in terms of incidence, prevalence and mortality rates. Such information is needed to demarcate the affected areas and for providing appropriate health care services.

Rural-urban variations

Rural/urban variations in disease distribution are well known. Chronic bronchitis, accidents, lung cancer, cardio-vascular diseases, mental illness and drug dependance are usually more frequent in urban than in rural areas. On the other hand, skin and zoonotic diseases and soil-transmitted helminths may be more frequent in rural areas than in urban areas. Death rates, especially infant and maternal mortality rates, are higher for rural than urban areas. These variations may be due to differences in population density, social class, deficiencies in medical care, levels of sanitation, education and environmental factors. The epidemiologist seeks to define groups which are at higher risk for particular diseases, and provides guidelines to the health administrator for their prevention and control.

Local distributions

Inner and outer city variations in disease frequency are well known. These variations are best studied with the aid of 'spot maps' or 'shaded maps'. These maps show at a glance areas of high or low frequency, the boundaries and patterns of disease distribution. For example if the map shows "clustering" of cases, it may suggest a common source of infection or a common risk factor shared by all the cases. It was by such a study (spot map of fatal cases), John Snow of England in his classic investigation of cholera epidemic in 1854 in the Golden Square district of London was able to focus attention on the common water pump in Broad street as the source of infection (Fig. 6). Based on his descriptive

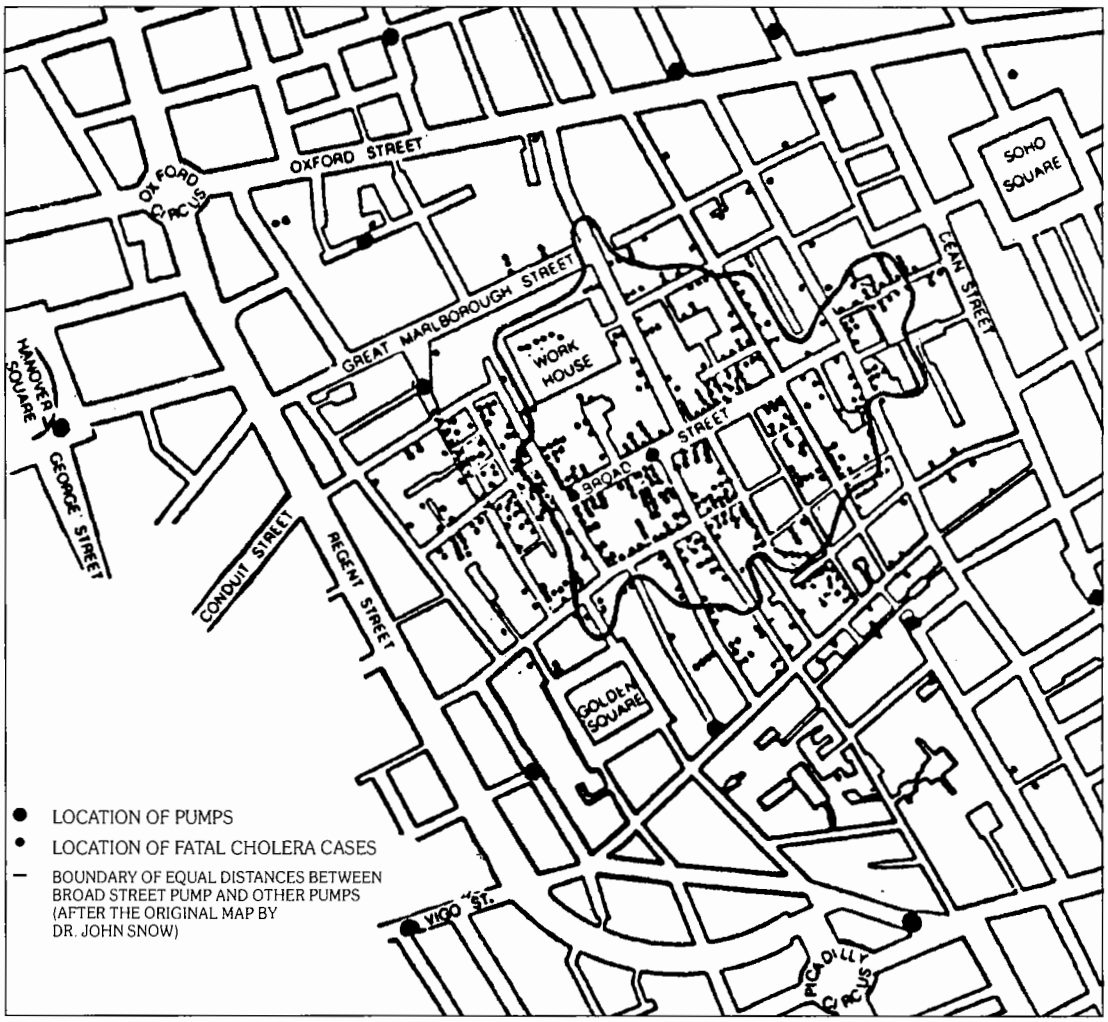

FIG. 6
Spot map of Asiatic cholera in London

findings, Snow was able to hypothesize that cholera was a water-borne disease, long before the birth of bacteriology. It was by a spot map by "place of employment" Maxcy hypothesized a rodent reservoir for typhus fever in 1920s which led to the discovery that typhus fever was not a single disease entity, as it was earlier thought. Also, the evidence of case clustering based on sexual contact or blood product use provided the clue that AIDS (Acquired Immune Deficiency Syndrome) was an infectious disease.

In short the geographic differences in disease occurrence is an important dimension of a descriptive study. These differences are determined by the agent, host and environmental factors. The classic example of place-related diseases include yellow fever, schistosomiasis, sleeping sickness and endemic goitre. There have also been studies on asthma, cancer, cardiovascular diseases, blood groups and abnormal haemoglobins by geographic location. In short, all diseases whether acute or chronic, communicable or non-communicable, show definite patterns of geographic distribution.

The epidemiologist is interested in geographic variations in disease occurrence. Geographic distribution may provide evidence of the source of disease and its mode of spread. By relating these variations to agent, host and environmental factors, he tries to derive clues to the source of disease and its mode of spread to formulate and test aetiological hypotheses. The clinician is also benefited from knowledge that a patient comes to him from a certain geographic area which is endemic for certain infrequent diseases such as yaws or leishmaniasis, as it helps him to focus attention on these diseases to which the patient may have been exposed.

The geographic distribution of disease may change, if changes occur in the agent, host and environmental factors. The empires of malaria, plague and many other diseases have shrunk due to changes in the epidemiological triad. On the other hand, since 1961 cholera has shown an increasing geographic distribution due to changes in the disease agent. Since the mode of living and environmental factors vary from country to country, one would expect to find differences in the geographic distribution and frequency of disease.

Migration studies

Large scale migration of human populations from one country to another provides a unique opportunity to evaluate the role of the possible genetic and environmental factors in the occurrence of disease in a population. Supposing there are marked geographic differences in the occurrence of a disease in two areas, area "A" and area "B". Let us assume that the environments in these two places are very different. The question arises whether the environmental differences in the two areas account for the variations in the occurrence of the disease in question.

Ideally, samples of population in area "A" should be sent to area "B", and vice versa to study change in incidence of disease. In human populations this is hardly possible, so we restrict our study to observation of changes in disease frequency among migrants.

Migrant studies can be carried out in two ways :

(a) comparison of disease and death rates for migrants with those of their kin who have stayed at home. This permits study of genetically similar groups but living under different environmental conditions or exposures. If the disease and death rates in migrants are similar to country of adoption over a period of time, the likely explanation would be change in the environment. A special case is the use of twins who have been exposed to different environments of migration.

(b) comparison of migrants with local population of the host country provides information on genetically different groups living in a similar environment. If the migration rates of disease and death are similar to the country of origin, the likely explanation would be the genetic factors.

Migrant studies have shown that men of Japanese ancestry living in USA experience a higher rate of coronary heart disease than do the Japanese in Japan *(27)*. Taking another example, Japan has a higher rate for stomach cancer and a lower rate for colon cancer than the United States has. However, third-generation descendants of Japanese immigrants to USA have rates of stomach and colon cancer like those of the total US population. These studies suggest that as the Japanese were probably adopting the American way of life, their susceptibility to coronary heart disease, gastric and colonic cancer was moving in the direction of that found in the Americans. Further, migrant studies may also indicate the duration of residence necessary to acquire susceptibility to the disease in question by comparing groups that left home at different ages. Studies of this kind provide a basis for further studies of specific environmental factors to which the migrants may have been exposed or of changes in their habits of life that may be of aetiological importance.

Migrant studies suffer from the usual defects of observational studies, deriving from lack of random assignment to the groups under observation. Migrants may be self-selected in that fit, vigorous and perhaps the temperamentally unstable are more likely to migrate *(28)*. The environmental factors may only act at a certain critical point or at a certain specific age. If the incubation period of the disease is very long, migrants may not show any increased incidence or mortality from the disease for many years.

PERSON DISTRIBUTION

In descriptive studies, the disease is further characterized by defining the persons who develop the disease by age, sex, occupation, martial status, habits, social class and other host factors. These factors do not necessarily represent aetiological factors, but they contribute a good deal to our understanding of the natural history of disease. Some of the host factors basic to epidemiological studies (Table 9) are discussed below.

(a) *Age* : Age is strongly related to disease than any other single host factor. Certain diseases are more frequent in certain age groups than in others, e.g., measles in childhood, cancer in middle age and atherosclerosis in old age. If the attack rate of a communicable disease is uniform in all the age groups, it implies that all age groups are equally susceptible, and there was no previous immunity. Many chronic and degenerative diseases (e.g., cancer) show a progressive increase in prevalence with advancing age. This may reflect a persistent and cumulative exposure to a causal agent or risk factor *(12)*.

Bimodality : Sometimes there may be two separate peaks instead of one in the age incidence curve of a disease as in the case of Hodgkin's disease, leukaemia, and female breast cancer. This phenomenon is known as bimodality. Fig. 7 shows the age incidence curve for Hodgkin's disease in USA *(29)*. The curve is bimodal with an initial peak between the ages 15 and 35 years, and a later peak starting at age 50. Bimodality is of special interest to epidemiologists. It indicates that the study material is not homogeneous, and that two distinct sets of causal factors might be operative, even though the clinical and pathological manifestations of the disease are the same at all ages.

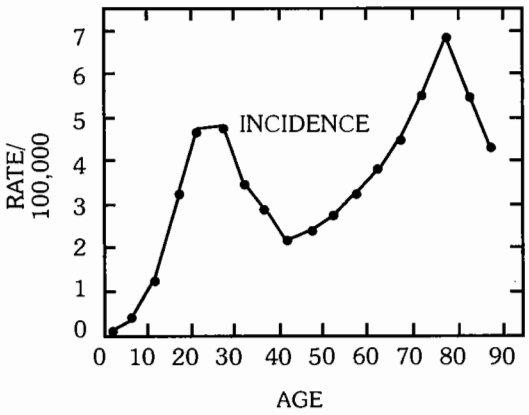

FIG. 7
Bimodality in Hodgkin's disease

However, there are two points relating to bimodality which make their interpretation difficult : (a) small numbers of observations are a frequent source of bimodality; (b) the absence of bimodality does not signify that data have come from a homogeneous source.

(b) *Sex* : Sex is another host characteristic which is often studied in relation to disease, using such indices as sex–ratio, sex–specific morbidity and mortality rates. It has been found that certain chronic diseases such as diabetes, hyperthyroidism and obesity are strikingly more common in women than in men, and diseases such as lung cancer and coronary heart disease are less frequent in women.

Variations in disease frequency between sexes have been ascribed to (a) basic biological differences between the sexes, including sex–linked genetic inheritance, and (b) cultural and behavioural differences between the sexes (e.g., smoking, automobile use, alcoholism) due to different roles in social setting. In fact, it is the 4:1 male to female ratio in lung cancer that has helped to identify cigarette smoking as a causal factor. Even larger differences exist in, for example, duodenal ulcer and coronary heart disease, that are as yet unexplained *(30)*.

(c) *Ethnicity* : Differences in disease occurrence have been noted between population subgroups of different racial and ethnic origin. These include tuberculosis, essential hypertension, coronary heart disease, cancer, and sickle cell anaemia. These differences, whether they are related to genetic or environmental factors, have been a stimulus to further studies.

(d) *Marital status* : In countries where studies on mortality

in relation to marital status have been conducted, it was found that mortality rates were always lower for married males and females than for the unmarried, of the same age and sex. According to demographers and sociologists, the reason for this phenomenon may be found in the fact that marriages are selective with respect to the health status of persons, for those who are healthy are more likely to get married, with the result that the risk of dying is also less. Besides, married persons are generally more secure and protected and they usually lead a more sober life than those who are unmarried. All these factors are thought to contribute to lower mortality rates among married persons.

Marital status can be a risk factor for some diseases and conditions. The observation that cancer cervix is rare in nuns led to the hypothesis regarding marital status and cancer cervix. Further studies led to the suggestion that cancer cervix may be associated with multiple sexual contacts and promiscuity. This in turn raised the possibility of a possible infectious agent transmitted venereally. Although the viral aetiology of cancer cervix is not yet proved, this chain of thinking serves to illustrate how an observation can be a starting point of an epidemiological enquiry.

(e) *Occupation* : It is now well recognized that man's occupation from which he earns his livelihood has an important bearing on his health status. Occupation may alter the habit pattern of employees e.g., sleep, alcohol, smoking, drug addiction, night shifts etc. It is obvious that persons working in particular occupations are exposed to particular types of risks. For instance, while workers in coal mines are more likely to suffer from silicosis, those in sedentary occupations face the risk of heart disease.

(f) *Social class* : Epidemiological studies have shown that health and diseases are not equally distributed in social classes. Individuals in the upper social classes have a longer life expectancy and better health and nutritional status than those in the lower social classes. Certain diseases (e.g., coronary heart disease, hypertension, diabetes) have shown a higher prevalence in upper classes than in the lower classes. Social class differences have also been observed in mental illness and utilization of medical and health care services.

However, there is one snag. Social classification varies from country to country. It has different meanings for different persons. Therefore associations of disease with social class vary according to one's concept of social class. Consequently, it is difficult to compare the results of studies in which social class has been used differently by different investigators *(30)*.

(g) *Behaviour* : Human behaviour is increasingly looked upon as a risk factor in modern–day diseases such as coronary heart disease, cancer, obesity and accidents. The behavioural factors which have attracted the greatest attention are cigarette smoking, sedentary life, over-eating and drug abuse. To this must be added the mass movement of people, such as occurs in pilgrimages, which lends themselves to the transmission of infectious diseases such as cholera and diarrhoeal diseases, insect–borne and sexually transmitted diseases.

(h) *Stress* : Stress has been shown to affect a variety of variables related to patients response, e.g., susceptibility to disease, exacerbation of symptoms, compliance with medical regimen, etc.

(i) *Migration* : In India diseases like leprosy, filaria and malaria are considered to be rural problems. However, because of the movement of people from rural to urban areas these diseases have created a serious problem in urban areas also.

Human movement may be classified (i) as short-term, long-term, and permanent (ii) according to age, sex, education, occupation, (iii) internal or external (iv) urban versus rural, etc. Migration has presented challenge to control/prevention of disease.

To sum up, a study of the host factors in relation to disease occurrence is an important dimension of descriptive epidemiology. Variations in the distribution of disease in age, sex, occupation and other subgroups of the population can be the starting point for an epidemiological enquiry leading to formulation of an aetiological hypothesis for further study. Knowledge of the frequency of disease in subgroups of the population has also generated the concept of "high risk groups".

4. Measurement of disease

It is mandatory to have a clear picture of the amount of disease ("disease load") in the population. This information should be available in terms of mortality, morbidity, disability and so on, and should preferably be available for different subgroups of the population. Measurement of mortality is straightforward. Morbidity has two aspects – incidence and prevalence (see page 60, 61). Incidence can be obtained from "longitudinal" studies, and prevalence from "cross-sectional" studies. Descriptive epidemiology may use a cross-sectional or longitudinal design to obtain estimates of magnitude of health and disease problems in human populations.

Cross-sectional studies

Cross-sectional study is the simplest form of an observational study. It is based on a single examination of a cross-section of population at one point in time – the results of which can be projected on the whole population provided the sampling has been done correctly. Cross-sectional study is also known as "prevalence study".

Cross-sectional studies are more useful for chronic than short-lived diseases. For example, in a study of hypertension, we can also collect data during the survey about age, sex, physical exercise, body weight, salt intake and other variables of interest. Then we can determine how prevention of hypertension is related to certain variables simultaneously measured. Such a study tells us about the distribution of a disease in population rather than its aetiology.

The most common reason that epidemiologist examines the inter-relationships between a disease, or one of its precursors, and other variables is to attempt to establish a causal chain and so give lead to possible ways of preventing that disease. A point which must be stressed is that the time sequence which is essential to the concept of causativity cannot be deduced from cross-sectional data. However, frequently there is evidence that permits ranking of events to form such a sequence. That is, the distribution patterns may suggest causal hypothesis which can be tested by analytical studies. Although a cross-sectional study provides information about disease prevalence, it provides very little information about the natural history of disease or about the rate of occurrence of new cases (incidence).

Longitudinal studies

There is an increasing emphasis on the value of longitudinal studies in which observations are repeated in the same population over a prolonged period of time by means of follow-up examinations. Cross-sectional studies

have been likened to a photograph, and longitudinal studies to a cine film. Longitudinal studies are useful (i) to study the natural history of disease and its future outcome (ii) for identifying risk factors of disease, and (iii) for finding out incidence rate or rate of occurrence of new cases of disease in the community. Longitudinal studies provide valuable information which the cross-sectional studies may not provide, but longitudinal studies are difficult to organize and more time-consuming than cross-sectional studies.

Measurement can also be extended to health states and events. For example, the study of blood pressure levels in a population will reveal the normal values, rather than abnormal ones related to disease.

5. Comparing with known indices

The essence of epidemiology is to make comparisons and ask questions. By making comparisons between different populations, and subgroups of the same population, it is possible to arrive at clues to disease aetiology. We can also identify or define groups which are at increased risk for certain diseases.

6. Formulation of a hypothesis

By studying the distribution of disease, and utilizing the techniques of descriptive epidemiology, it is often possible to formulate hypotheses relating to disease aetiology. A hypothesis is a supposition, arrived at from observation or reflection. It can be accepted or rejected, using the techniques of analytical epidemiology. An epidemiological hypothesis should specify the following *(12)* :

a. the population – the characteristics of the persons to whom the hypothesis applies
b. the specific cause being considered
c. the expected outcome – the disease
d. the dose–response relationship – the amount of the cause needed to lead to a stated incidence of the effect
e. the time–response relationship – the time period that will elapse between exposure to the cause and observation of the effect.

In other words, a hypothesis should be formulated in a manner that it can be tested taking into consideration the above elements. In practice, the components of a hypothesis are often less well–defined.

For example :

> "Cigarette smoking causes lung cancer" – is an incomplete hypothesis.

An improved formulation

> "The smoking of 30–40 cigarettes per day causes lung cancer in 10 per cent of smokers after 20 years of exposure"

The improved formulation suggests data needed to test the hypothesis, i.e., the number of cigarettes smoking per day, years of exposure, and so on. The success or failure of a research project frequently depends upon the soundness of the hypothesis *(12)*.

Uses of descriptive epidemiology

Descriptive studies : (a) provide data regarding the magnitude of the disease load and types of disease problems in the community in terms of morbidity and mortality rates and ratios (b) provide clues to disease aetiology, and help in the formulation of an aetiological hypothesis. That is, the existence of a possible causal association between a factor and a disease is usually recognized in descriptive studies. Thus, if the disease is observed to be more frequent in a particular group than in others, hypotheses are formulated to explain the increased frequency (c) provide background data for planning, organizing and evaluating preventive and curative services, and (d) they contribute to research by describing variations in disease occurrence by time, place and person.

ANALYTICAL EPIDEMIOLOGY

Analytical studies are the second major type of epidemiological studies. In contrast to descriptive studies that look at entire populations, in analytical studies, the subject of interest is the individual within the population. The object is not to formulate, but to test hypotheses. Nevertheless, although individuals are evaluated in analytical studies, the inference is not to individuals, but to the population from which they are selected.

Analytical studies comprise two distinct types of observational studies :

a. case control study
b. cohort study.

From each of these study designs, one can determine :

a. whether or not a statistical association exists between a disease and a suspected factor; and
b. if one exists, the strength of the Association.

A schematic design of case control and cohort studies is shown in Fig. 8.

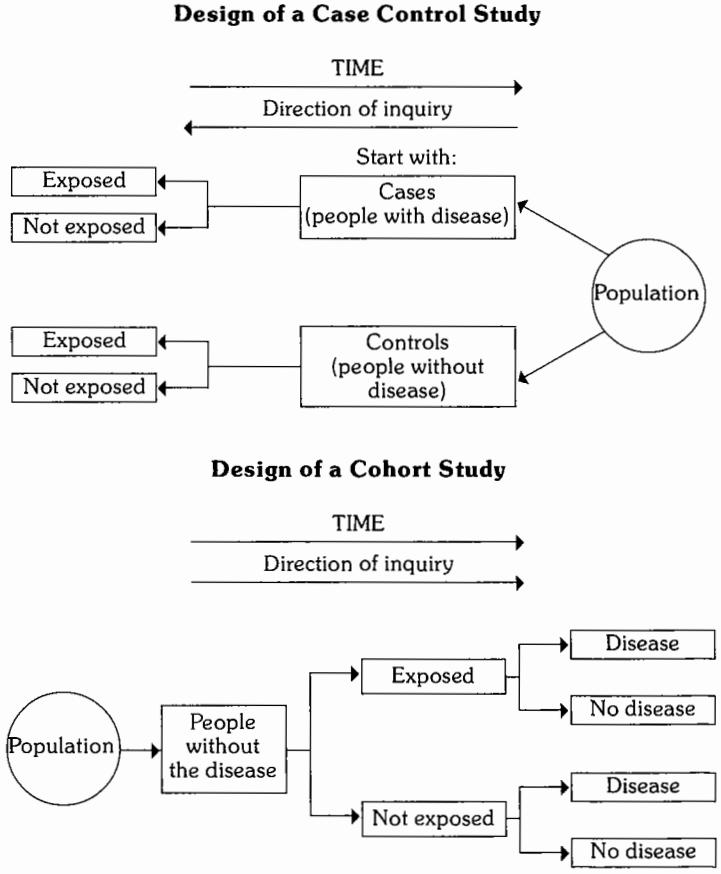

FIG. 8
Schematic diagram of the design of case control and cohort studies

Source : *(30A)*

CASE CONTROL STUDY

Case control studies, often called "retrospective studies" are a common first approach to test causal hypothesis. In recent years, the case control approach has emerged as a permanent method of epidemiological investigation. The case control method has three distinct features :

a. both exposure and outcome (disease) have occurred before the start of the study
b. the study proceeds backwards from effect to cause; and
c. it uses a control or comparison group to support or refute an inference.

By definition, a case control study involves two populations – cases and controls. In case control studies, the unit is the individual rather than the group. The focus is on a disease or some other health problem that has already developed.

Case control studies are basically comparison studies. Cases and controls must be comparable with respect to known "confounding factors" such as age, sex, occupation, social status, etc. The questions asked relate to personal characteristics and antecedent exposures which may be responsible for the condition studied. For example, one can use as "cases" the immunized children and use as "controls" un-immunized children, and look for factors of interest in their past histories. Case control studies have been used effectively for studies of many cancers, and other serious conditions such as cirrhosis of the liver, lupus erythematosis, and congestive heart failure.

The basic design of a case control study is shown in Table 11. It is a 2×2 table which provides a very useful framework to discuss the various elements which make up a case control study. To illustrate, if it is our intention to test the hypothesis that "cigarette smoking causes lung cancer", using the case control method, the investigation begins by assembling a group of lung cancer cases (a+c), and a group of suitably matched controls (b+d). One then explores the past history of these two groups for the presence or absence of smoking, which is suspected to be related to the occurrence of cancer lung. If the frequency of smoking, a/(a+c) is higher in cases than in controls b/(b+d), an association is said to exist between smoking and lung cancer. Case control studies have their major use in the chronic disease problem when the causal pathway may span many decades.

TABLE 11

Framework of a case control study
(The 2 × 2 contingency table)

Suspected or risk factors	Cases (Disease present)	Control (Disease absent)
Present	a	b
Absent	c	d
	a+c	b+d

Basic steps

There are four basic steps in conducting a case control study :

1. Selection of cases and controls
2. Matching
3. Measurement of exposure, and
4. Analysis and interpretation.

1. Selection of cases and controls

The first step is to identify a suitable group of cases and a group of controls. While identification of cases is relatively easy, selection of suitable controls may present difficulties. In this connection, definite guidelines have been laid down such as the following *(4,9,12)*.

(1) SELECTION OF CASES

(a) *Definition of a case* : The prior definition of what constitutes a "case" is crucial to the case control study. It involves two specifications : (i) DIAGNOSTIC CRITERIA : The diagnostic criteria of the disease and the stage of disease, if any (e.g., breast cancer Stage I) to be included in the study must be specified before the study is undertaken. Supposing we are investigating cases of cancer, we should be quite clear that we have, for our cases, a group histologically the same. Once the diagnostic criteria are established, they should not be altered or changed till the study is over. (ii) ELIGIBILITY CRITERIA : The second criterion is that of eligibility. A criterion customarily employed is the requirement that only newly diagnosed ***(incident)*** cases within a specified period of time are eligible than old cases or cases in advanced stages of the disease ***(prevalent cases)***.

(b) *Sources of cases* : The cases may be drawn from (i) hospitals, or (ii) general population. (i) HOSPITALS : It is often convenient to select cases from hospitals. The cases may be drawn from a single hospital or a network of hospitals, admitted during a specified period of time. The entire case series or a random sample of it is selected for study. (ii) GENERAL POPULATION : In a population-based case control study, all cases of the study disease occurring within a defined geographic area during a specified period of time are ascertained, often through a survey, a disease registry or hospital network. The entire case series or a random sample of it is selected for study. The cases should be fairly representative of all cases in the community.

(2) SELECTION OF CONTROLS

The controls must be free from the disease under study. They must be as similar to the cases as possible, except for the absence of the disease under study. As a rule, a comparison group is identified before a study is done, comprising of persons who have not been exposed to the disease or some other factor whose influence is being studied. Difficulties may arise in the selection of controls if the disease under investigation occurs in subclinical forms whose diagnosis is difficult. Selection of an appropriate control group is therefore an important prerequisite, for it is against this, we make comparisons, draw inferences and make judgements about the outcome of the investigation *(9)*.

Sources of controls : The possible sources from which controls may be selected include hospitals, relatives, neighbours and general population. (i) HOSPITAL CONTROLS: The controls may be selected from the same hospital as the cases, but with different illneses other than the study disease. For example, if we are going to study cancer cervix patients, the control group may comprise patients with cancer breast, cancer of the digestive tract, or patients with non-cancerous lesions and other patients. Usually it is unwise to choose a control group from a group of patients with one disease. This is because hospital controls are often a source of "selection bias". Many hospital patients may have diseases which are also influenced by the factor under study. For example, if one was studying the

relationship of smoking and myocardial infarction and chooses bladder cancer cases as controls, the relationship between smoking and myocardial infarction may not have been demonstrated. Therefore, great care must be taken when using other patients as comparison subjects, for they differ in many ways from a normal healthy population. Ideally the controls should have undergone the same diagnostic work-up as cases, but have been found to be negative. But this may not be acceptable to most controls (ii) RELATIVES : The controls may also be taken up from relatives (spouses and siblings). Sibling controls are unsuitable where genetic conditions are under study. (iii) NEIGHBOURHOOD CONTROLS : The controls may be drawn from persons living in the same locality as cases, persons working in the same factory or children attending the same school. (iv) GENERAL POPULATION : Population controls can be obtained from defined geographic areas, by taking a random sample of individuals free of the study disease. We must use great care in the selection of controls to be certain that they accurately reflect the population that is free of the disease of interest.

How many controls are needed ? If many cases are available, and large study is contemplated, and if the cost to collect case and control is about equal, then one tends to use one control for each case. If the study group is small (say under 50) as many as 2,3, or even 4 controls can be selected for each study subject.

To sum up, selection of proper cases and controls is crucial to the interpretation of the results of case control studies. Some investigators select cases from one source and controls from more than one source to avoid the influence of "selection bias". Such studies are recommended by epidemiologists. It is also desired to conduct more than one case control study, preferably in different geographic areas. If the findings are consistent, it serves to increase the validity (i.e., accuracy) of the inferences. Failure to select comparable controls can introduce "bias" into results of case control studies and decrease the confidence one can place in the findings.

2. Matching

The controls may differ from the cases in a number of factors such as age, sex, occupation, social status, etc. An important consideration is to ensure *comparability* between cases and controls. This involves what is known as "matching". Matching is defined as the process by which we select controls in such a way that they are similar to cases with regard to certain pertinent selected variables (e.g., age) which are known to influence the outcome of disease and which, if not adequately matched for comparability, could distort or confound the results. A "confounding factor" is defined as one which is associated both with exposure and disease, and is distributed unequally in study and control groups. More specifically a "confounding factor" is one that, although associated with "exposure" under investigation, is itself, independently of any such association, a "risk factor" for the disease. Two examples are cited to explain confounding.

(a) In the study of the role of alcohol in the aetiology of oesophageal cancer, smoking is a confounding factor because (i) it is associated with the consumption of alcohol and (ii) it is an independent risk factor for oesophageal cancer. In these conditions, the effects of alcohol consumption can be determined only if the influence of smoking is neutralized by matching *(31)*.

(b) Age could be a confounding variable. Supposing, we are investigating the relationship between steroid contraceptive and breast cancer. If the women taking these contraceptives were younger than those in the comparison group, they would necessarily be at lower risk of breast cancer since this disease becomes increasingly common with increasing age. This "confounding" effect of age can be neutralized by matching so that both the groups have an equal proportion of each age group. In other words, matching protects against an unexpected strong association between the matching factor (e.g., age) and the disease (e.g., breast cancer). In a similar fashion other confounding variables will have to be matched.

While matching it should be borne in mind that the suspected aetiological factor or the variable we wish to measure should not be matched, because by matching, its aetiological role is eliminated in that study. The cases and controls will then become automatically alike with respect to that factor. In the above example, it would be useless to match cases and controls on steroid contraceptive use; by doing so, the aetiological role of steroid contraceptive cannot be investigated.

There are several kinds of matching procedures. One is group matching. This may be done by assigning cases to sub-categories (strata) based on their characteristics (e.g., age, occupation, social class) and then establishing appropriate controls. The frequency distribution of the matched variable must be similar in study and comparison groups. Matching is also done by *pairs*. For example, for each case, a control is chosen which can be matched quite closely. Thus, if we have a 50 year old mason with a particular disease, we will search for 50 year old mason without the disease as a control. Thus one can obtain pairs of patients and controls of the same sex, age, duration and severity of illness, etc. But there may be great difficulties in obtaining cases and controls matched on all characteristics, and it may be necessary to wait a considerable period of time before obtaining a sufficient number of matched pairs. Therefore, some leeway is necessary in matching for variables *(32, 33)*. It should be noted that if matching is overdone, it may be difficult to find controls. Further with excess zeal in matching, there may be a tendency to reduce the odds ratio.

3. Measurement of exposure

Definitions and criteria about exposure (or variables which may be of aetiological importance) are just as important as those used to define cases and controls. Information about exposure should be obtained in precisely the same manner both for cases and controls. This may be obtained by interviews, by questionnaires or by studying past records of cases such as hospital records, employment records, etc. It is important to recognize that when case control studies are being used to test associations, the most important factor to be considered, even more important than the *P. values* obtained, is the question of "bias" or systematic error which must be ruled out (see page 73).

4. Analysis

The final step is analysis, to find out

(a) Exposure rates among cases and controls to suspected factor

(b) Estimation of disease risk associated with exposure (Odds ratio)

(a) EXPOSURE RATES

A case control study provides a direct estimation of the exposure rates (frequency of exposure) to a suspected factor in disease and non-disease groups. Table 12 shows how exposure rates may be calculated from a case control study.

TABLE 12

A case control study of smoking and lung cancer

	Cases (with lung cancer)	Controls (without lung cancer)	Total
Smokers (less than 5 cigarettes a day)	33 (a)	55 (b)	88 (a+b)
Non-smokers	2 (c)	27 (d)	29 (c+d)
Total	35 (a+c)	82 (b+d)	n = a+b +c+d

Source : *(34)*

Exposure rates

a. Cases = a/(a+c) = 33/35 = 94.2 per cent
b. Controls = b/(b+d) = 55/82 = 67.0 per cent
   $P < 0.001$

Table 12 shows that the frequency rate of lung cancer was definitely higher among smokers than among non-smokers. The next step will be to ascertain whether there is a *statistical association* between exposure status and occurrence of lung cancer. This question can be resolved by calculating the *P. value,* which in this case is less than 0.001.

The particular test of significance will depend upon the variables under investigation. If we are dealing with discrete variables, as in the present case (smoking and lung cancer; exposure and disease) the results are usually presented as rates or proportions of those present or absent in the study and in the control group. The test of significance usually adopted is the standard error of difference between two proportions or the Chi–square test. On the other hand, if we are dealing with *continuous variables* (e.g., age, blood pressure), the data will have to be grouped and the test of significance used is likely to be the standard error of difference between two means, or test.

According to convention, if *P* is less than or equal to 0.05, it is regarded as "statistically significant". The smaller the *P.* value, the greater the statistical significance or probability that the association is not due to chance alone. However, statistical association (*P.* value) does not imply causation. Statement of *P.* value is thus an inadequate, although common end-point of case control studies.

(b) ESTIMATION OF RISK

The second analytical step is estimation of disease risk associated with exposure. It should be noted (Table 12) that if the exposure rate was 94.2 per cent in the study group, it does not mean that 94.2 per cent of those smoked would develop lung cancer. The estimation of disease risk associated with exposure is obtained by an index known as "Relative Risk" (RR) or "risk ratio", which is defined as the ratio between the incidence of disease among exposed persons and incidence among non-exposed. It is given by the formula:

$$\text{Relative risk} = \frac{\text{Incidence among exposed}}{\text{Incidence among non-exposed}}$$

$$= \frac{a}{(a+b)} \div \frac{c}{(c+d)}$$

A typical case control study does not provide incidence rates from which relative risk can be calculated directly, because there is no appropriate denominator or population at risk, to calculate these rates. In general, the relative risk can be exactly determined only from a cohort study.

Odds Ratio (Cross-product ratio)

From a case control study, we can derive what is known as Odds Ratio (OR) which is a measure of the strength of the association between risk factor and outcome. Odds ratio is closely related to relative risk. The derivation of odds ratio is based on three assumptions : (a) the disease being investigated must be relatively rare; (b) the cases must be representative of those with the disease, and (c) the controls must be representative of those without the disease. The odds ratio is the cross product of the entries in Table 11 which is reproduced below :

	Diseases	
	Yes	*No*
Exposed	a	b
Not exposed	c	d

Odds ratio = ad/bc

Using the data in Table 12, the odds ratio would be estimated as follows :

$$\text{Odds ratio} = \left(\frac{a}{b}\right)/\left(\frac{c}{d}\right) = \frac{ad}{bc}$$

$$= \frac{33 \times 27}{55 \times 2} = 8.1$$

In the above example, smokers of less than 5 cigarettes per day showed a risk of having lung cancer 8.1 times that of non-smokers. Odds ratio is a key parameter in the analysis of case control studies.

Bias in case control studies

Bias is any systematic error in the determination of the association between the exposure and disease. The relative risk estimate may increase or decrease as a result of the bias; it reflects some type of non-comparability between the study and control groups. The possibility of bias must be considered when evaluating a possible cause and effect relationship.

Many varieties of bias may arise in epidemiological studies. Some of these are : (a) *Bias due to confounding* : Mention has already been made about confounding as an important source of bias. This bias can be removed by matching in case control studies. (b) *Memory or recall bias* : When cases and controls are asked questions about their past history, it may be more likely for the cases to recall the existence of certain events or factors, than the controls who are healthy persons. For example, those who have had a myocardial infarction might be more likely to remember and recall certain habits or events than those who have not. Thus cases may have a different recall of past events than controls. (c) *Selection bias* : The cases and controls may not be representative of cases and controls in the general population. There may be systematic differences in characteristics between cases and controls. The selection bias can be best controlled by its prevention (d) *Berkesonian bias* : A special example of bias is Berkesonian bias, termed

after Dr. Joseph Berkeson who recognized this problem. The bias arises because of the different rates of admission to hospitals for people with different diseases (i.e., hospital cases and controls). (e) *Interviewer's bias* : Bias may also occur when the interviewer knows the hypothesis and also knows who the cases are. This prior information may lead him to question the cases more thoroughly than controls regarding a positive history of the suspected causal factor. A useful check on this kind of bias can be made by noting the length of time taken to interview the average case and the average control. This type of bias can be eliminated by double-blinding (see page 83).

Advantages and disadvantages

Table 13 summarizes the advantages and disadvantages of case control studies.

TABLE 13

Advantages and disadvantages of case control studies

ADVANTAGES
1. Relatively easy to carry out.
2. Rapid and inexpensive (compared with cohort studies).
3. Require comparatively few subjects.
4. Particularly suitable to investigate rare diseases or diseases about which little is known. But a disease which is rare in the general population (e.g., leukaemia in adolescents) may not be rare in special exposure group (e.g. prenatal X-rays).
5. No risk to subjects.
6. Allows the study of several different aetiological factors (e.g., smoking, physical activity and personality characteristics in myocardial infarction).
7. Risk factors can be identified. Rational prevention and control programmes can be established.
8. No attrition problems, because case control studies do not require follow-up of individuals into the future.
9. Ethical problems minimal.
DISADVANTAGES
1. Problems of bias relies on memory or past records, the accuracy of which may be uncertain; validation of information obtained is difficult or sometimes impossible.
2. Selection of an appropriate control group may be difficult.
3. We cannot measure incidence, and can only estimate the relative risk.
4. Do not distinguish between causes and associated factors.
5. Not suited to the evaluation of therapy or prophylaxis of disease.
6. Another major concern is the representativeness of cases and controls.

Source : *(35,36)*

Examples of case control studies

Case control studies have provided much of the current base of knowledge in epidemiology. Some of the early case control studies centred round cigarette smoking and lung cancer *(34,37,38)*. Other studies include: maternal smoking and congenital malformations *(39)*, radiation and leukaemia *(40)*, oral contraceptive use and hepatocellular adenoma *(41)*, herpes simplex and Bell palsy *(42)*, induced abortion and spontaneous abortion *(43)*, physical activity and coronary death *(44)*, artificial sweeteners and bladder cancer *(45)*, etc.

A few studies are cited in detail :

Example 1: *Adenocarcinoma of vagina (26).*

An excellent example of a case control study is adenocarcinoma of the vagina in young women. It is not only a rare disease, but also the usual victim is over 50 years of age. There was an unusual occurrence of this tumor in 7 young women (15 to 22 years) born in one Boston hospital between 1966 and 1969. The apparent "time clustering" of cases – 7 occurring within 4 years at a single hospital – led to this enquiry. An eighth case occurred in 1969 in a 20 year old patient who was treated at another Boston hospital in USA.

The cause of this tumor was investigated by a case control study in 1971 to find out the factors that might be associated with this tumor. As this was a rare disease, for each case, four matched controls were put up. The controls were identified from the birth records of the hospital in which each case was born. Female births occurring closest in time to each patient were selected as controls. Information was collected by personal interviews regarding (a) maternal age (b) maternal smoking (c) antenatal radiology, and (d) diethyl-stilbestrol (DES) exposure in foetal life. The results of the study are shown in Table 14 which shows that cases differed significantly from the controls in their past history. Seven of the eight cases had been exposed to DES in foetal life. This drug had been given to their mothers during the first trimester of pregnancy to prevent possible miscarriage. But none of the mothers in the control group had received DES. Since this study, more cases have been reported and the association with DES has been confirmed. The case control method played a critical role in revealing exposure to DES *in utero* as the cause of vaginal adenocarcinoma in the exposed child 10–20 years later.

TABLE 14

Association between maternal DES therapy and adenocarcinoma of vagina amongst female offspring

Information acquired retrospectively	Cases (8)	Controls (32)	Significance level
Maternal age	26.1	29.3	n.s.
Maternal smoking	7	21	n.s.
Antenatal radiology	1	4	n.s.
Oestrogen exposure	7	–	P<0.00001

Example 2: *Oral contraceptives and thromboembolic disease (46,47).*

By August 1965, the British Committee on Safety of Drugs had received 249 reports of adverse reactions and 16 reports of death in women taking oral contraceptives. It became apparent that epidemiological studies were needed to determine whether women who took oral contraceptives were at greater risk of developing thromboembolic disease.

In 1968 and 1969, Vassey and Doll reported the findings of their case control studies in which they interviewed women who had been admitted to hospitals with venous thrombosis or pulmonary embolism without medical cause and compared the history with that obtained from other women who had been admitted to the same hospital with other diseases and who were matched for age, marital status and parity.

It was found that out of 84, 42 (50%) of those with venous thrombosis and pulmonary embolism had been using oral contraceptives, compared with 14% of controls (Table 15). The studies confirmed that taking the pill and having pulmonary embolism co-existed more frequently than would be expected by chance. The relative risk of users to non-users was 6.3:1. That is, the investigators found that users of oral contraceptives were about 6 times as likely as non-users to develop thromboembolic disease.

TABLE 15
Case control studies on the safety of oral contraceptives

	No.	Per cent who used oral contraceptives
Cases (venous thrombosis and pulmonary embolism)	84	50
Controls	168	14

Example 3 : Thalidomide tragedy (48).

Thalidomide was first marketed as a safe, non-barbiturate hypnotic in Britain in 1958. In 1961, at a congress of Gynaecologists, attention was drawn to the birth of a large number of babies with congenital abnormalities, which was previously rare. In the same year, it was suggested that thalidomide might be responsible for it.

A retrospective study of 46 mothers delivered of deformed babies showed that 41 were found to have thalidomide during their early pregnancy. This was compared with a control of 300 mothers who had delivered normal babies; none of these had taken thalidomide. Laboratory experiments confirmed that thalidomide was teratogenic in experimental studies *(48)*.

COHORT STUDY

Cohort study is another type of analytical (observational) study which is usually undertaken to obtain additional evidence to refute or support the existence of an association between suspected cause and disease. Cohort study is known by a variety of names : prospective study, longitudinal study, incidence study, and forward–looking study. The most widely used term, however, is "cohort study" *(4)*.

The distinguishing features of cohort studies are :

a. the cohorts are identified prior to the appearance of the disease under investigation
b. the study groups, so defined, are observed over a period of time to determine the frequency of disease among them
c. the study proceeds forward from cause to effect.

Concept of cohort

In epidemiology, the term "cohort" is defined as a group of people who share a common characteristic or experience within a defined time period (e.g., age, occupation, exposure to a drug or vaccine, pregnancy, insured persons, etc). Thus a group of people born on the same day or in the same period of time (usually a year) form a "birth cohort". All those born in 2010 form the birth cohort of 2010. Persons exposed to a common drug, vaccine or infection within a defined period constitute an "exposure cohort". A group of males or females married on the same day or in the same period of time form a "marriage cohort". A cohort might be all those who survived a myocardial infarction in one particular year.

The comparison group may be the general population from which the cohort is drawn, or it may be another cohort of persons thought to have had little or no exposure to the substance in question, but otherwise similar.

Indications for cohort studies

Cohort studies are indicated : (a) when there is good evidence of an association between exposure and disease, as derived from clinical observations and supported by descriptive and case control studies (b) when exposure is rare, but the incidence of disease high among exposed, e.g., special exposure groups like those in industries, exposure to X-rays, etc (c) when attrition of study population can be minimized, e.g., follow-up is easy, cohort is stable, co-operative and easily accessible, and (d) when ample funds are available.

Framework of a cohort study

In contrast to case control studies which proceed from "effect to cause", the basic approach in cohort studies is to work from "cause to effect" (Fig. 8). That is, in a case control study, exposure and disease have already occurred when the study is initiated. In a cohort study, the exposure has occurred, but the disease has not.

The basic design of a simple cohort study is shown in Table 16. We begin with a group or cohort (a+b) exposed to a particular factor thought to be related to disease occurrence, and a group (c+d) not exposed to that particular factor. The former is known as "study cohort", and the latter "control cohort".

TABLE 16
Framework of a cohort study

	Disease		
Cohort	yes	no	Total
Exposed to putative aetiologic factor	a	b	a + b
Not exposed to putative aetiologic factor	c	d	c + d

In assembling cohorts, the following general considerations are taken into account :

a. The cohorts must be free from the disease under study. Thus, if the disease under study is coronary heart disease, the cohort members are first examined and those who already have evidence of the disease under investigation are excluded.
b. Insofar as the knowledge of the disease permits, both the groups (i.e., study and control cohorts) should be equally susceptible to the disease under study, or efficiently reflect any difference in disease occurrence (for example, males over 35 years would be appropriate for studies on lung cancer).
c. Both the groups should be comparable in respect of all the possible variables, which may influence the frequency of the disease; and
d. The diagnostic and eligibility criteria of the disease must be defined beforehand; this will depend upon the availability of reliable methods for recognizing the disease when it develops.

The groups are then followed, under the same identical conditions, over a period of time to determine the outcome of exposure (e.g., onset of disease, disability or death) in both the groups. In chronic diseases such as cancer the time required for the follow-up may be very long.

Table 16 shows (a+b) persons were exposed to the factor under study, 'a' of which developed the disease during the follow-up period; (c+d) persons were not exposed, 'c' of which became cases (it is assumed for simplicity of presentation that there were no intermittent deaths or losses during the follow-up period). After the end of the follow-up,

the incidence rate of the disease in both the groups is determined. If it is found that the incidence of the disease in the exposed group, a/(a+b) is significantly higher than in the non-exposed group, c/(c+d), it would suggest that the disease and suspected cause are associated. Since the approach is prospective, that is, studies are planned to observe events that have not yet occurred, cohort studies are frequently referred to as "prospective" studies.

A well-designed cohort study is considered the most reliable means of showing an association between a suspected risk factor and subsequent disease because it eliminates many of the problems of the case control study and approximates the experimental model of the physical sciences.

Types of cohort studies

Three types of cohort studies have been distinguished on the basis of the time of occurrence of disease in relation to the time at which the investigation is initiated and continued :

1. Prospective cohort studies
2. Retrospective cohort studies, and
3. A combination of retrospective and prospective cohort studies.

1. Prospective cohort studies

A prospective cohort study (or "current" cohort study) is one in which the outcome (e.g., disease) has not yet occurred at the time the investigation begins. Most prospective studies begin in the present and continue into future. For example, the long-term effects of exposure to uranium was evaluated by identifying a group of uranium miners and a comparison group of individuals not exposed to uranium mining and by assessing subsequent development of lung cancer in both the groups. The principal finding was that the uranium miners had an excess frequency of lung cancer compared to non-miners. Since the disease had not yet occurred when the study was undertaken, this was a prospective cohort design. The US Public Health Service's Framingham Heart Study *(49)*, Doll and Hills *(50)* prospective study on smoking and lung cancer, and study of oral contraceptives and health by the Royal College of General Practitioners *(51)* are examples of this type of study.

2. Retrospective cohort studies

A retrospective cohort study (or "historical" cohort study) is one in which the outcomes have all occurred before the start of the investigation. The investigator goes back in time, sometimes 10 to 30 years, to select his study groups from existing records of past employment, medical or other records and traces them forward through time, from a past date fixed on the records, usually up to the present. This type of study is known by a variety of names : retrospective cohort study, "historical" cohort study, prospective study in retrospect and non-concurrent prospective study.

The successful application of this approach is illustrated in one study undertaken in 1978 – a cohort of 17,080 babies born between January 1, 1969 and December 31, 1975 at a Boston hospital were investigated of the effects of electronic foetal monitoring during labour. The outcome measured was neonatal death. The study showed that the neonatal death rate was 1.7 times higher in unmonitored infants *(52)*. The most notable retrospective cohort studies to date are those of occupational exposures, because the recorded information is easily available, e.g., study of the role of arsenic in human carcinogenesis, study of lung cancer in uranium miners, study of the mortality experience of groups of physicians in relation to their probable exposure to radiation *(53,54,55)*. More recently, angiosarcoma of the liver, a very rare disease, has been reported in excess frequency in relation to poly-vinyl chloride *(56)*. This association was picked up only because of the retrospective cohort design. Retrospective cohort studies are generally more economical and produce results more quickly than prospective cohort studies.

3. Combination of retrospective and prospective cohort studies

In this type of study, both the retrospective and prospective elements are combined. The cohort is identified from past records, and is assessed of date for the outcome. The same cohort is followed up prospectively into future for further assessment of outcome.

Court-Brown and Doll (1957) applied this approach to study the effects of radiation. They assembled a cohort in 1955 consisting of 13,352 patients who had received large doses of radiation therapy for ankylosing spondylitis between 1934 and 1954. The outcome evaluated was death from leukaemia or aplastic anaemia between 1935 and 1954. They found that the death rate from leukaemia or aplastic anaemia was substantially higher in their cohort than that of the general population. A prospective component was added to the study and the cohort was followed, as established in 1955, to identify deaths occurring in subsequent years *(57)*.

ELEMENTS OF A COHORT STUDY

The elements of a cohort study are :

1. Selection of study subjects
2. Obtaining data on exposure
3. Selection of comparison groups
4. Follow-up, and
5. Analysis.

1. Selection of study subjects

The subjects of a cohort study are usually assembled in one of two ways – either from general population or select groups of the population that can be readily studied (e.g., persons with different degrees of exposure to the suspected causal factor).

(a) *General population* : When the exposure or cause of death is fairly frequent in the population, cohorts may be assembled from the general population, residing in well-defined geographical, political and administrative areas (e.g., Framingham Heart Study). If the population is very large, an appropriate sample is taken, so that the results can be generalized to the population sampled. The exposed and unexposed segments of the population to be studied should be representative of the corresponding segments of the general population.

(b) *Special groups* : These may be special groups or exposure groups that can readily be studied : (i) *Select groups* : These may be professional groups (e.g., doctors, nurses, lawyers, teachers, civil servants), insured persons, obstetric population, college alumni, government employees, volunteers, etc. These groups are usually a homogeneous population. Doll's prospective study on smoking and lung cancer was carried out on British doctors listed in the Medical Register of the UK in 1951 *(58)* . The study by Dorn on smoking and mortality in 293,658 veterans (i.e., former military service) in United States

having life insurance policies is another example of a study based on special groups *(59)*. These groups are not only homogeneous, but they also offer advantages of accessibility and easy follow-up for a protracted period (ii) *Exposure groups* : If the exposure is rare, a more economical procedure is to select a cohort of persons known to have experienced the exposure. In other words, cohorts may be selected because of special exposure to physical, chemical and other disease agents. A readily accessible source of these groups is workers in industries and those employed in high-risk situations (e.g., radiologists exposed to X-rays).

When cohorts have been selected because of special exposure, it facilitates classification of cohort members according to the degree or duration of exposure to the suspected factor for subsequent analytical study.

2. Obtaining data on exposure

Information about exposure may be obtained directly from the (a) *Cohort members* : through personal interviews or mailed questionnaires. Since cohort studies involve large numbers of population, mailed questionnaires offer a simple and economic way of obtaining information. For example, Doll and Hill *(60)* used mailed questionnaires to collect smoking histories from British doctors. (b) *Review of records* : Certain kinds of information (e.g., dose of radiation, kinds of surgery, or details of medical treatment) can be obtained only from medical records. (c) *Medical examination or special tests* : Some types of information can be obtained only by medical examination or special tests, e.g., blood pressure, serum cholesterol, ECG. (d) *Environmental surveys* : This is the best source for obtaining information on exposure levels of the suspected factor in the environment where the cohort lived or worked. In fact, information may be needed from more than one or all of the above sources.

Information about exposure (or any other factor related to the development of the disease being investigated) should be collected in a manner that will allow classification of cohort members :

(a) according to whether or not they have been exposed to the suspected factor, and
(b) according to the level or degree of exposure, at least in broad classes, in the case of special exposure groups (Table 17).

In addition to the above, basic information about demographic variables which might affect the frequency of disease under investigation, should also be collected. Such information will be required for subsequent analysis.

3. Selection of comparison groups

There are many ways of assembling comparison groups :

(a) Internal comparisons

In some cohort studies, no outside comparison group is required. The comparison groups are in-built. That is, single cohort enters the study, and its members may, on the basis of information obtained, be classified into several comparison groups according to the degrees or levels of exposure to risk (e.g., smoking, blood pressure, serum cholesterol) before the development of the disease in question. The groups, so defined, are compared in terms of their subsequent morbidity and mortality rates. Table 17 illustrates this point. It shows that mortality from lung cancer increases with increasing number of cigarettes smoked reinforcing the conclusion that there is valid association between smoking and lung cancer.

TABLE 17

Age standardized death rates per 100,000 men per year by amount of current smoking

Classification of exposure (cigarettes)	No. of deaths	Death rate
1/2 pack	24	95.2
1/2–1 pack	84	107.8
1–2 packs	90	229.2
2 packs +	97	264.2

Source : *(5)*

(b) External comparisons

When information on degree of exposure is not available, it is necessary to put up an external control, to evaluate the experience of the exposed group, e.g., smokers and non–smokers, a cohort of radiologists compared with a cohort of ophthalmologists, etc. The study and control cohorts should be similar in demographic and possibly important variables other than those under study.

(c) Comparison with general population rates

If none is available, the mortality experience of the exposed group is compared with the mortality experience of the general population in the same geographic area as the exposed people, e.g., comparison of frequency of lung cancer among uranium mine workers with lung cancer mortality in the general population where the miners resided *(54)*; comparison of frequency of cancer among asbestos workers with the rate in general population in the same geographic area *(61)*.

Rates for disease occurrence in sub-groups of the control cohort by age, sex, and other variables considered important may be applied to the corresponding sub-groups of the study cohort (exposed cohort) to determine the "expected" values in the absence of exposure. The ratio of "observed" and "expected" values provides a measure of the effect of the factor under study.

The limiting factors in using general population rates for comparison are : (i) non-availability of population rates for the outcome required; and (ii) the difficulties of selecting the study and comparison groups which are representative of the exposed and non-exposed segments of the general population.

4. Follow-up

One of the problems in cohort studies is the regular follow-up of all the participants. Therefore, at the start of the study, methods should be devised depending upon the outcome to be determined (morbidity or death), to obtain data for assessing the outcome. The procedures required comprise :

(a) periodic medical examination of each member of the cohort
(b) reviewing physician and hospital records
(c) routine surveillance of death records, and
(d) mailed questionnaires, telephone calls, periodic home visits – preferably all three on an annual basis.

Of the above, periodic examination of each member of the cohort, yields greater amount of information on the individuals examined, than would the use of any other procedure.

However, inspiteof best efforts, a certain percentage of losses to follow-up are inevitable due to death, change of residence, migration or withdrawal of occupation. These losses may bias the results. It is, therefore, necessary to build into the study design a system for obtaining basic

information on outcome for those who cannot be followed up in detail for the full duration of the study *(13)*. The safest course recommended is to achieve as close to a 95 per cent follow-up as possible *(12)*.

5. Analysis

The data are analyzed in terms of :

(a) Incidence rates of outcome among exposed and non-exposed,

(b) Estimation of risk.

(a) Incidence rates

In a cohort study, we can determine incidence rates directly in those exposed and those not exposed. A hypothetical example is given in Table 18 showing how incidence rates may be calculated :

TABLE 18

Contingency table applied to hypothetical cigarette smoking and lung cancer example

Cigarette smoking	Developed lung cancer	Did not develop lung cancer	Total
Yes	70 (a)	6930 (b)	7000 (a + b)
No	3 (c)	2997 (d)	3000 (c + d)

Incidence rates

(a) among smokers = 70/7000 = 10 per 1000

(b) among non-smokers = 3/3000 = 1 per 1000

Statistical significance : $P < 0.001$

(b) Estimation of risk

Having calculated the incidence rates, the next step is to estimate the risk of outcome (e.g., disease or death) in the exposed and non-exposed cohorts. This is done in terms of two well-known indices: (a) relative risk, (b) attributable risk.

RELATIVE RISK

Relative risk (RR) is the ratio of the incidence of the disease (or death) among exposed and the incidence among non-exposed. Some authors use the term "risk ratio" to refer to relative risk.

$$RR = \frac{\text{Incidence of disease (or death) among exposed}}{\text{Incidence of disease (or death) among non-exposed}}$$

In our hypothetical example (Table 18)

$$\text{RR of lung cancer} = \frac{10}{1} = 10$$

Estimation of relative risk (RR) is important in aetiological enquiries. It is a direct measure (or index) of the "strength" of the association between suspected cause and effect. A relative risk of one indicates no association; relative risk greater than one suggests "positive" association between exposure and the disease under study. A relative risk of 2 indicates that the incidence rate of disease is 2 times higher in the exposed group as compared with the unexposed. Equivalently, this represents a 100 per cent increase in risk. A relative risk of 0.25 indicates a 75% reduction in the incidence rate in exposed individuals as compared with the unexposed *(35)*. It is often useful to consider the 95 per cent confidence interval of a relative risk since it provides an indication of the likely and maximum levels of risk.

In our hypothetical example (Table 18), the relative risk is 10. It implies that smokers are 10 times at greater risk of developing lung cancer than non-smokers. The larger the RR, the greater the "strength" of the association between the suspected factor and disease. It may be noted that risk does not necessarily imply causal association.

ATTRIBUTABLE RISK

Attributable risk (AR) is the difference in incidence rates of disease (or death) between an exposed group and non-exposed group. Some authors use the term "risk difference" to attributable risk.

Attributable risk is often expressed as a per cent. This is given by the formula :

$$= \frac{\text{Incidence of disease rate among exposed} - \text{incidence of disease rate among non-exposed}}{\text{Incidence rate among exposed}} \times 100$$

Attributable risk in our example (Table 18) would be :

$$\frac{10-1}{10} \times 100 = 90 \text{ per cent}$$

Attributable risk indicates to what extent the disease under study can be attributed to the exposure. The figure in our example indicates that the association between smoking and lung cancer is causal, 90 per cent of the lung cancer among smokers was due to their smoking. This suggests the amount of disease that might be eliminated if the factor under study could be controlled or eliminated.

POPULATION–ATTRIBUTABLE RISK

Another concept is "population–attributable risk". It is the incidence of the disease (or death) in the total population minus the incidence of disease (or death) among those who were not exposed to the suspected causal factor (Table 19).

TABLE 19

Lung cancer death rates among smokers and non-smokers : UK physicians

Deaths per 100,000 person-years		
Heavy smokers	224	Exposed to suspected factor (a)
Non-smokers	10	Non-exposed to suspected causal factor (b)
Deaths in total population	74 (c)	
Individual RR	a/b = $\frac{224}{10}$ = 22.40	
Population AR	(c–b)/c = 86 per cent	

Source : *(58)*

The concept of population attributable risk is useful in that it provides an estimate of the amount by which the disease could be reduced in that population if the suspected factor was eliminated or modified. In our example (Table 19) one might expect that 86 per cent of deaths from lung cancer could be avoided if the risk factor of cigarettes were eliminated.

Relative risk versus attributable risk

Relative risk is important in aetiological enquiries. Its size is a better index than is attributable risk for assessing the aetiological role of a factor in disease. The larger the relative

risk, the stronger the association between cause and effect. But relative risk does not reflect the potential public health importance as does the attributable risk. That is, attributable risk gives a better idea than does relative risk of the impact of successful preventive or public health programme might have in reducing the problem.

Two examples are cited (Tables 20 and 21) to show the practical importance of distinguishing relative and absolute risk. In the first example, (Table 20) the RR of a cardiovascular complication in users of oral contraceptives is independent of age, whereas the AR is more than 5 times higher in the older age groups. This epidemiological observation has been the basis for not recommending oral contraceptive in those aged 35 years and over.

TABLE 20

The relative and attributable risks of cardiovascular complications in women taking oral contraceptives

Cardiovascular risk 100,000 patient years	Age	
	30–39	40–44
Relative risk	2.8	2.8
Attributable risk	3.5	20.0

Source : *(62)*

The second example (Table 21) shows that smoking is attributable to 92 per cent of lung cancer, and 13.3 per cent of CHD. In CHD, both RR and AR are not very high suggesting not much of the disease could be prevented as compared to lung cancer.

TABLE 21

Risk assessment, smokers *vs* non-smokers

Cause of death	Death rate/1000		RR	AR (%)
	Smokers	Non-smokers		
Lung cancer	0.90	0.07	12.86	92.2
CHD	4.87	4.22	1.15	13.3

Source : *(63)*

Advantages and disadvantages of cohort studies

Advantages

(a) Incidence can be calculated. (b) Several possible outcomes related to exposure can be studied simultaneously – that is, we can study the association of the suspected factor with many other diseases in addition to the one under study. For example, cohort studies designed to study the association between smoking and lung cancer also showed association of smoking with coronary heart disease, peptic ulcer, cancer oesophagus and several others. (c) Cohort studies provide a direct estimate of relative risk. (d) Dose–response ratios can also be calculated, and (e) Since comparison groups are formed before disease develops, certain forms of bias can be minimized like mis-classification of individuals into exposed and unexposed groups.

Disadvantages

Cohort studies also present a number of problems : (a) Cohort studies involve a large number of people. They are generally unsuitable for investigating uncommon diseases or diseases with low incidence in the population. (b) It takes a long time to complete the study and obtain results (20–30 years or more in cancer studies) by which time the investigators may have died or the participants may have changed their classification. Even in very common chronic diseases like coronary heart disease, cohort studies are difficult to carry out. It is difficult to keep a large number of individuals under medical surveillance indefinitely. (c) Certain administrative problems such as loss of experienced staff, loss of funding and extensive record keeping are inevitable. (d) It is not unusual to lose a substantial proportion of the original cohort – they may migrate, lose interest in the study or simply refuse to provide any required information. (e) Selection of comparison groups which are representative of the exposed and unexposed segments of the population is a limiting factor. Those who volunteer for the study may not be representative of all individuals with the characteristic of interest. (f) There may be changes in the standard methods or diagnostic criteria of the disease over prolonged follow-up. Once we have established the study protocol, it is difficult to introduce new knowledge or new tests later. (g) Cohort studies are expensive. (h) The study itself may alter people's behaviour. If we are examining the role of smoking in lung cancer, an increased concern in the study cohort may be created. This may induce the study subjects to stop or decrease smoking. (i) With any cohort study we are faced with ethical problems of varying importance. As evidence accumulates about the implicating factor in the aetiology of disease, we are obliged to intervene and if possible reduce or eliminate this factor, and (j) Finally, in a cohort study, practical considerations dictate that we must concentrate on a limited number or factors possibly related to disease outcome.

The main differences between case control and cohort studies are summarized in Table 22.

TABLE 22

Main differences between case control and cohort studies

	Case control study	Cohort study
1.	Proceeds from "effect to cause".	Proceeds from "cause to effect".
2.	Starts with the disease.	Starts with people exposed to risk factor or suspected cause.
3.	Tests whether the suspected cause occurs more frequently in those with the disease than among those without the disease.	Tests whether disease occurs more frequently in those exposed, than in those not similarly exposed.
4.	Usually the first approach to the testing of a hypothesis, but also useful for exploratory studies.	Reserved for testing of precisely formulated hypothesis.
5.	Involves fewer number of subjects.	Involves larger number of subjects.
6.	Yields relatively quick results.	Long follow-up period often needed, involving delayed results.
7.	Suitable for the study of rare diseases.	Inappropriate when the disease or exposure under investigation is rare.
8.	Generally yields only estimate of RR (odds ratio).	Yields incidence rates, RR as well as AR.
9.	Cannot yield information about diseases other than that selected for study.	Can yield information about more than one disease outcome.
10.	Relatively inexpensive.	Expensive.

Examples of cohort studies

Example 1 : Smoking and lung cancer.

At least eight prospective studies on the relation of smoking to lung cancer had been done. Doll and Hill *(50, 60, 64)*, Hammond and Horn *(65,66)* and Dorn *(59)* were the first to report their findings.

In October 1951, Doll and Hill sent a questionnaire to 59,600 British doctors listed in the Medical Register of the UK enquiring about their smoking habits. This enabled them to form two cohorts (smokers and non-smokers) who were similar in all other respects like age, education and social class. They received usable replies from 40,701 physicians - 34,494 men and 6,207 women. These were followed for 4 years and 5 months by obtaining notifications of physicians' deaths from the Registrar General, the General Medical Council and the British Medical Association. For every death certified as due to lung cancer, confirmation was obtained by writing to the physician certifying the death and also, when necessary to the hospital or consultant to whom the patient had been referred. The results of the study are shown in Table 19.

Example 2 : The Framingham heart study (49).

The Framingham heart study was initiated in 1948 by the United States Public Health Service to study the relationship of a number of (risk) factors (e.g., serum cholesterol, blood pressure, weight, smoking) to the subsequent development of cardiovascular disease. The town of Framingham (Massachusetts) had a population of 28,000 in 1948. The study was planned for 20 years in view of the slow development of heart disease.

The lower and upper limits of the study population was set at 30 and 59 years. Out of 10,000 people in this age group a sample of 6,507 persons of both sexes were invited to participate in the study, out of which 5,209 participated. The initial examination revealed that 82 subjects had clinically evident CHD. These were excluded from the sample leaving a total of 5,127.

4,469 (69 per cent) of the 6,507 in the initial sample actually underwent the first examination. After the first examination, the study population was examined every 2 years for a 20 year period. Information was obtained with regard to serum cholesterol, blood pressure, weight and cigarette smoking. Although biennial examinations were the main source of follow up information, other means were also adopted to detect CHD (e.g., Death certificate records).

Among other things, the study showed increasing risk of CHD with increasing serum cholesterol levels in the 45–54 age group. The study also showed that the association between smoking and CHD varied with manifestations of the disease. Thus, smoking was more strongly associated with sudden death from CHD than with less fatal forms of the disease. Risk factors have been found to include male sex, advancing age, high serum lipid concentration, high blood pressure, cigarette smoking, diabetes mellitus, obesity, low vital capacity and certain ECG abnormalities. The predictive value of serum lipids, blood pressure and cigarette smoking have been repeatedly demonstrated. The Framingham heart study became a prototype of similar studies in US and other countries.

Example 3 : Oral contraceptives and health (51).

Another example is the cohort study of oral contraceptives and health conducted by the Royal College of General Practitioners in England (1974). It was initiated in 1968, after 2 years of planning. 23,000 users of the pill aged 15–49 years together with a similar number of controls using other methods or no method of contraception were brought under observation of 1400 general practitioners. During follow-up doctors recorded the diagnoses of episodes of illness, and information about pregnancies and deaths.

The study brought out the risks and benefits of oral contraceptive use. For example, the study showed that the risk of hypertension increases, and the risk of benign breast disease decreases with the dose of norethisterone acetate (progestogen) in the combined pill which is an important finding. The study found an increased mortality from diseases of cardiovascular system in pill users confirming the results of retrospective case control studies *(67)*.

EXPERIMENTAL EPIDEMIOLOGY

In the 1920s, "experimental epidemiology" meant the study of epidemics among colonies of experimental animals such as rats and mice. In modern usage, experimental epidemiology is often equated with RANDOMIZED CONTROLLED TRIALS *(2)*.

Experimental or intervention studies are similar in approach to cohort studies excepting that the conditions in which study is carried out are under the direct control of the investigator. Thus experimental studies involve some action, intervention or manipulation such as deliberate application or withdrawal of the suspected cause or changing one variable in the causative chain in the experimental group while making no change in the control group, and observing and comparing the outcome of the experiment in both the groups. This contrasts sharply with observational studies (e.g., descriptive, case control and cohort studies), where the epidemiologist takes no action but only observes the natural course of events or outcome.

The aims of experimental studies may be stated as follows : (a) to provide "scientific proof" of aetiological (or risk) factors which may permit the modification or control of those diseases : and (b) to provide a method of measuring the effectiveness and efficiency of health services for the prevention, control and treatment of disease and improve the health of the community.

Experimental studies have all the advantages and disadvantages of the usual prospective cohort studies plus three additional problems namely cost, ethics and feasibility. Experimental studies have become a major area of epidemiological studies. They may be conducted in animals or human beings.

Animal studies

Throughout history animals have played an important role in men's quest for knowledge about himself and his environment. Animal studies have contributed to our knowledge of anatomy, physiology, pathology, microbiology, immunology, genetics, chemotherapy and so many others. At the beginning of this century, Webster in United States and Topley, Wilson and Greenwood in England had carried out classical animal experiments. Their studies centred round inducing epidemics in animals and in studies of herd immunity under laboratory conditions.

More important application of animal experiments have been in (a) experimental reproduction of human disease in animals to confirm aetiological hypotheses and to study the

pathogenetic phenomena or mechanisms (b) testing the efficacy of preventive and therapeutic measures such as vaccines and drugs, and (c) completing the natural history of disease. For example, naturally occurring leprosy has been found in armadillos. Data obtained from studying these animals indicate that lepra bacilli might exist outside of humans.

Animal experiments have their own advantages and limitations. The **advantages** are that the experimental animals can be bred in laboratories and manipulated easily according to the wishes of the investigator. A more important point is that they multiply rapidly and enable the investigators to carry out certain experiments (e.g., genetic experiments) which in human population would take several years and involve many generations. The **limitations** of animal experiments are that not all human diseases can be reproduced in animals. Secondly, all the conclusions derived from animal experiments may not be strictly applicable to human beings. An excellent example to illustrate this point is the WHO trial of typhoid vaccine in Yugoslavia in the mid-1950s. Laboratory tests in animals showed the alcohol-killed and preserved vaccine to be more effective than the traditional heat-killed phenol-preserved vaccine. But randomized controlled trials in human beings demonstrated that, contrary to laboratory evidence, the alcohol-preserved vaccine was found to be less than half as effective in preventing typhoid fever as the traditional phenol-preserved vaccine introduced by Almorth Wright. This highlights the difficulties encountered in extrapolating findings from animal experiments in man.

Human experiments

Human experiments will always be needed to investigate disease aetiology and to evaluate the preventive and therapeutic measures. These studies are even more essential in the investigation of diseases that cannot be reproduced in animals.

Historically, in 1747, James Lind performed a human experiment (clinical trial) in which he added different substances to diet of 12 soldiers who were suffering from scurvy. He divided his patients into 6 pairs and supplemented the diets of each pair with cider, elixir vitriol, vinegar, sea water; a mixture of nutmeg, garlic, mustard and tamarind in barley water; and two oranges and one lemon daily. All the subjects were studied for 6 days. At the end of 6 days the LIMEYS recovered from scurvy and were found fit for duty. Then came Edward Jenner's experiment with cowpox in 1796. Other classical experiments are Finlay and Reed's experiments (1881–1900) to elucidate the mosquito–borne nature of yellow fever and Goldberger's classical experiments in 1915 inducing pellagra by diets deficient in nicotinic acid, thereby proving pellagra to be a nutritional deficiency disease, not an infectious disease as was then supposed. Since then, human beings have participated in studies of malaria, syphilis, hepatitis, measles, polio and others. These experiments have played decisive roles in investigating disease aetiology and in testing preventive and therapeutic measures.

Although the experimental method is unquestionably the most incisive approach to scientific problem, ethical and logistic considerations often prevent its application to the study of disease in humans. Therefore, before launching human experiments, the benefits of the experiment have to be weighed against risks involved. The volunteers should be made fully aware of all possible consequences of the experiment. Thus when an illness is fatal (e.g., excessive haemorrhage) and the benefit of treatment (e.g., blood transfusion) is self-evident, it would be ethically unacceptable to prove or disprove the therapeutic value of blood transfusion. However, such instances represent only a small part of the total research effort. On the other hand, in the present era of scientific medicine, many unscientific or scientifically unsound procedures are still being carried out. For instance, in the study of prescription drugs, a panel of experts in USA found that only 23 per cent of some 16,000 drugs could be classified unequivocally as "effective" *(36)*. It is now conceded that it is equally unethical if a drug or procedure is brought into general use without establishing its effectiveness by controlled trials. The thalidomide disaster and the occurrence of carcinoma of the vagina in the offspring of pregnant women treated with diethylstilbestrol highlight the unfortunate consequence of therapy on the basis of uncontrolled observations. The WHO in 1980 has laid down a strict code of practice in connection with human trials *(68)*.

Experimental studies are of two types :

a. Randomized controlled trials (i.e., those involving a process of random allocation); and
b. Non-randomized or "non-experimental" trials (i.e., those departing from strict randomization for practical purposes, but in such a manner that non-randomization does not seriously affect the theoretical basis of conclusions).

RANDOMIZED CONTROLLED TRIALS

Too often physicians are guided in their daily work by clinical impressions of their own or their teachers. These impressions, particularly when they are incorporated in textbooks and repeatedly quoted by reputed teachers and their students acquire authority, just as if they were proved facts. Similarly many public health measures are introduced on the basis of assumed benefits without subjecting them to rigorous testing. The history of medicine amply illustrates this. For instance, it took centuries before therapeutic blood letting and drastic purging were abandoned by the medical profession.

It is mainly in the last 35 to 40 years, determined efforts have been made to use scientific techniques to evaluate methods of treatment and prevention. An important advance in this field has been the development of an assessment method, known as Randomized Controlled Trial (RCT). It is really an epidemiologic experiment. Since its introduction, the RCT has questioned the validity of such widely used treatments as oral hypoglycaemic agents, varicose vein stripping, tonsillectomy, hospitalization of all patients with myocardial infarction, multiphasic screening, and toxicity and applicability of many preventive and therapeutic procedures.

The design of a randomized controlled trial is given in Fig. 9. For new programmes or new therapies, the RCT is the No.1 method of evaluation. The basic steps in conducting a RCT include the following :

1. Drawing up a protocol.
2. Selecting reference and experimental populations.
3. Randomization.
4. Manipulation or intervention.
5. Follow-up.
6. Assessment of outcome.

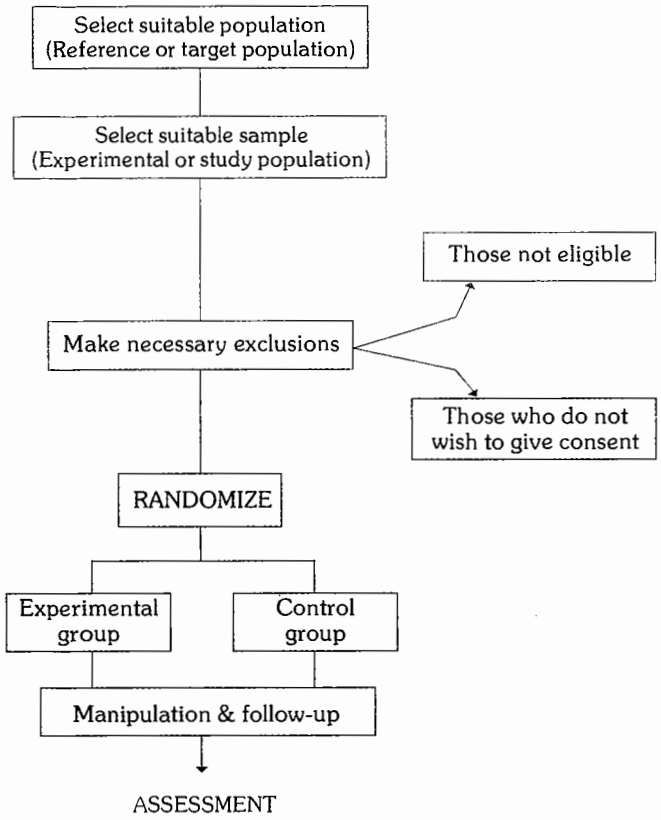

FIG.9
Design of a randomized controlled trial

1. *The protocol*

One of the essential features of a randomized controlled trial is that the study is conducted under a strict protocol. The protocol specifies the aims and objectives of the study, questions to be answered, criteria for the selection of study and control groups, size of the sample, the procedures for allocation of subjects into study and control groups, treatments to be applied – when and where and how to what kind of patients, standardization of working procedures and schedules as well as responsibilities of the parties involved in the trial, upto the stage of evaluation of outcome of the study. A protocol is essential especially when a number of centres are participating in the trial. Once a protocol has been evolved, it should be strictly adhered to throughout the study. The protocol aims at preventing bias and to reduce the sources of error in the study.

Preliminary test runs : Sometimes, before a protocol is completed, preliminary (pilot) studies have to be made to find out the feasibility or operational efficiency of certain procedures, or unknown effects, or on the acceptability of certain policies. Sometimes it is useful to have a short test run of the protocol to see whether it contains any flaws. It is important that the final version of the protocol should be agreed upon by all concerned before the trial begins.

2. *Selecting reference and experimental populations*

(a) *Reference or target population* : It is the population to which the findings of the trial, if found successful, are expected to be applicable (e.g., a drug, vaccine or other procedure). A reference population may be as broad as mankind or it may be geographically limited or limited to persons in specific age, sex, occupational or social groups. Thus the reference population may comprise the population of a whole city, or a population of school children, industrial workers, obstetric population and so on according to the nature of the study.

(b) *Experimental or study population* : The study population is derived from the reference population. It is the actual population that participates in the experimental study. Ideally, it should be randomly chosen from the reference population, so that it has the same characteristics as the reference population. If the study population differs from the reference population, it may not be possible to generalize the findings of the study to the reference population.

When an experimental population has been defined, its members are invited to participate in the study. It is important to choose a stable population whose cooperation is assured to avoid losses to follow-up. The participants or volunteers must fulfil the following three criteria :

a. they must give "informed consent", that is they must agree to participate in the trial after having been fully informed about the purpose, procedures and possible dangers of the trial;

b. they should be representative of the population to which they belong (i.e., reference population); and

c. they should be qualified or eligible for the trial. That is, let us suppose, we are testing the effectiveness of a new drug for the treatment of anaemia. If the volunteers are not anaemic, we will then say, they are not eligible or qualified for the trial. Similarly, let us suppose; we are going to test the effectiveness of a new vaccine against whooping cough. If the volunteers are already immune to the disease in question, we will then say, they are not qualified for the trial. In other words, the participants must be fully susceptible to the disease under study.

It must be recognized that persons who agree to participate in a study are likely to differ from those who do not, in many ways that may affect the outcome under investigation.

3. *Randomization*

Randomization is a statistical procedure by which the participants are allocated into groups usually called "study" and "control" groups, to receive or not to receive an experimental preventive or therapeutic procedure, manoeuvre or intervention. Randomization is an attempt to eliminate "bias" and allow for *comparability*. Theoretically it is possible to assure comparability by matching. But when one matches, one can only match those factors which are known to be important. There may be other factors which are important but whose effect is not recognized or cannot be determined. By a process of randomization, hopefully, these factors will be distributed equally between the two groups.

Randomization is the "heart" of a control trial. It will give the greatest confidence that the groups are comparable so that "like can be compared with like". It ensures that the investigator has no control over allocation of participants to either study or control group, thus eliminating what is known as "selection bias". In other words, by random allocation, every individual gets an equal chance of being allocated into either group or any of the trial groups.

It is crucial that both the groups should be alike with regard to certain variables or characteristics that might affect the outcome of the experiment (e.g., age, sex), the entire study population can be stratified into sub-groups according to the variable, and individuals within each sub-group can

then be randomly allocated into study and control groups. It is always desirable to check that the groups formed initially are basically similar in composition. Randomization is done only after the participant has entered the study, that is after having been qualified for the trial and has given his informed consent to participate in the study. Randomization is best done by using a table of random numbers (see chapter 18).

The essential difference between a randomized controlled trial and an analytical study is that in the latter, there is no randomization because a differentiation into diseased and non–diseased (exposed or non–exposed) groups has already taken place. The only option left to ensure comparability in analytical studies is by matching.

4. Manipulation

Having formed the study and control groups, the next step is to intervene or manipulate the study (experimental) group by the deliberate application or withdrawal or reduction of the suspected causal factor (e.g., this may be a drug, vaccine, dietary component, a habit, etc) as laid down in the protocol.

This manipulation creates an *independent* variable (e.g., drug, vaccine, a new procedure) whose effect is then determined by measurement of the final outcome, which constitutes the *dependent* variable (e.g., incidence of disease, survival time, recovery period).

5. Follow-up

This implies examination of the experimental and control group subjects at defined intervals of time, in a standard manner, with equal intensity, under the same given circumstances, in the same time frame till final assessment of outcome. The duration of the trial is usually based on the expectation that a significant difference (e.g., mortality) will be demonstrable at a given point in time after the start of the trial. Thus the follow-up may be short or may require many years depending upon the study undertaken.

It may be mentioned that some losses to follow-up are inevitable due to factors, such as death, migration and loss of interest. This is known as attrition. If the attrition is substantial, it may be difficult to generalise the results of the study to the reference population. Every effort, therefore, should be made to minimize the losses to follow-up.

6. Assessment

The final step is assessment of the outcome of the trial in terms of : (a) *Positive results* : that is, benefits of the experimental measure such as reduced incidence or severity of the disease, cost to the health service or other appropriate outcome in the study and control groups. (b) *Negative results* : that is, severity and frequency of side-effects and complications, if any, including death. Adverse effects may be missed if they are not sought.

The incidence of positive/negative results is rigorously compared in both the groups, and the differences, if any, are tested for statistical significance. Techniques are available for the analysis of data as they are collected (sequential analysis), but it is more useful to analyze the results at the end of the trial.

Bias may arise from errors of assessment of the outcome due to human element. These may be from three sources : *First,* there may be bias on the part of the participants, who may subjectively feel better or report improvement if they knew they were receiving a new form of treatment. This is known as "subject variation". *Secondly* there may be observer bias, that is the investigator measuring the outcome of a therapeutic trial may be influenced if he knows beforehand the particular procedure or therapy to which the patient has been subjected. This is known as "observer bias." *Thirdly*, there may be bias in evaluation – that is, the investigator may subconsciously give a favourable report of the outcome of the trial. Randomization cannot guard against these sorts of bias, nor the size of the sample. In order to reduce these problems, a technique known as "blinding" is adopted, which will ensure that the outcome is assessed objectively.

Blinding : Blinding can be done in three ways – (a) *SINGLE BLIND TRIAL* : The trial is so planned that the participant is not aware whether he belongs to the study group or control group. (B) *DOUBLE BLIND TRIAL* : The trial is so planned that neither the doctor nor the participant is aware of the group allocation and the treatment received. (C) *TRIPLE BLIND TRIAL* : This goes one step further. The participant, the investigator and the person analyzing the data are all "blind". Ideally, of course, triple blinding should be used; but the double blinding is the most frequently used method when a blind trial is conducted *(4)*. When an outcome such as death is being measured, blinding is not so essential.

SOME STUDY DESIGNS

It is useful to consider here some of the study designs of controlled trials :

1. Concurrent parallel study designs

In this situation (Fig.10–a), comparisons are made between two randomly assigned groups, one group exposed to specific treatment, and the other group not exposed. Patients remain in the study group or the control group for the duration of the investigation.

2. Cross-over type of study designs

This is illustrated in Fig. 10–b. With this type of study design, each patient serves as his own control. As before, the patients are randomly assigned to a study group and control group. The study group receives the treatment under consideration. The control group receives some alternate form of active treatment or placebo. The two groups are observed over time. Then the patients in each group are taken off their medication or placebo to allow for the elimination of the medication from the body and for the possibility of any "carry over" effects, as shown in Fig. 10–b by the diagonal lines. After this period of medication (the length of this interval is determined by the pharmacologic properties of the drug being tested), the two groups are switched. Those who received the treatment under study are changed to the control group therapy or placebo, and vice versa.

Cross-over studies offer a number of advantages. With such a design, all patients can be assured that sometime during the course of investigation, they will receive the new therapy. Such studies generally economize on the total number of patients required at the expense of the time necessary to complete the study. This method of study is not suitable if the drug of interest cures the disease, if the drug is effective only during a certain stage of the disease or if the disease changes radically during the period of time required for the study.

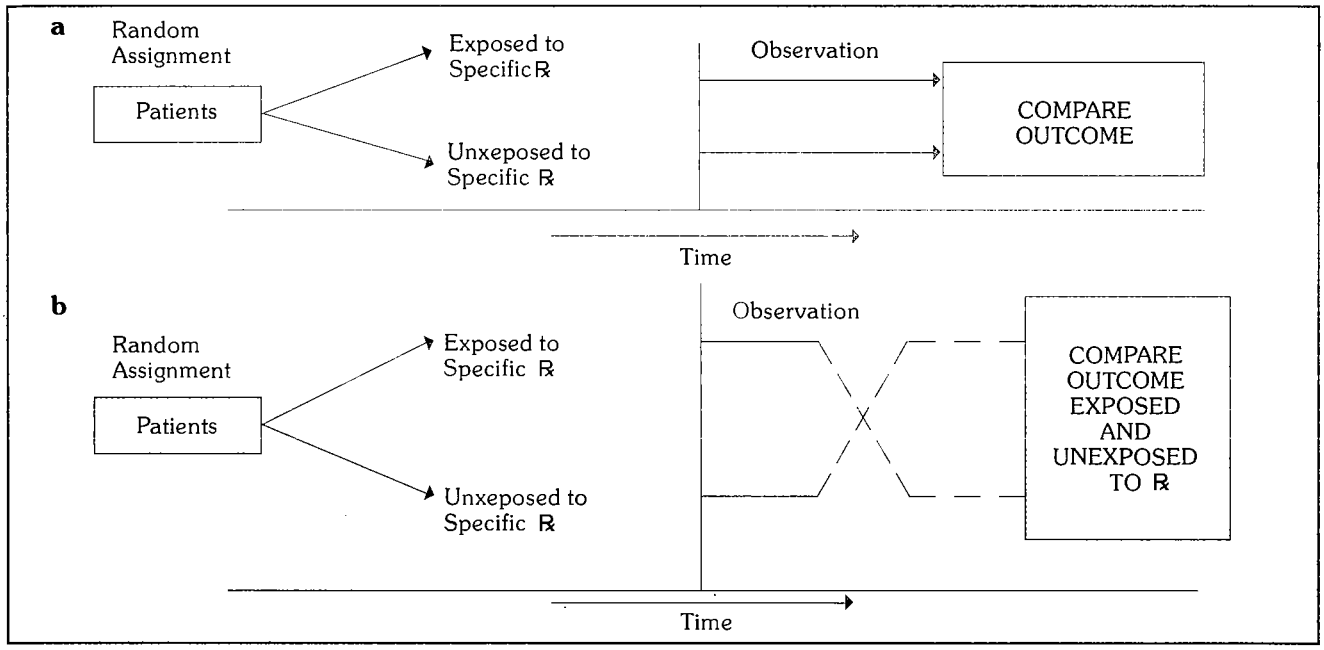

FIG. 10
Schematic diagram of the design of concurrent parallel and cross-over controlled therapeutic trials *(73)*.

TYPES OF RANDOMIZED CONTROLLED TRIALS

1. Clinical trials

For the most part, "clinical trials" have been concerned with evaluating therapeutic agents, mainly drugs. The last decades have seen clearly the utility of clinical trials. Some of the recent examples include – evaluation of beta-blockers in reducing cardiovascular mortality in patient surviving the acute phase of myocardial infarction *(69)*; trials of folate treatment/supplementation before conception to prevent recurrence of neural tube defects *(70)*; trials of aspirin on cardiovascular mortality and beta-carotene on cancer incidence; efficacy of tonsillectomy for recurrent throat infection *(71)*; randomized controlled trial of coronary bypass surgery for the prevention of myocardial infarction *(72)*, etc. The list is endless.

Unfortunately, not all clinical trials are susceptible to being blinded. For example, there is no way to perform a clinical trial of tonsillectomy and adenoidectomy without its being obvious who received surgery and who did not, a reason why the value of these procedures continues to be uncertain. Many ethical, administrative and technical problems are involved in the conduct of clinical trials. Nevertheless, they are a powerful tool and should be carried out before any new therapy, procedure or service is introduced.

2. Preventive trials

In general usage, prevention is synonymous with primary prevention, and the term "preventive trials" implies trials of primary preventive measures. These trials are purported to prevent or eliminate disease on an experimental basis. The most frequently occurring type of preventive trials are the trials of vaccines and chemoprophylactic drugs. The basic principles of experimental design are also applicable to these trials. It may be necessary to apply the trial to groups of subjects instead of to individual subjects. For example, in 1946, the Medical Research Council of UK conducted an extensive trial *(74)* to test whooping cough vaccine from three manufacturers in ten separate field trials. Those children between 6–18 months who were entered into the trial were randomly allocated in study and control groups. The vaccine was given in three, monthly injections, and the children were followed up at monthly intervals to detect the occurrence of whooping cough. The study group comprised of 3,801 children who were vaccinated, and 149 developed whooping cough. The control group consisted of 3,757 unvaccinated children, and 687 of them developed the infection. This gave an attack rate of 1.45 per 1000 child months in the vaccinated group and 6.72 per 1000 child months in the control group. The difference was significant.

Analysis of a preventive trial must result in a clear statement about (a) the benefit the community will derive from the measure (b) the risks involved, and (c) the costs to the health service in terms of money, men and material resources *(21)*. Since preventive trials involve larger number of subjects and sometimes a longer time span to obtain results, there may be greater number of practical problems in their organisation and execution.

3. Risk factor trials

A type of preventive trial is the trial of risk factors in which the investigator intervenes to interrupt the usual sequence in the development of disease for those individuals who have "risk factor" for developing the disease; often this involves risk factor modification. The concept of "risk factor" gave a new dimension to epidemiological research.

For example, the major risk factors of coronary heart disease are elevated blood cholesterol, smoking, hypertension and sedentary habits. Accordingly, the four main possibilities of intervention in coronary heart disease are : reduction of blood cholesterol, the cessation of smoking, control of hypertension and promotion of regular physical activity. Risk factor trials can be "single-factor" or "multi-factor" trials. Both the approaches are complementary, and both are needed.

The WHO *(75)* promoted a trial on primary prevention of coronary heart disease using clofibrate to lower serum cholesterol, which was accepted as a significant risk factor

for CHD. This study is the largest preventive trial yet conducted, comprising more than 15,000 men of whom one-third received clofibrate and two-third received olive oil as a control treatment. The study was conducted in 3 centres in Europe (Edinburgh, Prague, and Budapest). The design was double-blind and randomization was successfully achieved. The mean observation was 9.6 years. The trial showed a significant reduction in non-fatal cardiac infarction, but unfortunately, there were 25 per cent more deaths in the clofibrate-treated group than in the control group possibly due to long-term toxic effect of the drug. The trial illustrates the kind of contribution that an epidemiological approach can make to protect the public health against possible adverse effects of long-term medication with potent drugs *(75)*.

The other widely reported risk-factor intervention trials in coronary heart disease are : (a) The Stanford Three Community Study (b) The North Karelia Project in Finland (c) The Oslo Study, and (d) The Multiple Risk Factor Intervention Trial (MRFIT) in USA.

4. Cessation experiments

Another type of preventive trial is the cessation experiment. In this type of study, an attempt is made to evaluate the termination of a habit (or removal of suspected agent) which is considered to be causally related to a disease. If such action is followed by a significant reduction in the disease, the hypothesis of cause is greatly strengthened. The familiar example is cigarette smoking and lung cancer. If in a randomized controlled trial, one group of cigarette smokers continue to smoke and the other group has given up, the demonstration of a decrease in the incidence of lung cancer in the study group greatly strengthens the hypothesis of a causal relationship. A large randomized controlled trial has been mounted to study the role of smoking cessation in the primary prevention of coronary heart disease *(76)*.

5. Trial of aetiological agents

One of the aims of experimental epidemiology is to confirm or refute an aetiological hypothesis. The best known example of trial of an aetiological agent relates to retrolental fibroplasia (RLF). Retrolental fibroplasia, as a cause of blindness, was non-existent prior to 1938. It was originally observed and reported by T.L.Terry, a Boston ophthalmologist in 1942 *(77)*, and later in many other countries outside the USA.

RLF was recognized as a leading cause of blindness by descriptive studies which showed that beginning in about 1940–1941, the incidence of the disease increased at an alarming rate (Fig. 11), and that this previously unknown disease was occurring only in premature babies. Analytical studies demonstrated its close association with administration of oxygen to premature babies. A large randomized controlled trial was mounted involving 18 hospitals in United States by Kinsey and Hemphill *(78, 79)* in which premature babies with birth weight of 1500 gram or less were allocated into experimental and control groups. In the experimental group, all the babies received 50 per cent oxygen therapy for 28 days, while in the control group ("curtailed oxygen group") oxygen was used only for clinical emergency. It was later found that all of the babies in the "curtailed oxygen group" who developed RLF had received some oxygen. There were no cases among those who received none, confirming the aetiological hypothesis.

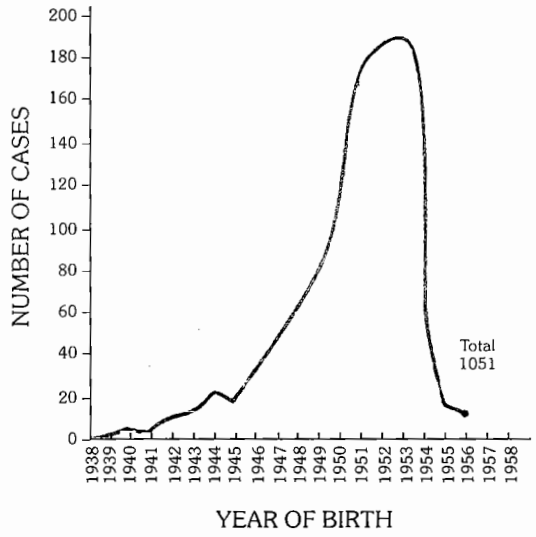

FIG. 11
Incidence of retrolental fibroplasia in New York, 1938–1956

The dramatic rise and fall in frequency of RLF can be seen in Fig. 11. It will be noted that RLF reached its peak during the years 1952–53. The sharp drop in the graph after 1953 highlights the results of the decreased use of oxygen. RLF illustrates one of the problems often introduced by technological or scientific advances.

Since most diseases are fatal, disabling or unpleasant, human experiments to confirm an aetiological hypothesis are rarely possible.

6. Evaluation of health services

Randomized controlled trials have been extended to assess the effectiveness and efficiency of health services. Often, choices have to be made between alternative policies of health care delivery. The necessity of choice arises from the fact that resources are limited, and priorities must be set for the implementation of a large number of activities which could contribute to the welfare of the society. An excellent example of such an evaluation is the controlled trials in the chemotherapy of tuberculosis in India, which demonstrated that "domiciliary treatment" of pulmonary tuberculosis was as effective as the more costlier "hospital or sanatorium" treatment. The results of the study have gained international acceptance and ushered in a new era – the era of domiciliary treatment, in the treatment of tuberculosis.

More recently, multiphasic screening which has achieved great popularity in some countries, was evaluated by a randomized controlled trial in South-East London. The study led to the withholding of vast outlay of resources required to mount a national programme of multiphasic screening in UK *(80,81)*. Another example is that related to studies which have shown that many of the health care delivery tasks traditionally performed by physicians can be performed by nurses and other paramedical workers, thus saving physician time *(82)*. These studies are also labelled as "health services research" studies.

NON-RANDOMIZED TRIALS

Although the experimental method is almost always to be preferred, it is not always possible for ethical, administrative and other reasons to resort to a randomized controlled trial in human beings. For example, smoking and lung cancer and induction of cancer by viruses have not lent themselves

to direct experimentation in human beings. Secondly, some preventive measures can be applied only to groups or on a community-wide basis (e.g., community trials of water fluoridation). Thirdly, when disease frequency is low and the natural history long (e.g., cancer cervix) randomized controlled trials require follow-up of thousands of people for a decade or more. The cost and logistics are often prohibitive. These trials are rare. In such situations, we must depend upon other study designs – these are referred to as non-randomized (or non-experimental) trials.

Where the approach is sophisticated in randomized controlled trials, it is rather crude in non-randomized trials. As there is no randomization in non-experimental trials, the degree of comparability will be low and the chances of a spurious result higher than where randomization had taken place. In other words, the validity of causal inference remains largely a matter of extra-statistical judgement. Nevertheless, vital decisions affecting public health and preventive medicine have been made by non-experimental studies. A few examples of non-randomized trials are discussed below :

1. Uncontrolled trials

There is room for uncontrolled trials (i.e., trials with no comparison group). For example, there were no randomized controlled studies of the benefits of the Pap test (cervical cancer) when it was introduced in 1920s. Today, there is indirect epidemiological evidence from well over a dozen uncontrolled studies of cervical cancer screening that the Pap test is effective in reducing mortality from this disease. Initially uncontrolled trials may be useful in evaluating whether a specific therapy appears to have any value in a particular disease, to determine an appropriate dose, to investigate adverse reactions, etc. However, even in these uncontrolled trials, one is using implied "historical controls", i.e., the experience of earlier untreated patients affected by the same disease.

Since most therapeutic trials deal with drugs which do not produce such remarkably beneficial results, it is becoming increasingly common to employ the procedures of a double-blind controlled clinical trial in which the effects of a new drug are compared to some concurrent experience (either placebo or a currently utilized therapy).

2. Natural experiments

Where experimental studies are not possible in human populations, the epidemiologist seeks to identify "natural circumstances" that mimic an experiment. For example, in respect of cigarette smoking, people have separated themselves "naturally" into two groups, smokers and non-smokers. Epidemiologists have taken advantage of this separation and tested hypothesis regarding lung cancer and cigarette smoking. Other populations involved in natural experiments comprise the following groups : (a) migrants (b) religious or social groups (c) atomic bombing of Japan (d) famines (e) earthquakes, etc. A major earthquake in Athens in 1981 provided a "natural experiment" to epidemiologists who studied the effects of acute stress on cardiovascular mortality. They showed an excess of deaths from cardiac and external causes on the days after the major earthquake, but no excess deaths from other causes *(83)*.

John Snow's discovery that cholera is a water-borne disease was the outcome of a natural experiment. Snow in his "grand experiment" identified two randomly mixed populations, alike in other important respects, except the source of water supply in their households. The results of the experiment are given in Table 23.

TABLE 23

Deaths from cholera per 10,000 houses and sources of water supply of these houses. London 1853

Sources of water supply	Number of houses	Deaths from cholera	Deaths in each 10,000 houses
Southwark & Vauxhall Co.	40,046	1263	315
Lambeth Co.	26,107	98	37

It will be seen from Table 23 that deaths were fewer in houses supplied by Lambeth company compared to houses supplied by Southwark and Vauxhall company. The inference was obvious – the Lambeth company water came from an intake on the River Thames well above London, whereas the Southwark and Vauxhall company water was derived from the sewage polluted water basin. The great difference in the occurrence of cholera among these two populations gave clear demonstration that cholera is a water-borne disease. This was demonstrated long before the advent of the bacteriological era; it also led to the institution of public health measures to control cholera.

3. Before and after comparison studies

These are community trials which fall into two distinct groups:

A. Before and after comparison studies without control, and
B. Before and after comparison studies with control.

*A. Before and after comparison studies **without** control*

These studies centre round comparing the incidence of disease before and after introduction of a preventive measure. The events which took place prior to the use of the new treatment or preventive procedure are used as a standard for comparison. In other words, the experiment serves as its own control; this eliminates virtually all group differences. The classic examples of "before and after comparison studies" were the prevention of scurvy among sailors by James Lind in 1750 by providing fresh fruit; studies on the transmission of cholera by John Snow in 1854; and later, prevention of polio by Salk and Sabin vaccines.

In order to establish evidence in before and after comparison studies, the following are needed; (a) data regarding the incidence of disease, before and after introduction of a preventive measure must be available (b) there should be introduction or manipulation of only one factor or change relevant to the situation, other factors remaining the same, as for example, addition of fluorine to drinking water to prevent dental caries (c) diagnostic criteria of the disease should remain the same (d) adoption of preventive measures should be over a wide area (e) reduction in the incidence must be large following the introduction of the preventive measure, because there is no control, and (f) several trials may be needed before the evaluation is considered conclusive.

Table 24 gives an example of a "before and after comparison study" in Victoria (Australia) following introduction of seat-belt legislation for prevention of deaths and injuries caused by motor vehicle accidents.

TABLE 24

Effect of adoption of compulsory seat-belt legislation in Victoria, Australia–1971

	1970	1971	% change
Deaths	564	464	– 17.7
Injuries	14620	12454	– 14.8

Table 24 shows a definite fall in the numbers of deaths and injuries in occupants of cars, following the introduction of compulsory seat-belts in one state of Australia.

*B. Before and after comparison studies **with** control*

In the absence of a control group, comparison between observations before and after the use of a new treatment or procedure may be misleading. In such situations, the epidemiologist tries to utilize a "natural" control group i.e., the one provided by nature or natural circumstances. If preventive programme is to be applied to an entire community, he would select another community as similar as possible, particularly with respect to frequency and characteristics of the disease to be prevented. One of them is arbitrarily chosen to provide the study group and the other a control group. In the example cited (e.g., seat-belt legislation in Victoria, Australia), a natural "control" was sought by comparing the results in Victoria with other states in Australia where similar legislation was not introduced. The findings are given in Table 25.

TABLE 25

Effect of adoption of compulsory seat-belt legislation in Victoria, 1971 compared with other states where similar legislation was not introduced

	1970	1971	% change
Deaths			
Victoria	564	464	– 17.7
Other states	1,426	1,429	0.2
Injuries			
Victoria	14,620	12,454	– 14.8
Other states	39,980	40,396	1.0

In the example cited above, the existence of a control with which the results in Victoria could be compared strengthens the conclusion that there was definite fall in the number of deaths and injuries in occupants of cars after the introduction of compulsory seat-belt legislation.

In the evaluation of preventive measures, three questions are generally considered : (a) How much will it benefit the community ? This will depend upon the effectiveness of the preventive measure and the acceptance of the measure by the community. The combined outcome of effectiveness and acceptability is measured by the difference in the incidence rate among the experimental and control groups. (b) What are the risks to the recipients? These include the immediate and long-term risks. (c) Cost in money and man power? This is done to find out whether the preventive measure is economical and practical in terms of money spent. It is now conceded that no health measure should be introduced on a large scale without proper evaluation.

Recent problems that have engaged the attention of epidemiologists are studies of medical care and health services; planning and evaluation of health measures, services and research.

ASSOCIATION AND CAUSATION

Descriptive studies help in the identification of the disease problem in the community; and by relating disease to host, agent and environmental factors, it endeavours to suggest an aetiological hypothesis. Analytical and experimental studies test the hypotheses derived from descriptive studies and confirm or refute the observed association between suspected causes and disease. When the disease is multifactorial (e.g., coronary heart disease) numerous factors or variables become implicated in the web of causation, and the notion of "cause" becomes confused. The more associations, the more investigations to disentangle the web of causation. The epidemiologist whose primary interest is to establish a "cause and effect" relationship has to sift the husk from the grain. He proceeds from demonstration of statistical association to demonstration that the association is causal.

The terms "association" and "relationship" are often used interchangeably. Association may be defined as the concurrence of two variables more often than would be expected by chance. In other words, events are said to be associated when they occur more frequently together than one would expect by chance *(2)*. Association does not necessarily imply a causal relationship.

It will be useful to consider here the concept of correlation. Correlation indicates the *degree* of association between two characteristics. The correlation coefficients range from –1.0 to +1.0. A correlation coefficient of 1.0 means that the two variables exhibit a perfect linear relationship. However, correlation cannot be used to invoke causation, because the sequence of exposure preceding disease (temporal association) cannot be assumed to have occurred. Secondly, correlation does not measure risk. It may be said that causation implies correlation, but correlation does not imply causation.

Association can be broadly grouped under three headings :

a. Spurious association
b. Indirect association
c. Direct (causal) association
   (i) one-to-one causal association
   (ii) multifactorial causation.

a. Spurious association

Sometimes an observed association between a disease and suspected factor may not be real. For example, a study in UK of 5174 births at home and 11,156 births in hospitals showed perinatal mortality rates of 5.4 per 1000 in the home births, and 27.8 per 1000 in the hospital births *(84)*. Apparently, the perinatal mortality was higher in hospital births than in the home births. It might be concluded that homes are a safer place for delivery of births than hospitals. Such a conclusion is spurious or artifactual, because in general, hospitals attract women at high risk for delivery because of their special equipment and expertise, whereas this is not the case with home deliveries. The high perinatal mortality rate in hospitals might be due to this fact alone, and not because the quality of care was inferior. There might be other factors also such as differences in age, parity, prenatal care, home circumstances, general health and disease state between the study and control groups. This type of bias where "like" is not compared with "like" (selection bias) is very important in epidemiological studies. It may lead to a spurious association or an association when none actually existed.

b. Indirect association

Many associations which at first appeared to be causal have been found on further study to be due to indirect association. The indirect association is a statistical association between a characteristic (or variable) of interest and a disease due to the presence of another factor, known or unknown, that is common to both the characteristic and the disease. This third factor (i.e., the common factor) is also known as the "confounding" variable. Since it is related both to the disease and to the variable, it might explain the statistical association between disease and a characteristic wholly or in part. Such confounding variables (e.g., age, sex, social class) are potentially and probably present in all data and represent a formidable obstacle to overcome in trying to assess the causal nature of the relationship. Two examples of an indirect association are given below.

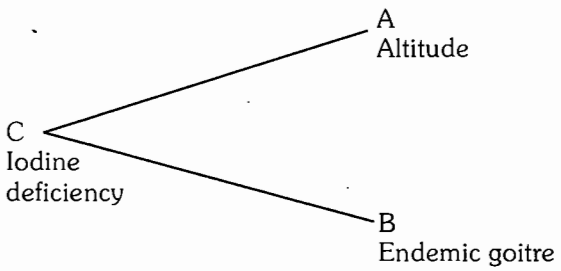

FIG. 12
Model of an indirect association

(a) Altitude and endemic goitre

Endemic goitre is generally found in high altitudes, showing thereby an association between altitude and endemic goitre (Fig. 12). We know, that endemic goitre is not due to altitude but due to environmental deficiency of iodine. Fig. 12 illustrates how a common factor (i.e., iodine deficiency) can result in an apparent association between two variables, when no association exists. This amplifies the earlier statement that statistical association does not necessarily mean causation.

(b) Sucrose and CHD

Yudkin and Roddy *(85)* found a higher intake of sugar by patients with myocardial infarction. Their study was based on an enquiry by questionnaire method into dietary habits of cases and controls. They put forward an attractive hypothesis that people who consume lot of sugar are far more likely to have a heart attack than those who take little.

Further studies were undertaken to test whether sugar intake was associated with other variables such as cigarette smoking, which might be causally related to CHD. Bennet and others *(86)* found that heavy cigarette smoking was positively associated with an increase in the number of cups of hot drinks consumed daily and the amount of sugar consumed. They concluded that it was cigarette smoking and not sugar consumption which was implicated in the aetiology of CHD. In their study, they did not find any evidence of increasing trend of CHD with increasing consumption of sugar. Finally, proof came from experimental studies that high sucrose feeding did not induce arteriosclerotic disease in animals.

Sometimes knowledge of indirect associations can be applied towards reducing disease risk. Before the discovery of the cholera vibrio, elimination of certain water supplies achieved a marked decrease in new cases of the disease. Such indirect associations must be pursued, for it is likely that they may provide aetiological clues.

c. Direct (causal) association

(i) One-to-one causal relationship

Two variables are stated to be causally related **(AB)** if a change in A is followed by a change in B. If it does not, then their relationship cannot be causal. This is known as "one-to-one" causal relationship. This model suggests that when the factor **A** is present, the disease **B** must result. Conversely, when the disease is present, the factor must also be present. Measles may be one disease in which such a relation exists *(3)*.

Epidemiologists are interested in identifying the "cause". The most satisfactory procedure to demonstrate this would be by direct experiment. But this procedure is scarcely available to the epidemiologist. And, in some cases, the "cause" is not amenable to manipulation.

The above concept of one-to-one causal relationship was the essence of Koch's postulates. The proponents of the germ theory of disease insisted that the cause must be :

a. necessary, and

b. sufficient for the occurrence of disease

before it can qualify as cause of disease. In other words, whenever the disease occurs, the factor or cause must be present.

Although Koch's postulates are theoretically sound, the "necessary and sufficient" concept does not fit well for many diseases. Taking for example tuberculosis, tubercle bacilli cannot be found in all cases of the disease but this does not rule out the statement that tubercle bacilli are the cause of tuberculosis *(4)*. That the cause must be "sufficient" is also not always supported by evidence. In tuberculosis, it is well–known that besides tubercle bacilli, there are additional factors such as host susceptibility which are required to produce the disease.

The concept of one-to-one causal relationship is further complicated by the fact that sometimes, a single cause or factor may lead to more than one outcome, as shown in Fig. 13. In short, one-to-one causal relationship, although ideal in disease aetiology, does not explain every situation.

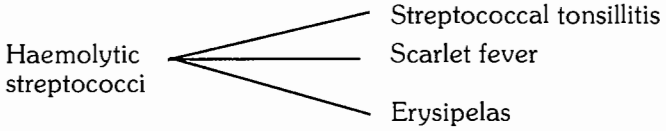

FIG. 13
Model in which one factor is shown to lead to more than one disease

(ii) Multifactorial causation

The causal thinking is different when we consider a non-communicable disease or condition (e.g., CHD) where the aetiology is multifactorial. Two models are presented in Figures 14 and 15 to explain the complex situation. In one model (Fig. 14), there are alternative causal factors (Factors 1, 2 and 3) each acting independently. This situation is exemplified in lung cancer where more than one aetiological factor (e.g., smoking, air pollution, exposure to asbestos) can produce the disease independently. It is possible as our knowledge of cancer increases, we may discover a common biochemical event at the cellular level that can be produced by each of the factors. The cellular or molecular factor will then be considered necessary as a causal factor *(4)*.

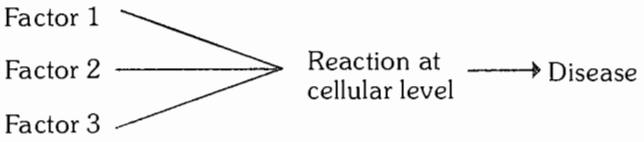

FIG. 14
A model of multifactorial causation *(4)*.

In the second model (Fig. 15) the causal factors act cumulatively to produce disease. This is probably the correct model for many diseases. It is possible that each of the several factors act independently, but when an individual is exposed to 2 or more factors, there may be a synergistic effect.

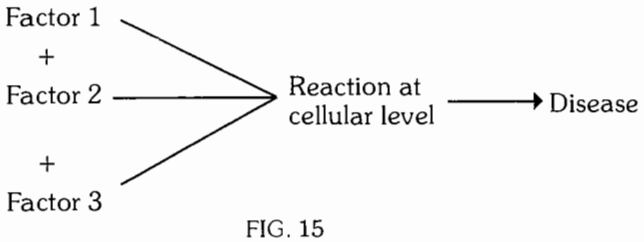

FIG. 15
A model of multifactorial causation showing synergism *(4)*

From the above discussion, it is reasonable to conclude that "one-to-one" relationship in causation is an oversimplification. In biological phenomena, the requirement that "cause" is both "necessary" and "sufficient" condition is not easily reached, because of the existence of multiple factors in disease aetiology. This has created a serious problem to the epidemiologist, who is in search of causes of disease.

ADDITIONAL CRITERIA FOR JUDGING CAUSALITY

In the absence of controlled experimental evidence to incriminate the "cause", certain additional criteria have been evolved for deciding when an association may be considered a causal association. An elegant elucidation of these criteria appears in "Smoking and Health" the Report of the Advisory Committee to the Surgeon General of the Public Health Service in US *(87)*. Bradford Hill *(88, 89)* and others *(90)* have pointed out that the likelihood of a causal relationship is increased by the presence of the following criteria.

1. Temporal association
2. Strength of association
3. Specificity of the association
4. Consistency of the association
5. Biological plausibility
6. Coherence of the association

The Surgeon–General's Report (1964) states that the causal significance of an association is a matter of judgement which goes beyond any statement of statistical probability. To judge or evaluate the causal significance of an association, all the above criteria must be utilized, no one of which by itself is self-sufficient or *sine qua-non* for drawing causal inferences from statistical associations, but each adds to the quantum of evidence, and all put together contribute to a probability of the association being causal.

ASSOCIATION BETWEEN CIGARETTE SMOKING AND LUNG CANCER

Cigarette smoking and lung cancer hypothesis provides an excellent example to illustrate the epidemiological criteria for establishing whether or not an observed association plays a causal role in the aetiology of a disease. The data fulfilling the criteria were covered adequately in *Smoking and Health*, the initial report of the Advisory Committee to the Surgeon General of the Public Health Service in 1964 *(87)*. The later reports of US Public Health Service from 1964–1973, and similar other reports (e.g., Report of the Royal College of Physicians, London : *Smoking or Health*, 1977) summarized newer data supporting the validity of the hypothesis. Let us examine the cigarette smoking and lung cancer hypothesis in the light of the above criteria.

1. Temporal association

This criterion centres round the question: Does the suspected cause precede the observed effect ? A causal association requires that exposure to a putative cause must precede temporarily the onset of a disease which it is purported to produce to allow for any necessary period of induction and latency. This requirement is basic to the causal concept.

In certain acute diseases such as water and food-borne outbreaks, discovery of temporal sequence of two variables (e.g., drinking contaminated water and diarrhoea) is not often a serious problem. However, in many chronic diseases, because of insidious onset and ignorance of precise induction periods, it becomes hard to establish a temporal sequence as to which came first – the suspected agent or the disease, because one is dealing with a continuous evolving process.

Lung cancer occurs in smokers of long-standing; this satisfies the temporal requirement. Further, the increase in consumption of cigarettes preceded by about 30 years the increase in death rates from lung cancer. These observations are compatible with the long latent period characteristic of carcinogenesis.

2. Strength of association

The strength of association is based on answers to two questions:

a. Relative risk – is it large ?
b. Is there a dose–response, duration–response relationship ?

In general, the larger the relative risk, the greater the likelihood of a causal association. Furthermore, the likelihood of a causal relationship is strengthened if there is a biological gradient or dose–response relationship – i.e., with increasing levels of exposure to the risk factor, an increasing rise in incidence of the disease is found. If there is no dose–response or duration–response relationship, that would be an argument against the relationship being causal.

In the absence of experimental data on humans, the causal relationship of cigarette smoking and lung cancer has been based on three points : (a) relative risk (b) dose–response relationship, and (c) the decrease in risk on cessation of smoking. Table 26 presents data showing relative risk and dose–response relationship. Such high relative risks are rarely seen in epidemiological studies. It has been stated that the relationship between lung cancer and smoking is one of the most impressive demonstrations of a dose–response relationship that can be found in epidemiology *(3)*. The dose–response relationship has, in fact, played a major role in acceptance of relationship as causal *(12)*. If there has been no dose–response relationship, that would have been a strong argument against the causal

hypothesis. Another factor that has added to the weight of evidence is the fact that lung cancer death rates among moderate smokers were intermediate between those among light smokers and heavy smokers.

TABLE 26

Death rate and relative risk for smokers and non-smokers

Daily average cigarettes smoked	Death rate per 1000		Relative risk
	Smokers	Non-smokers	
1–14	0.47	0.07	6.7
15–24	0.86	0.07	12.3
25+	1.66	0.07	23.7

Source : *(60)*

Cessation experiment

Another piece of evidence is provided by the cessation experiment. Table 27 shows the mortality ratios in ex-cigarette smokers by number of years stopped smoking among British doctors. The results confirmed that the mortality ratios were reduced in a way that would be expected if smoking were the cause of the disease. This is a strong point in the evidence favouring the hypothesis.

TABLE 27

Lung cancer mortality ratios in ex-cigarette-smokers, by number of years stopped smoking, British physicians

Years stopped smoking	Mortality ratio
Still smoking	15.8
1–4	16.0
5–9	5.9
10–14	5.3
15 +	2.0
Non-smokers	1.0

Source : *(58)*

3. Specificity of the association

The concept of specificity implies a "one-to-one" relationship between the cause and effect. In the past, much of the controversy over cigarette smoking and lung cancer centred round lack of specificity of the association. That is, cigarette smoking is linked with not only lung cancer but several others such as coronary heart disease, bronchitis, emphysema, cancer cervix, etc. This was used, for several years, as an argument against the acceptance of the association as causal. It is true that cigarette smoking is associated with so many diseases reflecting an apparent lack of specificity, but that cannot be a strong argument, so as to dismiss the causal hypothesis. This is because the requirement of specificity is a most difficult criterion to establish not only in chronic disease but also in acute diseases and conditions. The reasons are : first, a single cause or factor can give rise to more than one disease. Secondly, most diseases are due to multiple factors with no possibility of demonstrating one-to-one relationship.

The lack of specificity can be further explained by the fact that tobacco smoke is a complex of substances containing several harmful ingredients or factors such as nicotine, carbon monoxide, benzpyrene, particulate matter and many other ingredients with possible additive and synergistic action. The different components of tobacco smoke could as well be responsible for different states. In spite of this, it can be seen from Table 28 that the association of lung cancer with cigarette smoking is far more striking than any other association, reflecting a definite causal association. In short, specificity supports causal interpretation but lack of specificity does not negate it.

TABLE 28

Expected and observed deaths for smokers of cigarettes compared to non-smokers: Seven prospective studies combined, for selected causes of death

Underlying cause of death	Expected deaths (E)	Observed deaths (O)	Mortality ratio (O/E)
Cancer of lung	170.3	1,833	10.8
Bronchitis and emphysema	89.5	546	6.1
Cancer of larynx	14.0	75	5.4
Cancer oesophagus	37.0	152	4.1
Peptic ulcer	105.1	294	2.8
Cancer bladder	111.6	216	1.9
CHD	6,430.7	11,177	1.7
Cancer rectum	207.8	213	1.0
All causes of death	15,653.9	23,223	1.7

Source : *(36)*

The concept of specificity cannot be entirely dissociated from the concept of association. It has been estimated that about 80–90 per cent of lung cancer can be attributed to cigarette smoking. To say this, it is assumed that the association between smoking and lung cancer is causal. Under the heading of specificity, two more observations require comment : (a) not everyone who smokes develops cancer, and (b) not everyone who develops lung cancer has smoked. The first apparent paradox is related to the multifactorial nature of lung cancer. It may well be that there are other factors as yet unidentified which must be present in conjunction with smoking for lung cancer to develop. As for lung cancer in non-smokers, it is known that there are factors other than smoking which increase the risk of lung cancer such as occupational exposure to chromates, asbestos, nickel, uranium and exposure to air pollution. Deviations from one-to-one relationship between cigarette smoking and lung cancer therefore, cannot be said to rule out a causal relationship.

4. Consistency of the association

The association is consistent if the results are replicated when studied in different settings and by different methods. That is, evidence from a single study is seldom sufficient to establish "causal" association. If there is no consistency, it will weaken a causal interpretation.

A consistent association has been found between cigarette smoking and lung cancer. More than 50 retrospective studies and at least nine prospective studies in different countries had shown a consistent association between cigarette smoking and subsequent development of lung cancer, lending support to a causal association.

5. Biological plausibility

Causal association is supported if there is biological credibility to the association, that is, the association agrees with current understanding of the response of cells, tissues, organs, and systems to stimuli. For example, the notion that food intake and cancer are interrelated is an old one. The positive association of intestine, rectum and breast cancers is biologically logical, whereas the positive association of food and skin cancer makes no biological sense suggesting that strength of association by itself does not imply causality.

This is one of the pitfalls of correlation studies. Further, the criterion of biological plausibility should not be applied rigidly. That is, even if a biological mechanism cannot be postulated, it does not rule out the possibility of a cause and effect relationship, for it may be merely due to the limits of current knowledge.

The cigarette smoking and lung cancer hypothesis is biologically plausible. It is not hard to visualize the inhalation of hot smoke into the lungs and deposition of a chemical carcinogen over a period of time probably building itself up to a threshold level and initiating neoplastic changes in the lungs. Experimental studies in animals have strengthened the evidence for the aetiological role of cigarette smoking, although one cannot directly translate the results of such studies in humans. Many such studies have shown that lung cancer can be produced by tracheobronchial implantation of tobacco extracts or by inhalation of cigarette smoke or of aerosols of its constituents. Carcinogenic substances have been isolated from cigarette smoke, although the precise carcinogens responsible for lung cancer in man are unknown. The biological credibility, in fact, provides a convincing evidence in favour of a causal association.

6. Coherence of the association

A final criterion for the appraisal of causal significance of an association is its coherence with known facts that are thought to be relevant. For example, the historical evidence of the rising consumption of tobacco in the form of cigarettes and the rising incidence of lung cancer are coherent. Male and female differences in trends of lung cancer death rates are also coherent with the more recent adoption of cigarette smoking by women. Death rates rose first in males and are now increasing relatively more rapidly in females. The fall in the relative risk of lung cancer when cigarette smoking is stopped, and the occurrence of lung cancer from occupational exposure to other carcinogens such as asbestos and uranium and the demonstrated increase in lung cancer risk when workers exposed to these substances also smoked, enhance the significance of a causal association.

In conclusion, it may be stated that the association between cigarette smoking and lung cancer can never be proved by a direct experiment on humans. It is an illusory and virtually unattainable goal. It is well known that epidemiology depends heavily on inferences drawn from observations rather than on the ultimate experiment. The nearest approach to "scientific proof", therefore is the vast body of convincing evidence we have accumulated during the past few years meeting all the criteria proposed for judging the causality of such associations.

USES OF EPIDEMIOLOGY

While the study of disease distribution and causation remains central to epidemiology; the techniques of epidemiology have a wider application covering many more important areas relating not only to disease but also health and health services. In more utilitarian terms, epidemiology has been defined as "a means of learning, or asking questions....and getting answers that lead to further questions". In this context, Morris *(10)* has identified seven distinct uses of epidemiology, five of which extend epidemiology beyond the search for causes of disease and bring it closer to day-to-day concerns of modern medicine.These are :

1. To study historically the rise and fall of disease in the population

Winston Churchill said : "The farther back you look, the farther forward you can see". The first use of epidemiology relates to this aspect, that is, study of the history of disease in human population. It is well known that the health and disease pattern in a community is never constant. There are fluctuations both over short and long periods of time. For example, the first contribution of epidemiology to the study of coronary heart disease was that it was an "epidemic". Later many others such as accidents, cancer and diabetes were found to be "epidemic". As old diseases (e.g., smallpox) are conquered, new ones (e.g., Legionnaires' disease, Lassa fever, AIDS) have been identified, in which epidemiology has played a major role. Epidemiology provides a means to study disease profiles and time trends in human population. By a study of these trends, we can make useful projections into the future and identify emerging health problems and their correlates.

2. Community diagnosis

One of the uses of epidemiology is community diagnosis. Community diagnosis generally refers to the identification and quantification of health problems in a community in terms of mortality and morbidity rates and ratios, and identification of their correlates for the purpose of defining those individuals or groups at risk or those in need of health care. By quantification of health problems, we lay down priorities in disease control and prevention. Secondly, quantification of morbidity and mortality can serve as a benchmark for the evaluation of health services at a later date. Thirdly, the quantification of health problems can be a source of new knowledge about disease distribution, causation and prevention. Community diagnosis has also been effectively extended beyond population distributions and profiles of illness to include an understanding of the social, cultural and environmental characteristics of the community *(91)*. Epidemiology, therefore, has been described as a "diagnostic tool" of community medicine.

3. Planning and evaluation

Planning is essential for a rational allocation of the limited resources. For example, in developing countries, too many hospitals have been built and equipped without knowledge of the particular disease problems in the community. Epidemiologic information about the distribution of health problems over time and place provides the fundamental basis for planning and developing the needed health services and for assessing the impact of these services on the people's problems. The application of epidemiological principles to problems of health care constitutes the "new epidemiology" *(92)*. Examples of planning include planning facilities for medical care (e.g., number of hospital beds required for patients with specific diseases, health manpower planning); planning facilities for preventive services (e.g., screening programmes, immunization campaigns; provision of sanitary services); and planning for research.

Evaluation is an equally important concern of epidemiology. Any measures taken to control or prevent a disease must be followed by an evaluation to find out whether the measures undertaken are effective in reducing the frequency of the disease. Evaluation of a control method such as hepatitis vaccine requires more than the demonstration of its effectiveness in reducing disease

frequency. We have to measure the cost of its large-scale application in terms of the cost of the vaccine, trained personnel, storage, transport and other factors. The value of one method in relation to others is assessed by cost-effectiveness studies. It is now being recognized that not only vaccines, but in time all health services will have to submit to evaluation *(93)*. The development of randomized controlled trial has made it possible to evaluate treatment modalities on a firm scientific basis. Such trials have raised doubts about the utility of multiphasic screening, certain operative procedures (e.g., tonsillectomy, varicose vein, stripping), prolonged hospitalization of patients with myocardial infarction, etc. Clearly it is not enough to know that a programme provides some benefit; we need to know how much benefit and at what risk and cost *(93)*.

4. Evaluation of individual's risks and chances

One of the important tasks of epidemiologists is to make a statement about the degree of risk in a population. Besides the incidence rate and specific rates which are measures of absolute risk, the epidemiologists calculate relative risk and attributable risk for a factor related to or believed to be a cause of the disease. The risk of bearing a mongol child and of some hereditary disorders are classic examples of evaluating individual's risks and chances. The risk assessment for smokers and non-smokers, for selected causes of death (e.g., cancer CHD) is another well-known example.

5. Syndrome identification

Medical syndromes are identified by observing frequently associated findings in individual patients. It is worth recalling that, although approximately 3000 so-called syndromes are described in the contemporary paediatric literature, a primary defect is known only in about 20 per cent of these *(94)*. Epidemiological investigations can be used to define and refine syndromes. By observation of groups, such studies have been able to correct misconceptions concerning many disease syndromes. For example, there was less appreciation of the two main types of peptic ulcer (gastric and duodenal) till 1920. But the "poverty" gradient in the certification of the gastric ulcer and its absence in duodenal ulcer led to differentiation of gastric and duodenal ulcers. Another example is that of Patterson-Kelly syndrome of association between dysphagia and iron-deficiency anaemia, but when the association was tested by epidemiological methods, it was not found *(10)*. Clinical studies using plasma renin levels have suggested that aetiologically, prognostically and therapeutically distinct syndromes of essential hypertension may exist. It has been the subject of hot debate *(95, 96)*.

6. Completing the natural history of disease

Epidemiology is concerned with the entire spectrum of disease in a population. The picture of disease constructed on the basis of hospital patients is quite different from that found in the community. The epidemiologist by studying disease patterns in the community in relation to agent, host and environmental factors is in a better position to fill up the gaps in the natural history of disease than the clinician. For example an outstanding contribution by epidemiology to the natural history of atherosclerosis is the recognition that one-third to two-thirds of all deaths due to ischaemic heart disease are sudden, i.e., occur in less than one hour. Hospital studies could never have come to this conclusion, for most victims do not reach the hospital. This gave tremendous impetus to the development of intensive coronary care units *(97)*. Epidemiological investigations have yielded a large amount of data on risk factors in relation to chronic disease. The impact of these findings on our knowledge of the natural history of chronic disease remains to be elucidated. Since the epidemiologist is concerned with all cases in the defined population, regardless of severity or source of medical care, his perspective of disease is consequently the broadest.

7. Searching for causes and risk factors

Epidemiology, by relating disease to interpopulation differences and other attributes of the population or cohorts examined, tries to identify the causes of disease. The contributions of epidemiology have been many in this regard. Numerous examples can be cited : epidemiological studies have incriminated that rubella is the cause of congenital defects in the newborn, that thalidomide is a teratogenic agent, cigarette smoking is a cause of lung cancer, exposure of premature babies to oxygen is the cause of retrolental fibroplasia, etc. in the case of chronic disease, hopes of finding a single cause remains unfulfilled, but an important conceptual change has occurred – that is, search for risk factors. The concept of "risk factors" gave renewed impetus to epidemiological research. The search for causes and risk factors will be a ceaseless effort, as our ignorance about disease aetiology, particularly chronic disease, is profound, not to speak of the "new" diseases which are appearing.

INFECTIOUS DISEASE EPIDEMIOLOGY

Infectious disease epidemiology is a fundamental part of the whole of epidemiology. In fact, the subject of epidemiology originally developed from the study of epidemics of infectious diseases. There is a renaissance in the study of communicable diseases, stimulated by (a) changes in the pattern of communicable diseases, (b) by the discovery of "new" infections, and (c) by the possibility that some chronic diseases have an infective origin. The development of vaccines and antibiotics was not followed, as predicted, by the virtual disappearance of infectious disease. Its prevention and control needs epidemiological knowledge and experience *(98)*. This section focuses on infectious disease epidemiology.

Selected definitions

Definitions are essential for any kind of epidemiological activity, e.g., disease reporting, measurement of mortality and morbidity, etc. Clear-cut definitions of the terms such as "infection", "epidemic" and "surveillance" are needed in the study of infectious diseases. A few selected definitions pertaining to infectious disease epidemiology are given below :

INFECTION

The entry and development or multiplication of an infectious agent in the body of man or animals *(2,99)*. It also implies that the body responds in some way to defend itself against the invader, either in the form of an immune response (evidence of this may not be readily available) or disease. An infection does not always cause illness.

There are several levels of infection : *colonization* (e.g., *S. aureus* in skin and normal nasopharynx); subclinical or *inapparent infection* (e.g., polio); latent infection (e.g., virus of herpes simplex); and manifest or *clinical infection*.

CONTAMINATION

The presence of an infectious agent on a body surface; also on or in clothes, beddings, toys, surgical instruments or dressings, or other inanimate articles or substances including water, milk and food. *Pollution* is distinct from contamination and implies the presence of offensive, but not necessarily infectious matter in the environment. Contamination on a body surface does not imply a carrier state *(99)*.

INFESTATION

For persons or animals the lodgement, development and reproduction of arthropods on the surface of the body or in the clothing, e.g., lice, itch mite *(99)*. Some authorities use the term also to describe invasion of the gut by parasitic worms, e.g., ascariasis *(2)*.

Infested articles or premises are those which harbour or give shelter to animal forms, especially arthropods and rodents *(99)*.

HOST

A person or other animal, including birds and arthropods, that affords subsistence or lodgement to an infectious agent under natural (as opposed to experimental) conditions. An *obligate* host means the only host, e.g., man in measles and typhoid fever. Hosts in which the parasite attains maturity or passes its sexual stage are primary or *definitive* hosts; those in which the parasite is in a larval or asexual state are secondary or *intermediate* hosts. A *transport* host is a carrier in which the organism remains alive but does not undergo development *(2,99)*.

INFECTIOUS DISEASE

A clinically manifest disease of man or animals resulting from an infection *(99)*.

CONTAGIOUS DISEASE

A disease that is transmitted through contact *(2)*. Examples include scabies, trachoma, STD and leprosy.

COMMUNICABLE DISEASE

An illness due to a specific infectious agent or its toxic products capable of being directly or indirectly transmitted from man to man, animal to animal, or from the environment (through air, dust, soil, water, food, etc.) to man or animal *(100)*.

EPIDEMIC

(Epi = upon; demos = people). The "unusual" occurrence in a community or region of disease, specific health-related behaviour (e.g., smoking) or other health–related events (e.g., traffic accidents) clearly in excess of "expected occurrence". The amount of disease occurring in the past, in the absence of an epidemic, defines the "expected" frequency. Some use the term "outbreak" for a small, usually localized epidemic in the interest of minimizing public alarm, unless the number of cases is indeed very large *(13)*.

The above definition covers not only the usual epidemic diseases such as measles, chickenpox and cholera which are compressed in time, but also the modern "slow" epidemics of non-communicable diseases (e.g., CHD, lung cancer) in which the time scale of the epidemic is shifted from days or weeks to years *(13)*. The slow growth of these epidemics conceal their size.

The key words in the definition of an epidemic are : in excess of "expected occurrence". There is no agreement on what constitutes a significant excess. For example, in the US, a disease such as cholera is not normally present in the population. Therefore, even one case of cholera would constitute a "potential" epidemic in US. But in a country like India or Bangladesh, where cholera is always present in some population subgroups, a few hundred cases a year may be the "usual" or expected incidence (endemic situation). For cholera to be considered as an epidemic in India, hundreds of cases (i.e., cases above the endemic frequency) would have to occur. An arbitrary limit of two standard errors from the endemic frequency is used to define the epidemic threshold for common diseases *(3)*.

ENDEMIC

(En=in; demos=people). It refers to the constant presence of a disease or infectious agent within a given geographic area or population group, without importation from outside; may also refer to the "usual" or expected frequency of the disease within such area or population group. For instance, common cold is endemic because somebody always has one.

The term "hyperendemic" expresses that the disease is constantly present at a high incidence and/or prevalence rate and affects all age groups equally; and the term "holoendemic" a high level of infection beginning early in life and affecting most of the child population, leading to a state of equilibrium such that the adult population shows evidence of the disease much less commonly than do the children, as in the case of malaria *(2)*.

An endemic disease when conditions are favourable may burst into an epidemic (e.g., hepatitis A, typhoid fever). As new control or preventive measures are applied, the endemic status of a disease may change.

SPORADIC

The word sporadic means scattered about. The cases occur irregularly, haphazardly from time to time, and generally infrequently *(2)*. The cases are so few and separated widely in space and time that they show little or no connection with each other, nor a recognizable common source of infection, e.g., polio, tetanus, herpes-zoster and meningococcal meningitis. A sporadic disease may be the starting point of an epidemic when conditions are favourable for its spread. Many zoonotic diseases are characterised by sporadic transmission to man *(101)*.

PANDEMIC

An epidemic usually affecting a large proportion of the population *(2)*, occurring over a wide geographic area such as a section of a nation, the entire nation, a continent or the world e.g., influenza pandemics of 1918 and 1957, cholera El Tor in 1962 (still continuing) and acute haemorrhagic conjunctivitis in 1971 and 1981.

EXOTIC

Diseases which are imported into a country in which they do not otherwise occur, as for example, rabies in UK. An example is the occurrence of epidemic polyarthritis in visitors to Fizi, due to Ross River virus (an alpha virus presumed to have been introduced by infected mosquitoes harboured in aircraft *(101)*.

ZOONOSES

An infection or infectious disease transmissible under

natural conditions from vertebrate animals to man. May be enzootic or epizootic – e.g., rabies, plague, bovine tuberculosis, anthrax, brucellosis, salmonellosis, endemic typhus, hydatidosis, etc. In recent years several new zoonoses have emerged, e.g., Kyasanur forest disease, Monkeypox, Lassa fever, etc.

The term zoonoses has been further amplified as follows : (a) *anthropozoonoses* : that is, infections transmitted to man from vertebrate animals, e.g., rabies, plague, hydatid disease, anthrax and trichinosis; (b) *zooanthroponoses* : that is, infections transmitted from man to vertebrate animals, e.g., human tuberculosis in cattle; and (c) *amphixenoses* : that is infections maintained in both man and lower vertebrate animals that may be transmitted in either direction, e.g., *T.cruzi,* and *S.japonicum (102).*

EPIZOOTIC

An outbreak (epidemic) of disease in an animal population (often with the implication that it may also affect human populations) *(2).* Only a few zoonotic agents cause major epidemics. Notable among these are the agents of anthrax, brucellosis, rabies, influenza, Rift valley fever, Q fever, Japanese encephalitis and equine encephalitis. The study of epizootic diseases is given the name of epizootiology.

EPORNITHIC

An outbreak (epidemic) of disease in a bird population *(2).*

ENZOOTIC

An endemic occurring in animals e.g., anthrax, rabies, brucellosis, bovine tuberculosis, endemic typhus and tick typhus.

NOSOCOMIAL INFECTION

Nosocomial (hospital acquired) infection is an infection originating in a patient while in a hospital or other health care facility. It denotes a new disorder (unrelated to the patient's primary condition) associated with being in a hospital *(2).* That is, it was not present or incubating at the time of admission or the residual of an infection acquired during a previous admission. It includes infections acquired in the hospital but appearing after discharge, and also such infections among the staff of the facility *(99).* Examples include infection of surgical wounds, hepatitis B and urinary tract infections.

OPPORTUNISTIC INFECTION

This is infection by an organism(s) that takes the opportunity provided by a defect in host defence to infect the host and hence cause disease. The organisms include *Herpes simplex, Cytomegalovirus, Toxoplasma, M. tuberculosis, M. avium intracellulare, pneumocystis,* etc. (For example, opportunistic infections are very common in AIDS). Infection by an organism that is not normally pathogenic, but can cause disease if resistance is lowered.

IATROGENIC (PHYSICIAN–INDUCED) DISEASE

Any untoward or adverse consequence of a preventive, diagnostic or therapeutic regimen or procedure, that causes impairment, handicap, disability or death *(103)* resulting from a physician's professional activity or from the professional activity of other health professionals *(2).* The disease may be serious enough to prolong the hospital stay, require special treatment or actually threaten life. Most of the episodes are related to drug therapy, immunization or diagnostic procedures, e.g., reactions to penicillin and immunizing agents, aplastic anaemia following the use of chloramphenicol, childhood leukaemia due to prenatal X-rays, hepatitis B following blood transfusion, etc. These are all preventable. In short, iatrogenic disease is a hazard of health care.

SURVEILLANCE

Surveillance has been defined as "the continuous scrutiny of the factors that determine the occurrence and distribution of disease and other conditions of illhealth. Surveillance is essential for effective control and prevention, and includes the collection, analysis, interpretation and distribution of relevant data for action *(104).*

Surveillance also connotes exercise of continuous scrutiny of health indices, nutritional status, environmental hazards, health practices and other factors that may affect health. Thus we have epidemiological surveillance *(105),* nutritional surveillance *(106),* demographic surveillance *(107),* serological surveillance, etc.

The main purpose of surveillance is to detect changes in trend or distribution in order to initiate investigative or control measures *(2).*

ERADICATION

Termination of all transmission of infection by extermination of the infectious agent through surveillance and containment *(2).* Eradication is an absolute process, an "all or none" phenomenon, restricted to termination of an infection from the whole world. It implies that disease will no longer occur in a population. To-date, only one disease has been eradicated, that is smallpox.

The term *elimination* is sometimes used to describe "eradication" of disease (e.g., measles) from a large geographic region or political jurisdiction *(2).* In the state of our present knowledge, diseases which are amenable to eradication are measles, diphtheria, polio and guinea worm.

DYNAMICS OF DISEASE TRANSMISSION

Communicable diseases are transmitted from the reservoir/source of infection to susceptible host. Fig.16 illustrates the medical model of an infectious disease. Basically there are three links in the chain of transmission, viz, the reservoir, modes of transmission and the susceptible host.

Sources and reservoir

The starting point for the occurrence of a communicable disease is the existence of a reservoir or source of infection. The **source** of infection is defined as "the person, animal, object or substance from which an infectious agent passes or is disseminated to the host" *(99).* A **reservoir** is defined as "any person, animal, arthropod, plant, soil or substance (or combination of these) in which an infectious agent lives and multiplies, on which it depends primarily for survival, and where it reproduces itself in such manner that it can be transmitted to a susceptible host" *(99).* In short, the reservoir is the natural habitat in which the organism metabolizes and replicates.

The terms reservoir and source are not always synonymous. For example, in hookworm infection, the reservoir is man, but the source of infection is the soil contaminated with infective larvae. In tetanus, the reservoir and source are the same, that is soil. In typhoid fever, the

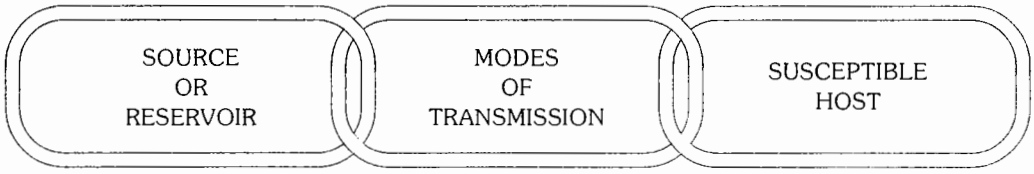

FIG. 16
Chain of Infection

reservoir of infection may be a case or carrier, but the source of infection may be faeces or urine of patients or contaminated food, milk or water. Thus the term "source" refers to the immediate source of infection and may or may not be a part of reservoir.

The term *homologous reservoir* is applied when another member of the same species is the victim, as for example man is the principal reservoir for some enteric pathogens, e.g., *vibrio cholerae*. The term heterologous is applied when the infection is derived from a reservoir other than man, as for example animals and birds infected with salmonella.

The reservoir may be of three types :

1. Human reservoir
2. Animal reservoir, and
3. Reservoir in non-living things.

1. Human reservoir

By far the most important source or reservoir of infection for humans is man himself. He may be a case or carrier. Man is often described as his own enemy because most of the communicable diseases of which man is heir to are contracted from human sources.

a. CASES

A case is defined as "a person in the population or study group identified as having the particular disease, health disorder or condition under investigation" *(2)*. A variety of criteria (e.g., clinical, biochemical, laboratory) may be used to identify cases. Broadly, the presence of infection in a host may be clinical, subclinical or latent. These variations in the manifestations of disease are referred to as "spectrum of disease" or "gradient of infection" (see page 39).

(1) The *clinical* illness may be mild or moderate, typical or atypical, severe or fatal depending upon the gradient of involvement. Epidemiologically, mild cases may be more important sources of infection than severe cases because they are ambulant and spread the infection wherever they go, whereas severe cases are usually confined to bed.

(2) The *subclinical cases* are variously referred to as inapparent, covert, missed or abortive cases. They are equally important as sources of infection. The disease agent may multiply in the host but does not manifest itself by signs and symptoms. The disease agent is, eliminated and contaminates the environment in the same way as clinical cases. Persons who are thus sick (unbeknown to themselves and others) contribute more than symptomatic patients to the transmission of infection to others and what is more, they do not appear in any of the statistics. Subclinical cases play a dominant role in maintaining the chain of infection (endemicity) in the community.

Subclinical infection can be detected only by laboratory tests, e.g., recovery of the organism, antibody response, biochemical and skin sensitivity tests.

Barring a few (e.g., measles), subclinical infection occurs in most infectious diseases. In some diseases (e.g., rubella, mumps, polio, hepatitis A and B, Japanese encephalitis, influenza, diphtheria), a great deal of subclinical infection occurs. Since subclinical infections occur frequently during a person's life time, they are responsible for the immunity shown by adult humans to a variety of disease–producing microbes.

(3) The term *latent infection* must be distinguished from subclinical infection. In latent infection, the host does not shed the infectious agent which lies dormant within the host without symptoms (and often without demonstrable presence in blood, tissues or bodily secretions of the host). For example, latent infection occurs in herpes simplex, Brill–Zinser disease, infections due to slow viruses, ancylostomiasis, etc. The role of latent infection in the perpetuation of certain infectious agents appears to be great *(108)*.

In epidemiological terminology, the term **primary case** refers to the first case of a communicable disease introduced into the population unit being studied. The term **index case** refers to the first case to come to the attention of the investigator; it is not always the primary case. **Secondary cases** are those developing from contact with primary case. A **suspect** case is an individual (or a group of individuals) who has all of the signs and symptoms of a disease or condition, yet has not been diagnosed as having the disease or had the cause of the symptoms connected to the suspected pathogen.

Whatever may be the "gradient of infection", all infected persons, whether clinical or subclinical, are potential sources of infection, because the disease agent is leaving the body through frequent stools, vomiting, coughing, sneezing or other means and is potentially available for transfer to a new host.

b. CARRIERS

In some diseases, either due to inadequate treatment or immune response, the disease agent is not completely eliminated, leading to a carrier state. A carrier is defined as "an infected person or animal that harbours a specific infectious agent in the absence of discernible clinical disease and serves as a potential source of infection for others" *(2)*. As a rule carriers are less infectious than cases, but epidemiologically, they are more dangerous than cases because they escape recognition, and continuing as they do to live a normal life among the population or community, they readily infect the susceptible individuals over a wider area and longer period of time, under favourable conditions. The "Typhoid Mary" is a classic example of a carrier.

The elements in a carrier state are : (a) the presence in the body of the disease agent (b) the absence of recognizable symptoms and signs of disease, and (c) the shedding of the disease agent in the discharges or excretions, thus acting as a source of infection for other persons.

Carriers may be classified as below :

A. Type
- (a) Incubatory
- (b) Convalescent
- (c) Healthy

B. Duration
- (a) Temporary
- (b) Chronic

C. Portal of exit
- (a) Urinary
- (b) Intestinal
- (c) Respiratory
- (d) Others

A. **By type** : (a) INCUBATORY CARRIERS : Incubatory carriers are those who shed the infectious agent during the incubation period of disease. That is, they are capable of infecting others before the onset of illness. This usually occurs during the last few days of the incubation period, e.g., measles, mumps, polio, pertussis, influenza, diphtheria and hepatitis B. (b) CONVALESCENT CARRIERS : That is, those who continue to shed the disease agent during the period of convalescence, e.g., typhoid fever, dysentery (bacillary and amoebic), cholera, diphtheria and whooping cough. In these diseases, clinical recovery does not coincide with bacteriological recovery. A convalescent carrier can pose a serious threat to the unprotected household members and those in the immediate environment, as in the case of a typhoid fever patient who may excrete the bacilli for 6–8 weeks. This highlights the importance of bacteriological surveillance of carriers, after clinical recovery. (c) HEALTHY CARRIERS : Healthy carriers emerge from subclinical cases. They are victims of subclinical infection who have developed carrier state without suffering from overt disease, but are nevertheless shedding the disease agent, e.g., poliomyelitis, cholera, meningococcal meningitis, salmonellosis, and diphtheria. It is well to remember that a person whose infection remains subclinical may or may not be a carrier. For example, in polio the infection may remain subclinical and the person may act as a temporary carrier by virtue of shedding the organism. On the other hand, in tuberculosis, most persons with positive tuberculin test do not actively disseminate tubercle bacilli and therefore are not labelled as carrier *(36)*.

B. **By duration** : (a) TEMPORARY CARRIERS : Temporary carriers are those who shed the infectious agent for short periods of time. In this category may be included the incubatory, convalescent and healthy carriers. (b) CHRONIC CARRIERS : A chronic carrier is one who excretes the infectious agent for indefinite periods. Chronic carrier state occurs in a number of diseases, e.g., typhoid fever, hepatitis B, dysentery, cerebro-spinal meningitis, malaria, gonorrhoea, etc. Chronic carriers are far more important sources of infection than cases. The longer the carrier state, the greater the risk to the community. Some carriers excrete the infectious agent only intermittently and some continuously. The duration of the carrier state varies with the disease. In typhoid fever and hepatitis B, the chronic carrier state may last for several years; in chronic dysentery, it may last for a year or longer. In diphtheria, the carrier state is associated with infected tonsils; in typhoid fever with gall bladder disease. Chronic carriers are known to reintroduce disease into areas which are otherwise free of infection (e.g., malaria). Therefore their early detection and treatment are essential to limit the spread of infection. Carriers of avirulent organisms are called *pseudo-carriers*. Pseudo-carriers are not important epidemiologically.

C. **By portal of exit** : Carriers may also be classified according to the portal of exit of the infectious agent. Thus we have urinary carriers, intestinal carriers, respiratory carriers, nasal carriers, etc. Skin eruptions, open wounds and blood are also portals of exit. In typhoid fever, the urinary carrier is more dangerous than an intestinal carrier. A typhoid carrier working in a food establishment or water works is more dangerous than a typhoid carrier working in an office establishment. Thus the portal of exit and the occupational status of the carrier are important epidemiological considerations.

2. Animal reservoir

The source of infection may sometimes be animals and birds. These, like the human sources of infection, may be cases or carriers. The diseases and infections which are transmissible to man from vertebrates are called zoonoses. There are over 100 zoonotic diseases which may be conveyed to man from animals and birds. The best known examples are rabies, yellow fever and influenza. The role of pigs and ducks in the spread of epidemic and pandemic influenza both as reservoirs, carriers and "amplifying hosts" is now well established. Pigeons in cities can lead to infection with chlamydia; dust mites from them can cause allergy in man. Ornithosis and arboviruses can be transmitted to man from various birds. Wild birds, in particular, are important hosts in the transmission cycles of most of the mosquito-borne encephalitis and several mosquito-borne undifferentiated febrile diseases *(101)*. Histoplasmosis is carried all over the world by birds *(109)*. As birds migrate from one locality to another they may carry ticks infected with viruses and rickettsiae that may cause disease in humans. In short, the migrations and movements of animals and birds may carry serious epizootiological and epidemiological risks. There is evidence that genetic recombination between animal and human viruses might produce "new" strains of viruses (e.g., influenza viruses).

3. Reservoir in non-living things

Soil and inanimate matter can also act as reservoirs of infection. For example, soil may harbour agents that cause tetanus, anthrax, coccidioidomycosis and mycetoma.

MODES OF TRANSMISSION

Communicable diseases may be transmitted from the reservoir or source of infection to a susceptible individual in many different ways, depending upon the infectious agent, portal of entry and the local ecological conditions. As a rule, an infectious disease is transmitted by only one route, e.g., typhoid fever by vehicle transmission and common cold by direct contact. But there are others which may be transmitted by several routes e.g., AIDS, salmonellosis, hepatitis B, brucellosis, Q fever, tularemia etc. The multiple transmission routes enhance the survival of the infectious agent. The mode of transmission of infectious diseases may be classified as below *(2,99)*.

A DIRECT TRANSMISSION
1. Direct contact
2. Droplet infection
3. Contact with soil
4. Inoculation into skin or mucosa
5. Transplacental (vertical)

B INDIRECT TRANSMISSION
1. Vehicle-borne
2. Vector-borne
   a. Mechanical
   b. Biological
3. Air-borne
   a. Droplet nuclei
   b. Dust
4. Fomite-borne
5. Unclean hands and fingers

A. Direct transmission

(1) *Direct contact* : Infection may be transmitted by direct contact from skin to skin, mucosa to mucosa, or mucosa to skin of the same or another person. This implies direct and essentially immediate transfer of infectious agents from the reservoir or source to a susceptible individual, without an intermediate agency, e.g., skin–to–skin contact as by touching, kissing or sexual intercourse or continued close contact. Direct contact not only reduces the period for which the organism will have to survive outside the human host but also ensures a larger dose of infection. Diseases transmitted by direct contact include STD and AIDS, leprosy, leptospirosis, skin and eye infections. (2) *Droplet infection* : This is direct projection of a spray of droplets of saliva and nasopharyngeal secretions during coughing, sneezing, (Fig.17) or speaking and spitting, talking into the surrounding atmosphere. The expelled droplets may impinge directly upon the conjunctiva, oro-respiratory mucosa or skin of a close contact. Particles of 10 mmm or greater in diameter are filtered off by nose. Those 5 mmm or less can penetrate deeply and reach the alveoli. The droplet spread is usually, limited to a distance of 30–60 cm between source and host *(110)*. In infectious diseases, these droplets, which may contain millions of bacteria and viruses can be a source of infection to others. When a healthy susceptible person comes within the range of these infected droplets he is likely to inhale some of them and acquire infection. Diseases transmitted by droplet spread include many respiratory infections, eruptive fevers, many infections of the nervous system, common cold, diphtheria, whooping cough, tuberculosis, meningococcal meningitis, etc. The potential for droplet spread is increased in conditions of close proximity, overcrowding and lack of ventilation. (3) *Contact with soil* : The disease agent may be acquired by direct exposure of susceptible tissue to the disease agent in soil, compost or decaying vegetable matter in which it normally leads a saprophytic existence e.g., hookworm larvae, tetanus, mycosis etc. (4) *Inoculation into skin or mucosa* : The disease agent may be inoculated directly into the skin or mucosa e.g., rabies virus by dog bite, hepatitis B virus through contaminated needles and syringes etc., and (5) *Transplacental (or vertical) transmission* : Disease agents can be transmitted transplacentally *(111, 112)*. This is another form of direct transmission. Examples include the so-called TORCH agents (Toxoplasma gondii, rubella virus, cytomegalovirus and herpes virus), varicella virus, syphilis, hepatitis B, Coxsackie B and AIDS. Some of the non-living agents (e.g., thalidomide, diethylstilbestrol) can also be transmitted vertically. In these cases, the disease agent produces malformations of the embryo by disturbing its development.

FIG. 17
Droplets sprayed into the air from a sneeze
(From : The Medical Clinics of North America, 1944 . p. 1301)

B. Indirect transmission

This embraces a variety of mechanisms including the traditional 5 F's – "flies, fingers, fomites, food and fluid". An essential requirement for indirect transmission is that the infectious agent must be capable of surviving outside the human host in the external environment and retain its basic properties of pathogenesis and virulence till it finds a new host. This depends upon the characteristics of the agent, the inanimate object and the influence of environmental factors such as temperature and humidity. If the disease agent acquires drug resistance, it will further facilitate its spread. Indirect transmission can occur in a variety of settings :

1. Vehicle-borne

Vehicle-borne transmission implies transmission of the infectious agent through the agency of water, food (including raw vegetables, fruits, milk and milk products), ice, blood, serum, plasma or other biological products such as tissues and organs. Of these water and food are the most frequent vehicles of transmission, because they are used by everyone. The infectious agent may have multiplied or developed in the vehicle (e.g., *S. aureus* in food) before being transmitted; or only passively transmitted in the vehicle (e.g., hepatitis A virus in water). Diseases transmitted by water and food include chiefly infections of the alimentary tract, e.g., acute diarrhoeas, typhoid fever, cholera, polio, hepatitis A, food poisoning and intestinal parasites. Those transmitted by blood include hepatitis B, malaria, syphilis, brucellosis, trypanasomes (Chaga's disease), infectious mononucleosis and cytomegalovirus infection *(113)*. Organ transplantation may result in the introduction of the disease agent such as cytomegalovirus in association with kidney transplants.

The epidemiological features of vehicle transmission are : (a) if the dose of contamination is heavy, the outbreak may be explosive as in the case of cholera and hepatitis A epidemics (b) cases are initially confined to those who are exposed to the contaminated vehicle, in some infections (c) when secondary cases occur, the primary case may be obscured (d) the distance travelled by the infectious agent may be great, e.g., outbreaks of food poisoning (e) it is not always possible to isolate the infectious agent in the incriminated vehicle, e.g., typhoid bacilli in contaminated water (f) when the vehicle is controlled or withdrawn, the epidemic subsides, e.g., epidemics of cholera, and (g) the common source of infection is often traceable.

2. Vector-borne

In infectious disease epidemiology, vector is defined as an arthropod or any living carrier (e.g., snail) that transports an infectious agent to a susceptible individual. Transmission by a vector may be mechanical or biological. In the latter

case, the disease agent passes through a developmental cycle or multiplication in the vector.

Epidemiological classification of vector-borne diseases

I. By vector

a) Invertebrate type : Arthropod vectors fall into seven orders largely
   (1) Diptera – flies and mosquitoes
   (2) Siphonaptera – fleas
   (3) Orthoptera – cockroaches
   (4) Anoplura – sucking lice
   (5) Hemiptera – bugs, including kissing bugs
   (6) Acarina – ticks and mites
   (7) Copepoda – cyclops

b) Vertebrate type – Mice, rodents, bats.

II. By transmission chain

Vector-borne diseases are classified under heterogeneous infection chain and involve three principal patterns :

a) Man and a non–vertebrate host
   1) Man–arthropod–man (malaria)
   2) Man–snail–man (schistosomiasis).

b) Man, another vertebrate host, and a non–vertebrate host
   1) Mammal–arthropod–man (plague)
   2) Bird–arthropod–man (encephalitis).

c) Man and 2 intermediate hosts
   1) Man–cyclops-fish–man (fish tape worm)
   2) Man–snail–fish–man (Clonorchis sinensis)
   3) Man–snail–crab–man (Paragonimiasis).

III. By methods in which vectors transmit agent

a) Biting
b) Regurgitation
c) Scratching-in of infective faeces
d) Contamination of host with body fluids of vectors.

IV. By methods in which vectors are involved in the transmission and propagation of parasites

(a) *Mechanical transmission* : The infectious agent is mechanically transported by a crawling or flying arthropod through soiling of its feet or proboscis; or by passage of organisms through its gastrointestinal tract and passively excreted. There is no development or multiplication of the infectious agent on or within the vector.

(b) *Biological transmission* : The infectious agent undergoing replication or development or both in vector and requires an incubation period before vector can transmit. Biological transmission is of three types : (i) *Propagative* : The agent merely multiplies in vector, but no change in form, e.g., plague bacilli in rat fleas. (ii) *Cyclo-propagative* : The agent changes in form and number, e.g., malaria parasites in mosquito. (iii) *Cyclo-developmental* : The disease agent undergoes only development but no multiplication, e.g., microfilaria in mosquito.

When the infectious agent is transmitted vertically from the infected female to her progeny in the vector, it is known as *transovarial transmission*. Transmission of the disease agent from one stage of the life cycle to another as for example nymph to adult is known as *transstadial transmission*.

The factors which influence the ability of vectors to transmit disease are : (a) host feeding preferences (b) infectivity, that is ability to transmit the disease agent (c) susceptibility, that is ability to become infected (d) survival rate of vectors in the environment (e) domesticity, that is degree of association with man, and (f) suitable environmental factors. Seasonal occurrence of some diseases (e.g., malaria) may be related to intense breeding and thereby greater density of the insect vector during certain periods of the year.

3. Airborne

(1) *Droplet nuclei* : "Droplet nuclei" are a type of particles implicated in the spread of airborne infection. They are tiny particles (1–10 microns range) that represent the dried residue of droplets *(2)*. They may be formed by (a) evaporation of droplets coughed or sneezed into the air or (b) generated purposefully by a variety of atomizing devices (aerosols). They may also be formed accidentally in microbiological laboratories, in abattoirs, rendering plants or autopsy rooms *(99)*. The droplet nuclei may remain airborne for long periods of time, some retaining and others losing infectivity or virulence. They not only keep floating in the air but may be disseminated by air currents from the point of their origin. Particles in the 1–5 micron range are liable to be easily drawn into the alveoli of the lungs and may be retained there. Diseases spread by droplet nuclei include tuberculosis, influenza, chickenpox, measles, Q fever and many respiratory infections. (Not considered airborne are droplets and other large particles which promptly settle out). Mention must also be made of the role of airborne spread of toxic air pollutants including "smog" resulting in air pollution epidemics.

(2) *Dust* : Some of the larger droplets which are expelled during talking, coughing or sneezing, settle down by their sheer weight on the floor, carpets, furniture, clothes, bedding, linen and other objects in the immediate environment and become part of the dust. A variety of infectious agents (e.g., streptococci, other pathogenic bacteria, viruses and fungal spores) and skin squamae have been found in the dust of hospital wards and living rooms. Some of them (e.g., tubercle bacilli) may survive in the dust for considerable periods under optimum conditions of temperature and moisture. During the act of sweeping, dusting and bed–making, the dust is released into the air and becomes once again airborne. Dust particles may also be blown from the soil by wind; this may include fungal spores. Coccidioidomycosis is an example of a disease spread through airborne transmission of fungal spores *(36)*. Other diseases carried by infected dust include streptococcal and staphylococcal infection, pneumonia, tuberculosis, Q fever and psittacosis. Airborne dust is primarily inhaled, but may settle on uncovered food and milk. This type of transmission is most common in hospital–acquired (nosocomial) infection.

4. Fomite-borne

Fomites (singular; fomes) are inanimate articles or substances other than water or food contaminated by the infectious discharges from a patient and capable of harbouring and transferring the infectious agent to a healthy person. Fomites include soiled clothes, towels, linen, handkerchiefs, cups, spoons, pencils, books, toys, drinking glasses, door handles, taps, lavatory chains, syringes, instruments and surgical dressings. The fomites play an important role in indirect infection. Diseases transmitted by fomites include diphtheria, typhoid fever, bacillary dysentery, hepatitis A, eye and skin infections.

5. Unclean hands and fingers

Hands are the most common medium by which pathogenic agents are transferred to food from the skin, nose, bowel, etc as well as from other foods. The transmission takes place both directly (hand–to–mouth) and indirectly. Examples include staphylococcal and streptococcal infections, typhoid fever, dysentery, hepatitis A and intestinal parasites. Unclean hands and fingers imply lack of personal hygiene. Lack of personal hygiene coupled with poor sanitation favour person–to–person transmission of infection, an example is the 1984 dysentery epidemic in India.

SUSCEPTIBLE HOST

Successful parasitism

Four stages have been described in successful parasitism : (a) First, the infectious agent must find a PORTAL OF ENTRY by which it may enter the host. There are many portals of entry, e.g., respiratory tract, alimentary tract, genitourinary tract, skin, etc. Some organisms may have more than one portal of entry, e.g., hepatitis B, Q fever, brucellosis. (b) On gaining entry into the host, the organisms must reach the appropriate tissue or "SITE OF ELECTION" in the body of the host where it may find optimum conditions for its multiplication and survival. (c) Thirdly, the disease agent must find a way out of the body (PORTAL OF EXIT) in order that it may reach a new host and propagate its species. If there is no portal of exit, the infection becomes a dead-end infection as in rabies, bubonic plague, tetanus and trichinosis. (d) After leaving the human body, the organism must survive in the external environment for sufficient period till a new host is found. In addition, a successful disease agent should not cause the death of the host but produce only a low-grade immunity so that the host is vulnerable again and again to the same infection. The best example is common cold virus.

Incubation period

An infection becomes apparent only after a certain incubation period, which is defined as "the time interval between invasion by an infectious agent and appearance of the first sign or symptom of the disease in question" *(2)*. During the incubation period, the infectious agent undergoes multiplication in the host. When a sufficient density of the disease agent is built up in the host, the health equilibrium is disturbed and the disease becomes overt. Also of interest to the epidemiologist is the **median incubation period,** defined as the time required for 50 per cent of the cases to occur following exposure. These concepts are explained in Fig.18. The factors which determine the incubation period include the generation time of the particular pathogen, infective dose, portal of entry and individual susceptibility. As a rule, infectious diseases are not communicable during the incubation period, but there are exceptions, as for example, measles, chickenpox, whooping cough and hepatitis A are communicable during the later part of the incubation period.

The length of the incubation period is characteristic of each disease. There is a minimum incubation period for every disease before which no illness can occur. That is, incubation period varies for different infectious diseases, and also from one person to another with the same disease. In some, the incubation period is very short ranging from a few hours to 2–3 days, e.g., staphylococcal food poisoning, cholera, bacillary dysentery and influenza. In some, the incubation period is of median length ranging from 10 days to 3 weeks; in this category, there are many examples : typhoid infections, virus diseases such as chickenpox, measles and mumps. Then there are infections with longer incubation periods (ranging from weeks to months or years) and whose incubation time is difficult to measure precisely, e.g., hepatitis A and B, rabies, leprosy and slow virus diseases.

Non-infectious diseases such as cancer, heart disease and mental illness also have incubation periods, which may be months or years. The term **latent period** is used in non-infectious diseases as the equivalent of incubation period in infectious diseases *(36)*. Latent period has been defined as "the period from disease initiation to disease detection" *(2)*. In chronic disease, the agent–host interactions leading to a sequence of cellular changes are not well understood.

Incubation period is of fundamental importance in epidemiological studies : (a) *Tracing the source of infection and contacts* : In the case of a disease with a short incubation period ranging from a few hours to a few days, it is relatively simple to trace the source of infection and "follow the trail" of the spread of infection as in the case of food poisoning, bacillary dysentery or typhoid fever. The position is quite different with diseases whose incubation period is of medium length (10 days to 3 weeks) or longer. So many things will have happened and such varied contacts taken place that the cause–effect relationship becomes "diluted". We will have a whole gamut of possible causes from among which we have to single out the main cause. Once the source of infection is traced, then only it will be possible to institute appropriate control measures. (b) *Period of surveillance* : Incubation period is useful in determining the period of surveillance (or quarantine) which may be advised (A in Fig. 18). This period is usually equal to the maximum incubation period of

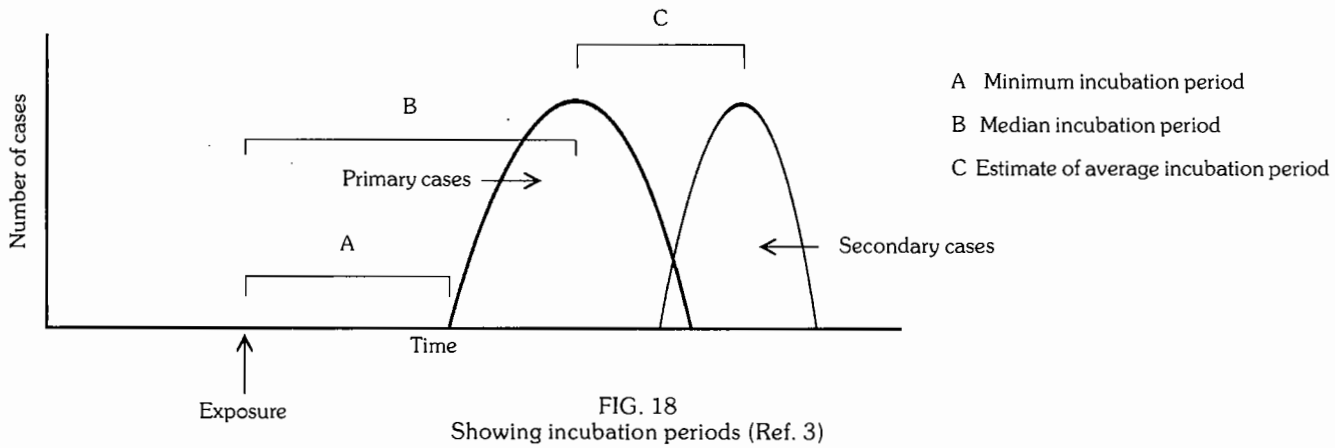

FIG. 18
Showing incubation periods (Ref. 3)

the disease. (c) *Immunization* : Prophylactically, a knowledge of incubation period helps us to prevent clinical illness by human immunoglobulins and antisera. (d) *Identification of point source or propagated epidemics* : In a point source epidemic, all the cases occur within one incubation period of the disease; in a propagated epidemic, cases occur later than the known length of the incubation period; and (e) *Prognosis* : Incubation period can also be used in estimating the prognosis of a disease. In some diseases (e.g., tetanus, rabies), the shorter the incubation period, the worse the prognosis of the disease. Thus prognosis is related to the incubation period of the disease *(13)*.

Serial interval

In actual practice we seldom know precisely the incubation period of a disease. But we know, when an outbreak of disease occurs, say in a family which is the smallest group and also a closed group, there is an initial primary case. The primary case is followed by 2 or 3 secondary cases within a short time. The gap in time between the onset of the primary case and the secondary case is called the "serial interval". By collecting information about a whole series of such onsets, we get a distribution of secondary cases from which we can guess the incubation period of disease.

Generation time

Another concept in infectious disease epidemiology is "generation time". It is defined as "the interval of time between receipt of infection by a host and maximal infectivity of that host" *(2)*. In general, generation time is roughly equal to the incubation period. However, these two terms are not the same. The time of maximum communicability may precede or follow the incubation period. For example, in mumps, communicability appears to reach its height about 48 hours before the onset of swelling of the salivary glands *(36)*. With person–to–person transmission of infection, the interval between cases is determined by the generation time *(2)*. A further difference is that the term "incubation period" can only be applied to infections that result in manifest disease, whereas "generation time" refers to transmissions of infection, whether clinical or subclinical *(36)*.

Communicable period

The communicable period is defined as "the time during which an infectious agent may be transferred directly or indirectly from an infected person to another person, from an infected animal to man, or from an infected person to an animal, including arthropods" *(2)*. Communicability varies in different diseases. Some diseases are more communicable during the incubation period than during actual illness. Communicability of some diseases can be reduced by early diagnosis and treatment. An important measure of communicability is Secondary attack rate.

Secondary attack rate

Secondary attack rate (SAR) is defined as "the number of exposed persons developing the disease within the range of the incubation period, following exposure to the primary case" *(4)*. It is given by the formula :

$$\text{SAR} = \frac{\text{Number of exposed persons developing the disease within the range of the incubation period}}{\text{Total number of exposed/"susceptible" contacts}} \times 100$$

The denominator consists of all persons who are exposed to the case. More specifically, the denominator may be restricted only to "susceptible" contacts, if means are available to distinguish the susceptible persons from the immune *(4)*. The primary case is excluded from both the numerator and denominator.

Supposing there is a family of 6 consisting of 2 parents (already immune) and 4 children who are susceptible to a specific disease, say measles. There occurs a primary case and within a short time 2 secondary cases among the remaining children. The secondary attack rate is 2/3 or 66.6 per cent. The primary case is excluded from both numerator and denominator.

Secondary attack rate is limited in its application to infectious diseases in which the primary case is infective for only a short period of time measured in days (e.g., measles and chickenpox). When the primary case is infective over a long period of time (e.g., tuberculosis), duration of exposure is an important factor in determining the extent of spread *(13)*. It is indicated by the formula :

$$\text{SAR} = \frac{\text{Number of contacts developing tuberculosis}}{\text{Number of person–weeks (months or years) of exposure}} \times 100$$

Another limitation of secondary attack rate is to identify "susceptibles". It is feasible only in diseases such as measles and chickenpox where history can be used as a basis for identification; but in many others, susceptibles cannot be readily identified (e.g., influenza). In such cases, secondary attack rate is based on all exposed family members and still remains a useful tool *(13)*. Where there are numerous subclinical cases, secondary attack rate has a limited meaning. Further spread cannot be measured without laboratory investigations *(108)*.

An additional advantage of the secondary attack rate is that vaccinees and non-vaccinees from several families can be added to determine the overall attack rates in the vaccinated and unvaccinated populations, provided the same definitions for cases and immunization status are used.

Secondary attack rate was initially developed to measure the spread of an infection within a family, household or any closed aggregate of persons who have had contact with a case of disease. It is also useful to determine whether a disease of unknown aetiology (e.g., Hodgkin's disease) is communicable or not; and in evaluating the effectiveness of control measures such as isolation and immunization.

HOST DEFENCES

Host defences against infection are at once local and systemic, non-specific and specific, and humoral and cellular. It is difficult to identify any infectious agent that fails to stimulate multiple host defence mechanisms. The concept of overlapping host defences is crucial to our understanding of susceptibility to infection. This overlapping underlies the reasonable measure of good health in the face of an apparently significant host immune defect *(114)*.

There is a phase of passive immunity transmitted to the baby from the mother across the placenta. Maternal antibody transmitted to infant is gradually lost over a period of 6 months. Thus a large proportion of infants remain free from potent infection up to 3 months, or even longer. There is good evidence that this protective "biological shield" is

due to the presence of high levels of immunoglobulins IgM and especially IgG in the cord blood and plasma of infants born of immune mothers. It has been postulated that some other factors (breast milk, presence of fetal haemoglobulin), are also responsible for the transient protection of infants.

SPECIFIC DEFENCES

Specific defences come into play, once microorganisms have breached local defence mechanisms. By virtue of these defences, the host is able to recognize, destroy and eliminate antigenic material (e.g., bacteria, viruses, proteins, etc.) foreign to his own. A person is said to be immune when he possesses "specific protective antibodies or cellular immunity as a result of previous infection or immunization, or is so conditioned by such previous experience as to respond adequately to prevent infection and/or clinical illness following exposure to a specific infectious agent" *(99)*.

The specific defences may be discussed for convenience under the following heads :

1. Active immunity
   - (1) Humoral immunity
   - (2) Cellular immunity
   - (3) Combination of the above.
2. Passive immunity
   - (1) Normal human Ig
   - (2) Specific human Ig
   - (3) Animal antitoxins or antisera.

1. Active immunity

It is the immunity which an individual develops as a result of infection or by specific immunization and is usually associated with presence of antibodies or cells having a specific action on the microorganism concerned with a particular infectious disease or on its toxin *(99)*. In other words, active immunity depends upon the humoral and cellular responses of the host. The immunity produced is specific for a particular disease, i.e., the individual in most cases is immune to further infection with the same organism or antigenically related organism for varying periods depending upon the particular disease.

Active immunity may be acquired in 3 ways :

(a) following clinical infection, e.g., chickenpox, rubella and measles.

(b) following subclinical or inapparent infection, e.g., polio and diphtheria.

(c) following immunization with an antigen which may be a killed vaccine, a live attenuated vaccine or toxoid.

The immune response

(a) PRIMARY RESPONSE : When an antigen is administered for the first time to an animal or human who has never been exposed to it, there is a latent period of induction of 3 to 10 days before antibodies appear in the blood (Fig. 19). The antibody that is elicited first is entirely of the IgM type. The IgM antibody titre rises steadily during the next 2–3 days or more, reaches a peak level and then declines almost as fast as it developed. Meanwhile, if the antigenic stimulus was sufficient, IgG antibody appears in a few days. IgG reaches a peak in 7–10 days and then gradually falls over a period of weeks or months (Fig. 19).

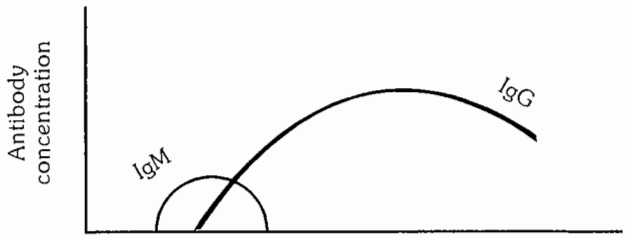

FIG. 19
The primary response

The nature and extent of primary response to an antigen is determined by a number of factors, e.g., dose of antigen, nature of antigen, route of administration, adjuvants, nutritional status of the host, etc *(115)*. For example, with small doses of antigen, only IgM type of response may be induced, and successive small doses of antigen at suitable intervals may also induce IgM antibody. The antigenic dose required for the induction of IgG is about 50 times that which is required to induce IgM antibody.

An important outcome of primary antigenic challenge is education of the reticuloendothelial system of the body. There is production of what are known as "memory cells" or "primed cells" by both B and T lymphocytes. These cells are responsible for the "immunological memory" which becomes established after immunization. In fact, the purpose of immunization is to develop immunological memory.

(b) SECONDARY (BOOSTER) RESPONSE: The response to a booster dose differs in a number of ways from the primary response : (1) shorter latent period. (2) production of antibody more rapid. (3) antibody more abundant. (4) antibody response maintained at higher levels for a longer period of time, and (5) the antibody elicited tends to have a greater avidity or capacity to bind to the antigen.

The secondary response also involves the production of IgM and IgG antibody. Collaboration between B and T cells is necessary to initiate a secondary response. There is a brief production of IgM antibody and much larger and more prolonged production of IgG antibody. This accelerated response is attributed to immunological memory. The immune response (primary and secondary) and immunological memory are the basis of vaccination and revaccination.

(1) Humoral immunity

Humoral immunity comes from the B-cells (bone-marrow derived lymphocytes) which proliferate and manufacture specific antibodies after antigen presentation by macrophages. The antibodies are localized in the immunoglobulin fraction of the serum. Immunoglobulins are divided into 5 main classes – IgG, IgM, IgA, IgD and IgE (and sub-classes within them) – each class representing a different functional group. These antibodies circulate in the body and act directly by neutralizing the microbe, or its toxin or rendering the microbe susceptible to attack by the polymorphonuclear leucocyte and the monocyte. The complement system, together with antibodies is necessary for efficient phagocytosis of bacteria *(116)*.

The antibodies are specific, i.e., they react with the same antigen which provoked their production, or a closely related one. As a result of this specificity, host response mediated by antibodies is somewhat limited in that it will not provide protection against more than one antigen *(117)*. This specificity has been a formidable problem in the production

of vaccines. For example, there are numerous antigenic types of rhinoviruses, and it is not possible to expect a single vaccine to be effective against all these types *(117)*.

(2) Cellular immunity

Although antibodies are quite effective in combating most infectious diseases, humoral immunity does not cover all the situation that one finds in infectious diseases *(117)*. For example, some pathogens (e.g., *M. leprae, M. tuberculosis, S. typhi, Candida albicans* and many viruses) escape the bactericidal action of leukocyte. They can even multiply in the mononuclear leukocyte (macrophage). However, these macrophages can be stimulated by substances (lymphokines) secreted by specific stimulated T–lymphocytes (thymus – derived lymphocytes). The activated macrophages perform a much more efficient phagocytic function than non-activated macrophages *(114)*.

It is now well-recognized that cellular immunity plays a fundamental role in resistance to infection. It is mediated by the T–cells which differentiate into sub-populations able to help B–lymphocytes. The T–cells do not secrete antibody, but are responsible for recognition of antigen. On contact with antigen, the T–cells initiate a chain of responses e.g., activation of macrophages, release of cytotoxic factors, mononuclear inflammatory reactions, delayed hypersensitivity reactions, secretion of immunological mediators (e.g., immune interferon), etc. There is growing evidence that cellular immunity is responsible for immunity against many diseases including tuberculosis, brucellosis and also for the body's rejection of foreign material, such as skin grafts. The importance of cell–mediated immunity can be appreciated from the fact that a child born with a defect in humoral antibody production may survive for as long as 6 years without replacement therapy, but a severe defect in cell–mediated immunity will result in death within the first six months of life *(118)*.

(3) Combination of the above

In addition to the B and T lymphoid cells which are responsible for recognizing self and non–self, very often, they cooperate with one another and with certain accessory cells such as macrophages and human K (killer) cells, and their joint functions constitute the complex events of immunity. For instance, one subset of T–cells (helper T–cells) are required for the optimal production of antibody to most antigens. Another set of T–cells (suppressor T–cells) inhibit immunoglobulin synthesis. Antibody-dependant cell-mediated (K) cytotoxic cells recognize membrane viral antigens through specific antibody, whereas natural killer (NK) cells destroy non-specifically virus-infected target cells. It is now increasingly recognized that vaccines to be effective must elicit both humoral and cell-mediated responses *(119)*.

Active immunity takes time to develop. It is superior to passive immunity because (a) the duration of protection, like that of the natural infection is frequently long–lasting (b) with few exceptions, severe reactions are rare (c) the protective efficacy of active immunization exceeds that of passive immunization, and in some instances, approaches 100 per cent, and (d) active immunization is less expensive than passive immunization. Vaccines are cheaper to produce than are antisera.

It is important to realize at this stage that an individual is immunized only against small doses of pathogenic agents or toxins. There exists a "threshold" at which resistance fails. Beyond a certain dosage, which here again varies with the individual, his physiological state and the micro-organism, the immune systems are overwhelmed and the disease develops. Many examples of this can be seen among individuals who, though immunized, nevertheless contact a typhoid or paratyphoid infection, diphtheria, or some other disease.

Moreover, many factors are involved in the maintenance of immunity. Fatigue, strange surroundings, change of diet, ingestion of drugs, and emotional shock are examples of these factors that can produce a fall in immunity or a lowering of the threshold at which resistance to infection fails *(120)*.

2. Passive immunity

When antibodies produced in one body (human or animal) are transferred to another to induce protection against disease, it is known as passive immunity. In other words, the body does not produce its own antibodies but depends upon ready-made antibodies. Passive immunity may be induced :

(a) by administration of an antibody–containing preparation (immune globulin or antiserum)
(b) by transfer of maternal antibodies across the placenta. Human milk also contains protective antibodies, (IgA).
(c) by transfer of lymphocytes, to induce passive cellular immunity – this procedure is still experimental.

Passive immunity differs from active immunity in the following respects : (a) immunity is rapidly established (b) immunity produced is only temporary (days to months) till the antibody is eliminated from the body, and (c) there is no education of the reticuloendothelial system.

Passive immunization is useful for individual who cannot form antibodies, or for the normal host who takes time to develop antibodies following active immunization.

Herd immunity

Herd immunity (or community immunity) describes a type of immunity that occurs when the vaccination of a portion of population (or herd) provides protection to unprotected individuals. Herd immunity theory proposes that in diseases passed from individual to individual, it is difficult to maintain a chain of infection when large numbers of a population are immune. The higher the number of immune individuals, the lower the likelihood that a susceptible person will come in contact with an infectious agent *(121)*.

Herd immunity provides an immunological barrier to the spread of disease in the human herd. For example, when an infectious disease is introduced into a "virgin" population, that is, population with a very low or no immunity, the attack and case fatality rates tend to be very high involving practically all susceptibles as it had happened in the very severe measles epidemic in the Faroe islands, in 1854, where the population had no previous experience of measles. The epidemic wave declined with a build-up of herd immunity following natural infection.

Elements which contribute to herd immunity are (a) occurrence of clinical and subclinical infection in the herd, (b) immunization of the herd, and (c) herd structure. Herd structure is never constant. It is subject to constant variation because of new births, deaths and population mobility. An on-going immunization programme will keep up the herd immunity at a very high level.

The herd structure includes not only the hosts (population) belonging to the herd species but also the

presence and distribution of alternative animal hosts and possible insect vectors as well as those environmental and social factors that favour or inhibit the spread of infection from host to host. The herd structure thus plays a decisive role in the immunity status of the herd.

If the herd immunity is sufficiently high, the occurrence of an epidemic is regarded as highly unlikely. If that high level of immunity is maintained and stepped up, by an on-going immunization programme, to the point where the susceptible persons are reduced to a small proportion of the population, it may lead (but not necessarily) to elimination of the disease in due course. This has been achieved in such diseases as diphtheria and poliomyelitis. In the case of smallpox, however, it may be mentioned that it was not herd immunity (although important as it was) that played a crucial role in its eradication, but elimination of the source of infection, by surveillance and containment measures. With the abolition of vaccination against smallpox, the herd immunity in the case of smallpox will naturally tend to decline with the passage of time. In the case of tetanus, however, herd immunity does not protect the individual.

Studies have shown that it is neither possible nor necessary to achieve 100 per cent herd immunity in a population to halt an epidemic or control disease, as for example, eradication of smallpox. Just how much less than 100 per cent is required is a crucial question, for which no definite answer can be given.

Herd immunity may be determined by serological surveys (serological epidemiology).

IMMUNIZING AGENTS

The immunizing agents may be classified as vaccines, immunoglobulins and antisera.

Vaccines

Over the last century, vaccination has been the most effective medical strategy to control infectious diseases. Smallpox has been eradicated world-wide and poliomyelitis has been almost eradicated. Most viral and bacterial diseases traditionally affecting children world-wide are now preventable by vaccines. Vaccination is estimated to save at least 2–3 million lives every year. The vaccines currently used are as shown in Table 29.

Vaccine is an immuno-biological substance designed to produce specific protection against a given disease. It stimulates the production of protective antibody and other immune mechanisms. Vaccines may be prepared from live modified organisms, inactivated or killed organisms, extracted cellular fractions, toxoids or combination of these.

a. Live vaccines

Live vaccines (e.g., BCG, measles, oral polio) are prepared from live or wild (generally attenuated) organisms. These organisms have been passed repeatedly in the laboratory in tissue culture or chick embryos and have lost their capacity to induce full–blown disease but retain their immunogenicity. In general, live vaccines are more potent immunizing agents than killed vaccines, the reasons being : (i) live organisms multiply in the host and the resulting antigenic dose is larger than what is injected, (ii) live vaccines have all the major and minor antigenic components, (iii) live vaccines engage certain tissues of the body, as for example, intestinal mucosa by the oral polio vaccine, and (iv) there may be other mechanisms such as the persistence of latent virus.

Live vaccines should not be administered to persons with immune deficiency diseases or to persons whose immune response may be suppressed because of leukaemia, lymphoma or malignancy or because of therapy with corticosteroids, alkylating agents, antimetabolic agents, or radiation *(123, 124)*. Pregnancy is another contraindication unless the risk of infection exceeds the risk of harm to the foetus of some live vaccines.

When two live vaccines are required they should be given either simultaneously at different sites or with an interval of atleast 3 weeks. In the case of live vaccines, protection is generally achieved with a single dose of vaccine. An additional dose is given to ensure seroconversion, e.g., 95 to 98 per cent of recipient will respond to single dose of measles vaccine. The second dose is given to ensure that 100 per cent of persons are immune. The other exception is polio vaccine which needs three or more doses to be given at spaced intervals to produce effective immunity. Live vaccines usually produce a durable immunity, but not always as long as that of the natural infection.

Live vaccines must be properly stored to retain effectiveness. Serious failures of measles and polio

TABLE 29
Vaccines currently in use

Live attenuated	Killed whole organism	Toxoid/Protein	Polysaccharide	Glycoconjugate	Recombinant
Tuberculosis (BCG)	Typhoid	Diphtheria	Pneumococcus	Hib	HBV
Yellow fever	Cholera	Tetanus	Meningococcus	Pneumococcus	Lyme disease
Polio (OPV)	Plague	Acellular Pertussis	Hib	MenACWY	Cholera toxin B
Measles	Pertussis	Anthrax	Typhoid (Vi)		HPV
Mumps	Influenza	Influenza subunit			
Rubella	Typhus				
Typhoid	Polio (IPV)				
Varicella	Rabies				
Rotavirus	JE				
Cholera	TBE				
Cold-adapted influenza	HAV				
Rotavirus reassortants					
Zoster					

BCG – Bacille Calmette-Guerin; HAV – hepatitis A virus; HBV – hepatitis B virus; Hib – Haemophilus influenzae type b; IPV – inactivated polio vaccine; JE – Japanese encephalitis; Men – meningococcus, OPV – oral polio vaccine; TBE – tick-borne encephalitis.

Source : *(122)*

immunization have resulted from inadequate refrigeration prior to use.

b. Inactivated or killed vaccines

Inactivated vaccines are produced by growing virus or bacteria in culture media and then inactivating them with heat or chemicals (usually formalin), when injected into the body they stimulate active immunity. They are usually safe but generally, less efficacious than live vaccines. For example, cholera vaccine offers only 50 per cent protection. The efficacy of 3 doses of pertussis vaccine is about 80 per cent in the first three years, and almost "nil" 12 years after immunization. Killed vaccines usually require a primary series of 2 or 3 doses of vaccine to produce an adequate antibody response, and in most cases "booster" injections are required. The duration of immunity following the use of inactivated vaccines varies from months to many years. Inactivated polio vaccine has been quite an effective vaccine, the widespread use of which in certain countries has led to the elimination of the disease. Killed vaccines are usually administered by subcutaneous or intramuscular route.

Because the vaccine is inactivated, the infective agent cannot grow in the vaccinated individual and therefore, can not cause the disease, even in an immunodeficient person.

The only absolute contraindication to their administration is a severe local or general reaction to a previous dose. Unlike live antigens, inactivited antigens are not affected by circulating antibody. They are often more stable than live attenuated vaccines.

Some features of attenuated vaccines versus inactivated (killed) vaccines are listed in Table 30 and some of the very important developments in the field of vaccines are listed in Table 31.

TABLE 30

Comparison of characteristics of killed and live vaccines

Characteristic	Killed vaccine	Live vaccine
Number of doses	Mutiple	Single
Need for adjuvant	Yes	No
Duration of immunity	Shorter	Longer
Effectiveness of protection (more closely mimics natural infection)	Lower	Greater
Immunoglobulins produced	IgG	IgA and IgG
Mucosal immunity produced	Poor	Yes
Cell-mediated immunity produced	Poor	Yes
Residual virulent virus in vaccine	Possible	No
Reversion to virulence	No	Possible
Excretion of vaccine virus and transmission to non-immune contacts	No	Possible
Interference by other viruses in host	No	Possible
Stability at room temperature	High	Low

TABLE 31

Milestones in vaccination

1798	Smallpox vaccine
1885	Rabies vaccine
1897	Plague vaccine
1917	Cholera vaccine
1917	Typhoid vaccine (parenteral)
1923	Diphtheria toxoid
1926	Pertussis vaccine
1927	Tuberculosis (BCG)
1927	Tetanus toxoid
1935	Yellow fever vaccine
1940s	DTP
1945	The first influenza vaccines
1955	Inactivated polio vaccine (IPV).
1955	Tetanus and diphtheria toxoids adsorbed (adult use, Td)
1961	Monovalent oral polio vaccine
1963	Trivalent oral polio vaccine (OPV).
1963	The first measles vaccine
1967	Mumps vaccine
1969	Rubella vaccine
1970	Anthrax vaccine
1971	Measles, Mumps, Rubella (MMR) vaccine licensed.
1978	Fluzone, the current flu vaccine.
1980	Smallpox declared eradicated from the world.
1981	Meningococcal polysaccharide vaccine, groups A, C, Y, W135 combined (Menomune)
1982	Hepatitis B vaccine
1983	Pneumococcal vaccine, 23 valent
1988	Worldwide Polio Eradication Initiative launched; supported by Rotary International, CDC and others.
1990	The Vaccine Adverse Reporting System (VAERS), a national programme monitoring the safety of vaccines established.
1990	Haemophilus influenzae type B (Hib) polysaccharide conjugate vaccine licensed for infants.
1990	Typhoid vaccine (oral)
1991	Hepatitis B vaccine recommended for all infants.
1991	Acellular pertussis vaccine (DTaP) licensed for use in older children aged 15 months to six years old.
1993	Japanese encephalitis vaccine.
1995	Varicella vaccine licensed.
1995	Hepatitis A vaccine licensed.
1996	Acellular pertussis vaccine (DTaP) licensed for use in young infants.
2000	Pneumococcal conjugate vaccine (Prevnar) recommended for all young children.
2003	First live attenuated influenza vaccine licensed (FluMist) for use in 5 to 49 year old persons.
2003	First Adult Immunization Schedule introduced.
2004	Inactivated influenza vaccine recommended for all children 6 to 23 months of age.
2004	Pediarix, a vaccine that combines the DTaP, IPV, and Hep B vaccines, into one shot, is approved.
2005	Boostrix and Adacel, Tdap vaccines, are approved for teens.
2005	Menatra, a new menigococcal vaccine is approved for people between the age of 11 to 55 years.
2006	Rota Teq is a new rotavirus vaccine from Merck.
	ProQuad is a new vaccine that combines the MMR and Varivax vaccines for measles, mumps, rubella, and chicken pox into a single shot.
2006	Gardasil, the first HPV vaccine is approved.
2007	A booster dose of Varivax, the chickenpox vaccine, is recommended for all children.
2007	The recommended age for Flumist, the nasal spray flu vaccine, was lowered to two years.
2008	Rotarix, a two dose rotavirus vaccine is approved.
2009	Influenza-A (H_1N_1) vaccine approved.

c. Subunit vaccines (122)

A vaccine can be made of single or multiple antigenic components of a microorganism that are capable of stimulating a specific immune response sufficient to protect from the relevant pathogen infection or from the clinical manifestation of the disease. Depending on the molecular composition of the purified antigen used to prepare the vaccine, and on the techniques applied to obtain the final material used as a vaccine, different types of subunit vaccines can be defined.

1. Toxoids

Certain organisms produce exotoxins, e.g., diphtheria and tetanus bacilli. The toxins produced by these organisms are detoxicated and used in the preparation of vaccines. The antibodies produced neutralize the toxic moiety produced during infection, rather than act upon the organisms. In general, toxoid preparations are highly efficacious and safe immunizing agents.

2. Protein vaccines

In case, immunization with a single protein or a combination of proteins from a pathogen is sufficient to stimulate a protective immune response against that particular microorganism, the approach of a protein-based vaccine is appropriate. Proteins can be purified from *in-vitro* cultures of a pathogenic microorganism. The resulting vaccine preparations contain different amounts of contaminants depending on the efficiency of the purification process. Licensed acellular pertussis vaccines currently available contain from two to four different proteins purified from *B. pertussis* and are able to confer protection against whooping cough comparable to that obtained with the whole cell vaccine. One of the most widely used subunit protein vaccines is the influenza vaccine composed of haemagglutinin (HA) and neuraminidase (NA) purified from the inactivated influenza virus.

3. Recombinant protein vaccines

Development of the recombinant deoxyribonucleic acid (DNA) technology has made possible the expression of protective protein antigens in heterologous expression systems such as *E. coli*, yeast, mammalian cells, or baculovirus. This technology avoids the problems related to growing and manipulating large amounts of a pathogen from which the antigen is purified. Moreover, recombinant proteins are generally better purified from cultured microorganisms resulting in cleaner vaccine preparations with a better safety profile. A drawback of a clean vaccine preparation containing pure recombinant protein(s) is their reduced immunogenicity that may require the addition of an adjuvant to achieve enhanced efficacy. For example, the hepatitis B vaccine is made by inserting a segment of the hepatitis B virus gene into a yeast cell. The modified yeast cell produces large amounts of hepatitis B surface antigen, which is purified and harvested and used to produce the vaccine. The recombinant hepatitis B vaccine is identical to the natural hepatitis B surface antigen, but does not contain virus DNA and is unable to produce infection.

4. Polysaccharide-based vaccines

The surface of many pathogenic bacteria is covered by a capsular shell that is mainly assembled from polymeric glycans. This extensive polysaccharide coat entirely shields the bacteria outer membrane, preventing other surface bacterial components from becoming a target of the host immune response. Nevertheless, antibodies to bacterial surface polysaccharides can clear the bacteria from the host by different mechanisms, such as complement-mediated killing and opsonophagocytosis. Hence, stimulation of an antibody response against the surface polysaccharide of pathogenic bacteria is a strategy for the development of vaccines against capsulated bacteria. The chemical structure or capsular polysaccharides varies not only between bacteria of different species but also between different strains within a single species, which are usually differentiated and typed based on their capsular polysaccharides. As a consequence, a limitation of polysaccharide-based vaccine is that the immune responses they elicit are often serotype specific. In addition to *S. pneumoniae*, for which a vaccine against 23 serotypes is available, polysaccharide-based vaccines have been developed for MenACWY, Hib, and *Salmonella typhimurium (122)*.

5. Conjugated vaccines

Children under two years of age do not respond well to antigens, such as polysaccharides, which produce antibodies via a T-cell independent mechanism. If these polysaccharide antigens are chemically linked (conjugated) to a protein that T-cells recognize, then these conjugate vaccines can elicit strong immune responses and immune memory in young children. Similar to the polysaccharide-based vaccines, the conjugate vaccines are also sero-type specific, and, therefore, multivalent formulations are required to achieve protection against multiple serotypes. Examples are *S. pneumococcal* and *meningococcal* vaccines *(121)*.

d. Combinations

If more than one kind of immunizing agent is included in the vaccine, it is called a mixed or combined vaccine. The aim of combined vaccines is to simplify administration, reduce costs, minimize the number of contacts of the patient with the health system, reducing the storage cost, improving timelines of vaccination, and facilitating the addition of new vaccine into immunization programme. No evidence exists that the administration of several antigens in combined vaccines increases the burden on the immune system which is capable of responding to millions of antigens at a time. Combining antigens usually does not increase the risk of adverse reactions and can infact lead to an overall reduction in adverse reactions *(121)*. The following are some of the well-known combinations :

DPT (Diphtheria–pertussis–tetanus)

DT (Diphtheria–tetanus)

DP (Diphtheria–pertussis)

DPT and typhoid vaccine

MMR (Measles, mumps and rubella)

DPTP (DPT plus inactivated polio)

Hepatitis A, and B

Hepatitis A, and typhoid.

DTwP (Diphtheria, tetanus, whole-cell pertussis)

DPT–Hep B–Hib (Diphtheria, pertussis, tetanus, hepatitis B and haemophilus influenza type B).

The term "polyvalent" is applied to vaccines (e.g., polio, influenza vaccines) which are prepared from two or more strains of the same species. The term "auto" or "autogenous" vaccine is applied when the organism in the vaccine is obtained from the same patient.

OTHER COMPONENTS IN VACCINES (EXCIPIENTS)

Adjuvant

Sometimes a substance is added to a vaccine to enhance the immune response by degree and/or duration, making it possible to reduce the amount of immunogen per dose or the total number of doses needed to achieve immunity. The commonly used adjuvant are aluminium salts (aluminium hydroxide, aluminium phosphate or potassium aluminium sulfate) which primarily enhance the immune response to proteins. They have been shown to be safe over several decades of use. Rarely, they may cause injection site reactions, including subcutaneous nodules, sterile abscess, granulomatous inflammation or contact hypersensitivity *(121)*.

Table 32 shows the approved human vaccine adjuvants in use, their class, components and the vaccines in which they are used *(122)*.

Antibiotics

Antibiotics are used during the manufacturing phase to prevent bacterial contamination of the tissue culture cells in which the viruses are grown. For example, MMR vaccine and IPV each contains less than 25 micrograms of neomycin per dose (less than 0.000025g). Persons who are known to be allergic to neomycin should be closely observed after vaccination so that any allergic reaction can be treated at once *(121)*.

Preservatives

These are chemicals (e.g. thiomersal, formaldehyde) added to killed or subunit vaccines in order to inactivate viruses, detoxify bacterial toxins, and to prevent serious secondary infections as a result of bacterial or fungal contamination *(121)*.

Stabilizers

To confirm product quality or stability, compounds may be added to vaccines for a variety of manufacture-related issues: controlling acidity (pH); stabilizing antigens through necessary steps in the manufacturing process, such as freeze drying; and preventing antigens from adhering to the sides of glass vials with a resultant loss in immunogenicity. Examples of such additives include potassium or sodium salts, lactose, human serum albumin and a variety of animal proteins, such as gelatine and bovine serum albumin *(121)*.

FUTURE PROSPECTS (125)

Molecular biology and modern technologies are combining to devise novel approaches to vaccine development. Many of these approaches avoid the incorporation of viral nucleic acid in the final product, improving vaccine safety. Examples of what is ongoing in this field can be listed as follows. The ultimate success of these new approaches remains to be determined.

(1) Use of recombinant DNA techniques to insert the gene coding for the protein of interest into the genome of an avirulent virus that can be administered as the vaccine (such as vaccinia virus).

(2) Including in the vaccine only those subviral components needed to stimulate protective antibody, thus minimizing the occurrence of adverse reactions to the vaccine.

(3) Use of purified proteins isolated from purified virus or synthesized from cloned genes (a recombinant hepatitis B virus vaccine contains viral proteins synthesized in yeast cells). Expression of cloned gene(s) sometimes results in formation of empty virus–like particles (VLPs).

(4) Use of synthetic peptides that correspond to antigenic determinants on a viral protein, thus avoiding any possibility of reversion to virulence since no viral nucleic acid would be present–although the immune response induced by synthetic peptides is considerably weaker than that induced by intact protein.

(5) Development of edible vaccines whereby transgenic plants synthesizing antigens from pathogenic viruses may provide new cost-effective ways of delivering vaccines.

(6) Use of naked DNA vaccines–potentially simple, cheap, and safe–in which recombinant plasmids carrying the gene for the protein of interest are injected into hosts and the DNA produces the immunizing protein.

(7) Administration of vaccine locally to stimulate antibody at the portal of entry (such as aerosol vaccines for respiratory disease viruses).

Immunoglobulins

The human immunoglobulin system is composed of 5 major classes (IgG, IgM, IgA, IgD and IgE) and sub-classes within them. The various classes and sub-classes of immunoglobulins represent different functional groups that are required to meet different types of antigenic challenges. All antibodies are immunoglobulins, but it is still an open

TABLE 32
Human vaccine adjuvants

Name	Class	Components	Vaccine
Alum	Mineral salts	Aluminium phosphate, aluminium hydroxide	Diphtheria, tetanus, pneumococcus, HAV, HBV, anthrax, tick-borne encephalitis, MenC, HPV
MF59	Oil-in-water emulsion	Squalene, Tween 80, Span 85	Seasonal and pandemic influenza
AS03	Oil-in-water emulsion	Squalene, Tween 80, α-tocopherol	Pandemic influenza
AF03	Oil-in-water emulsion	Squalene, Montane 80, Eumulgin B1PH	Pandemic influenza
Virosomes	Liposomes	Phospholipids, cholesterol, HA	Seasonal influenza, HAV
AS04	Alum-adsorbed TLR4 agonist	Aluminium hydroxide, MPL	HBV, HPV
RC-529	Alum-adsorbed TLR4 agonist	Aluminium hydroxide, synthetic MPL	HBV

HAV – hepatitis A virus; HBV – hepatitis B virus; HPV – human papillomavirus; Men – meningococcus, MPL – monophosphoryl lipid A; TLR – toll-like receptor

Source : *(122)*

question whether all immunoglobulins are antibodies *(114)*. The WHO recommends that the term "gamma globulin" should not be used as a synonym for "immunoglobulin" *(127)*.

IgG : IgG is the major immunoglobulin of serum, comprising about 80 per cent of the total serum immunoglobulins. Because of its relatively smaller molecular weight (150,000), IgG can diffuse into the interstitial fluid. In other words, IgG is largely extravascular. IgG is the only class of IgGs which is transported across the placenta. Antibodies to gram–positive pyogenic bacteria, anti-viral and anti-toxic antibodies are found exclusively among IgG globulins. Its half life is about 21 days. **IgM** : It accounts for about 6 per cent of normal serum immunoglobulins. It represents antibody that is promptly formed with exposure to antigen (Fig. 19). Its presence may be indicative of recent infection. IgM antibody has high agglutinating and complement–fixing ability. Its half life is about 7 days. It can be produced by a foetus undergoing an infection. **IgA** : Constitutes about 13 per cent of the total serum immunoglobulins. Antibody activity to a wide range of viral and bacterial antigens has been reported in this class. IgA is found relatively in large quantities in body secretions, e.g., saliva, milk, colostrum, tears, bronchial secretions, nasal mucosa, prostatic fluid, vaginal secretions and mucus secretions of the small intestine; it provides the primary defence mechanism at the mucos membranes against local infection. The half-life of IgA is approximately 6–8 days. **IgE** : The serum level of IgE is <0.0005 miligrams per ml. Half-life is 2 days. IgE is concentrated in submucous tissues. It is the major antibody responsible for immediate allergic anaphylactic reactions. In persons with such antibody–mediated allergic hypersensitivity, IgE concentration is greatly increased, and IgE may appear in external secretions. Serum IgE is also typically increased during helminth infestations. **IgD** : IgD acts as an antigen receptor when present on the surface of certain B lymphocytes. In serum it is present only in trace amount (<0.003 mg per ml). Its half-life is 2 days.

Immunoglobulin preparations

Two types of immunoglobulin preparations are available for passive immunization. These are (a) Normal human immunoglobulin and (b) Specific (hyper-immune) human immunoglobulin. These are used in the prophylaxis of viral and bacterial infections, and in replacement of antibodies in immunodeficient patients.

a. Normal human Ig

Normal human Ig is an antibody–rich fraction (Cohn fraction II), obtained from a pool of at least 1000 donors. The WHO has laid down definite standards for its preparation. For example, the preparation should contain at least 90 per cent intact IgG; it should be as free as possible from IgG aggregates; all IgG sub-classes should be present; there should be a low IgA concentration; the level of antibody against at least two bacterial species and two viruses should be ascertained etc. *(128)*.

Normal human Ig is used to prevent measles in highly susceptible individuals and to provide temporary protection (upto 12 weeks) against hepatitis A infection for travellers to endemic areas and to control institutional & household outbreaks of hepatitis A infection.

Live vaccines should not normally be given for 12 weeks after an injection of normal human Ig, and if a live vaccine has already been given. NHIg injection should be deferred for 2 weeks.

b. Specific human Ig

The specific (hyperimmune) human Ig should contain at least 5 times the antibody potential of the standard preparation per unit volume. These preparations are made from the plasma of patients who have recently recovered from an infection or are obtained from individuals who have been immunized against a specific infection. They therefore have a high antibody content against an individual infection and provide immediate protection e.g., specific human Igs are used for chickenpox prophylaxis of highly susceptible individuals and for post-exposure prophylaxis of hepatitis B, and rabies and for tetanus prophylaxis in the wounded.

Immunoglobulin is administered by intramuscular injection. Immunoglobulin suitable for intravenous administration has also become available *(128)*. The intramuscular injections are painful for some patients but can be better tolerated if procaine 1 per cent is mixed at 1 part in 10 with the immunoglobulin *(129)*. Doses larger than 5 ml must be divided and injected into 4–6 intragluteal sites through a 18 or 20 gauge needle because the preparation is viscous.

Peak blood levels are reached in 2 days after intramuscular injection. The half-life is 20–35 days. Generally, immunoglobulins should not be given shortly before or after active immunization to avoid inhibiting the immune response; tetanus and hepatitis B immunization are exceptions to this rule *(128)*.

The advantages of immunoglobulins are : (a) freedom from hepatitis B, (b) concentration of the antibodies into a small volume for intramuscular use, and (c) stable antibody content, if properly stored.

Adverse reactions to immunoglobulin can be local or systemic. Local reactions (e.g., pain, sterile abscesses) are relatively common when large volumes are injected intramuscularly. Systemic reactions can be rapid or late. Rapid reactions occur during or within minutes of administration, and are anaphylactic in type (flushing, flank pain, rigor, dyspnoea, and signs of shock). Late reactions may occur within hours or days, are usually less severe, and may include urticaria, arthralgia, pyrexia or diarrhoea. Systemic reactions are less common occurring once in every 500–1000 injections. They are more common with intravenous administration. Systemic reactions can be prevented by giving hydrocortisone before the injection *(128)*.

The uses of immunoglobulin are listed in Table 33. Use is recommended only where the efficacy has been proved; where efficacy has not been established conclusively, use is listed as optional. The target populations listed in the table have been well–defined in controlled studies, and use should be limited to these individuals *(128)*.

Antisera or antitoxins

The term *antiserum* is applied to materials prepared in animals. Originally passive immunization was achieved by the administration of antisera or antitoxins prepared from non-human sources such as horses. Since human immunoglobulin preparations exist only for a small number of diseases, antitoxins prepared from non-human sources (against tetanus, diphtheria, botulism, gas gangrene and snake bite) are still the mainstay of passive immunization. Administration of antisera may occasionally give rise to serum sickness and anaphylactic shock due to abnormal sensitivity of the recipient. The current trend is in favour of using immunoglobulins wherever possible. The uses of antisera are listed in Table 34.

Appropriate uses for human immunoglobulin in the prevention and treatment of disease

Agent/ Condition	Target population	Preparation[ab]	Dose[c]	Status
Hepatitis A	Family contacts Institutional outbreaks	IG	(0.02 ml/kg of body weight) (3.2mg/kg of body weight)	Recommended for prevention
	Travellers exposed to unhygienic conditions in tropical or developing countries	IG	0.02-0.05 ml/kg of body weight (3.2-8.0 mg/kg of body weight) every 4 months	
Hepatitis C	Percutaneous or mucosal exposure	IG	0.05 ml/kg of body weight (8 mg/kg of body weight)	Optional for prevention
Hepatitis B	Percutaneous or mucosal exposure	HBIG	0.05-0.07 ml/kg of body weight (8-11 mg/kg of body weight) Repeat in one month	Recommended for prevention
	Newborns of mothers with HBsAg	HBIG	0.05ml (8 mg) at birth, 3, and 6 months	Recommended for prevention
	Sexual contacts of acute hepatitis B patients	HBIG	0.05 ml/kg of body weight (8 mg/kg of body weight) Repeat after one month	Optional for prevention
Rubella	Women exposed during early pregnancy	IG	20 ml	Optional for prevention
Varicella-zoster	Immuno-suppressed contacts of acute cases or newborn contacts	VZIG[d]	15-25 units/kg body weight; minimum 125 units	Recommended for prevention
Measles (rubeola)	Infants less than 1 year old or immuno-suppressed contacts of acute cases exposed less than 6 days previously	IG	0.25 ml/kg of body weight or 0.5 ml/kg of body weight if immuno-suppressed	Recommended for prevention
Rabies	Subjects exposed to rabid animals	RIG	20 IU/kg of body weight	Recommended for prevention
Tetanus	Following significant exposure of unimmunized or incompletely immunized person or immediately on diagnosis of disease	TIG	250 units for prophylaxis 3000-6000 units for therapy	Recommended for prevention or treatment
Rh isoimmunization	Rh (D)-negative mother on delivery of Rh-positive infant, or after uncompleted pregnancy with Rh-positive father, or after transfusion of Rh-positive blood to Rh-negative mother	RhIG	1 vial (200-300 µg) per 15 ml of Rh (+) blood exposure	Recommended for prevention

a IG = immune globulin (human); HBIG = hepatitis B immune globulin; VZIG = varicella-zoster immune globulin; RIG = rabies immune globulin; TIG = tetanus immune globulin; RhIG = rhesus factor immune globulin.
b Hyperimmune immunoglobulins have also been used in prophylaxis of mumps and prophylaxis and treatment of pertussis and diphtheria; there are no conclusive data available, and no recommendations can be given.
c Dose based on intramuscular administration of 16.5% solution
d Of limited availability at the present time.

TABLE 34

Passive immunization procedures with antisera

	Disease	Passive immunization (ANTISERA)
1.	Diphtheria	A dose of 500-1,000 of IU of diphtheria antitoxin is given intramuscularly to susceptible contacts immediately after exposure. Protection does not last more than 2-3 weeks.
2.	Tetanus	The usual prophylactic dose is 1,500 units of horse A.T.S. given subcutaneously or intramuscularly, soon after injury.
3.	Gas gangrene	A polyvalent antitoxin is used. A patient who has sustained a wound possibly contaminated with spores of gas gangrene should receive a dose of 10,000 IU of *Cl. perfringens. (Cl. welchii)* antitoxin, 5,000 units of *Cl. septicum* antitoxin and 10,000 units of *Cl. oedematiens* antitoxin, intramuscularly, or in urgent cases intravenously.
4.	Rabies	Antirabies serum in a dose of 40 IU per kg. of body weight should be given intramuscularly within 72 hours and preferably within 24 hours of exposure. A part of the antiserum is applied locally to the wound.
5.	Botulism	When botulism is suspected, 10,000 units of polyvalent antitoxin is recommended every 3 to 4 hours.

The "cold chain" is a system of storage and transport of vaccines at low temperature from the manufacturer to the actual vaccination site. The cold chain system is necessary because vaccine failure may occur due to failure to store and transport under strict temperature controls. This is of concern in view of the fairly frequent reports of vaccine-preventable disease occurrence in populations thought to have been well immunized. In other words – the success of national immunization programme is highly dependant on supply chain system for delivery of vaccines and equipment, with a functional system that meets 6 rights of supply chain – The right vaccine in the right quantity at the right place at the right time in the right condition (no temperature breaks in cold chain) and at the right cost *(130)*. Among the vaccines, polio is the most sensitive to heat, requiring storage at minus 20 degree C. Vaccines which must be stored in the freezer compartment are : polio and measles. Vaccines which must be stored in the COLD PART but never allowed to freeze are : "T series" vaccines (DPT, tetanus toxoid, DT) hepatitis B, BCG, and diluents. A very useful tip to remember which vaccine should not be frozen is to look for the "T" in the name of the vaccine, e.g. DPT, TT, DT, td, hepatitis B, Hib type B and even diluents *(131)*. If the vials are frozen or contain floccules, discard them.

In general all vaccines must be stored under the conditions recommended by the manufacturer in the literature accompanying the vaccine, otherwise they may become denatured and totally ineffective. Vaccines must be protected from sunlight and prevented from contact with antiseptics. At the health centre, most vaccines (except polio) can be stored up to 5 weeks if the refrigerator temperature is strictly kept between 2 and 8 degrees C. Reconstituted BCG and measles vaccines can be kept at +2°C to +8°C for maximum of 4 hours and JE vaccine for 2 hours. To be on safe side, write the time of reconstitution on the label of these vaccine vials and discard them after 4 hours (2 hours for JE vaccine). ***Do not*** keep any used vials in the cold chain. Return the unused vaccine vials from session site to the PHC on the same day in the cold chain through alternative vaccine delivery. Keep the box labeled ***"returned unused"*** in the ILR for all unused vaccines that can be used in the subsequent session, but discard vaccines that have been returned unopened more than three times *(131)*.

The cold chain equipment : The cold chain equipment consists of the following

(a) Walk-in cold rooms (WIC) : They are located at regional level, meant to store vaccines upto 3 months and serve 4–5 districts.

(b) Deep freezers : Supplied to all districts (large) and PHCs (small) to store vaccines. The cabinet temperature is maintained between –15°C to –25°C. In case of power failure, these freezers can maintain the cabinet temperature for 18–22 hours. At the PHC level, deep freezers are used only for preparation of ice packs and are not used for storing UIP vaccines. About 20–25 icepacks can be prepared by a 140 L. deep freezer with at least 8 hours of continuous electricity supply.

(c) Ice-lined refrigerators (ILR) : ILR are kept at the PHC (small) and district level (large). The cabinet temperature is maintained at +2°C to +8°C. At the PHC level, ILR are used for storing all UIP vaccines. ILR are lined with tubes or ice packs filled with water which freezes and keeps the internal temperature at a safe level. ILRs can keep vaccine safe with 8 hours of continuous electricity supply in a 24 hours period. Since ILR are top-opening, they can hold the cold air inside better than front-opening refrigerators. All vaccines must be kept in the basket of the ILR along with diluents. Arrange the vaccines in order (top to bottom) hepatitis B; DPT and TT; BCG; measles; OPV (follow early expiry first out). Discard any frozen hepatitis B, DPT and TT. Keep space between boxes. Measles and OPV can be kept over two rows of empty ice-packs on the floor of the ILR *(131)*.

A dial thermometer should be kept in the ILR and temperature recorded twice a day. At the time of defrosting the vaccines are shifted to the cold boxes containing required number of frozen ice packs. In case of equipment failure or electric supply failure, vaccines should be transferred to ice boxes and then to alternate vaccine storage.

There are some DOs and DONTs for the use of ILR/ freezer. **DOs:** keep the equipment in cool room away from direct sunlight and atleast 10 cms away from the wall; keep the equipment levelled; fix the equipment through voltage stabilizer; keep vaccines neatly with space between the stacks for circulation of air; keep the equipment locked and open only when necessary; defrost periodically, supervise the temperature record; and if vaccines are kept in cartons, make holes on the sides of the cartons for cold air circulation. **DONTs :** do not keep any object on these equipments; do not store any other drug; do not keep drinking water or food in them; do not keep more than one months requirements at PHC level; and do not keep date expired vaccines.

(d) Cold boxes : Cold boxes are supplied to all peripheral centres. These are used mainly for transportation of the vaccines. Before the vaccines are placed in the cold boxes, fully frozen ice packs are placed at the bottom and sides. The vaccines are first kept in cartons or polythene bags. The vials of DPT, DT, TT, vaccines and diluents should not be placed in direct contact with the frozen ice packs.

(e) Vaccine carriers : Vaccine carriers are used to carry small quantities of vaccines (16–20 vials) for the out of reach sessions. 4 fully frozen ice packs are used for lining the sides, and vials of DPT, DT, TT and diluents should not be placed in direct contact with frozen ice packs. The carriers should be closed tightly.

(f) Day carriers : Day carriers are used to carry small quantities of vaccines (6–8 vials) to a nearby session. Two fully frozen packs are to be used. It is used only for few hours period.

(g) Ice packs : The ice packs contain water and no salt should be added to it. The water should be filled upto the level marked on the side. If there is any leakage such ice packs should be discarded.

The risk of cold chain failure is greatest at sub-centre and village level. For this reason, vaccines are not stored at the sub-centre level and must be supplied on the day of use.

(130, 131)

Only use the diluents supplied and packaged by the

manufacturer with the vaccine, since the diluent is specifically designed for the needs of that vaccine, with respect to volume, pH level and chemical properties.

Store the diluents, between +2° to + 8° C in the ILR. If there are constraints of space, then store diluents outside the cold chain. However, remember to cool diluents for at least 24 hours before use to ensure that vaccines and diluents are at +2° to +8°C when being reconstituted. Otherwise, it can lead to thermal shock i.e. the death of some or all the essential live organisms in the vaccine. Store the diluents and droppers with the vaccines in the vaccine carrier during transportation. Diluents should not come in direct contact with the ice pack.

The Vaccine Vial Monitor (VVM) *(130, 131)*

A VVM is a label containing a heat-sensitive material which is placed on a vaccine vial to register cumulative heat exposure over time.

The combined effects of time and temperature cause the inner square of the VVM to darken gradually and irreversibly as shown in Fig. 20. Before opening a vial, check the status of the VVM.

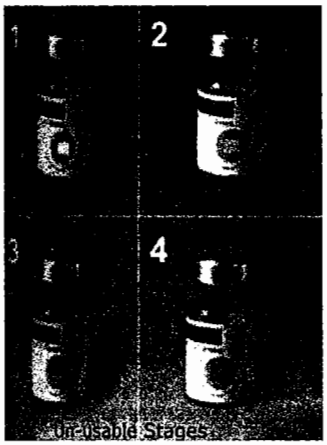

FIG. 20
Different stages of the VVM

Reading the Stages of the VVM

Stage 1. The inner square is lighter than the outer circle. If the expiry date has not been passed : **USE** the vaccine

Stage 2. The inner square is still lighter than the outer circle. If the expiry date has not been passed : **USE** the vaccine

Discard Point :

Stage 3. The colour of the inner square matches that of the outer circle : **DO NOT** use the vaccine

Beyond the Discard Point

Stage 4. The colour of the inner square is darker than the outer circle : **DO NOT** use the vaccine

The VVM does not directly measure vaccine potency but it gives information about the main factor that affects potency i.e. heat exposure over a period of time.

ADVERSE EVENTS FOLLOWING IMMUNIZATION

Vaccines used in national immunization programmes are extremely safe and effective. However, no immune response is entirely free from the risk of adverse reactions or remote sequelae.

An AEFI is any untoward medical occurrence which follows immunization and which does not necessarily have a causal relationship with the usage of the vaccine. The adverse event may be any unfavourable or unintended sign, abnormal laboratory finding, symptom or disease. Reported adverse events can either be true adverse events, i.e. really a result of the vaccine or immunization process, or coincidental events that are not due to the vaccine or immunization process but are temporally associated with immunization.

In 2012, the Council for International Organizations of Medical Sciences (CIOMS) and WHO revised the existing classification relevant to cause-specific categorization of AEFIs and a new categorization has been introduced (Table 35).

TABLE 35

Cause-specific categorization of AEFIs (CIOMS/WHO 2012)

Cause-specific type of AEFI	Definition
Vaccine product-related reaction	An AEFI that is caused or precipitated by a vaccine due to one or more of the inherent properties of the vaccine product.
Vaccine quality defect-related reaction	An AEFI that is caused or precipitated by a vaccine that is due to one or more quality defects of the vaccine product, including its administration device as provided by the manufacturer.
Immunization error-related reaction (formerly "programme error")	Immunization error-related reaction: an AEFI that is caused by inappropriate vaccine handling, prescribing or administration and thus by its nature is preventable.
Immunization anxiety-related reaction	An AEFI arising from anxiety about the immunization.
Coincidental event	An AEFI that is caused by something other than the vaccine product, immunization error or immunization anxiety.
Note : "Immunization" as used in these definitions means the usage of a vaccine for the purpose of immunizing individuals. "Usage" includes all processes that occur after a vaccine product has left the manufacturing/packaging site, i.e. handling, prescribing and administration of the vaccine.	

Source : *(121)*

1. Vaccine reactions *(121)*

The new cause-specific categorization is important for decision-making on a vaccine-product, since it clearly differentiates the two types of possible vaccine reactions. The first, vaccine product-related reaction, is a reaction in an individual's response to the inherent properties of the vaccine, even when the vaccine has been prepared, handled and administered correctly. The second, vaccine quality defect-related reaction, is the defect in a vaccine that occurred during manufacturing process. Such a defect may have an impact on an individual's response and thus increase the risk of adverse vaccine reactions. In early years of immunization programmes, a few major incidences of vaccine quality defect-related reactions were reported (e.g. Cutter case study). However, due to introduction of improved Good Manufacturing Practices (GMP), such defects are now very rare.

Vaccine reactions may be classified into common, minor reactions or rare, more serious reactions. Most vaccine reactions are minor and settle on their own. More serious reactions are very rare and, in general, do not result in long-term problems.

COMMON, MINOR VACCINE REACTIONS

The purpose of a vaccine is to induce immunity by causing the recipient's immune system to react to the vaccine. Local reaction, fever and systemic symptoms can result as part of the immune response. In addition, some of the vaccine's components (e.g. aluminium adjuvant, stabilizers or preservatives) can lead to reactions. A successful vaccine reduces these reactions to a minimum while producing the best possible immunity.

The local reactions include pain, swelling and/or redness at the injection site and can be expected in about 10% of vaccinees, except for those injected with DTP (whole cell), or tetanus boosters, where up to half can be affected. BCG causes a specific local reaction that starts as a papule (lump) two or more weeks after immunization, that then becomes ulcerated and heals after several months, leaving a scar. Keloid (thickened scar tissue) from the BCG lesion is more common among asian and african populations.

The systemic reactions include fever and occur in about 10% or less of vaccinees, except for DTP where it is again about half. Other common systemic reactions (e.g., irritability, malaise, 'off-colour', loss of appetite) can also occur after DTP. For measles/MMR and OPV the sytemic reactions arise from vaccine virus infection. Measles vaccine causes fever, rash and/or conjunctivitis, and affects 5–15% of vaccinees. It is very mild compared to 'wild' measles, but for severely immunocompromised individuals, it can be severe, even fatal. Vaccine reactions for mumps (swollen parotid gland) and rubella (joint pains and swollen lymph nodes) affect less than 1% of children. Rubella vaccine causes symptoms more often in adults, with 15% suffering from joint pains. Systemic reactions from OPV affect less than 1% of vaccinees with diarrhoea, headache and/or muscle pain.

The common minor vaccine reactions and their expected frequency are as shown in Table 36.

TABLE 36
Summary of common minor vaccine reactions

Vaccine	Possible minor adverse reaction	Expected frequency
BCG	Local reaction (pain, swelling, redness)	Common
Cholera	Oral presentation–none	
DTP	Local reaction (pain, swelling, redness)	Upto 50% [a]
	Fever	Upto 50%
Hepatitis A	Local reaction (pain, swelling, redness)	Upto 50%
Hepatitis B	Local reaction (pain, swelling, redness)	Adults up to 30%, Children upto 5%
	Fever	1-6%
Hib	Local reaction (pain, swelling, redness)	5-15%
	Fever	2-10%
Japanese encephalitis	Local reaction, low-grade fever, myalgia, gastrointestinal upset	Upto 20%
Measles/ MMR	Local reaction (pain, swelling, redness)	Upto 10%
	Irritability, malaise and non-specific symptoms, fever	Upto 5%
Pneumococcal	Local reaction (pain, swelling, redness)	30-50%
Poliomyelitis (OPV)	None	
Poliomyelitis (IPV)	None	
Rabies	Local and/or general reaction depending on type of vaccine (see product information)	15-25%
Meningococcal disease	Mild local reactions	Upto 71%
Tetanus/Td	Local reaction (pain, swelling, redness)[b]	Upto 10%
	Malaise and non-specific symptoms	Upto 25%
Tick-borne encephalitis	Local reaction (pain, swelling, redness)	Upto 10%
Typhoid fever	Depends on type of vaccine use (see product information)	–
Yellow fever	Headache	10%
	Influenza-like symptoms	22%
	Local reaction (pain, swelling, redness)	5%

[a] With whole-cell pertussis vaccine. Rates for acellular pertussis vaccine are lower.
[b] Rate of local reactions likely to increase with booster doses, up to 50-85%.

Source : *(132)*

RARE, MORE SERIOUS VACCINE REACTIONS *(121)*

'Serious' and 'severe' are often used as interchangeable terms but they are not. An AEFI will be considered serious, if it results in death, is life-threatening, requires in-patient hospitalization or prolongation of existing hospitalization, results in persistent or significant disability/incapacity, is a congenital anomaly/birth defect, or required intervention to prevent permanent impairment or damage. Severe is used to describe the intensity of a specification event (as in mild, moderate or severe). The event itself, however, may be of relatively minor medical significance. (For example, fever is

a common relatively minor medical event, but according to its severity it can be graded as mild fever or moderate fever. Anaphylaxis is always a serious event and life-threatening.) Table 37 details the rare vaccine reactions; the onset interval, the rate per doses and the case definitions. Most of the rare and more serious vaccine reactions (e.g. seizures, thrombocytopenia, HHEs, persistent inconsolable screaming) do not lead to long-term problems. Anaphylaxis, while potentially fatal, is treatable without leaving any long-term effects. Although encephalopthy is included as a rare reaction to measles or DTP vaccine, it is not certain that these vaccines in fact cause encephalopathy.

Table 37

Rare vaccine reactions, onset interval and rate per doses

Vaccine	Reaction	Onset interval	Rate/doses
BCG	Suppurative lymphadenitis	2–6 months	$1–10/10^4$
	BCG osteitis	1–12 months	$1–700/10^6$
	Disseminated BCG infection	1–12 months	$0.19–1.56/10^6$
Hib	None		
Hepatitis B	Anaphylaxis	0–1 hour	$1.1/10^6$
Influenza (inactivated)	Anaphylaxis		$0.7/10^6$
	Guillain-Barre syndrome (GBS)		$1–2/10^6$
	Oculo-respiratory syndrome		$76/10^6$
Influenza (live-attenuated)	Anaphylaxis		$2/10^6$
	Wheezing (children 6-11 months age)		14/100
Japanese encephalitis (inactivated)	Neurologic events (encephalitis, encephalopathy $, peripheral neuropathy)		$1–2.3/10^6$
Measles/MMR/	Febrile seizures	6–12 days	$3/10^3$
MR *	Thrombocytopaenia	15–35 days	$3/10^4$
	Anaphylaxis	0–1 hour	$\sim 1/10^6$
	Encephalopathy $	6–12 days	$<1/10^6$
Oral poliomyelitis	VAPP	4–30 days	$2-4/10^{6\dagger}$
Pertussis (DTwP)	Persistent (>3 hours) inconsolable screaming	0–24 hours	<1/100
	Seizures ††	0–3 days	<1/100
	Hypotonic, hypo responsive episode (HHE)	0–48 hours	$1–2/10^3$
	Anaphylaxis	0–1 hour	$20/10^6$
	Encephalopathy $	0–2 days	$0–1/10^6$
Pneumococcal	None proven ±		
Rotavirus	None known **		
Tetanus toxoid, DT	Brachial neuritis	2–28 days	$5–10/10^6$
	Anaphylaxis	0–1 hour	$1–6/10^6$
Yellow fever	Vaccine-associated viscerotropic disease ***		$1/10^6$
Varicella	Febrile seizures		$4–9/10^{4\dagger\dagger}$

Notes:

* Reactions (except anaphylaxis) do not occur if already immune (~90% of those receiving a second dose are immune): children over six years unlikely to have febrile seizures.

† VAPP Risk is higher following the first dose (1 in 750,000 compared to 1 in 5.1 million for subsequent doses), and for adults and immunocompromised.

± No proven risk of severe febrile or anaphylactic reactions or neurological disorders (e.g. Guillain-Barre syndrome)

** Post-marketing surveillance of currently available rotavirus vaccines has detected a small increased risk of intussusception (~1-2 cases per 100,000 infants vaccinated) in some settings shortly after the first dose of rotavirus vaccine.

*** Very rare in children

†† Seizures are mostly febrile and the risk depends on age, with much lower risk in infants under the age of four months.

$ Although encephalopathy is included as a rare possible reaction to measles, JE or DTP vaccines, it is not certain that these vaccines in fact cause encephalopathy. Hence, further scientific evaluation is necessary.

Although other serious events have been reported following immunization, it is likely that these events are coincidental, not true reactions.

The case definitions and treatments of adverse events following immunization are as follows *(121)* :

Adverse event	Case definition	Treatment	Vaccines
Acute flaccid paralysis (vaccine associated paralytic poliomyelitis)	Acute onset of flaccid paralysis within 4 to 30 days of receipt of oral poliovirus (OPV), or within 4 to 75 days after contact with a vaccine recipient with isolation of vaccine virus and absence of wild polio virus in the stool, and neurological deficits remaining 60 days after onset, or death.	No specific treatment available; supportive care.	OPV
Anaphylactoid reaction (acute hypersensitivity reaction)	Exaggerated acute allergic reaction, occurring within 2 hours after immunization, characterized by one or more of the following: • wheezing and shortness of breath due to bronchospasm • laryngospasm/laryngeal oedema • one or more skin manifestations, e.g. hives, facial oedema, or generalized oedema. Less severe allergic reactions do not need to be reported.	Self-limiting; anti-histamines may be helpful.	All
Anaphylaxis	Severe immediate (within 1 hour) allergic reaction leading to circulatory failure with or without bronchospasm and/or laryngospasm/laryngeal oedema	Adrenaline injection	All
Arthralgia	Joint pain usually including the small peripheral joints. Persistent, if lasting longer than 10 days, transient; if lasting up to 10 days.	Self-limiting; analgesics	Rubella, MMR
Brachial neuritis	Dysfunction of nerves supplying the arm/shoulder without other involvement of nervous system. A deep steady, often severe aching pain in the shoulder and upper arm followed in days or weeks by weakness and wasting in arm/shoulder muscles. Sensory loss may be present, but is less prominent. May present on the same or the opposite side to the injection and sometimes affects both arms.	Symptomatic only; analgesics.	Tetanus
Disseminated BCG infections	Widespread infection occurring within 1 to 12 months after BCG vaccination and confirmed by isolation of *Mycobacterium bovis* BCG strain. Usually in immunocompromised individuals.	Should be treated with anti-tuberculous regimens including isoniazid and rifampicin.	BCG
Encephalopathy	Acute onset of major illness characterized by any two of the following three conditions: • seizures • severe alteration in level of consciousness lasting for one day or more • distinct change in behaviour lasting one day or more. Needs to occur within 48 hours of DTP vaccine or from 7 to 12 days after measles or MMR vaccine, to be related to immunization.	No specific treatment available; supportive care.	Measles, Pertussis
Fever	The fever can be classified (based on rectal temperature) as mild (38 to 38.9°C), high (39 to 40.4°C) and extreme (40.5°C or higher). Fever on its own does not need to be reported.	Symptomatic; paracetamol.	All
Hypotonic, hyporesponsive episode (HHE or shock-collapse)	Event of sudden onset occurring within 48 (usually less than 12) hours of vaccination and lasting from one minute to several hours, in children younger than 10 years of age. All of the following must be present : • limpness (hypotonic) • reduced responsiveness (hyporesponsive) • pallor or cyanosis - or failure to observed/recall.	The episode is transient and self-limiting, and does not require specific treatment. It is not a contraindication to further doses of the vaccine.	Mainly DTP, rarely others

Adverse event	Case definition	Treatment	Vaccines
Injection site abscess	Fluctuant or draining fluid-filled lesion at the site of injection. Bacterial if evidence of infection (e.g. purulent, inflammatory signs, fever, culture), sterile abscess if not.	Incise and drain; antibiotics if bacterial.	All
Lymphadenitis (includes suppurative lymphadenitis)	Either at least one lymph nodes enlarged to >1.5 cm in size (one adult finger width), or a draining sinus over a lymph node. Almost exclusively caused by BCG and then occurring within 2 to 6 months after receipt of BCG vaccine, on the same side as inoculation (mostly axilliary).	Heals spontaneously (over months) and best not to treat unless lesion is sticking to skin. If so,or already draining, surgical drainage and local instillation of anti-tuberculous drug. Systemic treatment with anti-tuberculous drugs is ineffective.	BCG
Osteitis/ Osteomyelitis	Inflammation of the bone with isolation of *Mycobacterium bovis* BCG strain.	Should be treated with anti-tuberculous regimens including isoniazid and rifampicin.	BCG
Persistent inconsolable screaming	Inconsolable continuous crying lasting 3 hours or longer accompanied by high-pitched screaming.	Settles within a day or so; analgesics may . help	DTP, Pertussis
Seizures	Occurrence of generalized convulsions that are not accompanied by focal neurological signs or symptoms. Febrile seizures: if temperature elevated >38°C (rectal) Afebrile seizures : if temperature normal.	Self-limiting supportive care; paracetamol and cooling if febrile; rarely anticonvulsants.	All, especially Pertussis, Measles
Sepsis	Acute onset of severe generalized illness due to bacterial infection and confirmed (if possible) by positive blood culture. Needs to be reported as possible indicator of programme error.	Critical to recognize and treat early. Urgent transfer to hospital for parenteral antibiotics and fluids	All
Severe local reaction	Redness and/or swelling centred at the site of injection and one or more of the following: • swelling beyond the nearest joint • pain, redness, and swelling of more than 3 days duration • requires hospitalization. Local reactions of lesser intensity occur commonly and are trivial and do not need to be reported.	Settles spontaneously within a few days to a week. Symptomatic treatment with analgesics. Antibiotics are inappropriate.	All
Thrombocytopaenia	Serum platelet count of less than 50,000/ml leading to bruising and/or bleeding.	Usually mild and self-limiting; occasionally may need steroid or platelets.	MMR
Toxic shock syndrome (TSS)	Abrupt onset of fever, vomiting and watery diarrhoea within a few hours of immunization. Often leading to death within 24 to 48 hours. Needs to be reported as possible indicator of programme error.	Critical to recognize and treat early. Urgent transfer to hospital for parenteral antibiotics and fluids.	All

RECOGNITION OF ANAPHYLAXIS *(121)*

Administration of antisera may occasionally give rise to anaphylactic shock and serum sickness. Many viral vaccines contain traces of various antibiotics used in their preparation and some individuals may be sensitive to the antibiotic which it contains.

Anaphylaxis is a severe reaction of rapid onset, characterized by circulatory collapse. The early signs of anaphylaxis are generalized erythema and urticaria with upper and/or lower respiratory tract obstruction. In more

severe cases, limpness, pallor, loss of consciousness and hypotension may also become evident. Vaccinators should be able to recognize the following signs and symptoms of anaphylaxis:

Diagnostic features of anaphylaxis	
Respiratory	*Airway* • Throat and tongue swelling (pharyngeal/laryngeal oedema) – the patient has difficulty in breathing and swallowing and feels that the throat is closing up. • Hoarse voice. • Stridor *Breathing* • Bronchospasm • Respiratory distress – 2 or more of the following: – Tachypnoea – Increased use of accessory respiratory muscles – Recession – Cyanosis • Grunting • Respiratory arrest
Cardiovascular	• Hypotension • Clinical diagnosis of uncompensated shock, indicated by the combination of at least three of the following: – Tachycardia – Capillary refill time >3 seconds – Reduced central pulse volume – Decreased level of consciousness or loss of consciousness • Cardiac arrest • Bradycardia (a slow pulse) is usually a late feature, often preceding cardiac arrest
CNS	• Confusion/Agitation • Headache • Loss of consciousness
Dermatologic or mucosal	• Tingling of lips • Generalized urticaria or generalized erythema • Angioedema, localized or generalized (angioedema is similar to urticaria but involves swelling of deeper tissues, most commonly in the eyelids and lips, and sometimes in the mouth and throat) • Generalized itching of skin especially hands, forehead and eyes in children Note : Skin changes alone without life threatening cardio-respiratory signs do not signify an anaphylactic reaction
Gastrointestinal	• Diarrhoea • Colicky abdominal pain • Vomiting • Incontinence

In general, the more severe the reaction, the more rapid the onset. Most life-threatening reactions begin within 10 minutes of immunization. It is advisable to keep the recipient under observation for at least 20 minutes after the injection. Symptoms limited to only one system can occur, leading to delay in diagnosis. Biphasic reactions where symptoms recur 8 to 12 hours after onset of the original attack and prolonged attacks lasting up to 48 hours have been described.

Time Scale	Signs and symptoms of anaphylaxis	Severity
Early warning signs	Dizziness, perineal burning, warmth, pruritus	Mild
⇩	Flushing, urticaria, nasal congestion, sneezing, lacrimation, angioedema	Mild to moderate
⇩	Hoarseness, nausea, vomiting, sub-sternal pressure	Moderate
⇩	Laryngeal oedema, dyspnoea, abdominal pain	Moderate to severe
Late, life-threatening symptoms	Bronchospasm, stridor, collapse, hypotension, dysrhythmias	Severe

2. Immunization error-related reactions *(121)*

"Immunization" means the usage of a vaccine for the purpose of immunizing individuals. "Usage" includes all processes that occur after a vaccine product has left the manufacturing/packaging site, i.e. handling, prescribing and administration of the vaccine.

An immunization error-related reaction may lead to a cluster of events associated with immunization. These clusters are usually associated with a particular provider, or health facility, or even a single vial of vaccine that has been inappropriately prepared or contaminated. Immunization errors-related reactions can also affect many vials. For example, freezing vaccine during transport may lead to an increase in local reactions.

Table 38 shows the immunization error-related reactions *(121)*.

TABLE 38

Immunization error-related reactions

Immunization error		Related reaction
Error in vaccine handling	Exposure to excess heat or cold as a result of inappropriate transport, storage or handling of the vaccine (and its diluent) where applicable.	Systemic or local reactions due to changes in the physical nature of the vaccine such as agglutination of aluminium-based excipients in freeze-sensitive vaccines.
	Use of a product after the expiry date.	Failure to vaccinate as a result of loss of potency or non-viability of an attenuated product.
Error in vaccine prescribing or non-adherence to recommendations for use	Failure to adhere to a contraindication.	Anaphylaxis, disseminated infection with an attenuated live, VAPP.
	Failure to adhere to vaccine indications or prescription (dose or schedule).	Systemic and/or local reactions, neurologic, muscular, vascular or bony injury due to incorrect injection site, equipment or technique.
Error in administration	Use of an incorrect diluent or injection of a product other than the intended vaccine.	Failure to vaccinate due to incorrect diluent, Reaction due to the inherent properties of whatever was administered other than the intended vaccine or diluent.
	Incorrect sterile technique or inappropriate procedure with a multidose vial.	Infection at the site of injection/beyond the site of injection.

In the past, the most common immunization error was an infection (including bloodborne virus) as a result of non-sterile-injection. The infection could manifest as a local reaction (e.g. suppuration, abscess), systemic effect (e.g. sepsis or toxic shock syndrome), or blood-borne virus infection (e.g. HIV, hepatitis B or hepatitis C). However, with the introduction of auto disabled (AD) syringes, infection occurrence has reduced significantly. Still, infection can occur in cases of mass vaccination or disaster situations, particularly if there is any shortage or problems with logistics and supplies. This can be avoided by proper planning and preparedness of programme managers.

The symptoms arising from an immunization error may help to identify the likely cause. For example, children immunized with contaminated vaccine (usually the bacterium Staphylococcus aureus) become sick within a few hours; local tenderness and tissue infiltration, vomiting, diarrhoea, cyanosis and a high temperature are the most frequent symptoms. Bacteriological examination of the vial, if still available, can confirm the source of the infection.

3. Immunization anxiety–related reactions *(121)*

Individuals and groups can react in anticipation to and as a result of an injection of any kind. This reaction is unrelated to content of the vaccine. Fainting is relatively common. During fainting, the individual suddenly becomes pale, loses consciousness and collapses to the ground. Fainting is sometimes accompanied by brief clonic seizure activity (i.e. rhythmic jerking of the limbs), but this requires no specific treatment or investigation. Fainting is relatively common after immunization of adults and adolescents, but very rare in young children. It is managed by simply placing the patient in a recumbent position. Recovery of consciousness occurs within a minute or two, but patients may take some more time to recover fully. Table 39 shows the difference between fainting attack and anaphylaxis.

An anxiety spell can lead to pale, fearful appearance and symptoms of hyperventilation (light-headedness, dizziness, tingling in the hands and around the mouth). Breath-holding occurs in young children and will lead to facial flushing and cyanosis. It can end in unconsciousness, during which breathing resumes. Anaphylaxis develops over several minutes upto a few hours and usually involves multiple body systems. Unconsciousness is rarely the sole manifestation of anaphylaxis – it only occurs as a late event in severe cases. A strong central pulse (e.g. carotid) is maintained during a faint, but not in anaphylaxis.

4. Coincidental events

Occasionally following immunization there may occur a disease totally unconnected with the immunizing agent. Vaccines are normally scheduled early in life, when infections and other illnesses are common, including manifestations of an underlying congenital or neurological condition. The mechanism seems to be that the individual is harbouring the infectious agent and the administration of the vaccine shortens the incubation period and produces the disease or what may have been otherwise only a latent infection is converted into a clinical attack.

PRECAUTIONS TO BE TAKEN

Before administration of the antiserum or antitoxin, it is necessary to test for sensitivity reaction. This can be done in 2 ways: (a) instilling a drop of the preparation into the conjunctival sac. A sensitized person will develop pricking of the conjunctiva. (b) a more reliable way of testing is by intradermal injection of 0.2 ml of antiserum diluted 1 : 10 with saline. A sensitized patient will develop a wheal and flare within 10 minutes at the site of injection. It should be borne in mind that these tests are not infallible.

Adrenaline (1:1000 solution) should be kept ready when giving foreign serum. In the event of anaphylaxis, for an adult, 0.5 ml of adrenaline solution should be injected intramuscularly immediately, followed by 0.5 ml every 20 minutes if the systolic blood pressure is below 100 mm of mercury. An injection of antihistaminic drug should also be given, e.g., 10–20 mg of chlorpheniramine maleate by the intramuscular route, to minimize the after-effects such as urticaria or oedema. The patient should be observed for 30 minutes after any serum injection.

The risk of adverse reactions can be reduced by proper sterilization of syringes and needles, by proper selection of the subject and the product, and if due care is exercised in carrying out the procedure. Measles and BCG vaccines should be reconstituted only with the diluent supplied by the manufacturer. Reconstituted vaccine should be discarded at the end of each immunization session and NEVER retained for use in subsequent sessions. In the refrigerator of the immunization centre, no other drug and substances should be stored beside vaccines. Training of immunization worker and their close supervision to ensure that proper procedures are being followed are essential to prevent complications and deaths following immunization. Careful epidemiological investigation should be carried out when an adverse event following immunization occurs to pinpoint the cause of the incident and to correct immunization practices *(133, 121)*.

TABLE 39

Difference between a fainting attack and anaphylaxis

Clinical features	Fainting	Anaphylaxis
Timing	Before, during or few minutes after injection	A short time, upto a few hours
Skin	Generalized pallor, cold clammy skin	Itching, generalized erythema, urticaria, swelling of lips, face, tingling around lips
Respiratory system	Normal breathing Shallow breathing	Tachypnoea, difficulty in breathing, wheezing, stridor, hoarseness, cyanosis, recession of intercostal spaces
Cardiovascular	Bradycardia, weak pulse, carotid pulse felt, hypotension may occur-reversed by supine position	Tachycardia, weak pulse, carotid pulse may be weak, hypotension – not reversed by supine position
GIT	Vomiting	Vomiting, diarrhoea, abdominal cramps
CNS	Faintishness, light-headedness relieved by supine posture	Anxiety and distress, loss of consciousness not relieved by supine posture
Panic attack – no hypotension, pallor, wheeze, or urticarial rash or swelling. May have flushing or blotchy skin.		

Investigating adverse events following immunization *(121)*

The suggested reportable events believed by the public or health workers to be caused by immunization are listed below and could be considered for inclusion in the AEFI surveillance system. There is no point in reporting common minor reactions such as local reactions, fever and self-limiting systemic symptoms.

Events that should be reported after immunization

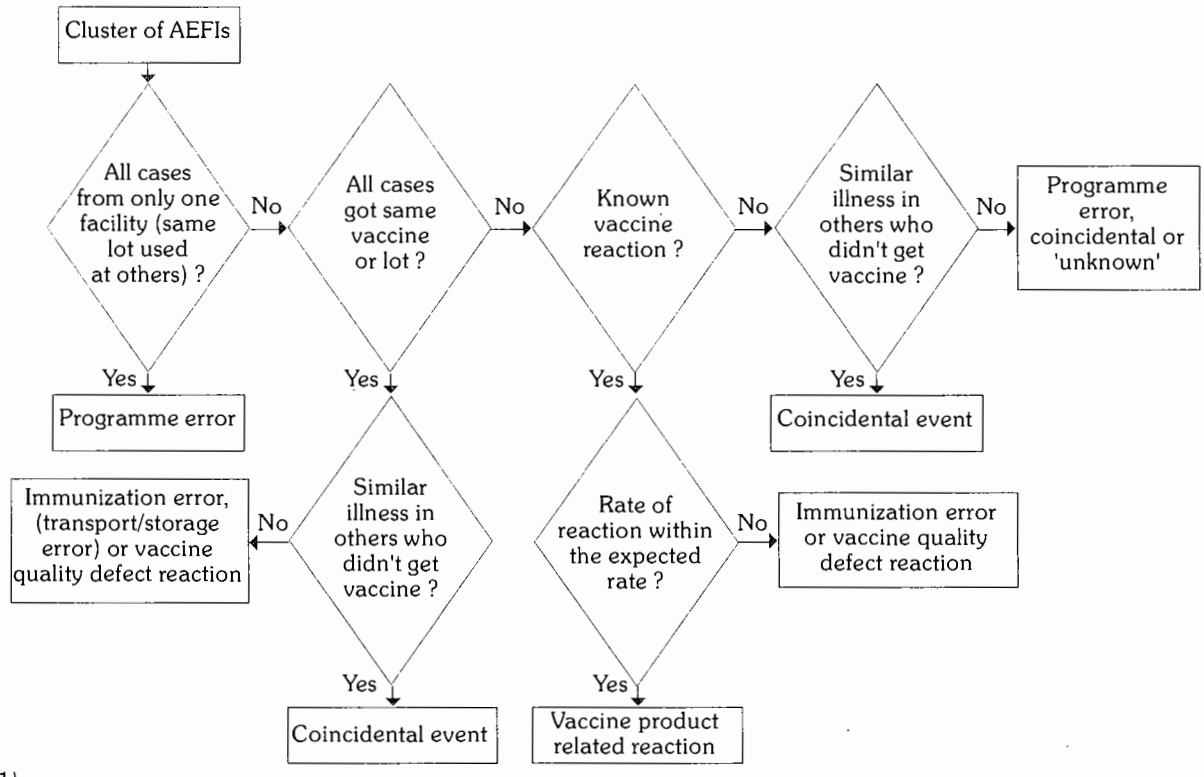
Occurring within 24–48 hours of immunization	• Anaphylactoid reaction (acute hypersensitivity reaction) • Anaphylaxis • Persistent (more than 3 hours) inconsolable screaming • Hypotonic hyporesponsive episode (HHE) • Toxic shock syndrome (TSS)
Occurring within 7 days of immunization	• Severe local reaction • Sepsis • Injection site abscess (bacterial/sterile)
Occurring within 14 days of immunization	• Seizures, including febrile seizures (6–12 days for measles/MMR; 0–2 days for DTP) • Encephalopathy (6–12 days for measles/MMR; 0–2 days for DTP)
Occurring within 3 months of immunization	• Acute flaccid paralysis (4–30 days for OPV recipient; 4–75 days for contact) • Brachial neuritis (2–28 days after tetanus containing vaccine) • Thrombocytopaenia (15–35 days after measles/MMR) • Intussusception commonly after rotavirus
Occurring between 1 and 12 months after BCG immunization	• Lymphadenitis • Disseminated BCG infection • Osteitis/Osteomyelitis
No time limit	Any death, hospitalization, disability or other severe and unusual events that are thought by health workers or the public to be related to immunization

Once the report has been received, an assessment should be made to determine whether or not an investigation is needed. The urgency of the investigation depends on the situation.

Investigating AEFI clusters

A cluster of AEFI is defined as two or more cases of the same adverse event related in time, place or vaccine administration. Cluster investigation begins by establishing the case definition and identifying all cases that meet the case definition.

A cluster of similar adverse events is likely to arise from programme errors. If the event also occured in unimmunized people, it may be coincidental. If all cases received the same vaccine or lot, and there are no similar cases in the community, a problem with the vaccine is likely. If the event is a known vaccine reaction but occurring at an increased rate, a programme error or a vaccine problem are likely causes (Fig. 21).



Source : *(121)*

FIG. 21
Identifying cause of AEFI cluster

Investigation of an AEFI *(121)*

AN AEFI investigation follows standard epidemiological investigation principles. In addition, investigation of the vaccine(s), immunization techniques and procedures, and service in action needs to be conducted.

STEPS IN AN AEFI INVESTIGATION

Step	Actions
1. Confirm information in report	• Obtain patient's medical file (or other clinical record). • Check details about patient and event from medical file and document information. • Identify any other cases that need to be included in the investigation.
2. Investigate and collect data: About the patient:	• Immunization history. • Previous medical history, including prior history of similar reaction or other allergies. • Family history of similar events.
About the event:	• History, clinical description, any relevant laboratory results about the AEFI and diagnosis of the event. • Treatment, whether hospitalized, and outcome.
About the suspected vaccine(s):	• Conditions under which the vaccine was shipped, its present storage condition, state of vaccine vial monitor, and temperature record of refrigerator. • Storage of vaccine before it arrived at health facility, where it has come from higher up the cold chain, vaccine monitor card.
About other people:	• Whether others received the same vaccine and developed illness. • Whether others had similar illness (may need case definition); if so exposure of cases of suspect vaccine(s). • Investigate the local immunization service.
3. Assess the service by: asking about:	• Vaccine storage (including open vials), distribution, and disposal. • Diluent storage and distribution. • Reconstitution (process and time kept). • Use and sterilization of syringes and needles. • Details of training in immunization practice, supervision and vaccinator(s). • Number of immunizations greater than normal ?
Observing the service in action:	• Refrigerator – what else is stored (note if similar containers stored next to vaccine vials which could be confused); which vaccines/diluents stored with other drugs; whether any vials have lost their label. • Immunization procedures (reconstitution, drawing up vaccine, injection technique, safety of needles and syringes; disposal of opened vials). • Do any open vials look contaminated ?
4. Formulate a working hypothesis:	• On the likely/possible cause(s) of the event.
5. Test working hypothesis	• Does case distribution match working hypothesis ? • Occasionally, laboratory tests may help.
6. Conclude investigation	• Reach a conclusion on the cause. • Complete AEFI Investigation Form. • *Take corrective action, and recommend further action*

A series of cases without comparison of disease and exposure among controls is not likely to reveal the cause of the AEFI, except in the case of programme errors. Clear case definitions, from the guidelines on reporting or defined during the investigation, are essential. The investigation needs to identify all cases in the community and find out the outcomes for all those who received the suspect vaccine. A working hypothesis should be established as soon as there is sufficient information. Laboratory testing may sometimes confirm or rule out the suspected cause. The vaccine may be tested for sterility and adjuvant (e.g. aluminium content); the diluent for sterility and chemical composition; and the needles and syringe for sterility. Testing should be requested on a *clear suspicion* and not as a routine, and *never* before the working hypothesis has been formulated.

Contraindications to vaccination

Vaccines are very rarely contraindicated. However, it is important to check for contraindications to avoid serious reactions. For example, vaccines are contraindicated if there is serious allergy to the vaccine or its components. Live vaccines should not be given to immune-deficient children.

The main contraindication to the administration of vaccines are summarized in Table 40.

DISEASE PREVENTION AND CONTROL

Every disease has certain weak points susceptible to attack. The basic approach in controlling disease is to identify these weak points and break the weakest links in the chain of transmission (Fig. 16). This requires sound epidemiological knowledge of the disease – that is its magnitude, distribution in time, place and person, multifactorial causation, sources of infection and dynamics of transmission.

Frequently it may be necessary to institute more than one method of control simultaneously. The choice of methods will depend upon factors such as availability of proper tools and techniques, relative cost effectiveness, efficiency and acceptability. Although effective control of a disease requires knowledge of its multifactorial causation, removal or elimination of a single known essential link or the weakest link may be sufficient to control a disease, even if complete knowledge about the aetiology of the disease in question is lacking. The classic example is that of John Snow controlling the cholera epidemic in London, by removing the handle of the incriminated water pump.

Disease control involves all the measures designed to prevent or reduce as much as possible the incidence, prevalence and consequences of disease *(134)*. This includes community participation, political support and intersectoral coordination *(135)*. Control measures should not be delayed because of incomplete or lack of accurate knowledge of the aetiological agent.

TABLE 40

Contraindications to vaccines

Vaccine	Contraindications
All	An anaphylactic reaction[a] following a previous dose of a particular vaccine is a true contraindication to further immunization with the antigen concerned and a subsequent dose should not be given, OR, Current serious illness.
Live vaccines (MMR, BCG, yellow fever)	Pregnancy. Radiation therapy (i.e. total-body radiation).
Yellow fever	Egg allergy. Immunodeficiency (from medication, disease or symptomatic HIV infection[b]).
BCG	Symptomatic HIV infection.
Influenza, yellow fever	History of anaphylactic reactions[a] following egg ingestion. No vaccines prepared in hen's egg tissues (i.e. yellow fever and influenza vaccines) should be given. (Vaccine viruses propagated in chicken fibroblast cells, e.g. measles or MMR vaccines, can however usually be given.)
Pertussis-containing	Anaphylactic reaction to a previous dose. Evolving neurological disease (e.g. uncontrolled epilepsy or progressive encephalopathy). Vaccines containing the whole-cell pertussis component should not be given to children with this problem. Acellular vaccine is less reactogenic and is used in many industrialized countries instead of whole-cell pertussis vaccine.

[a] Generalized urticaria, difficulty in breathing, swelling of the mouth and throat, hypotension or shock.
[b] In many industrialized countries yellow fever vaccine is administered to individuals with symptomatic HIV infection or who are suffering from other immunodeficiency diseases, provided that their CD_4 count is at least 400 cells/mm^3 and if they plan to visit areas where epidemic or endemic yellow fever actually occurs.

Source : *(132)*

Broadly these are measures, pending results of epidemiologic investigation.

1. The reservoir or source of infection
2. The route(s) of transmission
3. The susceptible host (people at risk).

The activities of disease prevention and control are now included in primary health care – it requires community participation (involvement), political support and inter-sectoral coordination *(135)*.

1. Controlling the reservoir

If the first link in the chain of causation (i.e., the disease agent) is deemed to be the weakest link, logically, the most desirable control measure would be to eliminate the reservoir or source, if that could be possible. Elimination of the reservoir may be pretty easy with the animal reservoir (e.g., bovine tuberculosis, brucellosis), but is not possible in humans in whom the general measures of reservoir control comprise : early diagnosis, notification, isolation, treatment, quarantine, surveillance and disinfection – all directed to reduce the quantity of the agent available for dissemination.

(1) EARLY DIAGNOSIS

The first step in the control of a communicable disease is its rapid identification. It is the cornerstone on which the edifice of disease control is built. It has been aptly said that prompt detection of cases (and carriers) and their treatment is like stamping out the "spark" rather than calling the fire brigade to put out the fire caused by the spark. Frequently, laboratory procedures may be required to confirm the diagnosis.

Early diagnosis is needed for (a) the treatment of patients (b) for epidemiological investigations, e.g., to trace the source of infection from the known or index case to the unknown or the primary source of infection (c) to study the time, place and person distribution (descriptive epidemiology) and (d) for the institution of prevention and control measures.

(2) NOTIFICATION

Once an infectious disease has been detected (or even suspected), it should be notified to the local health authority, whose responsibility is to put into operation control measures, including the provision of medical care to patients, perhaps in a hospital.

Certain diseases are statutorily notifiable. The diseases to be notified vary from country to country; and even within the same country. Usually, diseases which are considered to be serious menaces to public health are included in the list of notifiable diseases. Notifiable diseases may also include non-communicable diseases and conditions such as cancer, congenital defects, accidents, etc.

Notification is an important source of epidemiological information. It enables early detection of disease outbreaks, which permits immediate action to be taken by the health authority to control their spread. The other uses of notification are discussed elsewhere.

Notification of infectious diseases is often made by the attending physician or the head of the family, but any one, including the lay people (e.g., religious, political and administrative leaders, teachers and others) can report, even on suspicion. In all cases, the diagnosis is verified by the local health authority.

Under the **International Health Regulations (IHR)**, certain prescribed diseases are notified by the national health authority to WHO. These can be divided into :

(a) Those diseases subject to International Health Regulations (1969), Third Annotated Edition, 1983 - cholera, plague and yellow fever.
(b) Diseases under surveillance by WHO – louse-borne typhus fever, relapsing fever, paralytic polio, malaria, viral influenza–A, SARS, smallpox etc.

Health administrations are required to notify to WHO Geneva for any notification of communicable diseases under international surveillance and International Health Regulations.

(3) EPIDEMIOLOGICAL INVESTIGATIONS

An epidemiological investigation is called for whenever there is a disease outbreak, the methodology for which is given elsewhere (see page 131). Broadly, the investigation

covers the identification of the source of infection and of the factors influencing its spread in the community. These may include geographical situation, climatic condition, social, cultural and behavioural patterns, and more importantly the character of the agent, reservoir, the vectors and vehicles, and the susceptible host populations.

(4) ISOLATION

Isolation is the oldest communicable disease control measure. It is defined as "separation, for the period of communicability of infected persons or animals from others in such places and under such conditions, as to prevent or limit the direct or indirect transmission of the infectious agent from those infected to those who are susceptible, or who may spread the agent to others" *(99)*. In general, infections from human/animal sources can be controlled by physical isolation of the case or carrier, and if necessary, treatment until free from infection, provided cases and carriers can be easily identified and carrier rates are low.

The *purpose* of isolation is to protect the community by preventing transfer of infection from the reservoir to the possible susceptible hosts. The *type* of isolation varies with the mode of spread and severity of the disease. There are several types of isolation – standard isolation, strict isolation, protective isolation, high security isolation *(136)*. For each patient, the relative risks to the patient and to others should be assessed and the appropriate type of isolation determined. Hospital isolation, wherever possible, is better than home isolation. Isolation is particularly difficult in rural areas. In some situations (e.g., cholera outbreaks) the entire village or rural community may have to be isolated. Isolation may also be achieved in some diseases by "ring immunization", that is encircling the infected persons with a barrier of immune persons through whom the infection is unable to spread. This method when applied worldwide in the 1960s and 1970s eradicated smallpox. In North America, ring immunization is being applied in measles control and eradication. The duration of isolation is determined by the duration of communicability of the disease and the effect of chemotherapy on infectivity (Table 41).

Isolation has a distinctive value in the control of some infectious diseases, e.g., diphtheria, cholera, streptococcal respiratory disease, pneumonic plague, etc. In some diseases where there is a large component of subclinical infection and carrier state (polio, hepatitis A, and typhoid fever), even the most rigid isolation will not prevent the spread of the disease. It is also futile to impose isolation if the disease is highly infectious before it is diagnosed as in the case of mumps. Isolation has failed in the control of diseases such as leprosy, tuberculosis and STD. In the control of these diseases, the concept of physical isolation has been replaced by chemical isolation, i.e., rapid treatment of cases in their own homes and rendering them non-infectious as quickly as possible. Lastly, cases are usually reported after the disease has spread widely. Taking all these limitations into consideration, it may be stated that isolation which is a "barrier approach" to the prevention and control of infectious disease is not as successful as one would imagine and may well give rise to a false sense of security *(137)*. In modern-day disease control, isolation is more judiciously applied and in most cases replaced by surveillance because of improvements in epidemiological and disease control technologies. Today, isolation is recommended only when the risk of transmission of the infection is exceptionally serious.

TABLE 41
Periods of isolation recommended

Disease	Duration of isolation
Chickenpox	Until all lesions crusted; usually about 6 days after onset of rash.
Measles	From the onset of catarrhal stage through 3rd day of rash.
German measles	None, except that women in the first trimester or sexually active, non immune women in child-bearing years not using contraceptive measures should not be exposed.
Cholera Diphtheria	3 days after tetracyclines started, until 48 hours of antibiotics (or negative cultures after treatment).
Shigellosis Salmonellosis	Until 3 consecutive negative stool cultures.
Hepatitis A	3 weeks.
Influenza	3 days after onset.
Polio	2 weeks adult, 6 weeks paediatric.
Tuberculosis (sputum +)	Until 3 weeks of effective chemotherapy.
Herpes zoster	6 days after onset of rash.
Mumps	Until swelling subsides.
Pertussis	4 weeks or until paroxysms cease.
Meningococcal meningitis Streptococcal pharyngitis	Until the first 6 hours of effective antibiotic therapy are completed.

Source : *(138, 139)*

(5) TREATMENT

Many communicable diseases have been tamed by effective drugs. The object of treatment is to kill the infectious agent when it is still in the reservoir, i.e., before it is disseminated. Treatment reduces the communicability of disease, cuts short the duration of illness and prevents development of secondary cases. In some diseases (e.g., syphilis, tuberculosis, and leprosy), early diagnosis and treatment is of primary importance in interrupting transmission. Treatment is also extended to carriers.

Treatment can take the form of individual treatment or mass treatment. In the latter category, all the people in the community are administered the drugs whether they have the disease or not (e.g., trachoma). If the treatment is inadequate or inappropriate, it may induce drug resistance in the infectious agent and may frustrate attempts to control the disease by chemotherapy. It is well to remember that no disease has ever been conquered through attempting to treat every affected individual *(140)*. Yaws is a shining example.

(6) QUARANTINE

Quarantine has been defined as "the limitation of freedom of movement of such well persons or domestic animals exposed to communicable disease for a period of time not longer than the longest usual incubation period of the disease, in such manner as to prevent effective contact with those not so exposed" *(100)*. Quarantine measures are also "applied by a health authority to a ship, an aircraft, a train, road vehicle, other means of transport or container, to prevent the spread of disease, reservoirs of disease or vectors of disease" *(141)*.

Quarantine may comprise (a) *absolute quarantine*, as defined above; (b) *modified quarantine*, e.g., a selective partial limitation of freedom of movement, such as exclusion

of children from school; and (c) *segregation* which has been defined as "the separation for special consideration, control of observation of some part of a group of persons (or domestic animals) from the others to facilitate control of a communicable disease, e.g., removal of susceptible children to homes of immune persons" *(2)*.

In contrast to isolation, quarantine applies to restrictions on the healthy contacts of an infectious disease. Quarantine which was once a popular method of disease control has now declined in popularity *(137)*. With better techniques of early diagnosis and treatment, quarantine, as a method of disease control, has become outdated. It has been replaced by active surveillance.

2. Interruption of transmission

A major aspect of communicable disease control relates to "breaking the chain of transmission" or interruption of transmission (Fig. 16). This may mean changing some components of man's environment to prevent the infective agent from a patient or carrier from entering the body of susceptible person. For example, water can be a medium for the transmission of many diseases such as typhoid, dysentery, hepatitis A, cholera and gastroenteritis. Water treatment will eliminate these diseases. Depending upon the level of pollution, this may vary from simple chlorination to complex treatment. However, control of the source of contamination is an important long-term measure. Food-borne disease is particularly prevalent in areas having low standards of sanitation. Clean practices such as hand-washing, adequate cooking, prompt refrigeration of prepared foods and withdrawal of contaminated foods will prevent most food–borne illnesses *(142)*. When the disease is vector–borne, control measures should be directed primarily at the vector and its breeding places. Vector control also includes destruction of stray dogs, control of cattle, pets and other animals to minimize spread of infection among them, and from them to man. On the other hand, episodes of infection either by droplets or droplet nuclei are not usually controlled effectively by attempting to interrupt their mode of spread; reliance is placed on early diagnosis and treatment of patients, personal hygiene and proper handling of secretions and excretions. In short, blocking the routes of transmission imply an attack on environmental factors, that is, to bring about an adjusted equilibrium between host and environment through encouraging some ecological influences and inhibiting others *(140)*.

3. The susceptible host

The third link in the chain of transmission is the susceptible host or people at risk. They may be protected by one or more of the following strategies.

(1) ACTIVE IMMUNIZATION

One effective way of controlling the spread of infection is to strengthen the host defences. Under certain circumstances this may be accomplished by active immunization, which is one of the most powerful and cost-effective weapons of modern medicine. There are some infectious diseases whose control is solely based on active immunization, e.g., polio, tetanus, diphtheria and measles. Vaccination against these diseases is given as a routine during infancy and early childhood (Table 43), with periodic boosters to maintain adequate levels of immunity. Then there are immunizations against certain diseases (Table 42) which are offered to high-risk groups or restricted to definite geographic areas where the disease is endemic or a public health problem (e.g., yellow fever). Unfortunately we do not have vaccines for every infectious disease (e.g., malaria, diarrhoeal diseases). Diseases for which improved or less costly vaccines are needed include tuberculosis, pertussis, meningococcal meningitis, hepatitis B, rabies, Japanese encephalitis, etc. *(143)*.

Immunization is a mass means of protecting the greatest number of people. By reducing the number of susceptibles in the community, it augments "herd immunity" making the infection more difficult to spread. It also reduces the risk for those individuals who have escaped vaccination or those who have not developed satisfactory protection. It is well to bear in mind that immunizations are not all 100 per cent effective, particularly when an individual is exposed to a large dose of pathogenic organisms.

Immunization has to be planned according to the needs of the situation. Every country has its own immunization schedule, so does each medical society and each paediatric society, adding to confusion. Thus there is an infinite

TABLE 42

Active Immunization recommended under special circumstances

	Disease	Immunization
1.	Cholera	Two types of safe and effective oral cholera vaccines currently available. Given orally in two doses between seven days and six weeks apart.
2.	Plague	Given subcutaneously or intramuscularly in 2 doses at an interval of 7 to 14 days. Immunity starts 5 to 7 days after inoculation and lasts for about 6 months.
3.	Typhoid fever	Two vaccines are available for prevention of typhoid. Typhoid polysaccharide vaccine is injectable given subcutaneously or intramuscularly. One dose is required. Confers protection after 7 days. The other is oral Ty21a vaccine, administered on 1, 3 and 5th day. Protective immunity achieved 7 days after 3rd dose.
4.	Influenza	Inactivated vaccines are widely used. Two adequately spaced doses (1.0 ml each) of an aqueous or saline vaccine are recommended for primary immunization, although one dose may be given when an epidemic is threatened. The immunity lasts for about 3 to 6 months. Oil-adjuvanted vaccines give immunity of longer duration, but they tend to produce unpleasant local reaction.
5.	Yellow fever	The dose of the vaccine (17 D vaccine) is 0.5 ml given subcutaneously. Immunity begins 10-12 days after vaccination, and extends up to 10 years.

number of immunization schedules, each having its merits and demerits. If each vaccine were to be given separately, a minimum of at least 14 visits would be needed to the immunization clinic. The current trend is to combine immunizing agents into small packages and thus reduce the number of injections an individual must receive.

A well thought-out immunization schedule must be (a) *epidemiologically relevant*, that is, vaccinations should be included only against diseases which are public health problems and against which an effective vaccine exists (b) *immunologically effective* : children must be vaccinated at an age when they can benefit from it, i.e., when they are capable of forming defences and when they have lost the antibodies transmitted by the mother. Above all, children must be vaccinated at the right time, that is before they are exposed to possible infection. An immunization may not be effective if given within too short an interval between subsequent doses (c) *operationally feasible* : this includes cost and ability to achieve a high percentage of coverage which is a key factor in an effective immunization programme. The schedule must minimize the number of visits, by simultaneous administration of vaccines, and (d) *socially acceptable* : the schedule must take into account the local customs, beliefs and practices, seasonal and climatic factors and daily work pattern of the community. One important factor is to reduce long waiting time for patients whose sole purpose in visiting the clinic was to be immunized.

Universal Immunization Programme

In May 1974, the WHO officially launched a global immunization programme, known as Expanded Programme on Immunization (EPI) to protect all children of the world against six vaccine–preventable diseases, namely – diphtheria, whooping cough, tetanus, polio, tuberculosis and measles by the year 2000. EPI was launched in India in January 1978 *(144)*.

The Programme is now called *Universal Child Immunization*, 1990–that's the name given to a declaration sponsored by UNICEF as part of the United Nations' 40th anniversary in October 1985. It is aimed at adding impetus to the global programme of EPI.

The Indian version, the *Universal Immunization Programme,* was launched on November 19, 1985 and was dedicated to the memory of Smt. Indira Gandhi. The National Health Policy was aimed at achieving universal immunization coverage of the eligible population by 1990.

IMMUNIZATION SCHEDULES

1. National Immunization Schedule

The National Immunization Schedule is given in Table 43. The first visit may be made when the infant is 6 weeks old; the second and third visits, at intervals of 1–2 months. Oral polio vaccine may be given concurrently with DPT. BCG can be given with any of the three doses but the site for the injection should be different. The schedule also covers immunization of women during pregnancy against tetanus.

The Indian Academy of Paediatrics recommends inclusion of more vaccines in the immunization schedule. These vaccines are not included in the UIP because of financial constraints. The immunization schedule approved by the IAP is as follows :

BCG	–	Birth – 2 weeks
OPV	–	Birth; 6 weeks, 10 weeks and 14 weeks; 16–18 months, 5 years
DPT	–	6 weeks, 10 weeks and 14 weeks; 16–18 months and 5 years
Hepatitis B	–	Birth, 6 weeks and 14 weeks *or* 6 weeks, 10 weeks and 14 weeks
Hib Conjugate	–	6 weeks, 10 weeks and 14 weeks
Measles	–	9 months, 16–24 months
MMR	–	15 months
Typhoid	–	2 years, 5 years, 8 years, 12 years
TT/Td	–	10 years, 16 years
TT	–	2 doses one month apart for pregnant women, or booster dose if previously immunized.

Vaccines that can be given after discussion with parents

Varicella	–	15 months (or after 1 year)
Hepatitis A	–	high-risk selected infants, 18 months, and 6 months later
Pneumococcal conjugate vaccine	–	6 weeks
Influenza vaccine	–	6 months of age to high risk selected infants anually

2. WHO EPI Schedule

Table 44 summarizes the WHO recommendations for routine vaccination for children. The purpose is to assist health planners to develop an appropriate country specific immunization schedule based on local conditions. The health care workers should refer to their national immunization schedules.

The WHO EPI Global Advisory Committee has strongly recommended BCG and Polio vaccine to be given at birth or at first contact, in countries where tuberculosis and polio have not been controlled. In all countries routine immunization with DPT and oral polio vaccine can be safely and effectively initiated at 6 weeks of age. New vaccines are being added for the vaccination schedule e.g., hepatitis B, rubella and Japanese encephalitis vaccines are now included in several country's programmes.

The immunization schedule may be altered to suit the local needs of individuals and groups. Interruption of the schedule with a delay between doses does not interfere with the final immunity achieved. There is no basis for the mistaken belief that if a second (or third) dose in an immunization is delayed, the immunization schedule must be started all over again *(115)*. The ages shown in Table 44 for the various immunizations are considered the best. However, if there is any delay in starting the first dose the site for the injection should be different, the periods may be adjusted accordingly.

Immunization is frequently postponed if children are ill or malnourished. This is not acceptable in the light of present knowledge. In fact, it is particularly important to immunize children with malnutrition. Low grade fever, mild respiratory infections or diarrhoea and other minor illnesses should not be considered as contraindications to immunization. These are the very children who are most in need of immunization. They are most likely to die should they acquire a vaccine–preventable disease *(146)*.

TABLE 43

National Immunization Schedule (NIS) for Infants, Children and Pregnant Women (India)

Vaccine	When to give	Dose	Route	Site
For Pregnant Women				
TT-1	Early in pregnancy	0.5 ml	Intra-muscular	Upper Arm
TT-2	4 weeks after TT-1 *	0.5 ml	Intra-muscular	Upper Arm
TT-Booster	If received 2 TT doses in a pregnancy within the last 3 years*	0.5 ml	Intra-muscular	Upper Arm
For Infants				
BCG	At birth or as early as possible till one year of age	0.1 ml (0.05 ml until 1 month age)	Intra-dermal	Left Upper Arm
Hepatitis B	At birth or as early as possible within 24 hours	0.5 ml	Intra-muscular	Antero-lateral side of mid-thigh
OPV-0	At birth or as early as possible within the first 15 days	2 drops	Oral	Oral
OPV 1, 2 & 3	At 6 weeks, 10 weeks & 14 weeks	2 drops	Oral	Oral
DPT 1, 2 & 3	At 6 weeks, 10 weeks & 14 weeks	0.5 ml	Intra-muscular	Antero-lateral side of mid thigh
Hepatitis B 1, 2 & 3	At 6 weeks, 10 weeks & 14 weeks	0.5 ml	Intra-muscular	Antero-lateral side of mid-thigh
Measles	9 completed months-12 months. (give up to 5 years if not received at 9-12 months age)	0.5 ml	Sub-cutaneous	Right upper Arm
Vitamin A (1st dose)	At 9 months with measles	1 ml (1 lakh IU)	Oral	Oral
For Children				
DPT booster	16-24 months	0.5 ml	Intra-muscular	Antero-lateral side of mid-thigh
OPV Booster	16-24 months	2 drops	Oral	Oral
Measles (2nd dose)	16-24 months	0.5 ml	Sub-cutaneous	Right upper Arm
Japanese Encephalitis **	16-24 months with DPT/OPV booster	0.5 ml	Sub-cutaneous	Left Upper Arm
Vitamin A*** (2nd to 9th dose)	16 months with DPT/OPV booster. Then, one dose every 6 months up to the age of 5 years.	2 ml (2 lakh IU)	Oral	Oral
DPT Booster	5-6 years	0.5 ml.	Intra-muscular	Upper Arm
TT	10 years & 16 years	0.5 ml.	Intra-muscular	Upper Arm

* Give TT-2 or Booster doses before 36 weeks of pregnancy. However, give these even if more than 36 weeks have passed. Give TT to a woman in labour, if she has not previously received TT.

** SA 14-14-2 Vaccine, in select endemic districts of the Uttar Pradesh, West Bengal, Karnataka and Assam.

*** The 2nd to 9th doses of Vitamin A can be administered to children 1-5 years old during biannual rounds, in collaboration with ICDS.

**** In select states, districts and cities.

Note : (a) Interval between 2 doses of DPT, OPV and hepatitis B should not be less than one month.
(b) Minor cough, cold and mild fever are not a contraindication to vaccination.
(c) If the child has diarrhoea, give a dose of OPV, but do not count the dose and ask the mother to return in 4 weeks for the missing dose.
(d) Pentavalent Vaccine (DPT + Hep B + Hib) has been introduced in NIS in the states of Kerala, Tamil Nadu, Goa, Haryana, Gujarat, Karnataka and Jammu & Kashmir at 6, 10 and 14 weeks of age.

Source : *(130)*

Since the success of EPI is now being seen to have important long-term effects on the traditional epidemiological patterns of major infectious diseases, often raising the average age of incidence, the adolescent age group of 10–19 years represent an important additional target group for immunization. In the pre-immunization era, large proportion of adults had disease induced immunity to common infections, now majority of individuals have *vaccine induced* immunity, which may or may not have the same long-term stability. Questions therefore arise as to policy and strategy implications for post-infancy immunization programmes.

The WHO Scientific Advisory Group of Experts to EPI has indicated the need to expand immunization activities beyond infancy, either as part of routine immunization services or as part of disease elimination or eradication measure.

Adolescence presents certain challenges for immunization in relation to lifestyle and other social issues, while also offering special opportunities, such as a vaccine delivery in the setting of educational institutions. The vaccines of interest are MR and MMR as part of measles outbreak prevention or elimination campaign, Td as booster dose for neonatal tetanus elimination, hepatitis B, influenza, varicella and HPV vaccines etc.

(2) PASSIVE IMMUNIZATION

Three types of preparations are available for passive immunity – (a) Normal human immunoglobulin, (b) Specific (hyperimmune) human immunoglobulin, and (c) antisera or anti-toxins.

TABLE 44

WHO recommendations for routine immunization for children, 2010

Antigen		Age at 1st Dose	Doses in Primary Series	Interval Between Doses			Booster Dose
				1st to 2nd	2nd to 3rd	3rd to 4th	
Recommendations for all children							
BCG		As soon as possible after birth	1				
Hepatitis B	Option 1	As soon as possible after birth (<24h)	3	4 weeks (min), with DTP1	4 weeks (min), with DTP3		
	Option 2	As soon as possible after birth (<24h)	4	4 weeks (min), with DTP1	4 weeks (min), with DTP2	4 weeks (min), with DTP3	
Polio	OPV	6 weeks (min)	3	4 weeks (min) with DTP2	4 weeks (min) with DTP3		
	IPV/OPV Sequential	8 weeks (IPV 1st)	1-2 IPV 2 OPV	4-8 weeks	4-8 weeks	4-8 weeks	
	IPV	8 weeks	3	4-8 weeks	4-8 weeks		
DTP		6 weeks (min)	3	4 weeks (min)	4 weeks (min)		1-6 years of age
Haemophilus influenzae type b		6 weeks (min) with DTP1, 24 months (max)	3	4 weeks (min) with DTP2	4 weeks (min) with DTP3		
Pheumococcal (Conjugate)		6 weeks (min) with DTP1	3	4 weeks (min) with DTP2	4 weeks (min) with DTP3		
Rotavirus	Rotarix	6 weeks (min) with DTP1, 15 weeks (max)	2	4 weeks (min) with DTP2 no later than 32 weeks of age			
	Rota Teq	6 weeks (min) with DTP1 15 weeks (max)	3	4 weeks (min)– 10 weeks with DTP2	4 weeks (min) with DTP3, no later than 32 weeks of age		
Measles		9-15 months (6 months min)	2	4 weeks (min)			
HPV		Quadrivalent 9-13 years of age, Bivalent 10-13 years of age	3	Quadrivalent- 2 months (min 4 wks) Bivalent-1 month (max 2.5 months)	Quadrivalent- 4 months (min 12 wks) Bivalent- 5 months		
Recommendations for children residing in certain regions							
Japanese Encephalitis	Mouse-brain derived	1 year	2	4 weeks (min)			after 1 year and every 3 years upto 10-15 years of age
	Live attenuated	9-12 months	1				after 1 year
Yellow Fever		9-12 months with measles	1				
Recommendations for children in some high-risk populations							
Typhoid	ViPS	2 years (min)	1				every 3 years
	Ty21a	Capsules 5 years (min)	3 or 4	1 day	1 day	1 day	every 3-7 years
Cholera	Dukoral (WC-rBS)	2 years (min)	3 (2-5 yrs) 2 (≥6 yrs)	≥ 7 days (min) < 6 weeks (max)	≥ 7 days (min) < 6 weeks (max)		every 6 months every 2 years
	Shanchol and mORCVAX	1 year (min)	2	14 days			after 2 years
Meningococcal (polysaccharide)		2 years (min)	1				
Hepatitis A		1 year (min)	2	6-18 months			
Rabies		As required	3	6 days	14 days		every 5 years
Recommendations for children receiving vaccinations from immunization programmes with certain characteristics							
Mumps		12-18 months with measles	2	1 month (min) to school entry			
Rubella		9-15 months with measles	1				
Influenza (Inactivated)		6 months (min)	2	1 month			

- BCG and polio vaccine to be given at birth in countries where tuberculosis and polio have not been controlled.
- Vaccines such as varicella and pneumococcal polysaccharide vaccines, may be of individual benefit but are not recommended for routine immunization.
- Doses administered by campaign may or may not contribute to a child's routine immunization schedule depending on type and purpose of campaign (e.g. supplemental versus routine/pulse campaign for access reasons)

Source : *(145)*

Passive immunization is a short-term expedient useful only when exposure to infection has just occurred or is imminent within the next few days. The duration of immunity induced is short and variable (1–6 weeks). Undesirable reactions may occur, especially if antiserum is of non-human origin.

Passive immunization has a limited value in the mass control of disease. It is recommended for non-immune persons under special circumstances. The commonly employed passive immunization procedures are listed in Table 33 and 34.

(3) COMBINED PASSIVE AND ACTIVE IMMUNIZATION

In some diseases (e.g., tetanus, diphtheria, rabies) passive immunization is often undertaken in conjunction with inactivated vaccine products, to provide both immediate (but temporary) passive immunity and slowly developing active immunity. If the injections are given at separate sites, the immune response to the active agent, may or may not be impaired by immunoglobulin *(114)*.

But, according to current recommendations immunoglobulin should not be given within 3 weeks before, or until 2 weeks after administration of a live attenuated vaccine *(147)*. For example, the antibody response to live attenuated measles vaccine is diminished in persons who receive immunoglobulin concurrently *(148)*. However, there are exceptions to this rule, as for example, the simultaneous administration of hepatitis B vaccine and hepatitis B immunoglobulin *(128)*.

(4) CHEMOPROPHYLAXIS

Chemoprophylaxis implies the protection from, or prevention of, disease. This may be achieved by causal prophylaxis, or by clinical prophylaxis :

(i) Causal prophylaxis implies the complete prevention of infection by the early elimination of the invading or migrating causal agent. For example, there is no causal prophylaxis available against malaria.

(ii) Clinical prophylaxis implies the prevention of clinical symptoms; it does not necessarily mean elimination of infection.

The indications for chemoprophylaxis are given as in Table 45.

TABLE 45
Indications for chemoprophylaxis

Disease	Chemoprophylaxis
Cholera	Tetracycline or furazolidone for house-hold contacts
Conjunctivitis, bacterial	Erythromycin ophthalmic ointment (no effect on viral conjunctivitis)
Diphtheria	Erythromycin (and first dose of vaccine)
Influenza	Oseltamivir (effective only for type A) for contacts suffering from chronic diseases
Malaria	See Chapter 5
Meningitis, meningococcal	Ciprofloxacin and minocyclin, for household and close community contacts; immunization should be initiated in all cases (against serogroups A and C).
Plague	Tetracycline for contacts of pneumonic plague.

(5) NON-SPECIFIC MEASURES

Most of the non-specific measures to interrupt pathways of transmission are of general applicability. Improvements in the quality of life (e.g., better housing, water supply, sanitation, nutrition, education) fall into this category. Non-specific measures will also include "legislative measures", wherever needed, to formulate integrated programme and permit effective programme implementation. In fact, these non-specific factors have played a dominant role in the decline of tuberculosis, cholera, leprosy and child mortality in the industrialized world, long before the introduction of specific control measures. Another important non-specific measure is community involvement in disease surveillance, disease control and other public health activities. If community involvement is not an integral part of public health programmes, they are unlikely to succeed. Laws, regulations and policy measures alone will not bring the desired results *(101)*.

It is well worth considering some obstacles and new developments in the control of infectious diseases in developing countries. First and foremost is the scarcity of funds, lack of an effective health infrastructure, public health laboratory facilities, equipment, supplies, trained personnel (e.g., epidemiologists) and public awareness needed for the investigation and control of communicable diseases. This handicap is shared by all developing countries. A new development which has been supported by WHO is integration of communicable disease control into *primary health care*. How successfully this integration can be carried out, barring in China and Cuba, has not been demonstrated *(150)*. Some authorities emphasize the need for maintaining intensive vertical programmes for the control of the highly prevalent and controllable diseases such as malaria, tuberculosis and leprosy until their frequency has been reduced to low levels. The failure of the malaria eradication programmes emphasize this point.

Finally a major obstacle to disease control is human behaviour. Medical technology is often ineffective in changing behaviour. In this regard, health education remains the only approach to enlist public co-operation and to induce relevant changes in the behaviour and life-styles of people. Such changes could, in themselves, be powerful methods of disease control.

Surveillance

Surveillance must follow control measures. It has been defined as "the continuous scrutiny of all aspects of occurrence and spread of disease that are pertinent to effective control" *(99)*. Surveillance goes beyond the passive reporting of cases. It includes laboratory confirmation of presumptive diagnosis; finding out the source of infection, routes of transmission, identification of all cases and susceptible contacts; and still others who are at risk in order finally to prevent the further spread of the disease. Serological surveillance identifies patterns of current and past infection. Included in surveillance are systematic collection of pertinent morbidity and mortality data, the orderly consolidation of these data, special field investigations and rapid dissemination of this information to those responsible for control or prevention. Once control measures have been instituted, their effectiveness should be *evaluated*. If they have not been successful, the reason(s) for failure should be identified, the existing measures modified and evaluation continued *(110)*. The ultimate objective of surveillance is prevention.

Surveillance may comprise : (a) *Individual surveillance* : This is surveillance of infected persons until they are no longer a significant risk to other individuals, (b) *Local population surveillance* : e.g., surveillance of malaria, (c) *National population surveillance* : e.g., surveillance of smallpox after the disease has been eradicated, and (d) *International surveillance* : At the international level, the WHO maintains surveillance of important diseases (e.g., influenza, malaria, polio, etc.) and gives timely warning to all national governments. Surveillance, if properly pursued, can provide the health agencies with an overall intelligence and disease–accounting capability. Surveillance is an essential pre-requisite to the rational design and evaluation of any disease control programme.

HEALTH ADVICE TO TRAVELLERS

Emporiatrics is the term coined to describe the science of the health of travellers *(150)*. Travellers face special health risks. In the age of jet travel, international travellers are subject to various forms of stress that may reduce their resistance to disease, e.g., crowding, long hours of waiting, disruption of eating habit, change in the climate and time zone. These factors may in themselves provoke nausea, indigestion, extreme fatigue and insomnia.

Secondly, in developing countries, they are exposed to diseases which are not covered by International Health Regulations (IHR), e.g., malaria, giardiasis, dengue, influenza, filariasis, STD and AIDS, intestinal parasites, typhoid and paratyphoid fever, viral hepatitis, etc. Many of these may not manifest themselves immediately but occur during a varying period after the traveller returns to his normal way of life. Poor hygiene by food handler, poor water quality and improper disposal of wastes are other important causes of disease transfer *(151)*. International travellers have a personal responsibility to recognize these risks of travel, which can be minimized by immunization and chemoprophylaxis or chemotherapy. Thirdly, travellers are separated from familiar and accessible sources of medical care.

Some of the recommendations pertain to the following : (1) Avoid bathing with polluted water as this may result in ear, eye and skin infections. Excessive heat and humidity or over–exertion in these conditions may lead to exhaustion from loss of water and salt. (2) The measures for prevention of insect bites. (3) *Diarrhoeal Diseases* : "Be careful what you eat" is common advice to travellers, but very few truely understand its implications. Diarrhoea affects an estimated 20–50 per cent of all travellers. Contaminated food drinks are the most common source of these infections. Careful selection and preparation of food and drink offer the best protection. Unfortunately appearance of food is no guide as to its safety. The main personal protection is to consider unpasteurized milk, non–bottled drinks, uncooked food (apart from the fruits and vegetables that can be peeled or shelled), as likely to be contaminated and therefore unsafe. The food should be thoroughly and freshly cooked. Use boiled water or bottled mineral water (now available everywhere). Travellers should be aware of the importance of oral rehydration fluids containing salt and glucose for countering dehydration. (4) *Malaria* : There is a high risk of acquiring malaria in endemic areas. Travellers are advised to protect themselves by chemoprophylaxis. Drug prophylaxis should begin at the latest on the day of arrival in the malarious areas and continued for 4–6 weeks after leaving the malarious areas. (5) *Hepatitis A* : Normal human immunoglobulin in a dose of 0.02–0.05 mg/kg of body weight has been recommended every 4 months. Ideally immunoglobulin should not be given within 3 weeks before, or until 2 weeks after administration of a live vaccine. A highly safe, inactivated HAV vaccine is available in several European countries. (6) *Hepatitis E* : There is no vaccine against hepatitis E and immunoglobulin prepared in Europe and USA does not give much of protection. Avoidance of contaminated food and water is the only effective protective measure. (7) *Hepatitis B* : Hepatitis B vaccines are available and are safe. Three doses of vaccine constitute the complete course. The first two doses are given one month apart and the third dose about 6 months later. (8) *STD and HIV* : Measures for preventing STD are the same whether the individual is travelling abroad or not, i.e., avoidance of sex altogether or limit it to a single faithful, uninfected partner. Use of condom is an important preventive measure. To reduce the risk of acquiring HIV and hepatitis B from syringes and needles, travellers should avoid injectable drugs and if an injection is essential they should make sure that the needle and syringe come from sterile pack. (9) *Yellow fever:* Vaccination certificate for yellow fever is the only certificate required for international travel. Yellow fever vaccine is recommended for travellers to countries designated as yellow fever endemic zone. (10) *Tetanus* : It is a wise precaution for the traveller to have a booster dose of tetanus toxoid if 10 years or more have elapsed since the last injection of a complete course or booster.

Medical kit for travellers should contain a disinfectant and dressing that can be applied easily. Sun cream, mosquito repellent, oral rehydration salts and first-aid articles are basic necessities. Patients with chronic diseases like diabetes, cardiac problems etc. should carry enough medicines to avoid the risk of break in medication *(152)*. It is advisable to carry a card with noting of their blood group, drug sensitivity if any and name of any chronic disease he or she is suffering from.

For the benefit of travellers, the WHO publishes every year a booklet, now entitled "International Travel and Health, Vaccination requirements and Health advice ". It provides guidance on some of the main health risks to which travellers may be exposed in different parts of the world and advice on precautions that may be taken against them.

DISINFECTION

Semmelweis (1818–1865) demonstrated the value of handwashing with antiseptic solutions, when he obtained considerable reduction in the death rate from puerperal fever. Lister (1827–1912) was also successful in reducing the number of wound infections by prophylactic application of an antiseptic (carbolic acid) to wounds. The importance of antiseptics and disinfectants has not diminished in this "golden age of antibiotics". Their uses range from control of communicable diseases to sterilization of sophisticated instruments, and treatment of fungal and bacterial infections of the skin and mucous membrane.

Definitions

Disinfectant : Usually a chemical agent (but sometimes a physical agent) that destroys disease causing pathogens or other harmful microorganisms, but might not kill bacterial spores. It refers to substances applied to inanimate objects.

Disinfection : Thermal or chemical destruction of pathogen and other types of microorganisms. Disinfection is

less lethal than sterilization because it destroys most recognized pathogenic microorganisms but not necessarily all microbial forms (e.g., bacterial spores).

Sterilization : Validated process used to render a product free of all forms of viable microorganisms including bacterial spores. Sterilizer is the apparatus used to sterilize medical devices, equipment or supplies by direct exposure to the sterilizing agent.

Antiseptic : Substance that prevents or arrests the growth or action of micro-organisms by inhibiting their activity or by destroying them. The term is used especially for preparations applied topically to living tissue.

Asepsis : Prevention of contact with micro-organism.

Sanitizer : Agent that reduces the number of bacterial contaminants to safe levels as judged by public health requirements. Commonly used with substances applied to inanimate objects.

Sterile : State of being free from all living micro-organisms.

Hospital disinfectant : Disinfectant registered for use in hospitals, clinics, dental offices or any other medical-related facility. Efficacy is demonstrated against *Salmonella choleraesuis, Staphylococcus aureus,* and *Pseudomonas aeruginosa.*

Germicide : Agent that destroys micro-organisms, especially pathogenic organisms.

Detergent : Surface cleaning agent that makes no antimicrobial claims on the label. They comprise a hydrophilic component and a lipohilic component. It acts by lowering surface tension e.g. soap which removes bacteria along with dirt.

Cleaning : Removal, usually with detergent and water or enzyme cleaner and water, of adherent visible soil, blood, protein substances, micro-organisms and other debris from the surfaces, crevices, serrations, joints, and lumens of instruments, devices and equipment by a manual or mechanical process that prepares the items for safe handling and/or further decontamination.

Deodorant : Deodarant is a substance which suppresses or neutralizes bad odours, e.g., lime and bleaching powder.

Properties of an ideal disinfectant *(153)*

An ideal disinfectant fulfils the following criteria :

1. Broad spectrum: should have a wide antimicrobial spectrum.
2. Fast acting: should produce a rapid kill.
3. Not affected by environmental factors: should be active in the presence of organic matter (e.g., blood, sputum, faeces) and compatible with soaps, detergents, and other chemicals encountered in use.
4. Nontoxic: should not be harmful to the user or patient.
5. Surface compatibility: should not corrode instruments and metallic surfaces, and should not cause the deterioration of cloth, rubber, plastics, and other materials.
6. Residual effect on treated surfaces: should leave an antimicrobial film on the treated surface.
7. Easy to use with clear label directions.
8. Odourless: should have a pleasant odour or no odour to facilitate its routine use.
9. Economical: should not be prohibitively high in cost.
10. Solubility: should be soluble in water.
11. Stability: should be stable in concentrate and use-dilution.
12. Cleaner: should have good cleaning properties.
13. Environmentally friendly: should not damage the environment on disposal.

Types of disinfection

(a) **Concurrent disinfection** : It is the application of disinfective measures as soon as possible after the discharge of infectious material from the body of an infected person, or after the soiling of articles with such infectious discharges *(2)*. In other words, the disease agent is destroyed as soon as it is released from the body, and in this way further spread of the agent is stopped. Concurrent disinfection consists of usually disinfection of urine, faeces, vomit, contaminated linen, clothes, hands, dressings, aprons, gloves, etc throughout the course of an illness. (b) **Terminal disinfection** : It is the application of disinfective measures after the patient has been removed by death or to a hospital or has ceased to be a source of infection or after other hospital isolation practices have been discontinued *(9, 99)*. Terminal disinfection is now scarcely practised; terminal cleaning is considered adequate, along with airing and sunning of rooms, furniture and bedding *(9, 99)*. (c) **Precurrent (prophylactic) disinfection** : Disinfection of water by chlorine, pasteurization of milk and handwashing may be cited as examples of precurrent disinfection.

Natural agents

(1) *Sunlight* : Direct and continuous exposure to sunlight is destructive to many disease producing organisms. The ultraviolet rays of sunlight (these do not penetrate through glass) are particularly lethal to bacteria and some viruses. Articles such as linen, bedding, and furniture may be disinfected by exposure to direct sunlight for several hours (2) *Air* : Exposure to open air (airing) acts by drying or evaporation of moisture which is lethal to most bacteria. In general, natural agents such as sunlight and air, because of their vagaries, cannot be totally depended upon for disinfection.

Physical agents

(1) *Burning* : Burning or incineration is an excellent method of disinfection. Inexpensive articles such as contaminated dressings, rags and swabs can be disposed off by burning. Addition of sawdust, paper, kerosene or other combustible material aid in burning. Faeces can be disposed off by burning. Burning should not be done in open air; it is best done in an incinerator. (2) *Hot air* : Hot air is very useful for sterilizing articles such as glassware, syringes, swabs, dressings, french chalk, oils, vaseline and sharp instruments. The drawback of hot air is that it has no penetrating power, and is therefore not suitable for disinfection of bulky articles such as mattresses. Hot air sterilization is usually done in a hot air oven. The temperature of the air in the oven should be maintained at 160–180 deg C for at least one hour to kill spores. Unfortunately, such elevated temperatures destroy plastic,

rubber and other delicate substances. (3) *Boiling :* Boiling is an effective method of disinfection. It provides an atmosphere of boiling and steam. Boiling for 5–10 minutes (rolling boil) will kill bacteria, but not spores or viruses. Boilers provide temperature well above 90 deg C in an atmosphere of steam, which is exposed to open air. To ensure destruction of spores, temperatures above 100 deg C would be required which cannot be achieved in boilers. Boiling is suitable for disinfection of small instruments, tools which are not used for subcutaneous insertion, linen and rubber goods such as gloves. Linen stained with faeces, pus or blood should be first washed in cold water (preferably with a disinfectant such as $2^1/_2$ per cent cresol) and then subjected to boiling, with frequent stirring because linen and clothes are poor conductors of heat. Addition of 1 per cent soap and 0.3 per cent of washing soda enhances the effect of boiling. Boiling for about 30 minutes is adequate to disinfect linen, utensils and bedpans. The drawbacks of boiling are that it is a slow process, unsuitable for thick beddings and woollen materials as they shrink, and it fixes albuminous stains. (4) *Autoclaving :* Sterilizers which operate at high temperatures (in excess of 100 deg C) and pressure are called autoclaves. They generate steam under pressure (saturated steam) which is the most effective sterilizing agent. Autoclaves fall into two categories – gravity displacement autoclaves and the high–speed prevaccum sterilizers. Basically, the autoclave works on the same principle as the domestic pressure cooker. Autoclaving is widely used in hospital and laboratory practice. It destroys all forms of life, including spores. Steam attains a higher temperature under pressure, and has greater powers of penetration than ordinary steam. For example, it attains a temperature of 122 deg C under 15 lbs/sq. inch (1 kg/sq. cm.) pressure. It acts by giving off its latent heat. Absolute sterility can be obtained only by raising the temperature of articles to over 135 deg C. Autoclaving is the most effective method for sterilization of linen, dressings, gloves, syringes, certain instruments and culture media. It is not suitable for sterilization of plastics and sharp instruments. (5) *Radiation :* Ionizing radiation is being increasingly used for sterilization of bandages, dressings, catgut and surgical instruments. The objects to be sterilized are placed in plastic bags before radiation, and they will remain sterile until opened. Ionizing radiation has great penetrating powers with little or no heating effect. This method is most effective, but very costly. Commercial methods of sterilization are normally carried out by gamma radiation (atomic). This technique requires special packing and equipment. It is now one of the most viable, safe and economic methods used today.

Chemical agents

Articles which cannot be sterilized by boiling or autoclaving may be immersed in chemical disinfectants. Chemical agents may also be used for the disinfection of faeces, urine and other contaminated material. There are a wide range of chemical disinfectants, each with its advantages and disadvantages. These are discussed below :

1. Phenol and related compounds

(1) *Phenol :* Pure phenol or carbolic acid is the best known member of this group. On exposure to air, the colourless crystals of phenol become pinkish, and on longer exposure, the colour deepens to dark red. Pure phenol is not an effective disinfectant. It is used as a standard to compare the germicidal activity of disinfectants. (2) *Crude phenol :* The phenol that is commonly used for disinfection is "crude phenol", which is a mixture of phenol and cresol. It is a dark oily liquid. It is effective against gram-positive and gram-negative bacteria, but only slowly effective against spores and acid–fast bacteria. It is also effective against certain viruses. Phenol disinfectants are not readily inactivated by organic matter. Its effect is greatly weakened by dilution. Therefore, it should not be used in less than 10 per cent strength for disinfection of faeces. In 5 per cent strength, it may be used for mopping floors and cleaning drains. Aqueous solutions of 0.2 to 1 per cent are bacteriostatic. (3) *Cresol :* Cresol is an excellent coal-tar disinfectant. It is 3 to 10 times as powerful as phenol, yet no more toxic. Cresol is best used in 5 to 10 per cent strength for disinfection of faeces and urine. A 5 per cent solution may be prepared by adding 8 ounces of cresol to one gallon of water (or 50 ml to one litre of water). Cresol is an all-purpose general disinfectant. (4) *Cresol emulsions :* Cresol emulsified with soap is known as "saponified cresol". Lysol, izal and cyllin are cresol emulsions. Lysol contains 50–60 per cent cresol. They are very powerful disinfectants. A 2 per cent solution of lysol may be used for disinfection of faeces. (5) *Chlorhexidine (hibitane) :* This is one of the most useful skin antiseptics. Highly active against vegetative gram-positive organisms, and moderately active against gram-positive microbes. It is soluble in water and alcohol. It is inactivated by soaps and detergents. 0.5 per cent alcoholic or aqueous solutions can be used as effective handlotions. Creams and lotions containing 1 per cent chlorhexidine are recommended for burns and hand disinfection. (6) *Hexachlorphane :* This antiseptic is highly active against gram-positive organisms, but less active against gram-negative organisms. It is slow in action, but shows a cumulative effect on the skin and is compatible with soaps. Thus it may be incorporated in soap preparations without loss of activity. (7) *Dettol :* Dettol (chloroxylenol) is a relatively non-toxic antiseptic and can be used safely in high concentrations. It is more easily inactivated by organic matter than many other phenolic disinfectants. It is active against streptococci, but worthless against some gram-negative bacteria. Dettol (5%) is suitable for disinfection of instruments and plastic equipment; a contact of at least 15 minutes will be required for disinfection.

2. Quaternary ammonia compounds

(1) *Cetrimide :* It is manufactured under the trade name "cetavlon". It is actively bactericidal against vegetative gram-positive organisms, but much less so against gram-negative organisms. Cetavlon is soluble in water; it has a soapy feel. It may be used in 1–2 per cent strength. (2) *Savlon :* Savlon is a combination of cetavlon and hibitane. Plastic appliances may be disinfected by keeping them in normal strength savlon for 20 minutes. Savlon 1 in 6 in spirit is more effective than savlon 1 in 20 aqueous solution. Clinical thermometers may be best disinfected in savlon 1 in 6 in spirit in just under 3 minutes.

3. Halogens and their compounds

a. *Chlorine and chlorine compounds :* They are potent bactericidal, fungicidal, sporicidal, tuberculocidal and virucidal. Since long time chlorine has been used as disinfectant in water treatment.

(1) *Bleaching powder :* Bleaching powder or chlorinated lime ($CaOCl_2$) is a white amorphous powder with a pungent smell of chlorine. A good sample of bleaching powder contains about 33 per cent of "available chlorine". It kills most of the organisms when used in the strength of 1 to 3

per cent. Bleaching powder is widely used in public health practice in India for disinfection of water, faeces and urine; and as a deodorant. The chief drawback of bleaching powder is that it is an unstable compound and loses its chlorine content on storage. Its action is rapid but brief. A 5 per cent solution (3 to 4 rounded tablespoons to 1 litre of water) is suitable for disinfection of faeces and urine allowing a period of one hour for disinfection. (2) *Hypochlorites :* Hypochlorites are the most widely used chlorine disinfectant, available as liquid (e.g. sodium hypochlorite) or solid (e.g. calcium hypochlorite). The most prevalent chlorine products are aqueous solutions of 5.25–6.15 per cent of sodium hypochlorite, usually called household bleach. They have a broad spectrum of antimicrobial activity, do not leave toxic residues, are unaffected by water hardness, are inexpensive and fast acting, remove dried or fixed organisms and biofilms from surfaces *(153)*. (3) *Chlorine tablets :* Under various trade names (viz., halazone tablets) they are available in the market. They are quite good in disinfecting small quantities of water. (4) Alternative compounds that release chlorine and are used in the health-care setting include demand-release chlorine dioxide, sodium dichloroisocyanurate, and chloramine–T. The advantage of these compounds over hypochlorites is that they retain chlorine longer and so exert a more prolonged bactericidal effect. (5) The microbicidal activity of a new disinfectant, "superoxidized water" has been examined. The concept of electrolyzing saline to create a disinfectant or antiseptic is appealing because the basic materials of saline and electricity are inexpensive and the end product (i.e., water) does not damage the environment. The main products of this water are hypochlorous acid (e.g., at a concentration of about 144 mg/L) and chlorine.

b. *Iodine :* (1) Iodine solutions or tinctures have been used by health professionals primarily as antiseptic on skin (e.g.to prepare incision site prior to surgery) or tissue since long time. Iodine is bactericidal, fungicidal, virucidal and lethal to spore-bearing organisms. Iodine is cheap, readily available and quick in action. (2) *Iodophores :* An iodophore is a combination of iodine and a solubilizing agent or carrier; the resulting complex provides a sustained-release reservoir of iodine and releases small amounts of free iodine in aqueous solution. The best known and most widely used iodophore is povidone-iodine (Betadine). They are non-irritant and do not stain the skin. Besides their use as an antiseptic, iodophores have been used for disinfecting blood culture bottles and medical equipment.

4. Alcohols

Ethyl and isopropyl alcohols are commonly used as antiseptics and disinfectants. Ethyl alcohol in the form of industrial methylated spirit is the alcohol most commonly used for skin disinfection and hand washing. Pure alcohol has no powers of disinfection but when diluted with water to 60–90 per cent vol/vol, it is potent bactericidal, fungicidal, virucidal and tuberculocidal, but does not destroy bacterial spores *(153)*. Its activity decreases rapidly below 50 per cent concentration. 70 per cent alcohol is lethal in a period of seconds to all types of non-sporing bacteria, but when applied to the skin and other surfaces, its activity disappears as the alcohol dries off. Because of expense and flammability, its use is limited to small article disinfection. Available evidence suggests that the most effective skin antiseptics are alcoholic solutions of chlorhexidine and iodine. Alcohols are inflammable and consequently must be stored in cool areas. They also evaporate rapidly, making extended exposure time difficult to achieve unless the items are immersed *(153)*.

5. Formaldehyde

More commonly known in solution as formalin, formaldehyde is a highly toxic and irritant gas which precipitates and destroys protein. It is effective against vegetative bacteria, fungi and many viruses but only slowly effective against bacterial spores (e.g., tetanus spores) and acid-fast bacteria. It does not injure fabrics and metals. It may be used as a 2–3 per cent solution (20–30 ml of 40 per cent formalin in one litre of water) for spraying rooms, walls and furniture.

Formaldehyde gas is most commonly used for disinfection of rooms. The gas is most effective at a high temperature and a relative humidity of 80–90 per cent. The gas may also be used for disinfection of blankets, beds, books and other valuable articles which cannot be boiled.

6. Oxidizing agents

a. *Potassium permanganate :* It is a purplish black crystelline powder that colours everything it touches through strong oxidizing action, which limits its use. It is used to disinfect aquariums and is also widely used in community swimming pools to disinfect ones feet before entering the pool. It is also used to disinfect fruits and vegetables.

b. *Hydrogen peroxide :* Hydrogen peroxide is bactericidal, virucidal, sporicidal and fungicidal. It is used in hospital setting to disinfect surfaces. It is used as solution alone or in combination with other chemicals as a high level disinfectant. A 0.5 per cent accelerated hydrogen peroxide demonstrated bactericidal and virucidal activity in 1 minute and mycobactericidal and fungicidal activity in 5 minutes. A 3 per cent solution is also used as an antiseptic and for cleaning wounds and discharging ulcers.

c. *Paracetic acid :* It is a disinfectant produced by reacting hydrogen peroxide with acetic acid. It is broadly effective against microorganisms and is not deactivated by catalase and peroxidase, the enzymes that break down hydrogen peroxide. It inactivates gram-positive and gram-negative bacteria, fungi and yeast in less than 5 minutes at less than 100 ppm. In the presence of organic matter, 200–250 ppm is required. For viruses, the dose range is wide (12–2250 ppm). It breaks down to environment friendly residue (acetic acid and hydrogen peroxide) and therefore can be used in non–rinse applications.

7. Metals as microbicides

Anti-infective activity of some heavy metals has been known since antiquity. Heavy metals such as silver have been used for prophylaxis of conjunctivitis of the new-born, topical therapy for burn wounds, and bonding to indwelling catheters. Inactivation of bacteria on stainless steel surfaces by zeolite ceramic coating containing silver and zinc ions has also been demonstrated. Metals such as silver, iron, and copper could be used for environmental control, disinfection of water or reusable medical devices, or incorporated into medical devices.

8. Lime

Lime is the cheapest of all disinfectants. It is used in the form of fresh quick lime or 10–20 per cent aqueous suspension known as "milk of lime". Faeces and urine can be disinfected by mixing 10–20 per cent aqueous

suspension of lime and allowing the disinfectant to act for 2 hours. As lime wash, it is used for treating walls. As a deodorant, lime is sprinkled in cattle sheds and stables and in public places where urinals and latrines are located.

9. Ethylene oxide

Heat-sensitive articles may be sterilized at 55–60 deg.C by ethylene oxide which kills bacteria, spores (e.g., tetanus spores) and also viruses. Ethylene oxide is explosive, therefore, it is mixed with carbon dioxide (12 per cent). Water vapour is also often added to the mixture (relative humidity 33 per cent) since it increases the efficiency of the gas. Ethylene oxide has been effectively used to sterilize fabrics, plastic equipment, cardiac catheters, books, etc; but the process is difficult to control. Therefore ethylene oxide disinfection is discouraged when alternatives are available.

10. Miscellaneous inactivating agents

a. *Pasteurization :* Pasteurization is not a sterilization process; its purpose is to destroy all pathogenic microorganisms. However, pasteurization does not destroy bacterial spores. The time-temperature relation for hot-water pasteurization is generally ~70°C (158°F) for 30 minutes.

b. *Microwave :* Microwaves are used in medicine for disinfection of soft contact lenses, dental instruments, dentures, milk, and urinary catheters for intermittent self-catheterization. However, microwaves must only be used with products that are compatible (e.g., do not melt). Microwaves are radio-frequency waves, which are usually used at a frequency of 2450 MHz. The microwaves produce friction of water molecules in an alternating electrical field. The intermolecular friction derived from the vibrations generates heat. The microwaves produced by a "home–type" microwave oven (2.45 GHz) completely inactivate bacterial cultures, mycobacteria viruses, and *G. stearothermophilus* spores within 60 seconds to 5 minutes depending on the challenge organism.

c. *Flushing and Washer Disinfectors :* Flushing and washer-disinfectors are automated and closed equipment that clean and disinfect objects from bedpans, urinals and washbowls to surgical instruments and anesthesia tubes. They have a short cycle of a few minutes. They clean by flushing with warm water, possibly with a detergent, and then disinfect by flushing the items with hot water or with steam. Because this machine empties, cleans, and disinfects, manual cleaning is eliminated, fewer disposable items are needed, and fewer chemical gemicides are used.

d. *Ultraviolet radiation :* The wavelength of UV radiation ranges from 328 nm to 210 nm. Its maximum bactericidal effect occurs at 240–280 nm. Mercury vapour lamps emit more than 90 per cent of their radiation at 253.7 nm, which is near the maximum microbicidal activity *(153)*. UV radiation has been employed in the disinfection of drinking water, air, titanium implants and contact lenses. Bacteria and viruses are more easily killed by UV light than the bacterial spores.

e. Ozone : Ozone has been used for years as a drinking water disinfectant. Ozone is produced when O_2 is energized and split into two monatomic (O_1) molecules. The monatomic oxygen molecules then collide with O_2 molecules to form ozone, which is O_3. Ozone is a powerful oxidant that destroys microorganisms but it is highly unstable (i.e. half-life of 22 minutes of room temperature).

Factors affecting the efficacy of sterilization *(153)*

Following factors should be kept in mind while sterilizing the medical equipment :

	Factors	Effect
1.	Cleaning	Failure to adequately clean instruments results in higher bioburden, protein load, and salt concentration. These will decrease sterilization efficacy.
2.	Pathogen type	Spore-forming organisms are most resistant to sterilization. However, the contaminating microflora on surgical instruments consists mainly of vegetative bacteria.
3.	Biofilm accumulation	Biofilm accumulation reduces efficacy of sterilization by impairing exposure of the sterilant to the microbial cell.
4.	Luman length and luman diameter	Increasing lumen length and decreasing lumen diameter impairs sterilant penetration. May require forced flow through lumen to achieve sterilization.
5.	Restricted flow	Sterilant must come into contact with microorganisms. Device designs that prevent or inhibit this contact (e.g. sharp bends, blind lumens) will decrease sterilization efficacy.
6.	Device design and construction	Materials used in construction may affect compatibility with different sterilization processes.

Recommended disinfection procedures

1. Faeces and urine

Faeces and urine should be collected in impervious vessels and disinfected by adding an equal volume of one of the disinfectants listed in Table 46 and allowed to stand for 1–2 hours. Faeces should be broken up with a stick to allow proper disinfection. If the disinfectants listed in Table 46 are not available, an equal amount of quicklime or freshly prepared milk of lime (1 of lime to 4 of water) may be added, mixed and left for 2 hours. If none is available, a bucket of boiling water may be added to the faeces which is then covered and allowed to stand until cool. After disinfection, the excretal matter may be emptied into water closet or buried in ground. Bedpans and urinals should ideally be steam disinfected. Alternatively, they may be disinfected with $2^1/_2$ per cent cresol for an hour after cleaning.

TABLE 46

Agents suitable for disinfection of faeces and urine

Disinfectant	Amount per litre	Per cent
1. Bleaching powder	50 g	5
2. Crude phenol	100 ml	10
3. Cresol	50 ml	5
4. Formalin	100 ml	10

2. Sputum

This is best received in gauze or paper handkerchiefs and destroyed by burning. If the amount is considerable (as in TB hospitals), it may be disinfected by boiling or

autoclaving for 20 minutes at 20 lbs pressure. Alternatively, the patient may be asked to spit in a sputum cup half filled with 5 per cent cresol. When the cup is full, it is allowed to stand for an hour and the contents may be emptied and disposed off.

3. Room

Usually thorough cleaning, airing and exposure to direct sunlight, when possible, for several hours will be sufficient. If necessary, floors and hard surfaces in the room should be prohibited for 48 hours *(154)*. For chemical disinfection, floors and hard surfaces should be sprayed or mopped with one of the following disinfectants : chlorine preparations such as chlorinated lime in concentrations that leave 25 ppm or more of free chlorine; formaldehyde solution at a concentration of 1 per cent or more; phenolic disinfectants such as $2^1/_2$ per cent cresol. The solution should remain in contact with the surface for at least 4 hours before final washing *(154)*.

On rare occasions, when fumigation is required, the gas most commonly used is formaldehyde. It may be generated by boiling commercial formalin in 2 volumes of water (500 ml of formalin plus 1 litre of water per 30 cu. metres of space) in a stainless steel vessel, over an electric hot plate or by adding potassium permanganate to commercial formalin in large jars (170–200 gram to 500 ml of formalin plus 1 litre of water per 30 cu. metres) *(154)*. There is vigorous boiling and liberation of formaldehyde gas. The room is kept closed for 6–12 hours to allow disinfection. Formaldehyde disinfection is most effective at a high temperature and a relative humidity of 80–90 per cent.

INVESTIGATION OF AN EPIDEMIC

The occurrence of an epidemic always signals some significant shift in the existing balance between the agent, host and environment. It calls for a prompt and thorough investigation of the cases to uncover the factor(s) responsible and to guide in advocating control measures to prevent further spread. Emergencies caused by epidemics remain one of the most important challenges to national health administrations. Epidemiology has an important role to play in the investigation of epidemics. The objectives of an epidemic investigation are *(3, 21, 155)*.

a. to define the magnitude of the epidemic outbreak or involvement in terms of time, place and person.
b. to determine the particular conditions and factors responsible for the occurrence of the epidemic.
c. to identify the cause, source(s) of infection, and modes of transmission to determine measures necessary to control the epidemic; and
d. to make recommendations to prevent recurrence.

An epidemic investigation calls for inference as well as description. Frequently, epidemic investigations are called for after the peak of the epidemic has occurred; in such cases, the investigation is mainly retrospective. No step by step approach applicable in all situations can be described like a "cook–book" *(155)*. However, in investigating an epidemic, it is desired to have an orderly procedure or practical guidelines as outlined below which are applicable for almost any epidemic study. Some of the steps can be done concurrently.

1. Verification of diagnosis

Verification of diagnosis is the first step in an epidemic investigation, as it may happen sometimes that the report may be spurious, and arise from misinterpretation of signs and symptoms by the lay public. It is therefore necessary to have the verification of diagnosis on the spot, as quickly as possible. It is not necessary to examine all the cases to arrive at a diagnosis. A clinical examination of a sample of cases may well suffice. Laboratory investigations wherever applicable, are most useful to confirm the diagnosis but the epidemiological investigations should not be delayed until the laboratory results are available.

2. Confirmation of the existence of an epidemic

The next step is to confirm if epidemic exists. This is done by comparing the disease frequencies during the same period of previous years. An epidemic is said to exist when the number of cases (observed frequency) is in excess of the expected frequency for that population, based on past experience. An arbitrary limit of two standard errors from the endemic occurrence is used to define the epidemic threshold for common diseases such as influenza *(3)*. Often the existence of an epidemic is obvious needing no such comparison, as in the case of common-source epidemics of cholera, food poisoning and hepatitis A. These epidemics are easily recognized. In contrast the existence of modern epidemics (e.g., cancer, cardiovascular diseases) is not easily recognized unless comparison is made with previous experience.

3. Defining the population at-risk

(a) Obtaining a map of the area : Before beginning the investigation, it is necessary to have a detailed and current map of the area. If this is not available, it may be necessary to prepare such a map. It should contain information concerning natural landmarks, roads and the location of all dwelling units along each road or in isolated areas. The area may be divided into segments, using natural landmarks as boundaries. This may again be divided into smaller sections. Within each section, the dwelling units (houses) may be designated by numbers.

(b) Counting the population : The denominator may be related to the entire population or sub-groups of a population. It may also be related to total events (see page 55 for more details). For example, if the denominator is the entire population a complete census of the population by age and sex should be carried out in the defined area by house–to–house visits. For this purpose lay health workers in sufficient numbers may be employed. Using this technique it is possible to establish the size of the population. The population census will help in computing the much–needed attack rates in various groups and subgroups of the population later on. Without an appropriate denominator of "population at risk" attack rates cannot be calculated.

4. Rapid search for all cases and their characteristics

(a) *Medical survey* : Concurrently, a medical survey should be carried out in the defined area to identify all cases including those who have not sought medical care, and those possibly exposed to risk. Ideally, the complete survey (screening each member of the population for the presence

of the disease in question) will pick up all affected individuals with symptoms or signs of the disorder. Lay health workers may be trained to administer the "epidemiological case sheet" or questionnaire to collect relevant data.

(b) Epidemiological case sheet : The epidemiologist should be armed with an "epidemiological case sheet" for collecting data from cases and from persons apparently exposed but unaffected. The epidemiological case sheet or "case interview form" should be carefully designed (based on the findings of a rapid preliminary inquiry) to collect relevant information. This includes : name, age, sex, occupation, social class, travel, history of previous exposure, time of onset of disease, signs and symptoms of illness, personal contacts at home, work, school and other places; special events such as parties attended, foods eaten and exposure to common vehicles such as water, food and milk; visits out of the community, history of receiving injections or blood products, attendance at large gathering, etc. The information collected should be relevant to the disease under study. For example, if the disease is food–borne, detailed food histories are necessary. A case review form will ensure completeness and consistency of data collection.

If the outbreak is large, it may not be possible to interview all the cases (e.g., influenza). In such cases, a random sample should be examined and data collected.

(c) Searching for more cases : The patient may be asked if he knew of other cases in the home, family, neighbourhood, school, work place having an onset within the incubation of the index case. Cases admitted to the local hospitals should also be taken into consideration. This may reveal not only additional cases but also person-to-person spread. The search for new cases (secondary cases) should be carried out everyday, till the area is declared free of epidemic. This period is usually taken as twice the incubation period of the disease since the occurrence of last case.

5. Data analysis

The data collected should be analyzed on ongoing basis, using the classical epidemiological parameters – time, place and person. If the disease agent is known, the characteristics of time, place and person may be rearranged into Agent–Host–Environment model *(3)*.

a. Time : Prepare a chronological distribution of dates of onset and construct an "epidemic curve". Look for time clustering of cases. An epidemic curve may suggest : (a) a time relationship with exposure to a suspected source (Fig. 4), (b) whether it is a common–source or propagated epidemic, and (c) whether it is a seasonal or cyclic pattern suggestive of a particular infection.

b. Place : Prepare a "spot map" (geographic distribution) of cases, and if possible, their relation to possible sources of infection, e.g., water supply, air pollution, foods eaten, occupation, etc. Clustering of cases may indicate a common source of infection. Analysis of geographic distribution may provide evidence of the source of disease and its mode of spread. This was demonstrated by John Snow in the cholera outbreak in the Golden Square district, London (Figure 6).

c. Person : Analyze the data by age, sex, occupation and other possible risk factors. Determine the attack rates/case fatality rates, for those exposed and those not exposed and according to host factors. For example, in most food-borne outbreaks, food–specific attack rates must be calculated for each food eaten to determine the source of infection.

The purpose of data analysis is to identify common event or experience, and to delineate the group involved in the common experience.

6. Formulation of hypotheses

On the basis of time, place and person distribution or the Agent–Host–Environment model, formulate hypotheses to explain the epidemic in terms of (a) possible source (b) causative agent (c) possible modes of spread, and (d) the environmental factors which enabled it to occur. These hypotheses should be placed in order of relative likelihood. Formulation of a tentative hypothesis should guide further investigation.

7. Testing of hypotheses

All reasonable hypotheses need to be considered and weighed by comparing the attack rates in various groups for those exposed and those not exposed to each suspected factor. This will enable the epidemiologist to ascertain which hypothesis is consistent with all the known facts. When divergent theories are presented, it is not easy to distinguish immediately between those which are sound and those which are merely plausible. Therefore it is instructive to turn back to arguments which have been tested by the subsequent course of events *(156)*.

8. Evaluation of ecological factors

An investigation of the circumstances involved should be carried out to undertake appropriate measures to prevent further transmission of the disease. Ecological factors which have made the epidemic possible should be investigated such as sanitary status of eating establishments, water and milk supply; breakdown in the water supply system; movements of the human population, atmospheric changes such as temperature, humidity and air pollution, population dynamics of insects and animal reservoirs. The outbreak can be studied in a case control fashion. One of the primary concerns of the epidemiologist is to relate the disease to environmental factors to know the source(s) of infection, reservoirs and modes of transmission.

9. Further investigation of population at risk

A study of the population at risk or a sample of it may be needed to obtain additional information. This may involve medical examination, screening tests, examination of suspected food, faeces or blood samples, biochemical studies, assessment of immunity status, etc. The approach may be retrospective or prospective. For example, serological study may reveal clinically inapparent cases and throw light on the pathogenesis of the condition. Healthy individuals (those who are not ill) from the same universe may be studied in a case control fashion. This will permit classification of all members as to :

a. exposure to specific potential vehicles.

b. whether ill or not.

10. Writing the report

The report should be complete and convincing. Information to be included in the final report on an epidemic is given in Table 47 *(157)*.

TABLE 47

Information to be included in the final report on an epidemic

Section	Contents
1. Background	Geographical location Climatic conditions Demographic status (population pyramid) Socio-economic situation Organization of health services Surveillance and early warning systems Normal disease prevalence.
2. Historical data	Previous occurrence of epidemics – of the same disease, – locally or elsewhere Occurrence of related diseases, if any – in the same area – in other areas Discovery of the first cases of the present outbreak.
3. Methodology of investigations	Case definition Questionnaire used in epidemiological investigation Survey teams Household survey Retrospective survey Prospective surveillance Collection of laboratory specimens Laboratory techniques.
4. Analysis of data	Clinical data : – frequency of signs and symptoms – course of disease – differential diagnosis – death or sequelae rates Epidemiological data : – mode of occurrence – in time – by place – by population groups Modes of transmission : – source(s) of infection – route(s) of excretion and portal(s) of entry – factors influencing transmission Laboratory data : – isolation of agent(s) – serological confirmation – significance of results Interpretation of data : – comprehensive picture of the outbreak – hypotheses as to cause(s) – formulation and testing of hypotheses by statistical analysis.
5. Control measures	Definition of strategies and methodology of implementation – constraints – results Evaluation : – significance of results – cost/effectiveness Preventive measures.

It may be necessary to implement temporary control measures at the commencement of an epidemic on the basis of known facts of the disease. These measures may be modified or replaced in the light of new knowledge acquired by the epidemic investigation. As Frost *(156)* observed, an epidemiological investigation is more than the collection of established facts. It includes their orderly arrangement into chains of inference, which extend more or less beyond the bounds of direct observation.

4 Screening for Disease

"Health should mean a lot more than escape from death or, for that matter, escape from disease."

Iceberg phenomenon of disease

Epidemiologist and others who study disease find that the pattern of disease in hospitals is quite different from that in a community. That is, a far larger proportion of disease (e.g., diabetes, hypertension) is hidden from view in the community than is evident to physicians or to the general public. The analogy of an **iceberg**, only the tip of which is seen, is widely used to describe disease in the community.

The concept of the "iceberg phenomenon of disease" (Page 39) gives a better idea of the progress of a disease from its sub-clinical stages to overt or apparent disease than the familiar **spectrum of disease**. The submerged portion of the iceberg represents the hidden mass of disease (e.g., sub-clinical cases, carriers, undiagnosed cases). The floating tip represents what the physician sees in his practice. The hidden part of the iceberg thus constitutes the mass of unrecognized disease in the community, and its detection and control is a challenge to modern techniques in preventive medicine.

Concept of screening

The active search for disease among apparently healthy people is a fundamental aspect of prevention. This is embodied in screening, which has been defined as "the search for unrecognized disease or defect by means of rapidly applied tests, examinations or other procedures in apparently healthy individuals."

Historically, the annual health examinations were meant for the early detection of "hidden" disease. To bring such examinations within the reach of large masses of people with minimal expenditures of time and money, a number of alternative approaches have come into use. They are based primarily on conserving the physician–time for diagnosis and treatment and having technicians to administer simple, inexpensive laboratory tests and operate other measuring devices. This is the genesis of screening programmes. The original screening programmes were for individual diseases such as tuberculosis, syphilis or selected groups such as antenatal mothers, school children and occupational groups. Over the years, the screening tests have steadily grown in number (Table 8). Screening is considered a preventive care function, and some consider it a logical extension of health care.

Screening differs from **periodic health examinations** in the following respects *(1)*:

1) capable of wide application
2) relatively inexpensive, and
3) requires little physician–time. In fact the physician is not required to administer the test, but only to interpret it.

Screening and diagnostic tests

A screening test is not intended to be a diagnostic test. It is only an initial examination. Those who are found to have positive test results are referred to a physician for further diagnostic work-up and treatment. Screening and diagnostic tests may be contrasted as in Table 1.

TABLE 1
Screening and diagnostic tests contrasted

	Screening test	Diagnostic test
1	Done on apparently healthy	Done on those with indications or sick.
2	Applied to groups	Applied to single patients, all diseases are considered.
3	Test results are arbitrary and final	Diagnosis is not final but modified in light of new evidence, diagnosis is the sum of all evidence.
4	Based on one criterion or cut-off point	Based on evaluation of a number of symptoms, signs (e.g., diabetes) and laboratory findings.
5	Less accurate	More accurate.
6	Less expensive	More expensive.
7	Not a basis for treatment	Used as a basis for treatment.
8	The initiative comes from the investigator or agency providing care.	The initiative comes from a patient with a complaint.

Source : *(2)*

However, the criteria in Table 1 are not hard and fast. There are some tests which are used both for screening and diagnosis, e.g., test for anaemia and glucose tolerance test. Screening and diagnosis are not competing, and different criteria apply to each.

Concept of "lead time"

Fig. 1 shows the possible outcomes for a given disease process. There is nothing to be gained in screening for diseases whose onset is quite obvious. Detection programmes should be restricted to those conditions in which there is considerable **time lag** between disease onset and the usual time of diagnosis. In this period, there are

usually a number of critical points which determine both the severity of the disease and the success of any treatment in reversing the disease process. There is clearly little value in detecting disease in advance of the usual time of diagnosis unless such detection precedes the final critical point beyond which treatment would be unsuccessful and/or permanent damage would be done. Detection programmes should, therefore, concentrate on those conditions where the time lag between the disease's onset and its final critical point is sufficiently long to be suitable for population screening *(3)*.

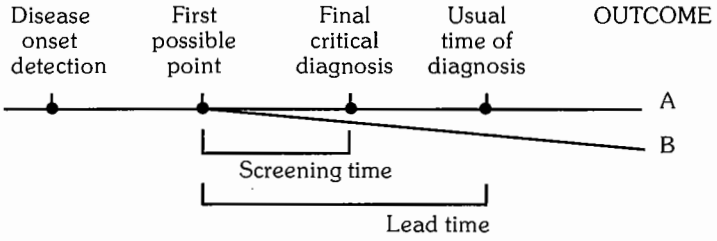

FIG.1
Model for early detection programmes

"Lead time" is the advantage gained by screening, i.e., the period between diagnosis by early detection and diagnosis by other means. In Fig.1, **A** is the usual outcome of the disease, and **B** is the outcome to be expected when the disease is detected at the earliest possible moment. The benefits of the programme are therefore **B–A**. The benefits of the programme must be seen in terms of its outcomes. It is also necessary for the complexities and costs of any detection programme to be viewed against the benefits accruing therefrom *(3)*.

Aims and objectives

The basic purpose of screening is to sort out from a large group of apparently healthy persons those likely to have the disease or at increased risk of the disease under study, to bring those who are "apparently abnormal" under medical supervision and treatment (Fig.2). Screening is carried out in the hope that earlier diagnosis and subsequent treatment favourably alters the natural history of the disease in a significant proportion of those who are identified as "positive" *(4)*.

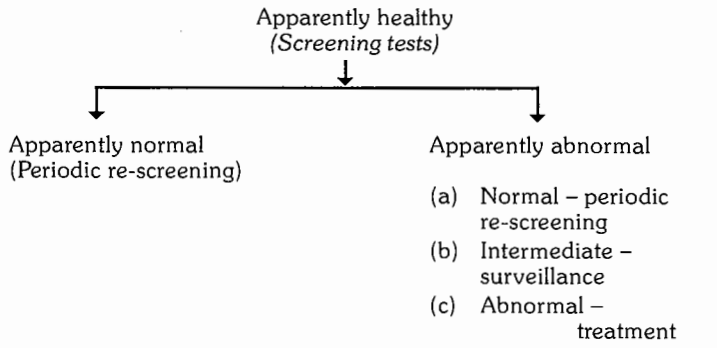

FIG.2
Possible outcomes of screening

Explanation of terms

a. Screening

Strictly speaking, screening is testing for infection or disease in populations or in individuals *who are not seeking health* care; for example, serological testing for AIDS virus in blood donors, neonatal screening, premarital screening for syphilis.

b. Case-finding

This is use of clinical and/or laboratory tests to detect disease in individuals *seeking health care* for other reasons; for example, the use of VDRL test to detect syphilis in pregnant women. Other diseases include pulmonary tuberculosis in chest symptomatics, hypertension, cervical cancer, breast cancer, diabetes mellitus, etc.

c. Diagnostic tests

Use of clinical and/or laboratory procedures to *confirm* or refute the existence of disease or true abnormality in patients with signs and symptoms presumed to be caused by the disease; for example, VDRL testing of patients with lesions suggestive of secondary syphilis; endocervical culture for *N. gonorrhoea*.

The distinction between screening, case-finding or diagnosis should be clear-cut. Often, however, it is blurred by the multiplicity of tests used and the haphazard nature of diagnostic decision-making. Thus the same test may be used in different contexts for both screening and diagnosis. Each step may involve multiple tests as in the case of syphilis. In evaluating a test, then, one must consider whether it is for screening or diagnosis, alone or in conjunction with other tests *(19)*.

Uses of screening

Four main uses have been described:

a. Case detection

This is also known as "prescriptive screening". It is defined as the presumptive identification of unrecognized disease, which does not arise from a patient's request, e.g., neonatal screening. In other words, people are screened primarily for their own benefit. Specific diseases sought by this method have included bacteriuria in pregnancy, breast cancer, cervical cancer, deafness in children, diabetes mellitus, iron deficiency anaemia, PKU, pulmonary tuberculosis, haemolytic disease of the newborn, etc. *(5)*. Since disease detection is initiated by medical and public health personnel, they are under special obligation to make sure that appropriate treatment is started early.

b. Control of disease

This is also known as "prospective screening". People are examined for the benefit of others, e.g., screening of immigrants from infectious diseases such as tuberculosis and syphilis to protect the home population; and screening for streptococcal infection to prevent rheumatic fever. The screening programme may, by leading to early diagnosis permit more effective treatment and reduce the spread of infectious disease and/or mortality from the disease.

c. Research purposes

Screening may sometimes be performed for research purposes. For example, there are many chronic diseases whose natural history is not fully known (e.g., cancer, hypertension). Screening may aid in obtaining more basic knowledge about the natural history of such diseases, as for example, initial screening provides a prevalence estimate and subsequent screening, an incidence figure. Where screening is done for research purposes, the investigator should inform the study participants that no follow-up therapy will be available.

d. Educational opportunities

Apart from possible benefits to the individual and the acquisition of information of public health relevance, screening programmes (as for example, screening for diabetes) provide opportunities for creating public awareness and for educating health professionals.

Types of screening

Three types of screening have been described:

a. Mass screening
b. High-risk or selective screening
c. Multiphasic screening.

a. Mass screening

Mass screening simply means the screening of a whole population *(6)* or a sub-group, as for example, all adults *(7)*. It is offered to all, irrespective of the particular risk individual may run of contracting the disease in question (e.g., tuberculosis).

Mass screening for disease received enthusiastic support in the past. However, when a number of mass screening procedures were subjected to critical review, there appeared to be little justification for their use in many instances *(8)*. Indiscriminate mass screening, therefore, is not a useful preventive measure unless it is backed up by suitable treatment that will reduce the duration of illness or alter its final outcome.

b. High-risk or selective screening

Screening will be most productive if applied selectively to high-risk groups, the groups defined on the basis of epidemiological research *(7)*. For example, since cancer cervix tends to occur relatively less often in the upper social groups, screening for cancer cervix in the lower social groups could increase the yield of new cases. One population sub-group where certain diseases (e.g., diabetes, hypertension, breast cancer) tend to be aggregated in the family. By screening the other members of the family (and close relatives), the physician can detect additional cases.

Epidemiologists have extended the concept of screening for disease to screening for "risk factors", as these factors apparently antedate the development of actual disease. For example, elevated serum cholesterol is associated with a high risk of developing coronary heart disease. Risk factors, particularly those of a patho-physiological nature such as serum cholesterol and blood pressure are amenable to effective interventions. In this way, preventive measures can be applied before the disease occurs. Besides effectiveness, economical use of resources will also occur if the screening tests are selectively applied to individuals in high-risk group.

c. Multiphasic screening

It has been defined as the application of two or more screening tests in combination to a large number of people at one time than to carry out separate screening tests for single diseases. The procedure may also include a health questionnaire, clinical examination and a range of measurements and investigations (e.g., chemical and haematological tests on blood and urine specimens, lung function assessment, audiometry and measurement of visual acuity) – all of which can be performed rapidly with the appropriate staffing organization and equipment *(7)*.

Multiphasic screening has enjoyed considerable popularity, and evidence from randomized controlled studies in UK and USA suggested that multiphasic screening has not shown any benefit accruing to the population in terms of mortality and morbidity reduction *(9)*. On the other hand, it has increased the cost of health services without any observable benefit. Furthermore, in multiphasic screening, as currently practised, most of the tests have not been validated. These observations have cast doubts on the utility of multiphasic screening *(10, 11)*.

CRITERIA FOR SCREENING

Before a screening programme is initiated, a decision must be made whether it is worthwhile, which requires ethical, scientific, and, if possible financial justification *(4)*. The criteria for screening are based on two considerations: the DISEASE to be screened, and the TEST to be applied *(12,13,14,15)*.

Disease

The disease to be screened should fulfil the following criteria before it is considered suitable for screening:

1. the condition sought should be an important health problem (in general, prevalence should be high);
2. there should be a recognizable latent or early asymptomatic stage;
3. the natural history of the condition, including development from latent to declared disease, should be adequately understood (so that we can know at what stage the process ceases to be reversible);
4. there is a test that can detect the disease prior to the onset of signs and symptoms;
5. facilities should be available for confirmation of the diagnosis;
6. there is an effective treatment;
7. there should be an agreed–on policy concerning whom to treat as patients (e.g., lower ranges of blood pressure; border-line diabetes);
8. there is good evidence that early detection and treatment reduces morbidity and mortality;
9. the expected benefits (e.g., the number of lives saved) of early detection exceed the risks and costs.

When the above criteria are satisfied, then only, it would be appropriate to consider a suitable screening test.

Screening test

The test must satisfy the criteria of acceptability, repeatability and validity, besides others such as yield, simplicity, safety, rapidity, ease of administration and cost. Tests most likely to fulfil one condition may however, be least likely to fulfil another – for example, tests with greater accuracy may be more expensive and time consuming. The choice of the test must therefore often be based on compromise.

1. Acceptability

Since a high rate of cooperation is necessary, it is important that the test should be acceptable to the people at whom it is aimed. In general, tests that are painful, discomforting or embarrassing (e.g., rectal or vaginal examinations) are not likely to be acceptable to the population in mass campaigns.

2. Repeatability

An attribute of an ideal screening test or any measurement (e.g., height, weight) is its repeatability (sometimes called reliability, precision or reproducibility). That is, the test must give consistent results when repeated more than once on the same individual or material, under the same conditions. The repeatability of the test depends upon three major factors, namely observer variation, biological (or subject) variation and errors relating to technical methods. For example, the measurement of blood pressure is poorly reproducible because it is subjected to all these three major factors.

A. Observer variation

All observations are subjected to variation (or error). These may be of two types:

a. Intra-observer variation

If a single observer takes two measurements (e.g., blood pressure, chest expansion) in the same subject, at the same time and each time, he obtained a different result, this is termed as **intra-observer** or **within-observer** variation. This is variation between repeated observations by the same observer on the same subject or material at the same time. Intra-observer variation may often be minimized by taking the average of several replicate measurements at the same time.

b. Inter-observer variation

This is variation between different observers on the same subject or material, also known as **between-observer** variation. Inter-observer variation has occurred if one observer examines a blood-smear and finds malaria parasite, while a second observer examines the same slide and finds it normal.

Table 2 shows the results when 14,867 chest X-ray films were each read independently by the same eight radiologists.

TABLE 2

Showing observer variation among radiologists

"Positive" readings	No.of films	Per cent
0/8	13,560	91.21
1/8	877	5.90
2/8	168	1.13
3/8	66	.44
4/8	42	.28
5/8	28	.19
6/8	23	.16
7/8	39	.26
8/8	64	.43
	14,867	100.00

Source : *(16)*

The results shown in Table 2 are sobering and instructive. There was concurrence of all 8 readers that 91.21 per cent of the films had one or more positive readings.

Observational errors are common in the interpretation of X-rays, ECG tracings, readings of blood pressure and studies of histopathological specimens. Observer errors can be minimized by (a) standardization of procedures for obtaining measurements and classifications (b) intensive training of all the observers (c) making use of two or more observers for independent assessment, etc. It is probable that these errors can never be eliminated absolutely.

B. Biological (subject) variation

There is a biological variability associated with many physiological variables such as blood pressure, blood sugar, serum cholesterol, etc. The fluctuation in the variate measured in the same individual may be due to: (a) *Changes in the parameters observed*: This is a frequent phenomena in clinical presentation. For example, cervical smears taken from the same woman may be normal one day, and abnormal on another day. Myocardial infarction may occur without pain. Subject variation of blood pressure is a common phenomenon. (b) *Variations in the way patients perceive their symptoms and answer*: This is a common subject variation. There may be errors in recollection of past events when a questionnaire is administered. When the subject is aware that he is being probed, he may not give correct replies. In short, subject variation can be a potential source of error in epidemiological studies. (c) *Regression to the mean*: An important example of biological variability is regression to the mean. There is a tendency for values at the extremes of a distribution, either very high or low, to regress towards the mean or average on repeat measurements. Many features of disease states vary considerably over time, for example, the pain of rheumatoid arthritis, stool frequency in ulcerative colitis, blood pressure in hypertension or the blood glucose in diabetes. This concept is particularly important to remember in evaluating the effects of a specific therapy on a variable such as the use of a specific drug to reduce blood pressure or serum cholesterol.

Whereas observer variation may be checked by repeat measurements at the *same time,* biological variation is tested by repeat measurements *over time.* This is due to the fact that measurement is done only on a tiny sample of the normal distribution of the physiological variable.

C. Errors relating to technical methods

Lastly, repeatability may be affected by variations inherent in the method, e.g., defective instruments, erroneous calibration, faulty reagents; or the test itself might be inappropriate or unreliable. Where these errors are large, repeatability will be reduced, and a single test result may be unreliable.

3. Validity (accuracy)

The term **validity** refers to what extent the test accurately measures which it purports to measure. In other words, validity expresses the ability of a test to separate or distinguish those who have the disease from those who do not. For example, glycosuria is a useful screening test for diabetes, but a more valid or accurate test is the glucose tolerance test. Accuracy refers to the closeness with which measured values agree with "true" values.

Validity has two components – sensitivity and specificity. When assessing the accuracy of a diagnostic test, one must consider both these components. Both measurements are expressed as percentages. Sensitivity and specificity are usually determined by applying the test to one group of

persons having the disease, and to a reference group not having the disease (Table 3). Sensitivity and specificity, together with "predictive accuracy" are inherent properties of a screening test. These are discussed below.

TABLE 3–A

Screening test result by diagnosis

Screening test results	Diagnosis		Total
	Diseased	Not diseased	
Positive	a (True-positive)	b (False-positive)	a+b
Negative	c (False-negative)	d (True-negative)	c + d
Total	a + c	b + d	a + b + c + d

The letter "a" (Table 3–A) denotes those individuals found positive on the test who have the condition or disorder being studied (i.e., true-positives). The group labelled "b" includes those who have a positive test result but who do not have the disease (i.e., false-positives). Group "c" includes those with negative test results but who have the disease (i.e., false-negatives). Finally, those with negative results who do not have the disease are included in group "d" (i.e., true-negatives).

Evaluation of a screening test

The following measures are used to evaluate a screening test:

(a) Sensitivity = a/ (a + c) × 100

(b) Specificity = d/(b + d) × 100

(c) Predictive value of a positive test = a/(a + b) × 100

(d) Predictive value of a negative test = d/(c + d) × 100

(e) Percentage of false-negatives = c/(a + c) × 100

(f) Percentage of false-positive = b/(b + d) × 100

Let us rewrite Table 3–A substituting hypothetical figures (Table 3–B) and calculate the above measures:

TABLE 3–B

Screening test result by diagnosis

Screening test results	Diagnosis		Total
	Diseased	Not diseased	
Positive	40 (a)	20 (b)	60 (a+b)
Negative	100 (c)	9,840 (d)	9,940 (c + d)
	140 (a + c)	9,860 (b + d)	10,000 (a + b + c + d)

(a) Sensitivity (true-positive) = (40/140) × 100 = 28.57%

(b) Specificity (true-negative) = (9840/9860) × 100 = 99.79%

(c) False-negative = (100/140) × 100 = 71.4%

(d) False-positive = (20/9860) × 100 = 0.20%

(e) Predictive value of a positive test = (40/60) × 100 = 66.66%

(f) Predictive value of a negative test = (9840/9940) × 100 = 98.9%

Sensitivity

The term **sensitivity** was introduced by Yerushalmy *(17)* in 1940s as a statistical index of diagnostic accuracy. It has been defined as the ability of a test to identify correctly all those who have the disease, that is "true-positive". A 90 per cent sensitivity means that 90 per cent of the diseased people screened by the test will give a "true-positive" result and the remaining 10 per cent a "false-negative" result.

Specificity

It is defined as the ability of a test to identify correctly those who do not have the disease, that is, "true-negatives". A 90 per cent specificity means that 90 per cent of the non-diseased persons will give "true-negative" result, 10 per cent of non-diseased people screened by the test will be wrongly classified as "diseased" when they are not.

To illustrate, let us compare the sensitivity and specificity of EEG and CAT screening for diagnosis of brain tumours (Tables 4 and 5).

It can be seen from Tables 4 and 5, the CAT screening test is both more sensitive and more specific than EEG in the diagnosis of brain tumours.

In dealing with diagnostic tests that yield a quantitative result (e.g., blood sugar, blood pressure) the situation is different. There will be overlapping of the distributions of an attribute for diseased and non-diseased persons (Fig. 3). False positives and false negatives comprise the area of the overlap. When the distributions overlap, it is not possible to correctly assign individuals with these values to either the normal or the diseased group on the basis of screening alone.

For example, if we decide to use the 2–hour post-prandial blood glucose level of 180 mg/100 ml as an index of the presence of diabetes mellitus, the sensitivity and specificity are 50 and 99.8 per cent respectively (Table 6). In other words, sensitivity is low, but specificity very high. Further it will be seen from Table 6 that sensitivity and specificity are inversely related. That is, sensitivity may be increased only at the expense of specificity and vice versa. An ideal screening test should be 100 per cent sensitive and 100 per cent specific. In practice, this seldom occurs.

TABLE 4

Diagnosis of brain tumours by EEG

EEG results	Brain tumour	
	Present	Absent
Positive	36	54,000
Negative	4	306,000
	40	360,000

Sensitivity = 36/40 × 100 = 90 per cent

Specificity = 306,000/360,000 × 100 = 85 per cent

TABLE 5

Diagnosis of brain tumours by computer assisted axial tomography

CAT results	Brain tumour	
	Present	Absent
Positive	39	18,000
Negative	1	342,000
	40	360,000

Sensitivity = 39/40 × 100 = 97.5 per cent

Specificity = 342,000/360,000 × 100 = 95 per cent

TABLE 6

Sensitivity and specificity of a 2-hour postprandial blood test for glucose for 70 true diabetics and 510 true non-diabetics at different levels of blood glucose

Blood glucose level (mg/100 ml)	Sensitivity	Specificity
80	100.0	1.2
90	98.6	7.3
100	97.1	25.3
110	92.9	48.4
120	88.6	68.2
130	81.4	82.4
140	74.3	91.2
150	64.3	96.1
160	55.7	98.6
170	52.9	99.6
180	50.0	99.8
190	44.3	99.8
200	37.1	100.0

Source : *(18)*

Predictive accuracy

In addition to sensitivity and specificity, the performance of a screening test is measured by its "predictive value" which reflects the diagnostic power of the test. The predictive accuracy depends upon sensitivity, specificity and disease prevalence. The "predictive value of a positive test" indicates the probability that a patient with a positive test result has, in fact, the disease in question. The more prevalent a disease is in a given population, the more accurate will be the predictive value of a positive screening test. The predictive value of a positive result falls as disease prevalence declines.

Table 7 shows the predictive value of positive Gram's stained cervical smear test to detect gonorrhoea at prevalences of 5,15 and 25 per cent. In this example, the predictive value of a positive test was calculated to be 21, 47 and 63 per cent respectively. Thus in female populations in which the gonorrhoea is low (5 per cent prevalence), only 21 per cent of patients with positive results really have gonorrhoea; the remaining 79 per cent have false-positive results. Furthermore, as the sensitivity of this test is only 50 per cent, half of the cases are not detected, which greatly reduces the impact of the detection programme on disease transmission.

False negatives and positives

Whereas the epidemiologist thinks in terms of sensitivity and specificity, the clinician thinks in terms of false negatives and false positives.

False-negatives: The term "false-negative" means that patients who actually have the disease are told that they do not have the disease. It amounts to giving them a "false reassurance". The patient with a "false-negative" test result might ignore the development of signs and symptoms and may postpone the treatment. This could be detrimental if the disease in question is a serious one and the screening test is unlikely to be repeated within a short period of time. A screening test which is very sensitive has few "false negatives". The lower the sensitivity, the larger will be the number of false negatives.

False-positives: The term "false-positive" means that patients who do not have the disease are told that they have the disease. In this case, normal healthy people may be subjected to further diagnostic tests, at some inconvenience, discomfort, anxiety and expense – until their freedom from disease is established. A screening test with a high specificity will have few false positives. False-positives not only burden the diagnostic facilities, but they also bring discredit to screening programmes.

In fact, no screening test is perfect, i.e., 100 per cent sensitive and 100 per cent specific.

Yield

"Yield" is the amount of previously unrecognized disease that is diagnosed as a result of the screening effort. It depends upon many factors, viz. sensitivity and specificity of the test, prevalence of the disease, the participation of the individuals in the detection programme. For example, by limiting a diabetes screening programme to persons over 40 years, we can increase the yield of the screening test. High-risk populations are usually selected for screening, thus increasing yield.

Combination of tests

Two or more tests can be used in combination to enhance the specificity or sensitivity of screening. For example, syphilis screening affords an example whereby all screenees are first evaluated by an RPR test. This test has high sensitivity, yet will yield false positives. However, all those positive to RPR are then submitted to FTA–ABS, which is a more specific test, and the resultant positives now truly have syphilis.

TABLE 7

Predictive value of a positive gram-stained cervical smear test (with constant sensitivity of 50% and specificity of 90%) at three levels of prevalence

Prevalence 5%				Prevalence 15%				Prevalence 25%			
	Culture				Culture				Culture		
	+	–	Total		+	–	Total		+	–	Total
Smear	+ 25	95	120	Smear	+ 75	85	160	Smear	+ 125	75	200
	– 25	855	880		– 75	765	840		– 125	675	800
Total	50	950	1000	Total	150	850	1000	Total	250	750	1000
Positive predictive value	$\frac{25}{120} \times \frac{100}{1} = 21\%$			Positive predictive value	$\frac{75}{160} \times \frac{100}{1} = 47\%$			Positive predictive value	$\frac{125}{200} \times \frac{100}{1} = 63\%$		

The problem of the borderline *(20)*

The question arises which of the two qualities (sensitivity or specificity) is more important in screening? No categorical answer can be given. Figure 3 illustrates graphically the concepts of sensitivity and specificity.

Figure 3–a is a bimodal distribution of a variable in the "normal" and "diseased" populations. Note that the two curves overlap. If the disease is bimodal, as may be expected in certain genetically transmitted characteristics such as phenylketonuria, the shaded area or the "borderline" group will comprise a mixture of persons with the disease and persons without the disease (i.e., a mixture of false positives and false negatives). The point at which the distributions intersect (i.e., at level E) is frequently used as the **cut-off** point between the "normal" and "diseased" persons, because it will generally minimize the false positives and false negatives.

Figure 3–b is a unimodal distribution. Many physiological variables such as blood pressure, blood sugar and serum cholesterol show this type of distribution. Their values are continuously distributed around the mean, confirming to a normal or skewed distribution. In these observations, there is no sharp dividing line between the "normal" and "diseased". The "borderline" group (C–D) will comprise a homogeneous sample of persons. The question arises whether the cut-off point between "disease" and "normality" should be set at C or D as in Figure 3-b. If the **cut-off** point is set at the level of A or C, it will render the test highly sensitive, missing few cases but yielding many false positives. If the **cut-off** point is set at B or D, it will increase specificity of the test. Furthermore, in the unimodal distribution, once a cut-off point level has been adopted, all persons above that level (i.e., above level C or D in Figure 3-b) would be regarded as "diseased".

Taking diabetes as our example, if the cut-off point for blood glucose is lowered to detect diabetes (say less than 120 mg per cent), the sensitivity of the test is increased at the cost of specificity. If the cut-off point is raised (say to 180 mg per cent), the sensitivity is decreased (Table 6). In other words, there is no blood sugar level which will ensure the separation of all those with the disease from those without the disease.

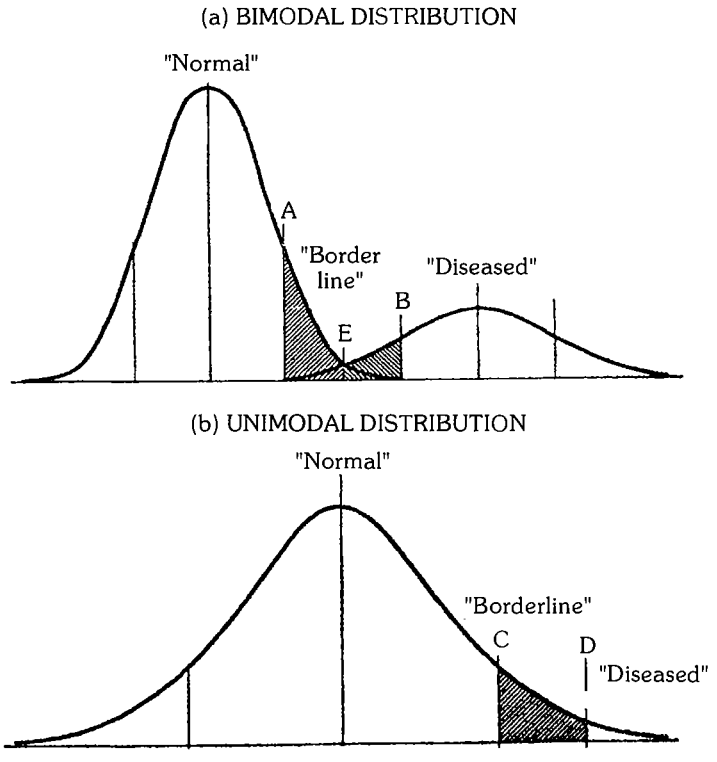

FIG. 3
Distribution of a variable in a population

In screening for disease, a prior decision is made about the cut-off point, on the basis of which individuals are classified as "normal" or "diseased". In making this decision, the following factors are taken into consideration: (a) *Disease prevalence*: When the prevalence is high in the community, the screening level is set at a lower level, which will increase sensitivity. (b) *The disease*: If the disease is very lethal (e.g., cervical cancer, breast cancer) and early detection markedly improves prognosis, a greater degree of sensitivity, even at the expense of specificity, is desired. In these cases, subsequent diagnostic work-up can be relied on to rule out the disease in the false-positives. That is, a proportion of false-positives is tolerable but not false-negatives. On the other hand, in a prevalent disease like diabetes for which treatment does not markedly alter outcome, specificity must be high and early cases may be missed, but false-positives should be limited; otherwise the health system will be overburdened with diagnostic demands on the positives, both true and false. That is, high specificity is necessary when false-positive errors must be avoided. A useful index in making this decision is the predictive value of a positive test. This index measures the percentage of positive results that are true positives; it is a function of the sensitivity and specificity as well as the frequency of the disease.

There are various other points which must also be taken into account in screening. First, people who participate in the screening programme may not be those who have most to gain from it, as for example, those at greatest risk of cancer of the cervix uteri are least likely to attend for cervical cytology. Therefore screening must be applied selectively to those people most likely to benefit. Selection might be based on a person's age, sex, medical history, occupation, family history or other factors. Secondly, tests with greater accuracy may be more expensive and time-consuming, and the choice of the test therefore often be based on compromise. Thirdly, screening should not be developed in isolation; it should be integrated into the existing health services. Lastly, the risks as well as the expected benefits must be explained to the people to be screened. These risks include any possible complications of the examination procedures, and the possibility of false-positive and false-negative test results.

Regardless of the approach taken to screening tests, regular patient follow-up visits are important (not to leave the patients high and dry) if effective health and medical care are to result from the effort. Garfield *(21)* has stressed the need to meet demands for medical care by separating screenees into well, asymptomatic-sick, and sick groups. This separation makes possible the optimal use of health care services.

Evaluation of screening programmes

Many screening tests (Table 8) were introduced in the past without subjecting them to rigid scrutiny. They were introduced because it was thought a good thing to detect and treat cases before they should reach an advanced stage. The modern view is that new screening programmes should be introduced only after proper evaluation.

TABLE 8
Some screening tests

Pregnancy	**Infancy**
Anaemia	LCB
Hypertension Toxemia	Congenital dislocation of hip
Rh status	Congenital heart disease
Syphilis (VDRL Test)	Spina bifida
Diabetes	Cerebral palsy
Cardiovascular disease	Hearing defects
Neural tube defects	Visual defects
Down's syndrome	Hypothyroidism
HIV	Developmental screening tests
	Haemoglobinopathies
Middle-aged men and women	Sickle cell anaemia
Hypertension	Undescended testis
Cancer	**Elderly**
Diabetes mellitus	Nutritional disorders
Serum cholesterol	Cancer
Obesity	Tuberculosis
	Chronic bronchitis
	Glaucoma
	Cataract

(1) *Randomized controlled trials*: Ideally evaluation should be done by a randomized controlled trial in which one group (randomly selected) receives the screening test, and a control which receives no such test. Ideally RCT should be performed in the setting where the screening programme will be implemented, and should employ the same type of personnel, equipment and procedures that will be used in that programme. If the disease has a low frequency in the population, and a long incubation period (e.g., cancer) RCT may require following tens of thousands of people for 10–20 years with virtually perfect record keeping. The cost and logistics are often prohibitive.

(2) *Uncontrolled trials*: Sometimes, uncontrolled trials are used to see if people with disease detected through screening appear to live longer after diagnosis and treatment than patients who were not screened. One such example is uncontrolled studies of cervical cancer screening which indicated that deaths from that disease could be very much reduced if every woman was examined periodically.

(3) *Other methods*: There are also other methods of evaluation such as case control studies and comparison in trends between areas with different degrees of screening coverage. Thus it can be determined whether intervention by screening is any better than the conventional method of managing the disease.

To conclude, the screening concept, filled with potential has been overburdened with problems, many of which remain unsolved. The construction of accurate tests that are both sensitive and specific is a key obstacle to the wide application of screening. Scientific and technical puzzles abound.

5 Epidemiology of Communicable Diseases

"Infectious diseases will last as long as humanity itself"

I. RESPIRATORY INFECTIONS

SMALLPOX
(VARIOLA)

An acute infectious disease caused by *variola virus,* and clinically characterized by a sudden onset of fever, headache, backache, vomiting and sometimes convulsions, especially in children. On the third day of fever, a typical rash appears which is centrifugal in distribution and passes through successive stages of macule, papule, vesicle, pustule, and scab with subsequent scarring.

Previously, it was one of the greatest killer disease. In 1967, WHO began an intensified worldwide campaign to eradicate smallpox, based on the technique of surveillance and containment. The last known case of smallpox in India occurred on 24th May 1975. India was declared smallpox free on 5th July 1975. The eradication of smallpox was confirmed in April 1977 by an international commission. The World Health Assembly confirmed the global eradication of smallpox in May 1980. All countries have discontinued routine vaccination against smallpox. However, WHO maintains a reserve stock of smallpox vaccine and vaccination needles – sufficient to protect more than 200 million people, should an emergency arise *(1)*.

Case definition for notification of smallpox under the International Health Regulations, 2005 *(2)*

Member states to the IHR (2005) are required to notify to WHO immediately of any confirmed case of smallpox. The case definition for a confirmed smallpox case includes the following:

Confirmed case of smallpox

An individual of any age presenting with acute onset of fever (≥38.3°C/101°F), malaise, and severe prostration with headache and backache occurring 2–4 days before onset of rash

AND

Subsequent development of a maculopapular rash starting on the face and forearms then spreading to the trunk and legs, and evolving within 48 hours to deep-seated, firm or hard and round well-circumscribed vesicles, and later pustules, which may become umbilicated or confluent

AND

Lesions that appear at the same stage of development (i.e. all are vesicles or all are pustules) on any given part of the body (e.g. the face or arm)

AND

No alternative diagnosis explaining the illness

AND

Laboratory confirmation.

By eradication of smallpox, 2 million deaths, a few hundred thousand cases of blindness, and 10–15 million cases of disease per year have been prevented. Over the last 34 years, it has become increasingly obvious that the strategy that was used to conquer smallpox cannot be copied for any other disease. Every disease like every human being is unique.

Smallpox eradication surveillance

Despite the absence of smallpox, surveillance of "rumours" continues in order to sustain public confidence in the eradication of the disease. However, the final chapter of the smallpox story remains to be written, as the smallpox virus has not been completely destroyed. Stocks are still held at government research centres in the Russian Federation and at the United States.

CHICKENPOX
(VARICELLA)

Chickenpox or varicella is an acute, highly infectious disease caused by *varicella-zoster* (V–Z) virus. It is characterized by vesicular rash that may be accompanied by fever and malaise. It is worldwide in distribution and occurs in both epidemic and endemic forms. Chickenpox and herpes zoster are now regarded as different host responses to the same aetiological agent. Inoculation of zoster vesicle fluid into children produces chickenpox, and children who have recovered from zoster virus related infection are resistant to varicella *(1)*.

Problem Statement

Based on conservative estimates, the global annual chickenpox disease burden includes 4.2 million severe complications leading to hospitalization and 4,200 deaths. In the pre-vaccine era in high-income developed countries,

case fatality rate was about 3 per lac cases compared to 1–3 per 1000 cases for measles. Factors which influence the severity of disease and outcome in populations include the proportion of cases among infants, pregnant women and other adults, the prevalence of immunocompromising conditions including HIV infections and the extent of access to care and appropriate treatment. In otherwise healthy children, the disease is usually self-limiting *(2)*.

The incidence and severity of herpes-zoster disease increases with age, with marked increase after 50 years of age, which correlates with ageing related decline in cell-mediated immunity. Among adults who reach 85 years of age, it is estimated that approximately half will have suffered atleast one episode of herpes zoster *(2)*.

In India, during the year 2013, about 28,090 cases of chickenpox were reported with 61 deaths. The case fatality rate was about 0.21 per cent. Kerala reported the highest number of cases (12,168) and West Bengal reported the maximum number of deaths (68) due to chickenpox *(3)*.

Epidemiological determinants

Agent factors

(a) AGENT : The causative agent of chickenpox, V–Z virus is also called "Human (alpha) herpes virus 3". Primary infection causes chickenpox. Recovery from primary infection is commonly followed by the establishment of latent infection in the cranial nerves, sensory, ganglia, and spinal dorsal root ganglia, often for decades, without clinical manifestations. When the cell-mediated immunity wanes with age or following immuno-suppressive therapy, the virus may reactivate, resulting in herpes zoster in about 10–30 per cent of persons *(4)*. It is, a painful, vesicular, pustular eruption in the distribution of one or more sensory nerve roots. The virus can be grown in tissue culture. (b) SOURCE OF INFECTION: Usually a case of chickenpox. The virus occurs in the oropharyngeal secretions and lesions of skin and mucosa. Rarely the source of infection may be a patient with herpes zoster. The virus can be readily isolated from the vesicular fluid during the first 3 days of illness. The scabs however are not infective *(5)*. (c) INFECTIVITY: The period of communicability of patients with varicella is estimated to range from 1 to 2 days before the appearance of rash, and 4 to 5 days thereafter *(5)*. The virus tends to die out before the pustular stage *(6)*. The patient ceases to be infectious once the lesions have crusted. (d) SECONDARY ATTACK RATE: Chickenpox is highly communicable. The secondary attack rate in household contacts approaches 90 per cent *(7)*.

Host factors

(a) AGE : Chickenpox occurs primarily among children under 10 years of age. Few persons escape infection until adulthood. The disease can be severe in normal adults. (b) IMMUNITY : One attack gives durable immunity; second attacks are rare. The acquisition of maternal antibody protects the infant during the first few months of life. No age, however, is exempt in the absence of immunity. The IgG antibodies persist for life and their presence is correlated with protection against varicella. The cell-mediated immunity appears to be important in recovery from V–Z infections and in protection against the reactivation of latent V–Z virus *(8)*. (c) PREGNANCY : Infection during pregnancy presents a risk for the foetus leading to congenital varicella syndrome. It occurs in 0.4–2.0 per cent of children born to mothers who become infected with VZV during the first 20 weeks of gestation. Infants, whose mothers had chickenpox during pregnancy, have a higher risk of developing herpes zoster in the first years of life *(2)*.

Environmental factors

Chickenpox shows a seasonal trend in temperate settings and in most tropical settings, with peak incidence during winter and spring, or in coolest, driest months in the tropics. Periodic large outbreaks occur with an inter-epidemic cycle of 2–5 years *(2)*.

VZV is heat labile. Outside host cell, the virus survives in the external environment for only a few hours, occasionally for a day or two, and it is readily inactivated by lipid solvents, detergents, and proteases *(2)*.

Transmission

Chickenpox is transmitted from person to person by droplet infection and by droplet nuclei. Most patients are infected by "face-to-face" (personal) contact. The portal of entry of the virus is the upper respiratory tract or the conjunctiva. Since the virus is extremely labile, it is unlikely that fomites play a significant role in its transmission *(9)*. Contact infection undoubtedly plays a role when an individual with herpes zoster is an index case. The virus can cross the placental barrier and infect the foetus, a condition known as congenital varicella.

Incubation period

Usually 14 to 16 days, although extremes as wide as 10 to 21 days have been reported.

Clinical features

The clinical spectrum of chickenpox may vary from a mild illness with only a few scattered lesions to a severe febrile illness with widespread rash. Inapparent infection is estimated to occur in no more than 5 per cent of susceptible children *(7)*. In the majority of cases, the disease tends to be mild and typical *(6)*. The clinical course of chickenpox may be divided into two stages :

(A) PRE-ERUPTIVE STAGE : Onset is sudden with mild or moderate fever, pain in the back, shivering and malaise. This stage is very brief, lasting about 24 hours. In adults, the prodromal illness is usually more severe and may last for 2–3 days before the rash comes out *(6)*.

(B) ERUPTIVE STAGE : In children the rash is often the first sign. It comes on the day the fever starts. The distinctive features of the rash are :

(a) *Distribution :* The rash is symmetrical. It first appears on the trunk where it is abundant, and then comes on the face, arms and legs where it is less abundant. Mucosal surfaces (e.g., buccal, pharyngeal) are generally involved. Axilla may be affected, but palms and soles are not usually affected. The density of the eruption diminishes centrifugally.

(b) *Rapid evolution :* The rash advances quickly through the stages of macule, papule, vesicle and scab. In fact, the first to attract attention are often the vesicles filled with clear fluid and looking like "dew-drops" on the skin. They are superficial in site, with easily ruptured walls and surrounded by an area of inflammation. Usually they are not umbilicated. The vesicles may form crusts without going through the pustular stage. Many of the lesions may abort. Scabbing begins 4 to 7 days after the rash appears.

(c) *Pleomorphism :* A characteristic feature of the rash in chickenpox is its pleomorphism, that is, all stages of the rash (papules, vesicles and crusts) may be seen simultaneously at

one time, in the same area. This is due to the rash appearing in successive crops for 4 to 5 days in the same area.

(d) *Fever* : The fever does not run high but shows exacerbations with each fresh crop of eruption.

The main points of difference between chickenpox and smallpox are given in Table 1.

TABLE 1

Differences between smallpox and chickenpox

	Smallpox	Chickenpox
1.	*Incubation :* About 12 days (range: 7–17 days).	About 15 days (range 7–21 days).
2.	*Prodromal symptoms:* Severe.	Usually mild.
3.	*Distribution of rash :*	
(a)	centrifugal	(a) centripetal
(b)	palms and soles frequently involved	(b) seldom affected
(c)	axilla usually free	(c) axilla affected
(d)	rash predominant on extensor surfaces and bony prominences.	(d) rash mostly on flexor surfaces.
4.	*Characteristics of the rash:*	
(a)	deep-seated	(a) superficial
(b)	vesicles multilocular and umbilicated	(b) unilocular; dew-drop like appearance
(c)	only one stage of rash may be seen at one time	(c) rash pleomorphic, i.e., different stages of the rash evident at one given time, because rash appears in successive crops
(d)	No area of inflammation is seen around the vesicles.	(d) an area of inflammation is seen around the vesicles.
5.	*Evolution of rash :*	
(a)	evolution of rash is slow, deliberate and majestic, passing through definite stages of macule, papule, vesicle and pustule.	(a) evolution of rash very rapid
(b)	scabs begin to form 10–14 days after the rash appears	(b) scabs begin to form 4–7 days after the rash appears
6.	*Fever :* Fever subsides with the appearance of rash, but may rise again in the pustular stage (secondary rise of fever).	Temperature rises with each fresh crop of rash.

Complications

In most cases, chickenpox is a mild, self–limiting disease. The mortality is less than 1 per cent in uncomplicated cases.

However, varicella may be accompanied by severe complications particularly in immunosuppressed patients and may also occur in normal children and adults. These include haemorrhages (varicella haemorrhagical), pneumonia, encephalitis, acute cerebellar ataxia and Reye's syndrome (acute encephalopathy associated with fatty degeneration of the viscera especially liver) *(10)*. Varicella pneumonia is rare in healthy children but is the most common complication in neonates, adults and immuno-compromised patients. It is related to many varicella-related deaths. Maternal varicella during pregnancy may cause foetal wastage and birth defects such as cutaneous scars, atrophied limbs, microcephaly and low birth weight, cataract, microphthalmia, chorioretinitis, deafness and cerebro-cortical atrophy. If varicella develops in a mother within 5 days after delivery, the newborn is at risk of disseminated disease and should receive varicella-zoster immunoglobulin *(4)*. The virus has a potential for oncogenicity.

Varicella-zoster virus is the major virus associated with acute retinal necrosis and progressive outer retinal necrosis, both of which occur with increased frequency among AIDS patients *(4)*.

Secondary bacterial infections, particularly with group A β-haemolytic streptococci and *staphylococcus aureus* are common. Cellulitis, erysipelas, epiglottitis, osteomyelitis, scarlet fever and rarely meningitis are observed. Pitted scars are frequent sequelae.

Immunocompromised patients are at increased risk of complications of varicella, including those with malignancies, organ transplants or HIV infection and those receiving high doses of corticosteroids. Disseminated intravascular coagulation may occur which is rapidly fatal. Children with leukaemia are especially prone to develop severe disseminated varicella-zoster virus disease *(1)*.

Laboratory diagnosis

During the smallpox post-eradication era the diagnosis of chickenpox is of great importance because of its resemblance to mild smallpox. Laboratory diagnosis is rarely required as clinical signs are usually clear-cut.

Laboratory confirmation of varicella or herpes zoster (HZ) is by detecting VZV DNA using polymerase chain reaction (PCR) or isolating VZV in cell culture from vesicular fluid, crusts, saliva, cerebrospinal fluid or other specimens. Direct immunofluorescence can also be used for rapid testing though this method has lower sensitivity than PCR. Detection of VZV-specific serum IgM antibody is considerably less sensitive than PCR and is not the method of choice for confirming varicella. Detection of serum IgM and PCR are of limited value for the confirmation of HZ. Serologic screening of serum for IgG antibodies is used to assess immunity or susceptibility to varicella in unvaccinated persons, e.g. in health-care workers *(2)*.

Control

The usual control measures are notifications, isolation of cases for about 6 days after onset of rash and disinfection of articles soiled by nose and throat discharges *(11)*.

Several antiviral compounds provide effective therapy for varicella including acyclovir, valaciclovir, famiciclovir and foscarnet. Acyclovir can prevent the development of systemic disease in varicella-infected immunosuppressed patients and can halt the progression of zoster in adults. Acyclovir does not appear to prevent post herpic neuralgia *(1)*.

Prevention

1. VARICELLA-ZOSTER IMMUNOGLOBULIN (VZIG)

Varicella-Zoster Immunoglobulin *(VZIG)* given within 72 hours of exposure has been recommended for prevention of chickenpox in exposed susceptible individuals particularly in immunosuppressed persons. These include (a) susceptible persons receiving immunosuppressive therapy; (b) persons with congenital cellular immunodeficiency; (c) persons with acquired immunodeficiency including HIV/AIDS; (d) susceptible and exposed persons, in particular pregnant women; (e) newborns; and (f) premature infants of low birth

weight. It has no therapeutic value in established disease. *VZIG* is given by intramuscular injection in a dose of 12.5 units/kg body weight up to a maximum of 625 units, with a repeat dose in 3 weeks, if a high-risk patient remains exposed. Because *VZIG* appears to bind the varicella vacine, the two should not be given concomitantly *(4)*.

2. VACCINE

A live attenuated varicella virus vaccine is safe and currently recommended for children between 12–18 months of age who have not had chickenpox.

Recommendations on dosage and interval between doses vary by manufacturer. Monovalent vaccine can be administered following one or two dose schedule (0.5 ml each by subcutaneous injection. A 2 dose schedule is recommended for all persons aged ≥ 13 years. When 2 doses are administered, the minimum interval between doses is either 6 weeks or 3 months for children (12 months to 12 years of age inclusive), and 4 or 6 weeks for adolescents and adults (13 years of age and older).

Combination vaccines (MMRV) can be administered to children from 9 months to 12 years. If 2 doses of MMRV are used, the minimum interval between doses should be 4 weeks. It is preferred that the 2nd dose be administered 6 weeks to 3 months after the first dose or at 4–6 years of age *(2)*.

The duration of immunity is not known but is probably 10 years. Although the vaccine is very effective in preventing disease, breakthrough infections do occur – but are much milder than in unvaccinated individuals (usually less than 50 lesions, with milder systemic symptoms). Although the vaccine is very safe, adverse reactions can occur as late as 4–6 weeks after vaccination. Tenderness and erythema at the injection site are seen in 25%, fever in 10–15%, and a localized maculopapular or vesicular rash in 5%; a smaller percentage develops a diffuse rash, usually with five or fewer vesicular lesions.

Spread of virus from vaccinees to susceptible individuals is possible, but the risk of such transmission even to immuno-compromised patients is small, and disease, when it develops, is mild and treatable with acyclovir. Nonetheless, the vaccine, being a live attenuated virus, should not be given to immunocompromised individuals, or pregnant women. The use of varicella vaccine may be considered in clinically stable HIV-infected children or adults with CD4+ T-cell levels ≥ 15 per cent including those receiving highly active antiretroviral therapy. HIV testing is not a prerequisite for varicella vaccination *(2)*. It is contraindicated in persons allergic to neomycin. For theoretic reasons, it is recommended that following vaccination, salicylates should be avoided for 6 weeks (to prevent Reye's syndrome).

Several unresolved issues remain, including the need for booster doses, whether universal childhood vaccination will shift the incidence of disease to adolescence or adulthood with the possibility of more severe disease, and whether vaccination might prevent development of herpes zoster.

MEASLES
(RUBEOLA)

An acute highly infectious disease of childhood caused by a specific virus of the group myxoviruses. It is clinically characterized by fever and catarrhal symptoms of the upper respiratory tract (coryza, cough), followed by a typical rash. Measles is associated with high morbidity and mortality in developing countries. Measles occurs only in humans. There is no animal reservoir of infection.

Problem statement

Measles is endemic virtually in all parts of the world. It tends to occur in epidemics when the proportion of susceptible children reaches about 40 per cent *(1)*. When the disease is introduced into a virgin community more than 90 per cent of that community will be infected *(2)*. While measles is now rare in industrialized countries, it remains a common illness in many developing countries. The primary reason for continuing high childhood measles mortality and morbidity is the failure to deliver at least one dose of measles vaccine to all infants *(3)*.

The challenges for measles elimination include : (1) weak immunization systems; (2) high infectious nature of measles; (3) populations that are inaccessible due to conflict; (4) the increasing refusal of immunization by some populations; (5) the changing epidemiology of measles which has led to increased transmission among adolescents and adults; (6) the need to provide catch-up measles vaccination to >130 million children in India; (7) the gaps in human and financial resources at the country, regional and global levels *(4)*.

In the year 2010, the world's two most populous countries made promising advances in measles control: China held the largest–ever SIA, vaccinating >103 million children, and India started implementation of a 2-dose vaccination strategy *(5)*.

In 1980, before widespread use of measles vaccine, an estimated 2.6 million measles deaths occurred worldwide. Recognizing this burden, WHO and UNICEF developed an accelerated measles mortality reduction strategy of delivering 2 doses of measles containing vaccine (MCV) to all children through routine services and supplementary immunizing activities (SIAs), and improving disease surveillance. Since implementation of this strategy began in 2001, the estimated number of measles deaths has fallen from 733,000 in year 2000 to 122,000 in year 2012. At the 2010 World Health Assembly, member states endorsed the following targets to be met by 2015 as milestones towards eventual global measles eradication : (1) raise routine coverage with the first dose of MCV (MCV_1) to ≥ 90 per cent nationally, and ≥ 80 per cent in every district or equivalent administrative unit; (2) reduce and maintain annual measles

incidence to < 5 cases per million; and (3) reduce measles mortality by ≥ 95 per cent in comparison with the estimated level in the year 2000 *(5)*.

Building on the previous WHO and UNICEF strategy; and recognizing the burden of congenital rubella syndrome and availability of combination vaccines, the Measles Initiative has developed a 2012–2020 Global Measles and Rubella Strategic Plan. This plan aims to: (1) achieve and maintain high levels of population immunity through high coverage with 2 doses of measles and rubella-containing vaccines; (2) establish effective surveillance to monitor disease and evaluate progress; (3) develop and maintain outbreak preparedness for rapid response and appropriate case management; (4) communicate and engage to build public confidence in, and demand for vaccination; and (5) conduct research and development to support operations and improve vaccination and diagnostic tools *(5)*.

In India, measles is a major cause of morbidity and a significant contributor to childhood mortality. Prior to the immunization programme, cyclical increase in the incidence of measles were recorded every third year. With the increase in immunization coverage levels, the intervals between cyclical peaks has increased and the intensity of the peak minimized. However, several outbreaks are reported in tribal and remote areas. The retrospective data indicate a declining trend of measles in the country. During 1987 about 2.47 lakh cases were reported, whereas, after implementation of UIP, the number of cases has come down to 15,768 with 56 deaths during the year 2013 *(6)*. However, the estimates are much higher as large number of cases go unreported. According to WHO estimates, measles is responsible for about 2 per cent of under-5 mortality in India *(7)*.

Epidemiological determinants

Agent factors

(a) AGENT : Measles is caused by an RNA paramyxovirus. So far as is known, there is only one serotype. The virus cannot survive outside the human body for any length of time, but retains infectivity when stored at sub-zero temperature. The virus has been grown in cell cultures. (b) SOURCE OF INFECTION : The only source of infection is a case of measles. Carriers are not known to occur. There is some evidence to suggest that subclinical measles occurs more often than previously thought. (c) INFECTIVE MATERIAL : Secretions of the nose, throat and respiratory tract of a case of measles during the prodromal period and the early stages of the rash. (d) COMMUNICABILITY : Measles is highly infectious during the prodromal period and at the time of eruption. Communicability declines rapidly after the appearance of the rash. The period of communicability is approximately 4 days before and 4 days after the appearance of the rash. Isolation of the patient for a week from the onset of rash more than covers the period of communicability *(8)*. (e) SECONDARY ATTACK RATE : There is only one antigenic type of measles virus. Infection confers life long immunity. Most so-called secondary attacks represent errors in diagnosis either in initial or second illness *(9)*.

Host factors

(a) AGE : Affects virtually everyone in infancy or childhood – between 6 months and 3 years of age in developing countries where environmental conditions are generally poor, and older children usually over 5 years in developed countries *(10)*. Following the use of measles vaccine, the disease is now seen in somewhat older age–groups *(11)*. This highlights the importance of periodic serological checking of the immunity status of the susceptible population. (b) SEX : Incidence equal. (c) IMMUNITY : No age is immune if there was no previous immunity. One attack of measles generally confers life-long immunity. Second attacks are rare. Infants are protected by maternal antibodies up to 6 months of age; in some, maternal immunity may persist beyond 9 months. Immunity after vaccination is quite solid and long-lasting. (d) NUTRITION : Measles tends to be very severe in the malnourished child, carrying a mortality upto 400 times higher than in well-nourished children having measles *(12)*. This may possibly be related to poor cell-mediated immunity response, secondary to malnutrition *(13)*. Additionally, severely malnourished children have been shown to excrete measles virus for longer periods than better nourished children indicating prolonged risk to themselves, and of intensity of spread to others *(14)*. Even in a healthy child, an attack of severe measles may be followed by weight loss, precipitating the child into malnutrition.

Environmental factors

Given a chance, the virus can spread in any season *(9)*. In tropical zones, most cases of measles occur during the dry season. In temperate climates, measles is a winter disease, probably because people crowd together indoors. Epidemics of measles are common in India during winter and early spring (January to April). Population density and movement do affect epidemicity *(15)*. In general, the less favourable the prevailing socio-economic conditions, the lower the average age at which children are attacked.

Transmission

Transmission occurs directly from person to person mainly by droplet infection and droplet nuclei, from 4 days before onset of rash until 4 days thereafter. The portal of entry is the respiratory tract. Infection through conjunctiva is also considered likely as the virus instilled into the conjunctiva can cause infection. Recipients of measles vaccine are not contagious to others *(16)*.

Incubation period

Incubation period is commonly 10 days from exposure to onset of fever, and 14 days to appearance of rash. When measles infection is artificially induced bypassing the respiratory tract (as with injection of live measles vaccine), the incubation period is somewhat shortened, averaging 7 days.

Clinical features

There are three stages in the natural history of measles, viz. the prodromal or pre-eruptive stage, eruptive stage and post-measles stage.

1. PRODROMAL STAGE

It begins 10 days after infection, and lasts until day 14. It is characterized by fever, coryza with sneezing and nasal discharge, cough, redness of the eyes, lacrimation and often photophobia. There may be vomiting or diarrhoea. A day or two before the appearance of the rash Koplik's spots like table salt crystals appear on the buccal mucosa opposite the first and second lower molars. They are small, bluish–white spots on a red base, smaller than the head of a pin *(9)*. Their presence is pathognomonic of measles.

2. ERUPTIVE PHASE

This phase is characterized by a typical, dusky–red, macular or maculo-papular rash which begins behind the ears and spreads rapidly in a few hours over the face and neck, and extends down the body taking 2 to 3 days to progress to the lower extremities. The rash may remain discrete, but often it becomes confluent and blotchy. In the absence of complications, the lesions and fever disappear in another 3 or 4 days signalling the end of the disease. The rash fades in the same order of appearance leaving a brownish discoloration which may persist for 2 months or more.

During the prodromal phase (2–4 days) and the first 2–5 days of rash, virus is present in tears, nasal and throat secretions, urine and blood. Just as the maculo-papular rash appears, the circulating antibodies become detectable, the viraemia disappears and the fever falls. The rash develops as a result of interaction of immune T cells with virus-infected cells in the small blood vessels. In patients with defective cell-mediated immunity, no rash develops *(9)*.

Diagnosis of measles is based on the typical rash and Koplik's spots seen in oral mucosa. The diagnosis would normally be incorrect in any febrile exanthem in which red eyes and cough are absent. In developed countries, where measles is uncommon, specific IgM antibodies are being used for diagnosis.

3. POST–MEASLES STAGE

The child will have lost weight and will remain weak for a number of days. There may be failure to recover and a gradual deterioration into chronic illness – due to increased susceptibility to other bacterial and viral infections, nutritional and metabolic effects and the tissue destructive effects of the virus. There may be growth retardation and diarrhoea, cancrum oris, pyogenic infections, candidosis, reactivation of pulmonary tuberculosis etc.

Complications

Measles is too often regarded as an unimportant infection, but this is not true. The most common complications are: measles–associated diarrhoea, pneumonia and other respiratory complications and otitis media. Otitis media occurs in about 5–15 per cent of cases. Penumonia is the most common life-threatening complication. This occurs in less than 10 per cent of cases in developed countries and 20–80 per cent cases in developing countries. Pulmonary complications account for more than 90 per cent of measles-related deaths. Pneumonia develops in 3–15 per cent of adults with measles, but most cases are due to the virus itself rather than bacteria, and fatalities are rare *(9)*.

The more serious are the neurological complications which include febrile convulsions, encephalitis and subacute sclerosing pan-encephalitis (SSPE). Subacute sclerosing pan-encephalitis is a rare complication which develops many years after the initial measles infection. It is characterized by progressive mental deterioration leading to paralysis, involuntary movements, muscle rigidity and coma, probably due to persistence of the virus in the brain. The diagnosis of SSPE may be made early by the demonstration of high levels of measles complement fixing antibodies in CSF and serum. The frequency of SSPE is about 1:300,000 cases of natural measles. It is usually fatal within 1–3 years after onset. The mortality rate in encephalitis associated with measles is about 10–20 per cent. The majority of survivors have neurologic sequelae *(9)*. Encephalitis is another serious complication. It occurs in about 1 in 1000 cases. The cause is unknown. Measles vaccination definitely constitutes a protection against the neurological and other complications by preventing natural measles from occurring *(9)*.

Measles during pregnancy is not known to cause congenital abnormalities of the foetus. However, it is associated with spontaneous abortion and premature delivery. Measles in the offspring of mothers with measles ranges from mild to severe; therefore, it is recommended that infants born to such mothers be passively immunized with immunoglobulin at birth *(17)*.

All cases of severe measles, and all cases of measles in areas with high case–fatality rates should be treated with vitamin A, as many children develop acute deficiency of vitamin A, which may lead to keratomalacia and blindness from corneal scarring. A high dose of vitamin A is given immediately on diagnosis and repeated the next day. The recommended age-specific daily doses are 50,000 IU for infants aged <6 months, 100,000 IU for infants aged 6–11 months, and 200,000 IU for children aged ≥ 12 months. If the child has clinical signs of vitamin A deficiency (such as Bitot's spots) a third dose should be given 4–6 weeks later *(18)*.

Measles and chickenpox

It has been noted that sometimes measles and chickenpox may occur together and one most remarkable finding in these cases of double infection is that the first infection may diminish the severity of the rash of the second infection *(19)*.

Prevention of measles

The following guidelines are important in combating measles:

a. achieving an immunization rate of over 95 per cent, and
b. on-going immunization against measles through successive generations of children.

1. Measles vaccination

Measles is best prevented by active immunization.

(1) VACCINE : Only live attenuated vaccines are recommended for use; they are both safe and effective, and may be used interchangeably within immunization programmes. Person to person transmission of measles vaccine strains has never been documented. The vaccine is presented as a freeze-dried product. Before use, the lyophilized vaccine is reconstituted with sterile diluent. Each dose of 0.5 ml contains ≥1000 viral infective units of the vaccine strain; this is also true when it is presented as an MCV combination. Measles vaccine may also contain sorbitol and hydrolysed gelatin as stabilizers, as well as a small amount of neomycin, but it does not contain thiomersal. In general, it is recommended that freeze-dried vaccine be stored in a refrigerated condition *(18)*. The diluent must not be frozen but should be cooled before reconstitution. Reconstituted measles vaccine loses about 50 per cent of its potency after 1 hour at 20°C; it loses almost all potency after 1 hour at 37°C. The vaccine is also sensitive to sunlight, hence it is kept in coloured glass vials. After reconstitution, the vaccine must be stored in the dark at 2–8°C and used within 4 hours.

(2) AGE : The principal problem of measles immunization is timing; immunization before the age of 9 months runs the risk of the vaccine being rendered ineffective by the natural antibodies acquired through the mother. Immunization later than 9 months means that a significant proportion of children will contract measles in the interval between wearing off natural protection, and the introduction of the vaccine. The most effective compromise is immunization as close to the age of 9 months as possible *(20)*. The WHO Expanded Programme on Immunization recommends immunization at 9 months age. This recommendation has been adopted in India. The age can be lowered to 6 months if there is measles outbreak in the community. For infants immunized between 6 months and 9 months of age, a second dose should be administered as soon as possible after the child reaches the age of 9 months provided that at least 4 weeks have elapsed since the last dose *(21)*.

In countries where the incidence of measles has declined, the age of immunization is being raised to 12 months in order to avoid the blocking effect of persistent transplacentally acquired antibody *(20)*.

(3) ADMINISTRATION : The reconstituted vaccine is generally injected subcutaneously, but it is also effective when administered intramuscularly.

(4) IMMUNE RESPONSES : Measles vaccine induces both humoral and cellular immune responses comparable to those following natural infection, although antibody titres are usually lower. Also, lower average concentrations of maternal antibodies are found in infants born to vaccinated mothers when compared with naturally infected mothers. Following vaccination, transient measles-specific immunoglobulin (Ig) M antibodies appear in the blood and IgA antibodies appear in mucosal secretions; IgG antibodies persist in the blood for years. Vaccination also induces measles virus-specific CD4+ and CD8+ T lymphocytes *(18)*.

(5) REACTIONS : When injected into the body, the attenuated virus multiplies and induces a mild "measles" illness (fever and rash) 5 to 10 days after immunization, but in reduced frequency and severity. This may occur in 15 to 20 per cent of vaccinees. The fever may last for 1–2 days and the rash for 1–3 days. There is no cause for alarm. The vaccines now given rarely cause severe reaction *(9)*. There is no spread of the virus from the vaccinees to contacts.

(6) IMMUNITY : The vaccine has convincingly demonstrated to provide immunity to even severely malnourished children. Immunity develops 11 to 12 days after vaccination *(22)* and appears to be of long duration, probably for life. One dose of the vaccine given at 11–12 months of age appears to give 99 per cent protection. Infants vaccinated at the age of 9 months show seroconversion of about 90 per cent *(18)*.

(7) CONTACTS : Susceptible contacts over the age of 9–12 months may be protected against measles with measles vaccine, provided that this is given within 3 days of exposure. This is because, the incubation period of measles induced by the vaccine is about 7 days, compared with 10 days for the naturally acquired measles.

(8) CONTRAINDICATIONS : Mild concurrent infections are not considered a contraindication to vaccination, but it should be avoided if the patient has a high fever or other signs of serious disease. Measles vaccine alone, or in combination with other vaccines, should also be avoided by pregnant women. Being in the early stages of HIV infection is not a contraindication to measles vaccination *(18)*.

People with a history of an anaphylactic reaction to neomycin, gelatin or other components of the vaccine should not be vaccinated. Furthermore, measles vaccine is contraindicated in persons who are severely immuno-compromised due to congenital disease, severe HIV infection, advanced leukaemia or lymphoma, serious malignant disease, treatment with high-dose steroids, alkylating agents or antimetabolites, or who receive immuno-suppressive therapeutic radiation *(18)*.

(9) ADVERSE EFFECTS OF VACCINE : Toxic shock syndrome (TSS) occurs when measles vaccine is contaminated or the same vial is used for more than one session on the same day or next day. The vaccine should not be used after 4 hours of opening the vial. TSS is totally preventable and reflects poor quality of immunization services. The symptoms of TSS are typical. Severe watery diarrhoea, vomiting and high fever are reported within few hours of measles vaccination. There are usually a cluster of cases as all infants vaccinated from contaminated vial will be affected. This may cause death within 48 hours. Case fatality rates are high *(23)*.

MEASLES AND HIV : Given the severe course of measles in patients with advanced HIV infection, measles vaccination should be routinely administered to potentially susceptible, asymptomatic HIV–positive children and adults. Vaccination may be considered for those with symptomatic HIV infection if they are not severely immunosuppressed according to conventional definitions. In areas where there is a high incidence of both measles and HIV infection, first dose of measles vaccine may be offered as early as age 6 months. Two additional doses of measles vaccine should be administered to these children according to the national immunization schedule *(18)*.

Second dose of measles vaccine may be added to the routine immunization schedule in countries that have achieved ≥80% coverage of the first dose of the vaccine at the national level for 3 consecutive years, as determined by the most accurate means available (for example, a well conducted population-based survey or WHO/UNICEF estimates). In general, countries that do not meet this criterion should prioritize improving MCV_1 coverage and conducting high-quality follow-up SIAs, rather than adding the second dose to their routine schedule.

COMBINED VACCINE : Measles vaccine can be combined with other live attenuated vaccines such as mumps, and rubella vaccines (MMR vaccine), measles, mumps, rubella and varicella (MMRV), and measles and rubella (MR), and such combinations are also highly effective.

2. Immunoglobulin

Measles may be prevented by administration of immunoglobulin (human) early in the incubation period. The dose recommended by WHO is 0.25 ml per kg of body weight (see Table 33 on page 108). It should be given within 3–4 days of exposure. The person passively immunized should be given live measles vaccine 8–12 weeks later. The need for immunoglobulin is now much reduced because of the availability of an effective live attenuated vaccine.

Eradication of measles

It is believed that measles, like smallpox, is amenable to eradication. Measles immunization has in its favour the fact that only one dose is needed, and that a measles vaccine has now been developed which is more heat stable. It

requires (a) achieving an immunization coverage of at least 96 per cent of children under one year of age, and that (b) the cumulation in the immunity gap be prevented.

Outbreak control measures

The following control measures have been recommended : (a) isolation for 7 days after onset of rash, (b) immunization of contacts within 2 days of exposure (if vaccine is contraindicated, immunoglobulin should be given within 3–4 days of exposure), and (c) prompt immunization at the beginning of an epidemic is essential to limit the spread.

RUBELLA
(GERMAN MEASLES)

Rubella or german measles is an acute childhood infection, usually mild, of short duration (approximately 3 days) and accompanied by low–grade fever, lymphadenopathy and a maculopapular rash. Infection in early pregnancy may result in serious congenital defects, including death of the foetus. The disease is worldwide in distribution and tends to occur in epidemics, in non-immunized populations, every 6 to 8 years *(1)*.

History

Rubella was considered a mild and benign disease until 1941 when Norman Gregg, an ophthalmologist reported an epidemic of congenital cataracts associated with other congenital defects in children born to mothers who had rubella during their pregnancies *(2)*. This discovery changed the concept that rubella is not merely a benign disease of childhood but also one with teratogenic potential. In 1962, the virus was isolated; in 1967, an attenuated vaccine was developed.

Epidemiological determinants

Agent factors

(a) AGENT : Rubella is caused by an RNA virus of the togavirus family. Only one antigenic type of the virus seems to exist. The virus has been recovered from the naso-pharynx, throat, blood, CSF and urine. It can be propagated in cell culture. (b) SOURCE OF INFECTION : Clinical or subclinical cases of rubella. A large number of rubella infections are, in fact, subclinical. This represents one of the major differences between measles and rubella. There is no known carrier state for postnatally acquired rubella. Infants born with congenital rubella may shed the virus for many months. The vaccine virus is not communicable. (c) PERIOD OF COMMUNICABILITY: Rubella is much less communicable than measles, probably because of the absence of coughing in rubella. It is difficult to state the exact period of infectivity. It probably extends from a week before symptoms to about a week after rash appears. Infectivity is greatest when the rash is erupting *(3)*.

Host factors

(a) AGE: Mainly a disease of childhood particularly in the age group 3 to 10 years. Persons older than 15 years now account for over 70 per cent cases in developed countries – this is similar to the changing epidemiological pattern with measles, following widespread immunization campaigns against the disease. (b) IMMUNITY : One attack results in life-long immunity; second attacks are rare. Infants of immune mothers are protected for 4 to 6 months. It is estimated that 10 to 40 per cent of the population could reach adulthood without experiencing rubella infection in the absence of immunization *(4)*. Thus many women of child-bearing age may remain rubella–susceptible. Studies in India indicate that approximately 40 per cent of women of child-bearing age are susceptible to rubella *(5)*.

Environmental factors

Disease usually occurs in a seasonal pattern i.e. in temperate zones during the late winter and spring, with epidemics every 4–9 years.

Transmission

The virus is transmitted directly from person to person by droplets from nose and throat, and droplet nuclei (aerosols), from one week before onset of rash to one week after it has faded. The portal of entry is *via* the respiratory route. The virus is maintained in human population by chain transmission. The virus can cross the placenta (vertical transmission) and infect the foetus *in utero*, leading to congenital rubella in the newborn.

Incubation period

2 to 3 weeks; average 18 days.

Clinical features

A large percentage of infections (50 to 65 per cent) are asymptomatic *(1)*. In a typical case, the clinical features comprise the following: (a) PRODROMAL : The prodromal symptoms (coryza, sore throat, low–grade fever) herald the onset of viraemia. They are generally mild and insignificant, and less frequent in children. (b) LYMPHADENOPATHY : In susceptible individuals, the enlargement of the post–auricular and posterior cervical lymph nodes appears as early as 7 days before the appearance of the rash. This,

however, is not pathognomonic since cases of clinical rubella without enlargement of lymph nodes have been documented *(6)*. The glands may be found enlarged for 10 to 14 days after the rash. (c) RASH: The rash is often the first indication of the disease in children. It appears first on the face, usually within 24 hours of the onset of prodromal symptoms. It is a minute, discrete, pinkish, macular rash and not confluent as the rash of measles. Conjunctivitis may occur. The rash spreads rapidly to the trunk and extremities, by which time it is often no longer apparent on the face. The rash spreads much faster and clears more rapidly than the rash of measles. It disappears altogether by the third day. The rash is an inconstant feature of the disease; it is absent in subclinical cases. The incidence of rubella infection without rash may be upto 25 per cent *(7)*. (d) COMPLICATIONS : In rare instances arthralgia may occur in several joints in adults, especially young women. Encephalitis is very rare. Thrombocytopenic purpura has also been observed as a complication. Mention has been made already about the congenital malformations.

Diagnosis

Because of its mildness and variability of symptoms, the disease can go unrecognized unless it is an epidemic. A definitive diagnosis of rubella is possible only through virus isolation and serology. Throat swabs should be cultured for virus isolation; it takes longer than serological diagnosis. The haemagglutination inhibition (HI) test is a standard serological test for rubella. However, serum must be pretreated to remove non-specific inhibitors before testing. ELISA tests are preferred because serum pretreatment is not required and they can be adapted to detect specific IgM. Detection of IgG is evidence of immunity because there is only one serotype of rubella virus. To accurately confirm a recent rubella infection, either a rise in antibody titer must be demonstrated between two serum samples taken at least 10 days apart or rubella-specific IgM must be detected in a single specimen. It is critically important in a pregnant woman *(9)*.

CONGENITAL RUBELLA

Congenital rubella syndrome (CRS) refers to infants born with defects secondary to intrauterine infection or who manifest symptoms or signs of intrauterine infection sometime after birth *(8)*. Congenital infection is considered to have occurred if the infant has IgM rubella antibodies shortly after birth (as IgM antibodies do not cross the placenta, their presence indicate that they must have been synthesized by the infant *in utero*) or if IgG antibodies persist for more than 6 months, by which time maternally derived antibodies would have disappeared. Intrauterine infection with rubella is associated with chronic persistence of the virus in the newborn. At birth, virus is easily detectable in pharyngeal secretions, multiple organs, cerebrospinal fluid, urine, and rectal swabs. Viral excretion may last for 12–18 months after birth, but the level of shedding gradually decreases with age *(9)*.

Rubella infection inhibits cell division, and this is probably the reason for congenital malformations and low birth weight *(10)*. The classic triad of congenital defects are deafness, cardiac malformations and cataracts. Other resulting defects include glaucoma, retinopathy, microcephalus, cerebral palsy, intrauterine growth retardation, hepato-splenomegaly, mental and motor retardation. These defects occurring singly or in combination have become known as "congenital rubella syndrome".

Congenital rubella is a chronic infection while acquired rubella is an acute infection. The foetus remains infected throughout gestation and for months and sometimes years postnatally. The gestational age at which maternal infection occurs is a major determinant for the extent of foetal infection as well as the effects on the foetus *(11)*.

The first trimester of pregnancy is the most disastrous time for the foetus as the organs are developing. Infection during this period results in abnormalities in the infant in about 85 per cent of cases, whereas detectable defects are found in about 16 per cent of infants, who acquired infection during the second trimester. Birth defects are uncommon if maternal infection occurs after 20 weeks of gestation. Inapparent maternal infections can produce these anomalies as well. It can result in foetal death and spontaneous abortion *(9)*.

Prevention

Active immunization against rubella is now possible with live attenuated vaccines. The goal of rubella immunization is the prevention of rubella infection during a future pregnancy *(8)*.

RUBELLA VACCINES: Since the isolation of the virus in 1962, several live attenuated vaccines have been developed. In 1979 the RA 27/3 vaccine, produced in human diploid fibro-blast has replaced all the other vaccines. This is because RA 27/3 vaccine induces higher antibody titres and produces an immune response more closely paralleling natural infection than the other vaccines *(12)*. There is evidence that it largely prevents subclinical superinfection with wild virus.

RA 27/3 vaccine is administered in a single dose of 0.5 ml subcutaneously. It may provoke mild reactions in some subjects such as malaise, fever, mild rash and transient arthralgia, but no serious disability. Seroconversion occurs in more than 95 per cent vaccinees. Vaccine–induced immunity persists in most vaccinees for at least 14 to 16 years and probably is lifelong *(13)*. There is no evidence in favour of the administration of second dose unless first vaccinated below the age of 12 months *(14)*. Infants under one year should not be vaccinated due to possible interference from persisting rubella antibody. Pregnancy is considered a contraindication to rubella immunization. The recipients of the vaccine should be advised not to become pregnant over the next 3 months.

Rubella vaccine is also available as combined measles, mumps and rubella (MMR) vaccine. It is equally effective *(15)*.

Vaccination strategy

In the light of the experience gained during the past years, the immunization strategies to prevent congenital rubella infection have been modified – the priorities being **first** to protect women of child-bearing age (15–34 or 39 years of age) and then to **interrupt transmission** of rubella by vaccinating all children currently aged 1–14 years, and subsequently all children at one year of age. The programme would then revert to one of routine universal immunization of all children at age 1 (preferably using combined measles–rubella or measles–mumps–rubella vaccines).

If the health care system cannot reach a substantial proportion of women of childbearing age, initial emphasis might be placed on interrupting transmission while

attempting to reach as many of the risk population as possible *(16)*.

MUMPS

An acute infectious disease caused by an RNA virus classified as genus *Rubulavirus* of the family paramyxoviridae which has a predilection for glandular and nervous tissues. Clinically, the disease is recognized by non-suppurative enlargement and tenderness of one or both the parotid glands. Other organs may also be involved. Constitutional symptoms vary, or may be inapparent. The disease occurs throughout the world. Although morbidity rate tends to be high, mortality rate is negligible.

In most parts of the world, the annual incidence of mumps in the absence of immunization is in the range of 100–1000 cases/100,000 population with epidemic peak every 2–5 years. Natural infection with this virus is thought to confer lifelong protection *(1)*.

Agent factors

(a) AGENT : The causative agent, *Myxovirus parotiditis* is a RNA virus of the myxovirus family. The virus can be grown readily in chick embryo or tissue culture. There is only one serotype. (b) SOURCE OF INFECTION : Both clinical and subclinical cases. Subclinical cases which account for 30–40 per cent of all cases *(2)* appear to be responsible for maintaining the cycle of infection. The virus can be isolated from the saliva or from swabs taken from the surface of Stenson's duct. Virus has also been found in the blood, urine, human milk and on occasion in the CSF. (c) PERIOD OF COMMUNICABILITY : Usually 4–6 days before the onset of symptoms and a week or more thereafter. The period of maximum infectivity is just before and at the onset of parotitis. Once the swelling of the glands has subsided, the case may be regarded as no longer infectious. (d) SECONDARY ATTACK RATE : Estimated to be about 86 per cent.

Host factors

(a) AGE AND SEX : Mumps is the most frequent cause of parotitis in children in the age group 5–9 years. The average age of incidence of mumps is higher than with measles, chickenpox or whooping cough. However, no age is exempt if there is no previous immunity. The disease tends to be more severe in adults than in children. (b) IMMUNITY : One attack, clinical or subclinical, is assumed to induce lifelong immunity. There is only one antigenic type of mumps virus, and it does not exhibit significant antigenic variation *(3)*. Most infants below the age of 6 months are immune because of maternal antibodies.

Environmental factors

Mumps is largely an endemic disease. Cases occur throughout the year, but the peak incidence is in winter and spring. Epidemics are often associated with overcrowding.

Mode of transmission

The disease is spread mainly by droplet infection and after direct contact with an infected person.

Incubation period

Varies from 2 to 4 weeks, usually 14–18 days.

Clinical features

Mumps is a generalized virus infection. In 30–40 per cent of cases mumps infection is clinically non-apparent. In clinically apparent cases, it is characterized by pain and swelling in either one or both the parotid glands but may also involve the sublingual and submandibular glands. Often the child complains of "ear ache" on the affected side prior to the onset of swelling. There may be pain and stiffness on opening the mouth before the swelling of the gland is evident. Mumps may also affect the testes, pancreas, CNS, ovaries, prostate, etc. In severe cases, there may be fever, headache and other constitutional symptoms which may last from 3–5 days. The swelling subsides slowly over 1–2 weeks.

COMPLICATIONS : Though frequent, are not serious. These include orchitis, ovaritis, pancreatitis, meningo-encephalitis, thyroiditis, neuritis, hepatitis and myocarditis. Testicular swelling and tenderness denote orchitis, which is the most common extrasalivary gland manifestation of mumps in adults. It is unilateral in about 75 per cent of cases. High fever usually accompanies orchitis, which develops typically 7–10 days after the onset of parotitis in about 25–40 per cent of post-pubertal men *(4)*. Bilateral orchitis is rare and the assumption that mumps orchitis may lead to sterility is ill-founded *(5)*. Upper abdominal pain, nausea and vomiting suggest pancreatitis. Mumps is a leading cause of pancreatitis in children. It occurs in about 4 per cent of patients *(6)*. Lower abdominal pain and ovarian enlargement suggest oophoritis which occurs in 5 per cent of post pubertal women, usually unilateral *(4)*. While some instances of diabetes have occurred in children following mumps infection, a causal relationship has yet to be demonstrated *(5)*. Rarer complications include nerve deafness, polyarthritis, hydrocephalus, encephalitis, cerebellar ataxia, facial palsy and transverse myelitis. Encephalitis is associated with cerebral oedema, serious neurologic manifestations and sometimes death *(4)*. Upto 15% of mumps patients may develop meningitis, and a much smaller proportion (0.02–0.03%) may develop encephalitis. Mumps is one of the main infectious causes of sensorineural deafness, which affects approximately 5 per 100,000 mumps cases *(6)*.

Mumps infection in the first trimester of pregnancy is associated with a 25% incidence of spontaneous abortion, although congenital malformations following mumps infection in pregnancy have not been reported *(6)*.

Prevention

VACCINATION : Highly effective live attenuated vaccine is now available for the prevention of mumps. Widely-used live attenuated mumps vaccine strains include the Jeryl-Lynn, RIT 4385, Leningrad-3, L-Zagreb and Urabe strains. Live attenuated mumps vaccine strains used only on a limited scale include the Hoshino, Torii and NKM-46 strains. The WHO recommends that the Rubini mumps vaccine strain should not be used in national immunization programmes because of its demonstrated low effectiveness *(6)*.

A single dose (0.5 ml) intramuscularly produces detectable antibodies in 95 per cent of vaccinees. The duration of long-term immunity is not known. It is recommended for routine immunization for children over 1 year of age, either alone or in combination with other virus vaccines, eg. in MMR vaccine or as a quadrivalent vaccine with varicella. A second dose is recommended for children at 4–6 years of age i.e., before starting the school. The current mumps strain (Jeryl Lynm) has the lowest associated incidence of post vaccine aseptic meningitis (from 1 in 150,000 to 1 in 1.8 million). There are no known cases of long-term sequelae associated with mumps vaccination *(4)*.

Countries including mumps vaccines in their national immunization programme are advised by WHO to set disease control targets (control or elimination) and to design their mumps immunization strategy accordingly. Strategies to achieve mumps elimination include very high coverage with the first dose of mumps vaccine, ensuring a second opportunity for vaccination and conducting catch-up immunization of susceptible cohorts *(6)*.

As with most other live virus vaccines, mumps vaccine should not be administered to pregnant women, patients receiving immunosuppressive therapy or those who are severely ill *(7)*.

Mumps surveillance *(6)*

Case definitions : WHO recommends the following case definitions for mumps surveillance :

a. *Clinical mumps :* acute onset of unilateral or bilateral tender, self-limited swelling of the parotid or other salivary gland, lasting 2 or more days and without other apparent cause.
b. *Laboratory confirmed mumps :* a patient with clinical mumps and laboratory confirmation by positive-mumps IgM antibody (without mumps immunization in the previous 6 weeks) or; sero-conversion with 4–fold or greater rise in mumps IgG titre; or isolation of mumps virus from saliva, urine or cerebrospinal fluid.
c. *Epidemiologically–confirmed mumps :* a patient with clinical mumps who is epidemiologically linked to a laboratory–confirmed mumps case.

Control

The control of mumps is difficult because the disease is infectious before a diagnosis can be made. The long and variable incubation period, and the occurrence of subclinical cases make the control of spread difficult. However, cases should be isolated till the clinical manifestations subside. Steps should be taken to disinfect the articles used by the patient. Contacts should be kept under surveillance.

INFLUENZA

Influenza is an acute respiratory tract infection caused by influenza virus, of which there are 3 types – A, B and C. All known pandemics were caused by influenza A strains. The disease is characterized by sudden onset of chills, malaise, fever, muscular pains and cough.

Problem statement

Influenza is truly an international disease. It occurs in all countries and affects millions of people every year. Its behaviour is unpredictable. It may occur in several forms. It may smoulder in a community without clinical recognition, being manifest only by serological surveys. It may occur in pandemics every 10–40 years due to major antigenic changes, as occurred in 1918 (Spanish influenza), 1957 (Asian influenza) and 1968 (Hong Kong influenza) *(1)*. In between pandemics, epidemics tend to occur at intervals of 2–3 years in case of influenza A and 3–6 years in the case of influenza B – but the periodicity is not regular as in the case of measles or whooping cough because several strains of the virus may be in simultaneous circulation, which means that there may be outbreaks of influenza practically every year, and sometimes even twice a year *(2)*.

Once an epidemic begins, the picture is quite characteristic. Preceded by a few early cases, there is a sudden outburst of the disease. This may be indicated by reports of increased febrile respiratory illness in children, followed by the same in adults. The next event is increased hospitalization of cases and sickness–absenteeism in schools and places of work. Attack rates tend to be high, varying from 5 to 10 per cent in adults and 20–30 per cent in children. The peak of the epidemic is reached in 3–4 weeks, before tending to decline. The time scale is compressed for smaller geographic areas *(1)*. The unique features of influenza epidemics are the suddenness with which they arise, and the speed and ease with which they spread. The short incubation period, large number of subclinical cases, high proportion of susceptible population, short duration of immunity, and absence of cross-immunity, all contribute to its rapid spread. World-wide, the annual epidemics are estimated to result in about 3–5 million cases of severe illness and about 250,000 to 500,000 deaths *(3)*. The fate of the virus during inter-epidemic periods is not known *(4)*. Possible explanations include transmission of virus to extra-human reservoirs (pigs, horses, birds), latent infection in humans or continuous transfer from one human to another. This explains the occurrence of sporadic cases.

At present three types of influenza viruses are circulating in the world : A (H_1N_1), A (H_3N_2) and B viruses. WHO global surveillance activities have identified human infection with a new influenza virus called A (H_5N_1) in Hong Kong in mid 1997. However, the possibility that the outbreak heralded a global influenza pandemic did not materialize. The threat

of a virus more easily transmitted between humans remains *(5)*. More recently, influenza A (H_1N_1) virus of swine origin emerged in Mexico during the spring of 2009 and was given name – pandemic influenza A (H_1N_1) 2009 virus. It spreads with travellers worldwide, resulting in the first influenza pandemic since 1968.

Epidemiological determinants

Agent factors

(a) AGENT : Influenza viruses are classified within the family Orthomyxoviridae. There are three viral subtypes, namely influenza type A, type B and type C. These three viruses are antigenically distinct. There is no cross immunity between them. Of importance are the influenza A and B viruses which are responsible for epidemics of disease throughout the world *(6)*. Influenza A virus has 2 distinct surface antigens – the haemagglutinin (H) and the neuraminidase (N) antigens. The H antigen initiates infection following attachment of the virus to susceptible cells. The N antigen is responsible for the release of the virus from the infected cell. The currently identified subtypes are 16 HA and 9 NA. Humans are generally infected by viruses of the subtype H1, H2 or H3, and N1 or N2. Type B virus does not exhibit antigenic shifts and is not divided into subtypes.

The influenza A virus is unique among the viruses because it is frequently subject to antigenic variation, both major and minor. When there is a sudden complete or major change, it is called a **shift,** and when the antigenic change is gradual over a period of time, it is called a **drift**. Antigenic shift appears to result from genetic recombination of human with animal or avian virus, providing a major antigenic change. This can cause a major epidemic or pandemic involving most or all age groups. Antigenic drift involves "point mutation" in the gene owing to selection pressure by immunity in the host population. Antigenic changes occur to a lesser degree in the B group influenza viruses. Influenza C appears to be antigenically stable.

Since the isolation of the virus A in 1933, major antigenic changes have occurred twice – once in 1957 (H_2N_2) and again in 1968 (H_3N_2). Strains occurring between 1946 and 1957 have been called (H_1N_1) strains. The shift in 1968 involved only the H antigen.

(b) RESERVOIR OF INFECTION : It has become increasingly evident that a major reservoir of influenza virus exists in animals and birds. Many influenza viruses have been isolated from a wide variety of animals and birds (e.g., swine, horses, dogs, cats, domestic poultry, wild birds, etc). Some of these include the major H and N antigens related to human strains. It is hypothesized. There is an increasing evidence that the animal reservoirs provide new strains of influenza virus by recombination between the influenza viruses of man, animals and birds.

(c) SOURCE OF INFECTION : Usually a case or subclinical case. During epidemics, a large number of mild and asymptomatic infections occur, which play an important role in the spread of infection. The secretions of the respiratory tract are infective.

(d) PERIOD OF INFECTIVITY : Virus is present in the nasopharynx from 1 to 2 days before and 1 to 2 days after onset of symptoms.

Host factors

(a) AGE AND SEX : Influenza affects all ages and both sexes. In general, the attack rate is lower among adults. Children constitute an important link in the transmission chain. The highest mortality rate during an epidemic occurs among certain high-risk groups in the population such as old people (generally over 65 years of age), children under 18 months, and persons with diabetes or chronic heart disease, kidney and respiratory ailments *(7)*. (b) HUMAN MOBILITY : This is an important factor in the spread of infection. (c) IMMUNITY : Immunity to influenza is subtype-specific. Antibodies against HA and NA are important in immunity to influenza. Resistance to initiation of infection is related to antibody against HA, which neutralizes the virus, whereas decreased severity of disease and decreased ability to transmit virus to contacts are related to antibody directed against the NA. Antibodies against ribonucleoprotein are type-specific and are useful in typing viral isolates as in influenza A and B. Protection correlates with both serum antibodies and secretory IgA antibodies in nasal secretions. The local secretory antibody is probably important in preventing infection. Serum antibodies persist for many months, whereas secretory antibodies are shorter-lived (usually only few months). Antibody also modifies the course of illness. A person with low titres of antibody may be infected but will experience a mild form of illness. Immunity can be incomplete as reinfection with the same virus can occur. The three types of influenza viruses are antigenically unrelated and therefore induce no cross-protection. When a viral type undergoes antigenic drift, a person with pre-existing antibody to the original strain may suffer only mild infection with the new strain *(8)*. Antibodies appear in about 7 days after the attack and reach a maximum level in about 2 weeks. After 8 to 12 months, the antibody level drops to pre-infection level.

Environmental factors

(a) Season : The seasonal incidence is striking, epidemics usually occurring in winter months in the Northern Hemisphere and in the winter or rainy season in the Southern Hemisphere *(6)*. In tropical countries, influenza virus circulates throughout the year with one or two peaks during rainy season. *(b) Overcrowding :* Enhances transmission. The attack rates are high in close population groups, e.g., schools, institutions, ships, etc.

Mode of transmission

Influenza is spread mainly from person to person by droplet infection or droplet nuclei created by sneezing, coughing or talking. The portal of entry of the virus is the respiratory tract.

Incubation period

18 to 72 hours.

Pathogenesis and clinical features

The virus enters the respiratory tract and causes inflammation and necrosis of superficial epithelium of the tracheal and bronchial mucosa, followed by secondary bacterial invasion. There is no viraemia. Both the viruses cause much the same symptoms – fever, chills, aches and pains, coughing and generalized weakness. Fever lasts from 1–5 days, averaging 3 days in adults. Frequent complications are acute sinusitis, otitis media, purulent bronchitis and pneumonia. The most dreaded complication is pneumonia, which should be suspected if fever persists beyond 4 or 5 days or recurs abruptly after convalescence *(1)*.

Reye syndrome (fatty liver with encephalopathy) is a rare and severe complication of influenza, usually B type,

particularly in young children. It consists of rapidly progressive hepatic failure and encephalopathy, and there is about 30 per cent mortality rate. The pathogenesis is unknown, but the syndrome is associated with aspirin use in a variety of viral infections *(9)*.

Laboratory diagnosis

Since clinical diagnosis is difficult except during epidemics, laboratory methods are needed to confirm the diagnosis. These are : (a) *VIRUS ISOLATION* : Nasopharyngeal secretions are the best specimens for obtaining large amounts of virus–infected cells. The virus can be detected by the indirect fluorescent antibody technique. However egg inoculation is required for virus isolation and antigenic analysis. (b) *SEROLOGY* : Routine serodiagnostic tests in use are based on haemagglutination inhibition (HI) and ELISA. Paired acute and convalescent sera are necessary, because normal individuals usually have influenza antibodies. A fourfold or greater increase in titer must occur to indicate influenza infection. Human sera often contains non-specific mucoprotein inhibitors that must be destroyed before testing by HI. The HI test reveals the strain of virus responsible for infection only if the correct antigen is available for use. The ELISA test is more sensitive than other assays.

Prevention of influenza

All attempts to control influenza epidemics have so far met with little success and the prospects of achieving control remain poor. Good ventilation of public buildings, the avoidance of crowded places during epidemics, encouraging sufferers to cover their faces with a handkerchief when coughing and sneezing, and to stay at home at the first sign of influenza are all sensible precautions. The vaccine is not recommended to control spread in the general population.

Immunization, in theory, offers the best prospect of controlling influenza at the present times. In view of the changing antigenic characteristics of the virus (antigenic drift and antigenic shift) new vaccines are constantly required, and they should contain the H and N components of the prevalent strain or strains to keep the vaccines upto date. The WHO makes recommendations every year as to what strains should be included in the vaccine. A number of field trials have shown that vaccines so constituted are highly effective (70–90%). To be effective the vaccine must be administered at least two weeks before the onset of an epidemic, or preferably 2 to 3 months before influenza is expected. Since epidemics of influenza are unpredictable, the hope of preventing influenza epidemics by prophylactic mass vaccination is remote.

Since influenza vaccines will not control epidemics, they are recommended only in certain selected population groups – e.g., in industry to reduce absenteeisms, and in public servants to prevent disruption of critical public services, such as the police, fire protection, transport and medical care. Also, certain groups e.g. the elderly and individuals in any age group who have a known underlying chronic or debilitating disease (e.g. disease of cardiovascular system, metabolic disease like diabetes, cystic fibrosis, chronic respiratory disease and chronic renal insufficiency, congenital or acquired immunodeficiency) and their close contacts (persons living with them or their care givers), are selectively immunized because of the high-risk of severe complications, including death *(6)*.

HIV infected persons can be safely vaccinated, and concerns about activating replication of HIV virus by the immunogen appear to be exaggerated and may be less severe than the increase in HIV viral load associated with a full influenza infection. Vaccination is less effective when CD4 counts are less than 100/mcL. False-positive assays for HIV, HTLV-1, and HCV antibodies have been reported in the wake of influenza vaccination *(10)*.

Prevention of exposure to avian influenza strains also includes hygienic practices during handling of poultry products, including handwashing and prevention of cross–contamination, as well as thorough cooking, to more than 70°C, of poultry products *(10)*.

Influenza vaccines

(a) KILLED VACCINES

Most influenza vaccination programmes make use of inactivated vaccines. The recommended vaccine strains for vaccine production are grown in the allantoic cavity of developing chick embryos, harvested, purified, killed by formalin or beta-propiolactone, and standardized according to the haemagglutinin content.

The vaccine is conventionally formulated in aqueous or saline suspension. One dose of the vaccine contains approximately 15 micrograms of HA. The vaccine is administered by the subcutaneous or intramuscular route. A single inoculation (0.5 ml for adults and children over 3 years and 0.25 ml for children from 6 months to 36 months of age) is usually given. However, in persons below 9 years of age with no previous immunological experience (unprimed individuals), 2 doses of the vaccine, separated by an interval of 3 to 4 weeks are considered necessary to induce satisfactory antibody levels. After vaccination, there is an increase in serum antibodies in about one week, which reaches a maximum in about 2 weeks. The protective value of the vaccine varies between 70–90 per cent *(6)* and immunity lasts for only 6–12 months. Revaccination on an annual basis is recommended.

The killed vaccine can produce fever, local inflammation at the site of injection, and very rarely Guillain-Barre syndrome (an ascending paralysis). Since the vaccine strains are grown in eggs, persons allergic to eggs may develop symptoms and signs of hypersensitivity.

(b) LIVE-ATTENUATED VACCINES

A trivalent, live-attenuated influenza vaccine administered as a single dose intranasal spray is as effective as inactivated vaccine in preventing the disease. It is approved for use in otherwise healthy individuals between age of 2 years and 49 years. Because the risk of transmission of the live-attenuated vaccine virus to immunocompromised individuals is unknown, it should not be used in household members of immunosuppressed individuals, health care workers, or others with close contact with immunosuppressed persons *(9)*.

CONTRAINDICATIONS *(11)* : As a general rule, inactivated vaccines should not be administered to :

(1) People who have a severe allergy to chicken eggs;
(2) People with a history of anaphylactic reactions or other life–threatening allergic reactions to any of the constituents or trace residue of the vaccine;
(3) People with history of a severe reaction to influenza vaccination;
(4) People who developed Guillain-Barre syndrome (GBS) within 6 weeks of getting an influenza vaccine;

(5) Children less than 6 months of age (inactivated influenza vaccine is not approved for this age group); and
(6) People who have a moderate-to-severe illness with a fever (they should wait till they recover to get vaccinated).

Antiviral drugs

Because of limitations in the efficacy of influenza vaccines antiviral drugs have been tried for the prophylaxis and therapy of seasonal influenza infections. Two neuraminidase inhibitors (zanamivir and oseltamivir) are available for prophylaxis and therapy of influenza A and B. The dose of oseltamivir is 75 mg per day for prophylaxis and 75 mg twice daily for 5 days for therapy. Zanamivir is administered by inhaler (10 mg dose) and is given twice daily for therapy and once daily for prophylaxis. The duration of prophylaxis depends on the clinical setting. The current recommendations are that influenza A be treated with zanamivir or a combination of oseltamivir and rimantadine. Influenza B can be treated with either oseltamivir or zanamivir *(9)*. For chemoprophylaxis against influenza A, zanamivir should be used. If this is contraindicated, patients should be given rimantadine. In an outbreak associated with influenza B, either oseltamivir or zanamivir can be used for prophylaxis *(9)*.

AVIAN INFLUENZA *(12)*

Avian influenza refers to a large group of different influenza viruses that primarily affect birds. On rare occasions, these bird viruses can infect other species, including pigs and humans. The vast majority of avian influenza viruses do not infect humans. However, avian H_5N_1 is a strain with pandemic potential, since it might ultimately adapt into a strain that is contagious among humans. Once this adaptation occurs, it will no longer be a bird virus – it will be a human influenza virus. Influenza pandemics are caused by new influenza viruses that have adapted to humans. Health experts have been monitoring a new and extremely severe influenza virus – the H_5N_1 strain – for almost 15 years. Fortunately, the virus does not jump easily from birds to humans or spread readily and sustainably among humans. Once a fully contagious virus emerges, its global spread is considered inevitable.

PANDEMIC INFLUENZA A (H_1N_1) 2009

The pandemic influenza A (H_1N_1) 2009 virus differs in its pathogenicity from seasonal influenza in two key aspects. First, as the majority of human population has little or no pre-existing immunity to the virus, the impact of the infection has been in a wider age range, in particular among children and young adults. Secondly, the virus can infect the lower respiratory tract and can cause rapidly progressive pneumonia, especially in children and young to middle-aged adults.

Following its emergence in March 2009, pandemic A (H_1N_1) 2009 virus spread rapidly throughout the world, leading to the declaration of an inlfuenza pandemic by WHO on 11th June 2009 *(14)*. The world is now in post-pandemic period. Between September 2012 and January 2013, all seasonal A (H_1N_1) viruses detected were A (H_1N_1) Pdm 09. In India it causes local outbreaks. During 2013, India reported 5,253 cases and 699 deaths, a case fatality rate of 13.3 per cent *(15)*.

Based on knowledge about past pandemics, the (H_1N_1) 2009 virus is expected to continue to circulate as a seasonal virus for some years to come. While level of concern is now greatly diminished, vigilance on the part of national health authorities remains important, when the behaviour of H_1N_1 virus as a seasonal virus cannot be reliably predicted *(16)*. On 26th September 2011 WHO has adapted a new nomenclature as Influenza A (H_1N_1) pdm09 *(17)*.

Incubation period

The incubation period appears to be approximately 2–3 days, but could range upto 7 days.

Case definitions *(18)*

Suspected case : A suspected case of influenza A (H_1N_1) 2009 is defined as a person with acute febrile respiratory illness (fever ≥ 38°C) with onset (a) within 7 days of close contact with a person who is a confirmed case of influenza A (H_1N_1) 2009 virus infection, or; (b) within 7 days of travel to areas where there are one or more confirmed cases, or (c) resides in a community where there are one or more confirmed influenza A (H_1N_1) 2009 cases.

Probable case : A probable case of influenza A (H_1N_1) 2009 virus infection is defined as a person with an acute febrile respiratory illness who : (1) is positive for influenza A, but unsubtypable for H_1 and H_3 by influenza RT–PCR or reagents used to detect seasonal influenza virus infection, or; (2) is positive for influenza A by an influenza rapid test or an influenza immunofluoresence assay (IFA) and meets criteria for a suspected case, or; (3) individual with a clinically compatible illness who died of an unexplained acute respiratory illness who is considered to be epidemiollogically linked to a probable or confirmed case.

Confirmed case : A confirmed case of pandemic influenza A (H_1N_1) 2009 virus infection is defined as a person with an acute febrile respiratory illness with laboratory confirmed influenza A (H_1N_1) 2009 virus infection at WHO approved laboratory by one or more of the following tests :

a. Real Time PCR
b. Viral culture
c. Four–fold rise in influenza A (H_1N_1) virus specific neutralizing antibodies.

Clinical features *(19)*

A wide clinical spectrum of disease ranging from non-febrile mild upper respiratory illness, febrile influenza like illness (ILI), to severe or even fatal complications including rapidly progressive pneumonia has been described. The case fatality rate is smilar to seasonal influenza i.e. about 0.5 per cent; however this could change *(9)*. The clinical features are as described below :

(a) *Uncomplicated influenza*

(1) ILI symptoms include : fever, cough, sore throat, rhinorrhoea, headache, muscle pain, and malaise, but no shortness of breath and no dyspnoea. Patients may present with some or all of these symptoms.

(2) Gastrointestinal illness may also be present, such as diarrhoea and/or vomiting, especially in children, but without evidence of dehydration.

(b) *Complicated or severe influenza*

(1) Presenting clinical (e.g. shortness of breath/ dyspnoea, tachypnea, hypoxia) and/or radiological signs of lower respiratory tract disease (e.g.

pneumonia), central nervous system (CNS) involvement (e.g. encephalopathy, encephalitis), severe dehydration, or presenting secondary complications, such as renal failure, multiorgan failure, and septic shock. Other complications can include rhabdomyolysis and myocarditis.

(2) Exacerbation of underlying chronic disease, including asthma, COPD, chronic hepatic or renal failure, diabetes, or other cardiovascular conditions.

(3) Any other condition or clinical presentation requiring hospital admission for clinical management.

(4) Any of the signs of progressive disease.

Signs and symptoms of progressive disease

Patients who present initially with uncomplicated influenza may progress to more severe disease. Progression can be rapid (i.e. within 24 hours). The following are some of the indicators of progression, which would necessitate an urgent review of patient management.

(a) Symptoms and signs suggesting oxygen impairment or cardiopulmonary insufficiency :
- Shortness of breath (with activity or at rest), difficulty in breathing, turning blue, bloody or coloured sputum, chest pain, and low blood pressure;
- In children, fast or laboured breathing; and
- Hypoxia, as indicated by pulse oximetry.

(b) Symptoms and signs suggesting CNS complications:
- Altered mental status, unconsciousness, drowsiness, or difficult to awaken and recurring or persistent convulsions (seizures), confusion, severe weakness, or paralysis.

(c) Evidence of sustained virus replication or invasive secondary bacterial infection based on laboratory testing or clinical signs (e.g. persistent high fever and other symptoms beyond 3 days).

(d) Severe dehydration, manifested as decreased activity, dizziness, decreased urine output, and lethargy.

Risk factors for severe disease *(19)*

Risk factors for severe disease from pandemic influenza A (H_1N_1) 2009 virus infection reported to date are considered similar to those risk factors identified for complications from seasonal influenza. These include the following groups :

(1) Infants and young children, in particular <2 years

(2) Pregnant women

(3) Persons of any age with chronic pulmonary disease (e.g. asthma, COPD)

(4) Persons of any age with chronic cardiac disease (e.g. congestive cardiac failure)

(5) Persons with metabolic disorders (e.g. diabetes)

(6) Persons with chronic renal disease, chronic hepatic disease, certain neurological conditions (including neuromuscular, neurocognitive, and seizure disorders), haemoglobinopathies, or immunosuppression, whether due to primary immunosuppressive conditions, such as HIV infection, or secondary conditions, such as immunosuppressive medication or malignancy

(7) Children receiving chronic aspirin therapy

(8) Persons aged 65 years and older.

A higher risk of severe complications from pandemic influenza A (H_1N_1) 2009 virus infection has also been reported in individuals who are obese particularly in those who are morbidly obese.

Laboratory diagnosis *(19)*

Laboratory diagnosis of pandemic influenza A (H_1N_1) 2009 virus, especially at the beginning of a new community outbreak or for unusual cases, has important implications for case managment, such as infection control procedures, consideration of antiviral treatment options and avoiding the inappropriate use of antibiotics. Currently, the diagnostic tests can be done by specialized laboratories in many countries. Reverse transcriptase polymerase chain reaction (RT–PCR) will provide the most timely and sensitive detection of the infection.

Clinical specimens to be collected for laboratory diagnosis are respiratory samples. Samples from the upper respiratory tract, including a combination of nasal or nasopharyngeal samples, and a throat swab are advised. Recent evidence supports viral replication and recovery of pandemic A (H_1N_1) 2009 virus from lower respiratory tract samples (tracheal and bronchial aspirates) in patients presenting lower respiratory tract symptoms and in these patients, such samples have higher diagnostic yields than samples from the upper respiratory tract.

When influenza viruses are known to be circulating in a community, patients presenting with features of uncomplicated influenza can be diagnosed on clinical and epidemiological grounds. All patients should be instructed to return for follow-up, should they develop any signs or symptoms of progressive disease or fail to improve within 72 hours of the onset of symptoms.

Diagnostic testing, when available, should be prioritized for patients in whom confirmation of influenza virus infection may affect clinical management, including patients considered at-risk and/or those with complicated, severe, or progressive respiratory illness. In addition, results of diagnostic testing may also be valuable in guiding infection control practices and management of a patient's close contacts. Under no circumstances should influenza diagnostic testing delay initiation of infection control practices or antiviral treatment, if pandemic influenza A (H_1N_1) 2009 disease is suspected clinically and epidemiologically *(19)*.

Several rapid influenza diagnostic tests including (so-called *point-of-care* diagnostic tests) are commercially available. However, studies indicate that rapid diagnostic tests miss many infections with pandemic (H_1N_1) 2009 virus and, therefore, negative results cannot rule out disease, and should not be used as grounds to withhold therapy or lift infection control measures.

Infection control

Evidence to date suggests that pandemic (H_1N_1) 2009 virus is transmitted similarly as seasonal influenza A and B viruses. Appropriate infection control measures (standard plus droplet precautions) should be adhered to at all times, which includes strict adherence to hand hygiene with soap and water or an alcohol based hand sanitizer, and to cover mouth and nose with tissue or handkerchief when coughing or sneezing. If ill persons must go into the community e.g. to seek medical care, they should wear a face mask to reduce the risk of spreading the virus in the community.

Whenever performing high-risk aerosol-generating procedures (for example, bronchoscopy or any procedure involving aspiration of the respiratory tract) use a particulate

respirator (N95, FFP2 or equivalent), eye protection, gown, and gloves, and carry out the procedure in an adequately ventilated room, either naturally or mechanically.

The duration of isolation precautions for hospitalized patients with influenza symptoms should be continued for 7 days after onset of illness or 24 hours after the resolution of fever and respiratory symptoms, whichever is longer, while a patient is in a health-care facility. For prolonged illness with complications (i.e. pneumonia), control measures should be used during the duration of acute illness (i.e. until the patient has improved clinically). Special attention is needed in caring for immunosuppressed patients who may shed virus for a longer time period and are also at increased risk for development of antiviral resistant virus.

Pandemic influenza A (H_1N_1) 2009 vaccine

In response to the pandemic, over 30 pandemic (H_1N_1) 2009 vaccines were licensed worldwide. These include live attenuated vaccines; inactivated unadjuvanted vaccines (split, subunit virion or whole virion); and inactivated adjuvanted vaccines (split or subunit virion) *(20)*. Pandemic A (H_1N_1) viruses were antigenically and genetically similar to A/California/7/2009 like viruses. Vaccines containing A/California/7/2009 antigen stimulated anti-HA antibodies of similar titres against the vaccine virus and recent pandemic A (H_1N_1) viruses *(14)*.

(a) INACTIVATED VACCINE

It is a monovalent vaccine containing antigen equivalent to A/California/7/2009 (H_1N_1) V – like strain, 15 micrograms of haemagglutinin per 0.5 ml dose *(21)*. Inactivated vaccines contain thiomersal if they are supplied in multidose vials (10 dose of 0.5 ml). It is a commonly used vaccine preservative to prevent vaccine contamination by bacteria during use.

Though the vaccine can be used within 7 days after opening the vial, it is preferred that the open vial is used completely in a given session day. This will minimize the risk of adverse effects of immunization due to programmatic errors and also reduce vaccine wastage. To facilitate tracking and timely disposal of multidose vials, it is suggested that the date of opening be clearly written on the label *(21)*.

The vaccine should be stored between 2°C–8°C. It should not be frozen.

The vaccine is administered as single dose intramuscular injection in the upper arm. In infants aged more than 6 months and young children thigh is the preferred site for vaccination. Inactivated influenza vaccine can be given at the same time as other injectable, non-influenza vaccines, but the vaccine should be administered at different injection site. Seasonal influenza and pandemic influenza vaccines can be administered together, and there is a public health value in doing so. Clinical studies on this area of vaccination are continuing *(11)*.

SIDE-EFFECTS : Inactivated vaccines, administered by injection, commonly cause local reactions such as soreness, swelling and redness at the injection site, and less often can cause fever, muscle or joint-aches or headache. These symptoms are generally mild and do not need medical attention, and last for 1–2 days. Fever, aches and headaches can occur more frequently in children compared to elderly people. Rarely, these inlfuenza vaccines can cause allergic reactions such as hives, rapid swelling of deeper skin layers and tissues, asthma or a severe multisystem allergic reaction due to hypersensitivity to certain components.

CONTRAINDICATIONS *(11)* : As a general rule, inactivated vaccines should not be administered to certain category of people. For details please refer to page 155.

Immunity

Pandemic influenza vaccine does not give 100 per cent protection against the disease but they greatly reduce the risk of disease. Influenza vaccine only becomes effective about 14 days after vaccination. Those infected shortly before (1–3 days) or shortly after immunization can still get the disease *(11)*. Vaccinated individuals can also get influenza caused by a different strain of influenza virus, for which the vaccine does not provide protection *(11)*.

(b) LIVE ATTENUATED VACCINE

Live attenuated vaccines are given *via* a nasal spray, and can commonly cause runny nose, nasal congestion, cough and can less frequently cause sore throat, low grade fever, irritability and muscle-aches and headache. Wheezing and vomiting episodes have been described in children receiving live influenza vaccines *(11)*.

Since the spread of the pandemic virus is unstoppable and there is limitation of vaccine availability, WHO recommends that all the countries should immunize their health care workers as a first priority to protect the essential health infrastructure, and to prevent initiation of nosocomial spread of disease to vulnerable patients. Furthermore, WHO suggests the following groups for vaccination according to their order of priority : (a) pregnant women; (b) individuals aged more than 6 months with one of the several chronic medical conditions; (c) healthy young adults between age 15–49 years, (d) healthy children; (e) healthy adults between age 49–65 years; and (f) healthy adults aged more than 65 years *(22)*.

Treatment

Key principles for clinical management include basic symptomatic care, early use of antiviral drugs if available, for high risk populations, antimicrobials for co-infections, and proactive observation for progression of illness.

Hospital care requires early supplemental oxygen therapy to correct hypoxaemia, with saturation monitoring at triage and during hospitalization, if possible, careful fluid replacement, antimicrobials, and other supportive care. It is important to provide appropriate antimicrobials for other infections which also present with severe respiratory distress. A number of severely ill patients with pandemic (H_1N_1) 2009 disease develop respiratory distress requiring mechanical ventilation and intensive care support.

Antiviral therapy *(19)*

Pandemic influenza A (H_1N_1) 2009 virus is currently susceptible to the neuraminidase inhibitors (NAIs) oseltamivir and zanamivir, but resistant to the M2 inhibitors amantadine or rimantadine.

The following is a summary of treatment recommendations.

(1) Patients who have severe or progressive clinical illness should be treated with oseltamivir. Treatment should be initiated as soon as possible.
   (a) This recommendation applies to all patient groups, including pregnant women, and young children <2 years, including neonates.
   (b) In patients with severe or progressive illness not responding to normal treatment regimens, higher

doses of oseltamivir and longer duration of treatment may be appropriate. In adults, a dose of 150 mg twice daily is being used in some situations.

(c) Where oseltamivir is not available or not possible to use, or if the virus is resistant to oseltamivir, patients who have severe or progressive clinical illness should be treated with zanamivir.

(2) Patients at higher risk of developing severe or complicated illness, but presenting with uncomplicated illness due to influenza virus infection, should be treated with oseltamivir or zanamvir. Treatment should be initiated as soon as possible following onset of illness.

(3) Patients not considered to be at higher risk of developing severe or complicated illness and who have uncomplicated illness due to confirmed or strongly suspected influenza virus infection need not be treated with antivirals.

If used, antiviral treatment should ideally be started early following the onset of symptoms, but it may also be used at any stage of active disease when ongoing viral replication is anticipated or documented. Recent experience strongly indicates that earlier treatment is associated with better outcomes. Therefore, antiviral treatment should be initiated immediately and without waiting for laboratory confirmation of diagnosis.

In patients who have persistent severe illness despite oseltamivir treatment, there are few licensed alternative antiviral treatments. In these situations, clinicians have considered intravenous administration of alternative antiviral drugs such as zanamivir, peramivir, and ribavirin. The use of such treatments should be done only in the context of prospective clinical and virological data collection and with regard to the following cautions:

- ribavirin should not be administered as monotherapy;
- ribavirin should not be administered to pregnant women; and
- zanamivir formulated as a powder for inhalation should not be delivered *via* nebulization due to the presence of lactose, which may compromise ventilator function.

Standard antiviral treatment regimens *(19)*

Oseltamivir

Oseltamivir is indicated for treatment of influenza. For adults the recommended oral dose is 75 mg oseltamivir twice daily for 5 days.

For infants less than 1 year of age recommended oral doses are as follows:

>3 months to 12 months	3 mg/kg, twice daily for 5 days
>1 month to 3 months	2.5 mg/kg, twice daily for 5 days
0 to 1 month *	2 mg/kg, twice daily for 5 days
* There are no data available regarding the adminstration of oseltamivir to infants less than one month of age.	

For older children the recommended oral doses according to body weight are as follows:

15 kg or less	30 mg twice a day for 5 days
15-23 kg	45 mg twice a day for 5 days
24-40 kg	60 mg twice a day for 5 days
>40 kg	75 mg twice a day for 5 days

Zanamivir

Zanamivir is indicated for treatment of influenza in adults and children (>5 years). The recommended dose for treatment of adults and children from the age of 5 years is two inhalations (2 x 5 mg) twice daily for 5 days.

Chemoprophylaxis *(18)*

Oseltamivir is the drug of choice for chemoprophylaxis to health care personnels and close contacts of suspected, probable or confirmed case of pandemic influenza A (H_1N_1) 2009. It should be given till 10 days after last exposure. The dose by body weight is a follows :

Weight less than 15 kg	–	30 mg OD
15–23 kg	–	45 mg OD
24–40 kg	–	60 mg OD
> 40 kg	–	75 mg OD
For infants		
< 3 months	–	not recommended unless situation is critical
3–5 months	–	20 mg OD
6–11 months	–	25 mg OD

DIPHTHERIA

Diphtheria is an acute infectious disease caused by toxigenic strains of *Corynebacterium diphtheriae*. Three major clinical types have been described : anterior nasal,

faucial and laryngeal; however, the skin, conjunctiva, vulva and other parts of the body may be affected. The bacilli multiply locally, usually in the throat, and elaborate a powerful exotoxin which is responsible for :

(a) the formation of a greyish or yellowish membrane ("false membrane") commonly over the tonsils, pharynx or larynx (or at the site of implantation), with well-defined edges and the membrane cannot be wiped away;
(b) marked congestion, oedema or local tissue destruction;
(c) enlargement of the regional lymph nodes; and
(d) signs and symptoms of toxaemia.

Fatality rate on the average is about 10 per cent which has changed little in the past decades in untreated cases, and in children under 5 years of age, one out of 5 children who get diphtheria dies *(1)*.

Problem statement

WORLD : Diphtheria is a rare disease in most developed countries owing to routine children vaccination. In countries where satisfactory vaccination schemes have been instituted the disease has so declined that it is no longer regarded as a public health problem. However the disease is seen occasionally among non-immunized children in developed countries.

Improved socio-economic conditions are changing the epidemiology of diphtheria. Changes in lifestyle allow far less opportunity to maintain natural immunity, such as through frequent skin infection with *C.diphtheriae (2)*. These epidemics are largely due to decreasing immunization coverage among infants and children, waning immunity to diphtheria in adults, movement of large groups of population in the last few years, and an irregular supply of vaccine *(3)*. These outbreaks highlight the need for booster vaccinations. Recent diphtheria outbreaks in a number of countries have demonstrated a shift in the age distribution of cases to older children and adults *(4)*. In developing countries, the disease continues to be endemic due to lack of adequate widespread immunization. The true numbers of diphtheria cases and deaths are unknown because of incomplete reporting from most countries where the disease occurs. During the year 2012, about 4,490 diphtheria cases were reported globally *(5)*.

INDIA : Diphtheria is an endemic disease. The available retrospective data indicate a declining trend of diphtheria in the country. It is due to increasing coverage of child population by immunization. The reported incidence of the disease in the country during 1987 (before wide coverage of immunization) was about 12,952, whereas during the year 2013, 4,090 cases and 64 deaths were reported showing a case fatality rate of about 2.61 *(6)*.

Epidemiological determinants

Agent factors

(a) AGENT : The causative agent, *C.diphtheriae* is a gram-positive, non-motile organism. It has no invasive power, but produces a powerful exotoxin. Four types of diphtheria bacilli are differentiated – *gravis, mitis, belfanti* and *intermedius*, all pathogenic to man. In general, *gravis* infections tend to be more severe than *mitis* infections. Not all the strains of the organism are toxigenic. There is evidence that a non-toxigenic strain may become toxigenic when exposed to a particular bacteriophage – the beta phage – carrying the gene for toxin production *(7)*. The toxin can affect the heart leading to myocarditis or the nerves leading to paralysis. Diphtheria bacilli are sensitive to penicillin and are readily killed by heat and chemical agents. They may survive for short periods in dust and fomites. (b) SOURCE OF INFECTION : The source of infection may be a case or carrier: *(i) CASE :* Cases range from subclinical to frank clinical cases. Mild or silent infections may exhibit no more than a mere running nose or sore throat; these cases play a more important role than frank cases in spreading the infection. *(ii) CARRIER :* Carriers are common sources of infection, their ratio is estimated to be 95 carriers for 5 clinical cases *(1)*. Carriers may be temporary or chronic; nasal or throat carriers. The nasal carriers are particularly dangerous as source of infection because of frequent shedding of the organism into the environment, than do throat carriers. The temporary carrier state may last for about a month, but the chronic carrier state may persist for a year or so, unless the patient is treated. The incidence of carriers in a community may vary from 0.1 to 5 per cent *(8)*. Immunization does not prevent the carrier state. (c) INFECTIVE MATERIAL : Nasopharyngeal secretions, discharges from skin lesions, contaminated fomites and possibly infected dust. (d) PERIOD OF INFECTIVITY : Unless treated, the period of infectivity may vary from 14 to 28 days from the onset of the disease, but carriers may remain infective for much longer periods. A case or carrier may be considered non-communicable, when at least 2 cultures properly obtained from nose and throat, 24 hours apart, are negative for diphtheria bacilli.

Host factors

(a) AGE : Diphtheria particularly affects children aged 1 to 5. In countries where widespread immunization is practised, a shift in age incidence has been observed from preschool to school age. (b) SEX : Both sexes are affected. (c) IMMUNITY : Infants born of immune mothers are relatively immune during the first few weeks or months of life. Before artificial immunization, large proportion of population in developing countries were acquiring active immunity through inapparent infection which resulted in widespread production of antitoxin in the population. Thus most members of the population except children were immune. By age 6–8 years, approximately 75 per cent of children in developing countries where skin infection with *C. diphtheriae* are common have protective serum antitoxin levels *(12)*.

Since diphtheria is principally the result of action of the toxin formed by the organism rather than invasion by the organism, resistance to the disease depends largely on the availability of specific neutralizing antitoxin in the bloodstream and tissues. It is generally true that diphtheria occurs only in persons who possess no antitoxin (or less than 0.01 Lf unit/ml.). Assessment of immunity to diphtheria toxin for individual patients can best be made by review of documented diphtheria toxoid immunizations and primary or booster immunization if needed *(12)*.

Environmental factors

Cases of diphtheria occur in all seasons, although winter months favour its spread.

Mode of transmission

The disease is spread mainly by droplet infection. It can

also be transmitted directly to susceptible persons from infected cutaneous lesions. Transmission by objects (e.g., cups, thermometers, toys, pencils), contaminated by the nasopharyngeal secretions of the patient is possible, but for only short periods.

Portal of entry

(a) RESPIRATORY ROUTE : Commonly the portal of entry is the respiratory tract. *(b) NON-RESPIRATORY ROUTES :* The portal of entry sometimes may be the skin where cuts, wounds and ulcers not properly attended to, may get infected with diphtheria bacilli, and so is the umbilicus in the newborn. Occasionally, the site of implantation may be the eye, genitalia or middle ear. The non-respiratory routes of infection are less common in developed countries where spread by droplet infection is more common.

Incubation period

2 to 6 days, occasionally longer.

Clinical features

Respiratory tract forms of diphtheria consist of pharyngotonsillar, laryngotracheal, nasal, and combinations thereof. Patients with pharyngotonsillar diphtheria usually have a sore throat, difficulty in swallowing, and low grade fever at presentation. Examination of the throat may show only mild erythema, localized exudate, or a pseudo-membrane. The membrane may be localized or a patch of the posterior pharynx or tonsil, may cover the entire tonsil, or, less frequently, may spread to cover the soft and hard palates and the posterior portion of the pharynx. In the early stage the pseudo-membrane may be whitish and may wipe off easily. The membrane may extend to become thick, blue-white to grey-black, and adherent. Attempts to remove the membrane result in bleeding. A minimal area of mucosal erythema surrounds the membrane. Patients with severe disease may have marked oedema of the submandibular area and the anterior portion of the neck, along with lymphadenopathy, giving a characteristic "bull-necked" appearance.

Laryngotracheal diphtheria most often is preceded by pharyngotonsillar disease, usually is associated with fever, hoarseness and croupy cough at presentation, and, if the infection extends into bronchial tree, it is the most severe form of disease. Initially it may be clinically indistinguishable from viral croup or epiglottitis. Prostration and dyspnoea soon follow because of the obstruction caused by the membrane. This obstruction may even cause suffocation if not promptly relieved by intubation or tracheostomy.

The diphtheria bacilli within the membrane continue to produce toxin actively. This is absorbed and results in distant toxic damage, particularly parenchymatous degeneration, fatty infiltration and necrosis in heart muscle, liver, kidneys, and adrenals, sometimes accompanied by gross haemorrhage. Irregularities of cardiac rhythm indicate damage to the heart. Later, there may be difficulties with vision, speech, swallowing, or movement of the arms or legs. The toxin also produces nerve damage, resulting often in paralysis of the soft palate, eye muscles, or extremities *(12)*. Patients who survive complications recover completely.

Nasal diphtheria, the mildest form of respiratory diphtheria, usually is localized to the septum or turbinates of one side of the nose. Occasionally a membrane may extend into the pharynx.

Non-respiratory mucosal surface i.e., the conjunctiva and genitals may also be sites of infection.

Cutaneous diphtheria is common in tropical areas. It often appears as a secondary infection of a previous skin abrasion or infection. The presenting lesion, often an ulcer, may be surrounded by erythema and covered with a membrane. Patients generally seek treatment because of the chronicity of the skin lesion.

CONTROL OF DIPHTHERIA

1. CASES AND CARRIERS

(a) ***Early detection :*** An active search for cases and carriers should start immediately amongst family and school contacts *(14)*. Carriers can be detected only by culture method. Swabs should be taken from both the nose and throat and examined by culture methods for diphtheria bacilli. Tests should be made for the virulence of the organism. (b) ***Isolation :*** All cases, suspected cases and carriers should be promptly isolated, preferably in a hospital, for at least 14 days or until proved free of infection. At least 2 consecutive nose and throat swabs, taken 24 hours apart, should be negative before terminating isolation. (c) ***Treatment :*** (i) CASES : When diphtheria is suspected, diphtheria antitoxin should be given without delay, IM or IV, in doses ranging from 20,000 to 100,000 units or more, depending upon the severity of the case, after a preliminary test dose of 0.2 ml subcutaneously to detect sensitization to horse serum. For mild early pharyngeal or laryngeal disease the dose is 20,000–40,000 units; for moderate nasopharyngeal disease, 40,000–60,000 units; for severe, extensive or late (3 days or more) disease, 80,000–100,000 units *(15)*. In addition to antitoxin, every case should be treated with penicillin or erythromycin for 5 to 6 days to clear the throat of *C.diptheriae* and thereby decrease toxin production, (ii) CARRIERS : The carriers should be treated with 10 days course of oral erythromycin, which is the most effective drug for the treatment of carriers. The immunity status should be upgraded as discussed below.

2. CONTACTS

Contacts merit special attention. They should be throat swabbed and their immunity status determined. Different situations pose different options : (a) where primary immunization or booster dose was received within the previous 2 years, no further action would be needed (b) where primary course or booster dose of diphtheria toxoid was received more than 2 years before, only a booster dose of diphtheria toxoid need be given (c) non-immunized close contact should receive prophylactic penicillin or erythromycin. They should be given 1000–2000 units of diphtheria antitoxin and actively immunized against diphtheria. Contacts should be placed under medical surveillance and examined daily for evidence of diphtheria for at least a week after exposure *(16)*. The bacteriological surveillance of close contacts should be continued for several weeks by repeated swabbing at approximately weekly intervals *(14)*.

3. COMMUNITY

The only effective control is by active immunization with diphtheria toxoid of all infants as early in life as possible, as scheduled, with subsequent booster doses every 10 years thereafter *(16)*. The aim should be to immunize before the infant loses his maternally derived immunity so that there

will be continuous protection from birth without any gap in immunity to natural disease *(17)*. The vaccine being a toxoid is not directed against organisms. Therefore immunization does not prevent the carrier state; consequently, the non-immune individuals are not protected by a high level of population immunity *(18)*. This implies that immunization rate must be maintained at a high level.

DIPHTHERIA IMMUNIZATION

Current prophylactics

These may be grouped as below :

a. Combined or mixed vaccines

- DPT (diphtheria–pertussis–tetanus vaccine)
- DTPw (diphtheria, tetanus, whole–cell pertussis)
- DTPa (diphtheria, tetanus, acellular pertussis)
- DT (diphtheria–tetanus toxoid)
- dT (diphtheria–tetanus, adult type)

b. Single vaccines

- FT (formal–toxoid)
- APT (alum–precipitated toxoid)
- PTAP (purified toxoid aluminium phosphate)
- PTAH (purified toxoid aluminium hydroxide)
- TAF (toxoid–antitoxin flocculus)

c. Antisera

- Diphtheria antitoxin.

a. COMBINED VACCINES

DPT Vaccine

For immunizing infants, the preparation of choice is DPT. Firstly because, the infant can be immunized simultaneously against three diseases, viz., diphtheria, pertussis and tetanus which is a great gain administratively. Secondly the pertussis component in DPT vaccine enhances the potency of the diphtheria toxoid.

There are two types of DPT vaccines – plain and adsorbed. Adsorption is usually carried out on a mineral carrier like aluminium phosphate or hydroxide. Studies have shown that adsorption increases the immunological effectiveness of the vaccine. The WHO recommends that only adjuvant DPT preparations be utilized in immunization programmes *(17)*.

STORAGE : DPT/DT vaccines should not be frozen. They should be stored in a refrigerator between 2 to 8 deg. C. The vaccine should be used before the date of expiry indicated on the vial. When issued to a sub–centre, the vaccine should be used within a week *(19)*. The vaccine will lose potency if kept at room temperature over a longer period of time.

(a) *Optimum age :* It has been found that young infants respond well to immunization with potent vaccines and toxoids even in the presence of low to moderate levels of maternal antibodies. Accordingly, the Global Advisory Group of the Expanded Programme on Immunization (EPI), has recommended that DPT vaccine can be safely and effectively administered as early as 6 weeks after birth *(20, 21)*.

(b) *Number of doses :* Three doses of DPT each of which is usually 0.5 ml, should be considered optimal for primary immunization. It is associated with higher and more sustained levels of diphtheria and tetanus antitoxin and acceptable level of pertussis protection i.e., vaccine efficiency 70 per cent *(22)*.

(c) *Interval between doses :* The current recommendation is to allow an interval of 4 weeks between the 3 doses, with a booster injection at one and a half year to two years, followed by another booster (DT only) at the age of 5 to 6 years. Studies have shown that two-month intervals do not offer any advantage over one-month intervals for protection against diphtheria and tetanus, and may not enhance pertussis protection. On the other hand, shorter intervals confer protection at an earlier age which may be particularly important in pertussis control *(22)*.

(d) *Mode of administration :* All vaccines containing mineral carriers or adjuvants should be injected deep intramuscular. This applies to DPT also which may be given in the upper and outer quadrant of the gluteal region. One of the principal recommendations of the 1984 Global Advisory Group is that "especially for children under one year of age, DPT should be administered in (lateral aspect) the thigh" *(23)*.

(e) *Reactions :* Fever and mild local reactions following DPT immunization are common. It is estimated that 2 to 6 per cent of vaccinees develop fever of 39 deg. C or higher, and that 5 to 10 per cent experience swelling and induration or pain lasting more than 48 hours. In studies in USA and Australia, about 50 per cent of children had local reactions *(24)*.

The most severe complications following DPT immunization are neurological (encephalitis/ encephalopathy, prolonged convulsions, infantile spasms and Reye's syndrome) and are thought to be due primarily to the pertussis component of the vaccine – the estimated risk is 1:170, 000 doses administered *(24)*.

(f) *Contraindications :* Minor illnesses such as cough, cold, mild fever are not considered contraindications to vaccination, only such children who are seriously ill or need hospitalization are not vaccinated. DPT should not be repeated if a severe reaction occurred after a previous dose. Such reactions include collapse or shock–like state, persistent screaming episodes, temperature above 40 deg.C, convulsions, other neurological symptoms and anaphylactic reactions. In the case of DPT, subsequent immunization with DT only is recommended, without the pertussis component. Local reactions at the site of injection or mild fever do not by themselves preclude the further use of DPT *(24)*.

Since the severity of pertussis infection decreases with age, the pertussis component in DPT vaccine is not usually recommended after the age of 6 years *(25)*. Therefore, children over the age of 5 years who have not received DPT, need only 2 doses of DT vaccine, 4 weeks apart, with a booster dose 6 months to 1 year later. Those children who received the primary course of DPT earlier, should receive only DT as booster at 5–6 years or at school entry.

For immunizing children over 12 years of age and adults, the preparation of choice is dT, which is an adult–type of diphtheria tetanus vaccine *(16)*. This preparation contains no more than 2 Lf of diphtheria toxoid per dose, compared with 25 Lf in the ordinary (paediatric) DPT/DT vaccines. Administration of dT vaccine to adults is carried out in 2 doses at an interval of 4 to 6 weeks, followed by a booster 6 to 12 months after the second dose *(26)*. This vaccine (dT) is not followed by the high incidence of reactions associated

with the use of DPT or DT. Alternatively, for primary immunization of adults, FT or TAF may be used and they cause fewer reactions than APT or PTAP.

b. SINGLE VACCINES

Single vaccines (e.g., FT, PTAP, APT, PTAH) are less frequently used. They are all good immunizing agents. APT is hardly used because it is prone to give rise to serious reactions. Each dose of these antigens generally contains 25 Loeffler (Lf) units of diphtheria toxoid.

c. ANTISERA

Diphtheria antitoxin prepared in horse serum is still the mainstay of passive prophylaxis and also for treatment of diphtheria.

It has been shown, protection against diphtheria toxin is a quantitative phenomenon, so that a serum antitoxin titre that protects against a small dose of toxin may not protect against a large dose: for this reason, failures of diphtheria immunization may take place *(27)*.

WHOOPING COUGH
(PERTUSSIS)

An acute infectious disease, usually of young children, caused by *B. pertussis.* It is clinically characterized by an insidious onset with mild fever and an irritating cough, gradually becoming paroxysmal with the characteristic "whoop" (loud crowing inspiration) often with cyanosis and vomiting. The spectrum of disease varies from severe illness to atypical and mild illness without whoop. The Chinese call it a "Hundred Day Cough" *(1)*.

Problem statement

Pertussis is an important cause of death in infants worldwide, and continues to be a public health concern even in countries with high vaccination coverage. During 2012, about 2.49 lac cases were reported to WHO globally *(2)* and the DPT_3 immunization rate was 83 per cent.

It is one of the most lethal diseases of the infants and young children who have not been immunized, particularly those with underlying malnutrition and other respiratory infections *(3)*. Pertussis is increasingly reported in older children, adolescents and adults. A serological study from the United States showed that 21 per cent of adults with prolonged cough (lasting more than 2 weeks) had pertussis *(4)*.

In India, there is marked decline of the disease after launch of universal immunization programme. During the year 1987; the reported incidence was about 1.63 lakh cases, whereas during 2013 only 36,661 cases were reported showing a decline of about 77 per cent *(5)*.

Epidemiological determinants

Agent factors

(a) AGENT : The causative agent in a large proportion of cases is *B. pertussis.* In a small percentage of cases (less than 5 per cent), *B. parapertussis* is probably responsible. Certain viruses (e.g., adenoviruses, parainfluenza viruses) are also implicated in the whooping cough syndrome, but their presence in cases of whooping cough is probably coincidental and not causal *(6)*. *B. pertussis* occurs in smooth and rough phases, capsulated and non–capsulated forms, and elaborates an exotoxin and endotoxin. Clinical disease is associated with encapsulated, phase 1 strains. *B. pertussis* is antigenically highly complex. It carries 3 major agglutinogens – 1, 2 and 3 and several minor ones. The nature of the protective antigen is not known *(6)*. The bacterium survives only for very short periods outside the human body. (b) SOURCE OF INFECTION : *B. pertussis* infects only man. The source of infection is a case of pertussis. More often, the source may be mild, missed and unrecognized cases. There is no evidence that infection is ever subclinical *(6)*. A chronic carrier state does not exist. (c) INFECTIVE MATERIAL : The bacilli occurs abundantly in the nasopharyngeal and bronchial secretions, which are infective. Objects freshly contaminated by such discharges are also infective. (d) INFECTIVE PERIOD : Whooping cough is most infectious during catarrhal stage. The infective period may be considered to extend from a week after exposure to about 3 weeks after the onset of the paroxysmal stage although communicability diminishes rapidly after the catarrhal stage. Asymptomatic chronic carriers of *B. pertussis* are uncommon *(7)*. (e) SECONDARY ATTACK RATE : Averages 90 per cent in unimmunized household contacts *(7)*.

Host factors

(a) AGE : Whooping cough is primarily a disease of infants and pre-school children. The highest incidence is found below the age of 5 years. The median age of infection, i.e., the age when half the children are likely to develop whooping cough is between 20–30 months in developing countries as compared to 50 months in

developed countries *(1)*. Infants below 6 months have the highest mortality. In older children, adolescents and adults, pertussis is often unrecognized because of its atypical course. However, older age groups represent an important source of infection for susceptible infants *(7)*. (b) SEX : Incidence and fatality are observed to be more among female than male children *(6)*. (c) IMMUNITY : Recovery from whooping cough or adequate immunization is followed by immunity. Second attacks may occur in persons with declining immunity, but these are usually mild. It is possible that the first defence against pertussis infection is the antibody that prevents attachment of the bacteria to the cilia of the respiratory epithelium *(8)*. Infants are susceptible to infection from birth because maternal antibody does not appear to give them protection. There is no cross immunity with *B. parapertussis*.

Environmental factors

Pertussis occurs throughout the year, but the disease shows a seasonal trend with more cases occurring during winter and spring months, due to overcrowding. Socio-economic conditions and ways of life also play a role in the epidemiology of the disease. Thus, the risk of exposure is greater in the lower social classes living in overcrowded conditions than in well–to–do groups.

Mode of transmission

Whooping cough is spread mainly by droplet infection and direct contact. Each time the patient coughs, sneezes or talks, the bacilli are sprayed into the air. Most children contract infection from their playmates who are in the early stages of the disease. The role of fomites in the spread of infection appears to be very small, unless they are freshly contaminated.

Incubation period

Usually 7 to 14 days, but not more than 3 weeks.

Clinical course

B. pertussis produces a local infection; the organism is not invasive. It multiplies on the surface epithelium of the respiratory tract and causes inflammation and necrosis of the mucosa leading to secondary bacterial invasion. Three stages are described in the clinical course of the disease: (a) catarrhal stage, lasting for about 10 days. It is characterized by its insidious onset, lacrimation, sneezing and coryza, anorexia and malaise, and a hacking night cough that becomes diurnal. (b) paroxysmal stage, lasting for 2–4 weeks. It is characterized by bursts of rapid, consecutive coughs followed by a deep, high-pitched inspiration (whoop). It is usually followed by vomiting. In young infants it may cause cyanosis and apnoea. In adults and adolescents, uncharacteristic, persistent cough may be the only manifestation of the disease, and (c) convalescent stage, lasting for 1–2 weeks. The illness generally lasts 6 to 8 weeks.

Complications occur in 5–6 per cent of cases, most frequently in infants aged less than 6 months. The chief complications of pertussis are bronchitis; bronchopneumonia and bronchiectasis. The violence of the paroxysms may precipitate subconjunctival haemorrhages, epistaxis, haemoptysis and punctate cerebral haemorrhages which may cause convulsions and coma.

Bronchopneumonia occurs in about 5.2 per cent of cases. It is the most prominent problem, with relatively high mortality. The incidence of pertussis-associated encephalopathy is 0.9 per cent 100,000. In industrialized countries, lethality of pertussis is very low (<1/1000), whereas in developing countries the average mortality is estimated at 3.9 per cent in infants and 1 per cent in children aged 1–4 years *(7)*.

Control of Whooping Cough

1. CASES AND CONTACTS

(i) Cases : Early diagnosis, isolation and treatment of cases, and disinfection of discharges from nose and throat are the general principles of control of whooping cough. Early diagnosis is possible only by bacteriological examination of nose and throat secretions which may be obtained by naso-pharyngeal swabs. The chances of isolating the organism are < 60 per cent if the material is obtained within 10–14 days from the onset of illness. The value of fluorescent antibody technique has been emphasized in facilitating the rapid diagnosis of pertussis. The patient should be isolated until considered to be non–infectious. Although several antibiotics are effective against *B. pertussis*, erythromycin is probably the drug of choice. A dose of 30–50 mg/kg of body weight in 4 divided doses for 10 days has been recommended. Possible alternatives are ampicillin, septran or tetracycline. Antibiotics may prevent or moderate clinical pertussis when given during incubation period or in early catarrhal stage. During paroxysmal phase of disease, antimicrobial drugs will not change the clinical course but may eliminate the bacterium from the nasopharynx and thus reduce transmission of disease *(7)*. They are useful in controlling secondary bacterial infections *(9)*.

(ii) Contacts : Infants and young children should be kept away from cases. Those known to have been in contact with whooping cough may be given prophylactic antibiotic (erythromycin or ampicillin) treatment for 10 days to prevent the infecting bacteria to become established. The best protection that can be given to an infant is to administer a booster dose of DPT/DT to his siblings before he is born *(6)*.

2. ACTIVE IMMUNIZATION

The vaccine is usually administered in the national childhood immunization programme as combined DPT, DTWP or DTaP vaccine. In India, the national policy is to immunize against diphtheria, whooping cough and tetanus simultaneously, by administering 3 doses (each dose about 0.5 ml) of DPT vaccine intramuscularly, at one month interval, starting at the age of 6 weeks. A booster dose is given at 18–24 months. Children whose vaccination series has been interrupted should have their series resumed, without repeating previous doses. In some countries, an additional vaccine dose is now offered to health-care workers and young parents. Only acellular pertussis vaccines are used for vaccination of older children and adults *(7)*.

Despite major differences in the content, mode of preparation and efficacy among both whole-cell pertussis vaccines and acellular pertussis vaccines; comprehensive clinical trials have demonstrated that the most efficacious vaccines of either category will protect 85 per cent of the recipients from clinical disease. The duration of protection following the primary 3-dose course in infants and 1 booster dose atleast 1 year later is believed to be on an average 6–12 years for both whole-cell and acellular pertussis vaccines. This is similar to, or somewhat shorter than, immunity following natural infection *(7)*. Some studies

suggest that pertussis vaccination affects pharyngeal colonization of *B. pertussis*, resulting in some reduction of bacterial transmission in the community *(7)*. All infants, including HIV-positive individuals should be immunized against pertussis.

In principle, the same type of acellular vaccine should be given throughout the primary course of vaccination. However, if the previous type of vaccine is unknown, any type of acellular vaccine may be used *(7)*.

Commercially available vaccines containing acelluar pertussis include combination with some or all of the following components : diphtheria toxoid, tetanus toxoid, Hib, HepB and IPV.

UNTOWARD REACTIONS : With some vaccines available in the early 1960s, persistent screaming and collapse were reported, but these reactions are rarely observed with the vaccines now available. Pertussis vaccines may give rise to local reactions at the site of injection, mild fever and irritability. The rare vaccine reactions are persistent (more than 3 hours) inconsolable screaming, seizures, hypotonic hypo-responsive episodes, anaphylactic reaction and very rarely encephalopathy. For details kindly refer to Table 36 of chapter 3 page 111.

CONTRAINDICATIONS : The contraindications to pertussis vaccination are anaphylactic reaction, encephalopathy, a personal or strong family history of epilepsy, convulsions or similar CNS disorders: any febrile upset until fully recovered: or a reaction to one of the previously given triple vaccine injections *(10)*.

3. PASSIVE IMMUNIZATION

The merit of hyperimmune globulin in pertussis prophylaxis has yet to be established. So far, there is no evidence of its efficacy in well–controlled trials *(9)*.

The control of pertussis by immunization is still an unsolved problem. Even if the level of immunization reaches 100 per cent, it is possible that the disease would not be entirely eliminated because whooping cough vaccines have never been claimed to be more than 90 per cent effective.

MENINGOCOCCAL MENINGITIS

Meningococcal meningitis or cerebrospinal fever is an acute communicable disease caused by *N.meningitidis*. It usually begins with intense headache, vomiting and stiff neck and progresses to coma within a few hours. The meningitis is part of a septicaemic process. The fatality of typical untreated cases is about 80 per cent. With early diagnosis and treatment, case fatality rates have declined to less than 10 per cent.

Problem statement

Distribution worldwide, occurring sporadically and in small outbreaks in most parts of the world. In some regions this endemic situation may alternate with devastating, unpredictable epidemics. This is the case in the African meningitis belt, which is the region in sub–Saharan Africa stretching from Senegal in the west to Ethiopia in the east. This region is inhabited by around 400 million people. In the African meningitis belt, the WHO definition of a meningococcal epidemic is >100 cases per 100,000 population per year. In the endemic countries, the incidence of >10 cases, 2–10 cases and <2 cases per 100,000 population per year characterize high, moderate and low endemicity respectivety. An outbreak outside the meningitis belt may be defined as a substantial increase in invasive meningococcal disease in a defined population above that which is expected by place and time *(1)*.

During recent years, several serious outbreaks affecting numerous countries have occurred in tropical and temperate zones of other continents, viz, Americas, Asia and Europe. In Europe, the incidence of disease ranges from 0.2 to 14 cases per 100,000 population and majority cases are caused by serogroup B strains. In Americas, the incidence of disease is in the range of 0.3 to 4 cases per 100,000 population. In United States, the majority cases are caused by serogroups B, C and Y. In Asia most meningococcal disease is caused by meningococci belonging to serogroup A or C *(1)*.

Meingococcal disesase is endemic in India. Cases of meningococcal meningitis are reported sporadically or in small clusters. During 2013, about 3,380 cases of meningococcal meningitis were reported in India with about 176 deaths. Majority of the cases were reported from only few states as shown in Table 1.

TABLE 1
Reported cases and deaths due to meningococcal meningitis in India – 2013

State	Cases	Deaths
Andhra Pradesh	397	27
Madhya Pradesh	302	6
Uttar Pradesh	12	0
West Bengal	64	13
Delhi	876	53
Gujarat	112	13
Tamil Nadu	57	4
Bihar	69	1
Jharkhand	125	0
Odisha	248	17
Haryana	107	0
Manipur	205	0
Puducherry	181	23
India	3,380	176

Source : *(2)*

Epidemiological features

(a) AGENT : The causative agent, *N. meningitidis* is a gram-negative diplococci. 12 serotypes have been identified, viz. Groups A, B, C, 29E, H, I, K, L, W135, X, Y, Z based on the structure of the polysaccharide capsule. The majority of invasive meningococcal infections are caused by organisms of serogroups A, B, C, X, W135 and Y. Meningococci of these

serogroups have the potential to cause both endemic disease and outbreaks. In African meningitis belt, subgroup A has been the most important cause of disease *(1)*. *N. meningitidis* is a delicate organism; it dies rapidly on exposure to heat and cold. (b) SOURCE OF INFECTION : The organism is found in the nasopharynx of cases and carriers. Clinical cases present only a negligible source of infection. More often the infection causes mild or even unnoticeable symptoms of nasopharyngitis. 4 to 35 per cent of the normal population may harbour the organism in the nasopharynx during inter-epidemic periods. Carriers are the most important source of infection. The mean duration of temporary carriers is about 10 months *(3)*. During epidemics, the carrier rate may go up to 70–80 per cent. (c) PERIOD OF COMMUNICABILITY : Until meningococci are no longer present in discharges from nose and throat. Cases rapidly lose their infectiousness within 24 hours of specific treatment. (d) AGE AND SEX : This is predominantly a disease of children and young adults of both sexes with highest attack rate in infants aged 3–12 months. (e) IMMUNITY : All ages are susceptible. Younger age groups are more susceptible than older groups as their antibodies are lower. Immunity is acquired by subclinical infection (mostly), clinical disease or vaccination. Infants derive passive immunity from the mother. (f) ENVIRONMENTAL FACTORS : The seasonal variation of the disease is well established; outbreaks occur more frequently in the dry and cold months of the year from December to June. Overcrowding, as occurs in schools, barracks, refugee and other camps, is an important predisposing factor. The incidence is also greater in the low socio-economic groups living under poor housing conditions, with exposure to tobacco smoke, asplenia, HIV infection and travel to endemic areas.

Mode of transmission

The disease spreads mainly by droplet infection. The portal of entry is the nasopharynx.

Incubation period

Usually 3 to 4 days, but may vary from 2 to 10 days.

Clinical course

Most infections do not cause clinical disease. Many infected people become asymptomatic carriers of the bacteria and serve as a reservoir and source of infection for others. In general, susceptibility to meningococcal disease decreases with age. Meningococcal meningitis has a sudden onset of intense headache, fever, nausea, vomiting, photophobia, stiff neck and various neurological signs. The disease is fatal within 24–48 hours in 5–10 per cent of cases even with prompt antimicrobial treatment in good health care facility. Among individuals who survive, upto 15–20 per cent have permanent neurological sequelae. Meningococcal septicaemia, in which there is rapid dissemination of bacteria in the bloodstream, is a less common form of meningococcal disease, characterized by circulatory collapse, haemorrhagic skin rash and high fatality rate *(4)*.

Prevention and control

(a) CASES : Treatment with antibiotics can save the lives of 95 per cent of patients provided that it is started during the first 2 days of illness. Penicillin is the drug of choice. In penicillin-allergic patients, ceftriaxone and other third-generation cephalosporins should be substituted. A single dose of long-acting chloramphenicol or cetriaxone is used for treatment of epidemic meningococcal meningitis in sub-Saharan Africa. Septicaemic shock and raised intracranial pressure in meningitis are particular problem in the management of meningococcal disease. Treatment of cases has practically no effect on the epidemiological pattern of the disease because it only reduces the fatality rate of the disease according to the treatment efficiency *(3)*. Isolation of cases is of limited usefulness in controlling epidemics because the carriers outnumber cases.

(b) CARRIERS : Treatment with penicillin does not eradicate the carrier state; more powerful antibiotics such as rifampicin are needed to eradicate the carrier state *(5)*.

(c) CONTACTS : Close contacts of persons with confirmed meningococcal disease are at an increased risk of developing meningococcal illness. Antibiotics are effective in preventing additional cases through eradicating carriage of the invasive strain. Most secondary case occur within the first 72 hours after presentation of the index case; risk of secondary disease decreases to near baseline by 10–14 days. Close contacts include household, child care, and preschool contacts. In outbreaks involving limited populations, those with direct, prolonged contact with a case of meningococcal disease may also be offered clearance treatment. Ideally, where indicated, treatment should be started within 24 hours of identification of the index case. Antibiotics effective for this purpose include rifampicin, ciprofloxacin, ceftriaxone or azithromycin.

(d) MASS CHEMOPROPHYLAXIS : This is in fact mass medication of the total population some of which are not infected. It is recommended that mass chemoprophylaxis be restricted to closed and medically supervised communities. Mass treatment causes an immediate drop in the incidence rate of meningitis and in the proportion of carriers. The efficacy of this preventive measure depends to a large extent on the population coverage *(3)*. The drugs of choice are ciprofloxacin, minocycline, spiramycin and ceftriaxone.

(e) VACCINE *(1, 4)* : Currently available meningococcal vaccines include polysaccharide vaccines and polysaccharide-protein conjugate vaccines. The conjugate vaccines are more immunogenic and also induce immunogenic memory. Both vaccines are available against meningococci of serogroup A, C, W135 and Y.

Polysaccharide vaccines : Internationally marketed meningococcal polysaccharide vaccines are available in bivalent (A, C), trivalent (A,C, W 135), and quadrivalent (A, C, W135, Y) formulations. The vaccines contain 50 µg of each of the individual polysaccharides. Meningococcal polysaccharide vaccines are administered as a single dose to persons ≥2 years old; most of these vaccines are given subcutaneously.

Adverse reactions to polysaccharide meningococcal vaccines are usually mild; the most frequent reaction is 1–2 days of pain and redness at the site of injection, which occur in 4%–56% of vaccine recipients. Transient fever is reported in <5% of recipients.

Conjugate vaccines : Licensed meningococcal conjugate vaccines are monovalent (A or C) or quadrivalent (A, C, W135, Y), and also include a combination vaccine based on *Haemophilus influenzae type b* and *Neisseria meningitidis* serogroup C vaccines (Hib/MenC).

Conjugate vaccine should be given as intramuscular injection, preferably in the deltoid muscle (or in the anterolateral aspect of the upper thigh in children <12 months of age).

Monovalent Men A conjugate vaccine should be given as a single dose to individuals 1–29 years of age. For

monovalent Men C conjugate vaccine, one single intramuscular dose is recommended for children aged ≥ 12 months, teenagers and adults. Children 2–11 months of age require 2 dose administration at an interval of at least 2 months and a booster about 1 year thereafter. Quadrivalent vaccines are administered as a single dose to individuals aged ≥ 2 years.

Meningococcal vaccines should be stored at 2–8°C. Conjugate vaccines are preferred over polysaccharide vaccines due to their potential for herd protection and their increased immunogenicity, particularly in children < 2 years of age. Both vaccines are safe when used during pregnancy *(1)*. WHO recommends that countries with high or medium endemic rates of invasive meningococcal disease and countries with frequent epidemics should introduce appropriate large-scale meningococcal vaccination programmes *(1)*.

ACUTE RESPIRATORY INFECTIONS

Infections of the respiratory tract are perhaps the most common human ailment. While they are a source of discomfort, disability and loss of time for most adults, they are a substantial cause of morbidity and mortality in young children and the elderly. Many of these infections run their natural course in older children and in adults without specific treatment and without complications. However, in young infants, small children and in the elderly, or in persons with impaired respiratory tract reserves, it increases the morbidity and mortality rates.

Acute respiratory infections (ARI) may cause inflammation of the respiratory tract anywhere from nose to alveoli, with a wide range of combination of symptoms and signs. ARI is often classified by clinical syndromes depending on the site of infection and is referred to as ARI of upper (AURI) or lower (ALRI) respiratory tract. The upper respiratory tract infections include common cold, pharyngitis and otitis media. The lower respiratory tract infections include epiglottitis, laryngitis, laryngotracheitis, bronchitis, bronchiolitis and pneumonia.

The clinical features include running nose, cough, sore throat, difficult breathing and ear problem. Fever is also common in acute respiratory infections. Most children with these infections have only mild infection, such as cold or cough. However, some children may have pneumonia which is a major cause of death. In less developed countries, measles and whooping cough are important causes of severe respiratory tract infection.

Problem statement

Every year ARI in young children is responsible for an estimated 3.9 million deaths worldwide. About 90 per cent of the ARI deaths are due to pneumonia which is usually bacterial in origin. The incidence of ARI is similar in developed and developing countries. However, while the incidence of pneumonia in developed countries may be as low as 3–4 per cent, its incidence in developing countries range between 20 to 30 per cent. This difference is due to high prevalence of malnutrition, low birth weight and indoor air pollution in developing countries *(1)*.

ARI is an important cause of morbidity in the children. On an average, children below 5 years of age suffer about 5 episodes of ARI per child per year, thus accounting for about 238 million attacks. Consequently, although most of the attacks are mild and self limiting episodes, ARI is responsible for about 30–50 per cent of visits to health facilities and for about 20–40 per cent of admissions to hospitals *(1)*. It is also a leading cause of disabilities including deafness as a sequelae of otitis media *(2)*.

Pneumonia kills more children than any other disease (more than AIDS, malaria and measles combined). More than 1.1 million under 5 years of age children die from pneumonia each year, accounting for almost 17 per cent under-five deaths worldwide. Yet, little attention is paid to this disease *(3)*. *Streptococcus pneumoniae* is a major cause of illness and death in children, as well as in adults. According to a WHO estimate, about 1.6 million cases of fatal pneumococcal disease occur worldwide, mostly in infants and elderly. In addition, immunocompromised individuals of all ages are at increased risk *(4)*. Disease rates and mortality are higher in developing than industrialized countries, with majority of deaths occurring in Sub-Saharan Africa and South Asia. Children who are poor, undernourished in remote areas are more likely to suffer from pneumonia. Moreover, only 34 per cent of children with suspected pneumonia received antibiotics during 2012 *(4)*. Likewise, *haemophilus influenzae* type B (Hib) bacteria is estimated to cause 3 million cases of severe pneumonia and meningitis, and approximately 386,000 deaths per year in children under 5 years of age *(5)*.

The key pneumonia indicators developed for prevention and treatment of pneumonia are as shown in Table 1. It also shows the data pertaining to pneumonia from South-East Asia countries for the year 2008–2012.

In India, in the states and districts with high infant and child mortality rates, ARI is one of the major causes of death. ARI is also one of the major reasons for which children are brought to the hospitals and health facilities. Hospital records from states with high infant mortality rates show that upto 13% of inpatient deaths in paediatric wards are due to ARI. The proportion of death due to ARI in the community is much higher as many children die at home. The reason for high case fatality may be that children are either not brought to the hospitals or brought too late.

In India, during the year 2013, about 31.7 million cases of ARI were reported. During 2013 about 3,278 people died of ARI and 2,597 died of pneumonia. Pneumonia was responsible for about 18 per cent of all 'under 5 year' deaths in India *(8)*.

Epidemiological determinants

Agent factors

The microbial agents that cause acute respiratory infections are numerous and include bacterias and viruses. Even within species they can show a wide diversity of antigenic type. The agents are those most frequently encountered in a normal population. The bacteria involved can all be isolated with varying frequency from carriers, and cause illness in only minority of infected persons. The viruses that have been found in association with acute

TABLE 1

Key pneumonia indicators : mortality, prevention and treatment in South-East Asia countries (2008–2012)

Countries	Pneumonia deaths	Prevention					Treatment
	% of under 5 deaths due to pneumonia (2012)	% of children who are under weight, 0–59 months		% of infants who are exclusively breast-fed (< 6 months) (2008–2012)	% of one year old immunized against		% of under 5 with pneumonia taken to appropriate health care provider (2008–2012)
		Moderate to severe (2008–2012)	Severe (2008–2012)		Measles 2012	Hib 2012

respiratory disease are numerous. They are the primary cause of the great majority of respiratory illnesses. However, the severity of the illness is often determined by whether or not secondary bacterial infection occurs, particularly in the case of lower respiratory tract infections. The agents considered to be capable of acute respiratory diseases, the age group most frequently affected, and the characteristic clinical features are as shown in Table 2.

TABLE 2

The agents causing ARI, age group affected and clinical features

Agent	Age group (s) most frequently affected	Characteristic clinical features
Bacteria		
Bordetella pertussis	Infants and young children	Paroxysmal cough
Corynebacterium diphtheriae	Children	Nasal/tonsillar/pharyngeal membranous exudate ± severe toxaemia
Haemophilus influenzae	Adults	Acute exacerbations of chronic bronchitis pneumonia
	Children	Acute epiglottitis (*H.influenzae* type B)
Klebsiella pneumoniae	Adults	Lobar pneumonia ± lung abscess
Legionella pneumophila	Adults	Pneumonia
Staphylococcus pyogenes	All ages	Lobar and broncho-pneumonia (esp. secondary to influenza) ± lung abscess
Streptococcus pneumoniae	All ages	Pneumonia (lobar or multilobular) Acute exacerbations of chronic bronchitis
Streptococcus pyogenes	All ages	Acute pharyngitis and tonsillitis
Virus		
Adenoviruses – endemic types (1,2,5)	Young children	Lower respiratory
– epidemic types (3,4,7)	Older children and young adults	Febrile pharyngitis and influenza-like illness
Enteroviruses (ECHO and Coxsackie)	All ages	Variable respiratory
Influenza A	All ages	Fever, aching, malaise, variable respiratory
B	School children	Occasional primary pneumonia
		Secondary bacterial pneumonia in elderly
C	Rare	Mild upper respiratory
Measles	Young children	Variable respiratory with characteristic rash
Parainfluenza 1	Young children	Croup re-infection in later life : mild upper respiratory
2		
3	Infants	Bronchiolitis and pneumonia
Respiratory syncytial virus	Infants and young children	Severe bronchiolitis and pneumonia
Rhinoviruses (multiple serotypes)	All ages	Common cold
Coronavirus		
Other agents		
Chlamydia type B (Psittacosis)	Adults exposed to infected birds	Influenza-like illness and atypical pneumonia
Coxiella burnetti (Q fever)	Adults exposed to sheep and cattle	Atypical pneumonia
Mycoplasma pneumoniae	School children and young adults	Febrile bronchitis and atypical pneumonia

Source : *(9)*

Host factors

Small children can succumb to the disease within a matter of days. Case fatality rates are higher in young infants and malnourished children. Age-specific mortality rates show wide differences between countries. In general, rates tend to be high in infants and young children, and in the elderly in all countries, although the age group with the highest rates can differ. In developing countries where malnutrition and low birth weight is often a major problem, the rates in children tend to be the highest. By contrast, in developed countries respiratory infections are only exceptionally fatal in infants but are commonly terminal in the elderly.

Upper respiratory tract infections, e.g., common cold and pharyngitis are several times higher in children than in adults. Rates for pharyngitis and otitis media increase from infancy to a peak at the age of 5 years. Illness rates are highest in young children and decrease with the increasing age, except in the third decade of life when young adults are exposed to infection by their own young children. Adult women experience more illness than men. The greater exposure of women to small children may be responsible for this. Under 3 years of age boys are affected more often and more severely.

Risk factors

Many risk factors for respiratory tract infections have been identified. They include not only the climatic conditions but also the housing, level of industrialization and socio-economic development. In developing countries, overcrowded dwellings, poor nutrition, low birth weight and intense indoor smoke pollution underline the high rates. Local mortality rates are particularly affected by the extent of influenza epidemics. Studies in developed countries have shown that higher rate of infection is common in younger sibling of school going children who introduce infection into the household. Maternal cigarette smoking has also been linked to increased occurrence of respiratory tract infections during the first year of life. Children from low socio-economic status tend to have more respiratory infections. The infection is more common in preschool children attending day-care centres. The infections tend to be more common in urban communities than in rural communities.

Mode of transmission

All the causative organisms are normally transmitted by the airborne route. As most viruses do not survive for long outside the respiratory tract, the chain of transmission is maintained by direct person–to–person contact.

CONTROL OF ACUTE RESPIRATORY INFECTIONS

Improving the primary medical care services and developing better methods for early detection, treatment and where possible, prevention of acute respiratory infections is the best strategy to control ARI. Effective reduction of mortality due to pneumonia is possible if children suffering from pneumonia are treated correctly. Education of mother is also crucial since compliance with treatment and seeking care promptly when signs of pneumonia are observed, are among the key factors which determine the outcome of the disease. The recommendations by WHO for the management of acute respiratory infections in children and the practical guidelines for out-patient care are discussed below *(10)*. The same guidelines are followed in India *(11)*.

Clinical assessment

History taking and clinical assessment is very important in the management of the acute respiratory infections. Note the age of the child, for how long the child is coughing, whether the child is able to drink (if the child is aged 2 months upto 5 years), has the young infant stopped feeding well (child less than 2 months), has there been any antecedent illness such as measles, does the child have fever, is the child excessively drowsy or difficult to wake (if yes, for how long), did the child have convulsions, is there irregular breathing, short periods of not breathing or the child turning blue, any history of treatment during the illness.

Physical examination

Look and listen for the following :

(1) COUNT THE BREATHS IN ONE MINUTE : As the children get older, their breathing rate slows down. Therefore, the cut-off point used to determine if a child has fast breathing will depend on the age of the child. Count the respiratory rate for full one minute using the second's hand of the watch looking at the abdominal movement or lower chest when the child is calm. The chest and abdomen must be exposed for counting. Increased respiratory rate is of significance only if it persists.

Fast breathing is present when the respiratory rate is :

- 60 breaths per minute or more in a child less than 2 months of age
- 50 breaths per minute or more in a child aged 2 months upto 12 months
- 40 breaths per minute or more in a child aged 12 months upto 5 years.

However, repeat the count for a young infant (age less than 2 months) if the count is 60 breaths per minute or more. This is important because the breathing rate of young infant is often erratic. Occasionally young infants stop breathing for a few seconds, and then breath very rapidly for a short period.

(2) LOOK FOR CHEST INDRAWING : Look for chest indrawing when the child breaths IN. The child has indrawing *if the lower chest wall goes in when the child breaths in.* Chest indrawing occurs when the effort required to breath in, is much greater than normal.

(3) LOOK AND LISTEN FOR STRIDOR : A child with stridor makes a harsh noise when breathing IN. Stridor occurs when there is narrowing of the larynx, trachea or epiglottis which interferes with air entering the lungs. These conditions are often called *croup.*

(4) LOOK FOR WHEEZE : A child with wheezing makes a soft whistling noise or shows signs that breathing *OUT* is difficult, wheezing is caused by narrowing of the air passage in the lungs. The breathing–out phase takes longer than normal and requires effort.

If the child is wheezing, ask the mother if her child has had a previous episode of wheezing within the past year. If so, the child should be classified as having recurrent wheeze.

(5) See if the child is abnormally sleepy or difficult to wake. An abnormally sleepy child is drowsy most of the time when he or she should be awake and alert.

(6) Feel for fever or low body temperature.

(7) CHECK FOR SEVERE MALNUTRITION : Malnutrition when present is a high risk factor and case fatality rates are

higher in such children. In severely malnourished children with pneumonia, fast breathing and chest indrawing may not be as evident as in other children. A severely malnourished child may have an impaired or absent response to hypoxia and a weak or absent cough reflex. These children need careful evaluation for pneumonia as well as careful management.

(8) Cyanosis is a sign of hypoxia. Cyanosis must be checked in good light.

CLASSIFICATION OF ILLNESS

A. Child aged 2 months upto 5 years

Classifying the illness means making decisions about the type and severity of disease. The sick child should be put into one of the four classifications :

I. Very severe disease
II. Severe pneumonia
III. Pneumonia (not severe)
IV. No pneumonia : cough or cold

Each disease classification has a corresponding treatment plan which should be followed. The following guidelines are used to manage a child who is 2 months upto 5 years of age.

I. Very severe disease

The danger signs and possible causes are :

a. Not able to drink : A child who is not able to drink could have severe pneumonia or bronchiolitis, septicaemia, throat abscess, meningitis or cerebral malaria.
b. Convulsions, abnormally sleepy or difficult to wake : A child with these signs may have severe pneumonia resulting in hypoxia, sepsis, cerebral malaria or meningitis. Meningitis can develop as a complication of pneumonia or it can occur on its own.
c. Stridor in calm child : If a child has stridor when calm, the child may be in danger of life-threatening obstruction of the air-way from swelling of larynx, trachea or epiglottis.
d. Severe malnutrition : A severely malnourished child is at high risk of developing and dying from pneumonia. In addition, the child may not show typical signs of the illness.

A child who is classified as having severe disease is very ill and should be referred urgently to a hospital. Management of a child having very severe disease is summarized in Table 3.

TABLE 3
Management of very severe disease

SIGNS	Not able to drink, Convulsions Abnormally sleepy or difficult to wake Stridor in calm child, or Severe malnutrition
CLASSIFY AS	VERY SEVERE DISEASE
TREATMENT	Refer URGENTLY to hospital Give first dose of an antibiotic Treat fever, if present Treat wheezing, if present If cerebral malaria is possible, give an antimalarial

Source : *(10)*

II. Severe pneumonia

The most important signs to consider when deciding if the child has pneumonia are the child's respiratory rate, and whether or not there is chest indrawing. A child with chest indrawing may not have fast breathing if the child becomes exhausted, and if the effort needed to expand the lungs is too great. Then the breathing slows down. In such cases, chest indrawing may be the *only* sign in a child with severe pneumonia. A child with chest indrawing is at higher risk of death from pneumonia than a child with fast breathing alone. A child classified as having severe pneumonia also has other signs such as :

- nasal flaring, when the nose widens as the child breaths in;
- grunting, the short sounds made with the voice when the child has difficulty in breathing; and
- cyanosis, a dark bluish or purplish coloration of the skin caused by hypoxia.

Some children with chest indrawing also have wheezing. Children who have chest indrawing and a first episode of wheezing often have severe pneumonia. However, children with chest indrawing and recurrent wheezing most often do not have severe pneumonia. Chest indrawing in these children is caused by the asthmatic condition. Therefore, they must be assessed before deciding the line of treatment.

Management of the child classified as having severe pneumonia is summarized in Table 4.

III. Pneumonia (not severe)

A child who has fast breathing and no chest indrawing is classified as having pneumonia (not severe). Most children are classified in this category if they are brought early for treatment. Management of the child with pneumonia (not severe) is summarized in the Table 4.

IV. No pneumonia : cough or cold

Most children with a cough or difficult breathing do not have any danger signs or signs of pneumonia (chest indrawing or fast breathing). These children have a simple cough or cold. They are classified as having "no pneumonia : cough or cold". They do not need any antibiotic. Majority of such cases are viral infections where antibiotics are not effective. Normally a child with cold will get better within 1–2 weeks. However, a child with chronic cough (lasting more than 30 days) may have tuberculosis, asthma, whooping cough or some other problem. Refer the child with chronic cough for further investigations. Management of a child classified as no pneumonia : cough or cold is summarized in Table 4.

B. Classifying illness of young infant

Infants less than 2 months of age are referred to as young infants. Young infants have special characteristics that must be considered when their illness is classified. They can become sick and die very quickly from bacterial infections, are much less likely to cough with pneumonia, and frequently have only non-specific signs such as poor feeding, fever or low body temperature. Further, mild chest indrawing is normal in young infants because their chest wall bones are soft. The presence of these characteristics means that they will be classified and treated differently from older children. Many of the cases may have added risk factor of low birth weight. Such children are very susceptible to temperature changes and even in tropical climates, death due to cold stress or hypothermia are common. In young infants the cut-off point for fast breathing is 60 breaths per

TABLE 4

Management of pneumonia in a child aged 2 months upto 5 years

SIGNS	Chest indrawing (if also recurrent wheezing, go directly to treat wheezing)	No chest indrawing and fast breathing (50 per minute or more if child 2 months upto 12 months; 40 per minute or more if child 12 months upto 5 years).	No chest indrawing and No fast breathing (Less than 50 per minute if child 2 months up to 12 months; Less than 40 per minute if child is 12 months up to 5 years).
CLASSIFY AS	SEVERE PNEUMONIA	PNEUMONIA	NO PNEUMONIA: COUGH OR COLD
TREATMENT	Refer URGENTLY to hospital Give first dose of an antibiotic Treat fever, if present, Treat wheezing, if present (if referral is not feasible, treat with an antibiotic and follow closely)	Advise mother to give home care. Give an antibiotic. Treat fever, if present. Treat wheezing, if present. Advise mother to return with child in 2 days for reassessment, or earlier if the child is getting worse.	If coughing more than 30 days, refer for assessment. Assess and treat ear problem or sore throat, if present. Assess and treat other problems. Advise mother to give home care. Treat fever, if present. Treat wheezing, if present.

	Re-assess in 2 days a child who is taking an antibiotic for pneumonia		
SIGNS	WORSE Not able to drink Has chest indrawing Has other danger signs	THE SAME	IMPROVING Breathing slower Less fever Eating better
TREATMENT	Refer URGENTLY to hospital	Change antibiotic or Refer	Finish 5 days of antibiotic.

Source : *(10)*

minute. Any pneumonia in young infant is considered to be severe. They should be referred immediately to a hospital. Table 5 is used to classify the illness of a young infant.

TABLE 5

Classification and management of illness in young infants

SIGNS	Stopped feeding well, Convulsions, Abnormally sleepy or difficult to wake, Stridor in calm child, Wheezing, or Fever or low body temperature	
CLASSIFY AS	VERY SEVERE DISEASE	
TREATMENT	Refer URGENTLY to hospital Keep young infant warm Give first dose of an antibiotic	
SIGNS	Severe chest indrawing, or Fast breathing (60 per minute or more)	No severe chest indrawing and No fast breathing (less than 60 per minute)
CLASSIFY AS	SEVERE PNEUMONIA	NO PNEUMONIA : COUGH OR COLD
TREATMENT	Refer URGENTLY to hospital. Keep young infant warm. Give first dose of an antibiotic(If referral is not feasible,treat with an antibiotic and follow closely).	Advise mother to give the following home care : – Keep young infant warm. – Breast-feed frequently. – Clear nose if it interferes with feeding. Return quickly if :- Breathing becomes difficult, Breathing becomes fast, Feeding becomes a problem The young infant becomes sicker.

Source: *(10)*

Some of the danger signs of very severe disease are :

(a) Convulsions, abnormally sleepy or difficult to wake : A young infant with these signs may have hypoxia from pneumonia, sepsis or meningitis. Malaria infection is unusual in children of this age, so antimalarial treatment is not advised.

(b) Stridor when calm : Infections causing stridor (e.g. diphtheria, bacterial tracheitis, measles or epiglottitis) are rare in young infants. A young infant who has stridor when calm should be classified as having very severe disease.

(c) Stopped feeding well : A young infant who stops feeding well (i.e., takes less than half of the usual amount of milk) may have a serious infection and should be classified as having very severe disease.

(d) Wheezing : Wheezing is uncommon in young infants and is often associated with hypoxia.

(e) Fever or low body temperature : Fever (38°C or more) is uncommon in young infants and more often means a serious bacterial infection. In addition, fever may be the only sign of a serious bacterial infection. In young infants an infection may sometimes cause the body temperature to drop (hypothermia).

A young infant who is classified as having very severe disease should be referred urgently to a hospital for treatment. The management is summarized in Table 5.

TREATMENT

(A) TREATMENT FOR CHILDREN AGED 2 MONTHS UPTO 5 YEARS

The standard treatment for childhood acute respiratory infections in India is as follows *(10)* :

PNEUMONIA (CHILD WITH COUGH AND FAST BREATHING)

Cotrimoxazole is the drug of choice for the treatment of pneumonia. Studies carried out in India have confirmed the efficacy of cotrimoxazole to be similar to ampicillin and procaine penicillin and cure rates of upto 95% have been recorded. Cotrimoxazole is less expensive with few side effects and can be used safely by health workers at the peripheral health facilities and at home by the mothers. Recommended dose schedule is as shown in Table 6.

TABLE 6

Treatment of pneumonia
Daily dose schedule of cotrimoxazole

AGE/WEIGHT	Paediatric tablet : Sulphamethoxazole 100 mg and Trimethoprim 20 mg	Paediatric syrup : Each spoon (5 ml) : Sulphamethoxazole 200 mg and Trimethoprim 40 mg
< 2 months (Wt. 3–5 kg)	One tablet twice a day	Half spoon (2.5 ml) twice a day
2–12 months (Wt. 6–9 kg)	Two tablets twice a day	One spoon (5 ml) twice a day
1–5 years (Wt. 10–19 kg)	Three tablets twice a day	One and half spoon (7.5 ml) twice a day.

In children less than two months, cotrimoxazole is not routinely recommended. These children are to be treated as for severe pneumonia. However, in case of delay in referral, cotrimoxazole may be initiated. Cotrimoxazole should not be given to premature babies and cases of neonatal jaundice. Such children when seen by a health worker must be referred to a health facility.

The condition of the child should be assessed after 48 hours. Cotrimoxazole should be continued for another 3 days in children who show improvement in clinical condition. If there is no significant change in condition (neither improvement nor worsening), cotrimoxazole should be continued for another 48 hours and condition reassessed. If at 48 hours or earlier the condition worsens, the child should be hospitalized immediately.

SEVERE PNEUMONIA (CHEST IN-DRAWING)

Children with severe pneumonia should be treated as inpatients with intramuscular injections of benzyl penicillin (after test dose), ampicillin or chloramphenicol. The condition of the child must be monitored every day and reviewed after 48 hours for antibiotic therapy as detailed in Table 7. Antibiotic therapy must be given for a minimum of 5 days and continued for at least 3 days after the child gets well.

VERY SEVERE DISEASE

Children with signs of very severe disease are in imminent danger of death, and should be treated in a health facility, with provision for oxygen therapy and intensive monitoring, as these cases require supportive therapy in addition to specific treatment of pneumonia. Chloramphenicol IM is the drug of choice in all such cases.

Treat for 48 hours – if condition improves switch over to oral chloramphenicol. Chloramphenicol should be given for a total of 10 days. If condition worsens or does not improve after 48 hours, switch to IM injections of cloxacillin and gentamycin.

TABLE 7

Treatment of severe pneumonia (2 months – 5 years)

Antibiotics	Dose*	Interval	Mode
A. First 48 hours Benzyl penicillin	50,000 IU per kg/dose	6 hourly	IM
OR Ampicillin	50 mg/kg/dose	6 hourly	IM
OR Chloramphenicol	25 mg/kg/dose	6 hourly	IM
B. 1. If condition IMPROVES, then for the next 3 days give :			
Procaine penicillin	50,000 IU/kg (maximum 4 lac IU)	Once	IM
OR Ampicillin	50 mg/kg/dose	6 hourly	Oral
OR Chloramphenicol	25 mg/kg/dose	6 hourly	Oral
B. 2. If NO IMPROVEMENT, then for the next 48 hours : CHANGE ANTIBIOTIC			
If ampicillin is used change to chloramphenicol IM; If chloramphenicol is used, change to cloxacillin 25 mg/kg/dose, every 6 hours along with gentamycin 2.5 mg/kg/dose, every eight hours.			
If condition improves continue treatment orally.			
C. Provide symptomatic treatment for fever and wheezing, if required			
D. Monitor fluid and food intake			
E. Advise mother on home management on discharge			
* The doses can be rounded off to nearest administrable doses			

(B) PNEUMONIA IN YOUNG INFANTS UNDER 2 MONTHS OF AGE

The treatment in these conditions is, basically the same. The child must be hospitalized. Treatment with cotrimoxazole may be started by the health worker before referring the child. If pneumonia is suspected the child should be treated with intramuscular injections of benzyl penicillin or injection ampicillin, along with injection gentamycin. Chloramphenicol is not recommended as the first line of treatment in young infants. The treatment plan is as shown in Table 8.

TABLE 8

Treatment of pneumonia in children aged less than 2 months

ANTIBIOTIC	DOSE	FREQUENCY	
		Age < 7 days	Age 7 days to 2 months
Inj. Benzyl Penicillin	50,000 IU/kg/dose	12 hourly	6 hourly
OR Inj Ampicillin	50 mg/kg/dose	12 hourly	8 hourly
AND Inj. Gentamycin	2.5 mg/kg/dose	12 hourly	8 hourly

Besides antibiotics, therapy for the associated conditions, if any, must be instituted immediately. The child should be kept warm and dry. Breast-feeding must be promoted strongly as the child who is not breast-fed is at a much higher risk of diarrhoea.

MANAGEMENT OF AURI (NO PNEUMONIA)

Many children with presenting symptoms of cough, cold and fever do not have pneumonia (no fast breathing or chest indrawing) and DO NOT require treatment with antibiotics.

Antibiotics are not recommended for coughs and colds because majority of cases are caused by viruses and antibiotics are not effective, they increase resistant strains

and cause side-effects while providing no clinical benefit, and are wasteful expenditure. Symptomatic treatment and care at home is generally enough for such cases. The mothers must be advised on how to take care of the child at home.

Prevention of Acute Respiratory Infections

Present understanding of risk factors of respiratory tract infection in childhood indicates several approaches for primary prevention. In developing countries, improved living conditions, better nutrition and reduction of smoke pollution indoors will reduce the burden of mortality and morbidity associated with ARI. Other preventive measures include better MCH care. Immunization is an important measure to reduce cases of pneumonia which occur as a complication of vaccine preventable disease, especially measles. It is obvious that community support is essential to reduce the disease burden. Families with young children must be helped to recognize pneumonia. Health promotional activities are specially important in vulnerable areas *(11)*.

Immunization

Vaccines hold promise of saving millions of children from dying of pneumonia. Three vaccines have potential of reducing deaths from pneumonia. These vaccines work to reduce the incidence of bacterial pneumonia.

1. MEASLES VACCINE

Pneumonia is a serious complication of measles and the most common cause of death associated with measles worldwide. Thus, reducing the incidence of measles in young children through vaccination would also help to reduce deaths from pneumonia. A safe and effective vaccine against measles is available for past 40 years. Please refer to page 148 for details.

2. HIB VACCINE

Haemophilus influenzae type B (Hib, is an important cause of pneumonia and meningitis among children in developing countries. Hib vaccine has been available for more than a decade. It reduces dramatically the incidence of Hib meningitis and pneumonia in infants and nasopharyngeal colonization by Hib bacteria. It's high cost has posed obstacle to its introduction in developing countries.

The vaccine is often given as a combined preparation with DPT and poliomyelitis vaccine. Three or four doses are given depending on the manufacturers and type of vaccine used, and is given intramuscularly. The vaccine schedule is at 6, 10, and 14 weeks of age or according to national immunization schedule. In many industrialized countries a booster dose is given between 12–18 months which provides additional benefit to limit burden of Hib disease among children *(12)*. For children more than 12 months of age, who have not received their primary immunization series a single dose is sufficient for protection. The vaccine is not generally offered to children aged more than 24 months *(12)*.

No serious side-effects have been recorded, and no contraindications are known, except for hyper-sensitivity to previous dose of vaccine. All conjugate vaccine have an excellent safety record, and where tested, do not interfere substantially with immunogenecity of other vaccines given simultaneously *(13)*.

3. PNEUMOCOCCAL PNEUMONIA VACCINE

a. *PPV23* : For years, the polysaccharide non-conjugate vaccine containing capsular antigens of 23 serotypes against this infection have been available for adults and children over 2 years of age. Children under 2 years of age and immunocompromised individuals do not respond well to the vaccine. It is recommended for selected groups, e.g., those who have undergone splenectomy or have sickle-cell disease, chronic diseases of heart, lung, liver or kidney; diabetes mellitus, alcoholism, generalized malignancies, organ transplants etc. In some industrialized countries like USA it is routinely advised for everyone aged above 65 years *(13)*.

A dose of 0.5 ml of PPV23 contains 25 micrograms of purified capsular polysaccharide from each 23 serotypes. For primary immunization, PPV23 is administered as a single intra-muscular dose preferably in the deltoid muscle or as subcutaneous dose. The vaccine should not be mixed in the same syringe with other vaccines, for e.g. with influenza vaccine, but may be administered at the same time by separate injection in the other arm. Simultaneous administration does not increase adverse events or decrease the antibody response to either vaccine. Protective capsular type-specific antibody levels generally develop by the third week following vaccination *(4)*.

Minor adverse reactions, such as transient redness and pain at the site of injection occur in 30–50 per cent of those who have been vaccinated, more commonly following subcutaneous administration. Local reactions are more frequent in recipients of the 2nd dose of the vaccine *(4)*.

b. *PCV* : Two conjugate vaccines are available since 2009 PCV_{10} and PCV_{13}. The PCV_7 conjugate vaccine is gradually being removed from the market *(14)*. Both PCV_{10} and PCV_{13} are preservative free and their recommended storage temperature is 2–8°C. The vaccine must not be frozen.

For PCV administration to infants, WHO recommends 3 primary doses (the 3p+0 schedule) or, as an alternative, 2 primary doses plus one booster (the 2p+1 schedule). In 3p+0 schedule, vaccination can be initiated as early as 6 weeks of age with an interval betweeen doses of 4–8 weeks, with doses given at 6, 10 and 14 weeks or 2, 4, and 6 months, depending on programme convenience *(14)*.

If 2p+1 schedule is selected, the 2 primary doses are given during infancy as early as 6 weeks of age at an interval preferably of 8 weeks or more for young infant, and 4–8 weeks or more between primary doses for infants ≥7 months of age. One booster dose should be given between 9–15 months of age *(14)*.

Mild reactions like erythema and tenderness to PCV-7 occur in upto 50 per cent of recipients, but systemic reactions are unknown. Revaccination is not recommended for those who had a anaphylactic reaction to initial dose.

HIV positive and preterm babies who have received their 3 primary doses of vaccine before reaching 12 months of age may benefit from a booster dose in the second year of life. Interrupted schedules should be resumed without repeating the previous doses *(14)*.

When primary immunization is initiated with one of these vaccines, it is recommended that remaining doses are administered with the same product. Interchangeability between PCV_{10} and PCV_{13} has yet not been documented. WHO recommends inclusion of PCVs in childhood immunization programme worldwide, particularly in countries with high under-five mortalities *(14)*.

The Integrated Global Action Plan for the Prevention and Control of Pneumonia and Diarrhoea *(15)*

The Integrated Global Action Plan for the Prevention and Control of Pneumonia and Diarrhoea (GAPPD) proposes a cohesive approach to ending preventable pneumonia and diarrhoea deaths. It brings together critical services and interventions to create healthy environments, promotes practices known to protect children from disease, and ensures that every child has access to proven and appropriate preventive and treatment measures.

The specific goals for 2025 are to:

- reduce mortality from pneumonia in children less than 5 years of age to fewer than 3 per 1000 live births;
- reduce mortality from diarrhoea in children less than 5 years of age to fewer than 1 per 1000 live births;
- reduce the incidence of severe pneumonia by 75% in children less than 5 years of age compared to 2010 levels;
- reduce the incidence of severe diarrhoea by 75% in children less than 5 years of age compared to 2010 levels;
- reduce by 40% the global number of children less than 5 years of age who are stunted compared to 2010 levels.

Theses goals are ambitious and will require significant political will and mobilization of additional resources if they are to be reached.

Coverage targets to be maintained or reached have also been set to define efforts needed to attain the above goals. These are:

- By the end of 2025:
  - 90% full-dose coverage of each relevant vaccine (with 80% coverage in every district);
  - 90% access to appropriate pneumonia and diarrhoea case management (with 80% coverage in every district);
  - at least 50% coverage of exclusive breast-feeding during the first 6 months of life;
  - virtual elimination of paediatric HIV.
- By the end of 2030:
  - universal access to basic drinking-water in health care facilities and homes;
  - universal access to adequate sanitation in health care facilities by 2030 and in homes by 2040;
  - universal access to handwashing facilities (water and soap) in health care facilities and homes;
  - universal access to clean and safe energy technologies in health care facilities and homes.

SEVERE ACUTE RESPIRATORY SYNDROME (SARS)

Severe acute respiratory syndrome (SARS) is a communicable viral disease, caused by a new strain of coronavirus, which differs considerably in genetic structure from previously recognized coronavirus.

The most common symptoms in patient progressing to SARS include fever, malaise, chills, headache myalgia, dizziness, cough, sore throat and running nose. In some cases there is rapid deterioration with low oxygen saturation and acute respiratory distress requiring ventilatory support. It is capable of causing death in as many as 10 per cent cases *(1)*.

Chest X-ray findings typically begin with a small, unilateral patchy shadowing, and progress over 1–2 days to become bilateral and generalized, with interstitial/confluent infiltration. Adult respiratory distress syndrome has been observed in a number of patients in the end stages.

Problem statement

The earliest case was traced to a health care worker in China, in late 2002, with rapid spread to Hong Kong, Singapore, Vietnam, Taiwan and Toranto. As of early August 2003, about 8,422 cases were reported to the WHO from 30 countries with 916 fatalities *(2)*.

Incubation period

The incubation period has been estimated to be 2 to 7 days, commonly 3 to 5 days *(1)*.

Mode of transmission

The primary mode of transmission appears to be through direct or indirect contact of mucous membranes of eyes, nose, or mouth with respiratory droplets or fomites. The use of aerosol–generating procedures (endotracheal intubation, bronchoscopy, nebulization treatments) in hospitals may amplify the transmission of the SARS coronavirus. The virus is shed in stools but the role of faecal–oral transmission is unknown. The natural reservoir appears to be the horseshoe bat (which eats and drops fruits ingested by civets, the earlier presumed reservoir and a likely amplifying host).

The SARS virus can survive for hours on common surfaces outside the human body, and up to four days in human waste. The virus can survive at least for 24 hours on a plastic surface at room temperature, and can live for extended periods in the cold.

Case definition *(4)*

The case definition is based on current understanding of

the clinical features of SARS, and available epidemiological data. It may be revised as new information accumulates.

Case definition for notification of SARS under the International Health Regulation (2005)

In the period following an outbreak of SARS, a notifiable case of SARS is defined as an individual with laboratory confirmation of infection with SARS coronavirus (SARS-CoV) who either fulfils the clinical case definition of SARS or has worked in a laboratory handling live SARS-CoV or storing clinical specimens infected with SARS-CoV.

Clinical case definition of SARS

1. A history of fever, or documented fever
   AND
2. One or more symptoms of lower respiratory tract illness (cough, difficulty in breathing, shortness of breath)
   AND
3. Radiographic evidence of lung infiltrates consistent with pneumonia or acute respiratory distress syndrome (ARDS) or autopsy findings consistent with the pathology of pneumonia or ARDS without an identifiable cause
   AND
4. No alternative diagnosis fully explaining the illness.

Diagnostic tests required for laboratory confirmation of SARS

(a) Conventional reverse transcriptase PCR (RT-PCR) and real-time reverse transcriptase PCR (real-time RT-PCR) assay detecting viral RNA present in:
   1. At least 2 different clinical specimens (e.g. nasopharyngeal and stool specimens)
      OR
   2. The same clinical specimen collected on 2 or more occasions during the course of the illness (e.g. sequential nasopharyngeal aspirates)
      OR
   3. A new extract from the original clinical sample tested positive by 2 different assays or repeat RT-PCR or real-time RT-PCR on each occasion of testing
      OR
   4. Virus culture from any clinical specimen.

(b) Enzyme-linked immunosorbent assay (ELISA) and immunofluorescent assay (IFA)
   1. Negative antibody test on serum collected during the acute phase of illness, followed by positive antibody test on convalescent-phase serum, tested simultaneously
      OR
   2. A 4-fold or greater rise in antibody titre against SARS-CoV between an acute-phase serum specimen and a convalescent-phase serum specimen (paired sera), tested simultaneously.

In the absence of known SARS-CoV transmission to humans, the positive predictive value of a SARS-CoV diagnostic test is extremely low; therefore, the diagnosis should be independently verified in one or more WHO international SARS reference and verification network laboratories. Every single case of SARS must be reported to WHO.

Epidemiological aspect

Health care workers, especially those involved in procedures generating aerosols, accounted for 21 per cent of all cases. Maximum virus excretion from the respiratory tract occurs on about day 10 of illness and then declines. The efficiency of transmission appears to be greatest following exposure to severely ill patients or those experiencing rapid clinical deterioration, usually during the second week of illness. When symptomatic cases were isolated within 5 days of the onset of illness, few cases of secondary transmission occurred. There was no evidence that patient transmits infection 10 days after fever has resolved.

Children are rarely affected by SARS. To date, there have been two reported cases of transmission from children to adults and no report of transmission from child to child. Three separate epidemiological investigations have not found any evidence of SARS transmission in schools. Furthermore, no evidence of SARS has been found in infants of mothers who were infected during pregnancy.

International flights have been associated with the transmission of SARS from symptomatic probable cases to passengers or crew. WHO recommends exit screening and other measures to reduce opportunities for further international spread associated with air travel during the epidemic period.

Complications

As with any viral pneumonia, pulmonary decompensation is the most feared problem. ARDS occurs in about 16% patients, and about 20–30% of patients require intubation and mechanical ventilation. Sequelae of intensive care include infection with nosocomial pathogens, tension pneumothorax from ventilation at high peak pressures, and non-cardiogenic pulmonary edema.

Treatment

Severe cases require intensive support. Although a number of different agents including ribavirin (400–600 mg/d and 4 g/d), lopinavir/ritonavir (400 mg/100 mg), interferon type 1, intravenous immunoglobulin, and systemic cortiocosteroids were used to treat SARS patients during the 2003 epidemic, the treatment efficacy of these therapeutic agents remains inconclusive and further research is needed. Subsequent studies with ribavirin show no activity against the virus in vitro, and a retrospective analysis of the epidemic in Toronto suggests worse outcomes in patients who receive the drug *(5)*.

Prognosis

The overall mortality rate of identified cases is about 14%. Mortality is age-related, ranging from less than 1% in persons under 24 years of age to greater than 50% in persons over 65 years of age. Poor prognostic factors include advanced age, chronic hepatitis B infection treated with lamivudine, high initial or high peak lactate dehydrogenase concentration, high neutrophil count on presentation, diabetes mellitus, acute kidney disease, and low counts of CD4 and CD8 on presentation. Many subclinical cases probably go undiagnosed. Seasonality, as with influenza, is not established *(5)*.

Prevention

As there is no vaccine against SARS, the preventive measures for SARS control are appropriate detection and protective measures which include :

1. Prompt identification of persons with SARS, their movements and contacts;
2. Effective isolation of SARS patients in hospitals;
3. Appropriate protection of medical staff treating these patients;
4. Comprehensive identification and isolation of suspected SARS cases;
5. Simple hygienic measures such as hand-washing after touching patients, use of appropriate and well-fitted masks, and introduction of infection control measures;
6. Exit screening of international travellers;
7. Timely and accurate reporting and sharing of information with other authorities and/or governments.

TUBERCULOSIS

Tuberculosis is a specific infectious disease caused by *M. tuberculosis.* The disease primarily affects lungs and causes pulmonary tuberculosis. It can also affect intestine, meninges, bones and joints, lymph glands, skin and other tissues of the body. The disease is usually chronic with varying clinical manifestations. The disease also affects animals like cattle; this is known as "bovine tuberculosis", which may sometimes be communicated to man. Pulmonary tuberculosis, the most important form of tuberculosis which affects man, will be considered here.

Problem statement

WORLD

Tuberculosis remains a worldwide public health problem despite the fact that the causative organism was discovered more than 100 years ago and highly effective drugs and vaccine are available making tuberculosis a preventable and curable disease. Technologically advanced countries have achieved spectacular results in the control of tuberculosis. This decline started long before the advent of BCG or chemotherapy and has been attributed to changes in the "non-specific" determinants of the disease such as improvements in the standard of living and the quality of life of the people coupled with the application of available technical knowledge and health resources.

It is estimated that about one-third of the current global population is infected asymptomatically with tuberculosis, of whom 5–10 per cent will develop clinical disease during their lifetime. Most new cases and deaths occur in developing countries where infection is often acquired in childhood. The annual risk of tuberculosis infection in high burden countries is estimated to be 0.5–2 per cent *(1).* Patients with infectious pulmonary tuberculosis disease can infect 10–15 persons in a year.

Tuberculosis remains a major global health problem. The current global picture of TB shows continued progress but not fast enough. During the year 2013, an estimated 9 million people developed TB, which is equivalent to 126 cases per 100,000 population. Most of the cases occurred in Asia (56 per cent) and the African regions (29 per cent). Of these incident cases 1.1 million (13 per cent) were HIV positives, and 3.5 per cent of the new and 20.5 per cent of previously treated cases were of MDR-TB. It is estimated that about 1.5 million people died of TB, of these 360,000 were HIV positive and 210,000 MDR-TB cases.

About 60 per cent of TB cases and deaths occur among men, but burden of disease (3.3 million) among women is high. In 2013, an estimated 510,000 women died as a result of TB, more than one-third of whom were HIV positive. An estimated 550,000 (6 per cent of total cases) children under 15 years of age had TB of whom 80,000 died.

TB detection and treatment outcome : During 2013, of the estimated 9 million cases, only 6.1 million cases were reported to WHO. Of these 5.7 million were people newly diagnosed and 0.4 million were already on treatment. The notification rate was about 64 per cent. About 3 million missed cases were either not diagnosed or diagnosed but not reported.

In 2013, the treatment success rate continued to be high at 86 per cent among all new TB cases.

The South East Asia Region accounts for 39 per cent of the global burden of TB in terms of incidence and India alone accounts for 24 per cent of the world's TB cases. It is estimated that about 3.4 million new cases of TB continue to occur each year in this Region, most of them in India, Bangladesh, Indonesia, Myanmar and Thailand. 6.2 per cent of the cases with HIV known status (39 per cent of total SEAR cases) were HIV-positive. 89 per cent of HIV-positive TB cases were on co-trimoxazole preventive therapy and 61 per cent of these cases were put on antiretroviral therapy. Level of MDR-TB is still low in the Region (less than 2.2 per cent), however, this translates into nearly 90,000 estimated MDR-TB cases among all the notified TB cases in 2012 *(3).* Each year, more than 2 million TB cases are registered for treatment with more than 85 per cent success rate of new sputum smear positive cases. TB mortality rate has decreased more than 40 per cent since 1990 *(3).*

The actual burden of paediatric TB is not known due to diagnostic difficulties. It is assumed that about 10 per cent of total TB load is found in children. Globally, about 1 million cases of paediatric TB are estimated to occur every year, with more than 100,000 deaths *(4).* Childhood deaths from TB are usually caused by meningitis or disseminated disease *(1).* Though MDR-TB and XDR-TB is documented among paediatric age groups, there are no estimates of overall burden because of diagnostic difficulties and exclusion of children in most of the drug resistant surveys *(4).*

In many developing countries, acquired drug resistance remains high, because national tuberculosis control programmes in these countries have not been able to achieve a high cure rate over a very long period of time, even after the introduction of short–course chemotherapy. Poverty, economic recession, malnutrition, overcrowding, indoor air pollution, tobacco, alcohol abuse and diabetes make populations more vulnerable to tuberculosis. Increase in human migration has rapidly mixed infected with uninfected communities. To make global situation worse, tuberculosis has formed a lethal combination with HIV.

DOTS remains central to the public health approach to tuberculosis control, which is now presented as *Stop TB Strategy.* To be classified as DOTS, a country must have officially accepted and adopted the strategy by 2004, and must have implemented the four technical components of DOTS in at least part of the country. DOTS coverage is defined as the percentage of the national population living

in areas where health services have adopted DOTS. "Areas" are the lowest administrative or management units in the country (township, district, counties, etc.). The target of DOTS programme is successful treatment or cure rate of 85 per cent of new smear positive cases, and detection of 70 per cent of such cases.

The advantages of DOTS are : (a) Accuracy of TB diagnosis is more than doubled; (b) Treatment success rate is upto 95 per cent; (c) Prevents the spread of the tuberculosis infection, thus reducing the incidence and prevalence of tuberculosis; (d) Improves quality of health care and removes stigma associated with TB; (e) Prevents failure of treatment and the emergence of MDR-TB by ensuring patient adherence and uninterrupted drug supply; (f) Helps alleviate poverty by saving lives, reducing duration of illness and preventing spread of infection; (g) Lends credibility to TB control efforts.

The WHO has set *International Standards for Tuberculosis Care*. These standards are intended to facilitate the effective engagement of all care-providers in delivering high-quality care for patients of all ages, including those with smear-positive, smear-negative, extrapulmonary tuberculosis, drug-resistant tuberculosis, and tuberculosis combined with HIV infection. The basic principles of care for people with, or suspected of having tuberculosis are the same worldwide. The standards are intended to be complementary to local and national tuberculosis control policies that are consistent with WHO recommendations. They are not intended to replace local guidelines. There are 6 standards for diagnosis, 9 standards for treatment and 2 standards for public health responsibilities. Please refer to WHO publication : Weekly Epidemiological Record, No. 5, dated 3rd Feb. 2006 for further details.

The WHO has launched global plan for *Stop TB Strategy* (2006–2015), with the objective of reducing incidence of tuberculosis. Please refer to page 200 for further details.

INDIA

India is the highest TB burden country in the world in terms of absolute number of incident cases that occur each year. It accounts for one-fourth of the estimated global incident TB cases in 2013.

As per WHO estimations, tuberculosis prevalence per lac population has reduced from 465 in year 1990 to 211 in 2013. In absolute numbers, prevalence has reduced from 40 lacs to 26 lacs annually. Incidence per lac population has reduced from 216 in year 1990 to 171 in 2013. Tuberculosis mortality has reduced from 38 per lac population in 1990 to 19 in 2013. In absolute numbers, mortality due to TB has reduced from 3.3 lacs to 2.4 lacs annually. Among the new TB cases, 5 per cent of patients were in paediatric age-group (0–14 years). HIV among estimated incident cases of TB was about 5 per cent. MDR-TB among notified new pulmonory TB patients was about 2.2 per cent, and among retreatment cases was about 15 per cent *(4)*.

The first nation-wide standardized tuberculin survey was carried out during the period 2000–2003. For the purpose of survey, country was stratified into 4 zones (north, west, south and east). An identical methodology of sampling was used across all zones to estimate ARTI (annual risk of TB infection), allowing for stratified analysis for children with and without BCG scar. The survey showed the national ARTI was about 1.5 per cent. The second survey (2009–2010) shows that the national ARTI is 1.1 per cent, but the sample size of survey 2 was substantially smaller *(5)*. The first survey showed that BCG scar did not influence ARTI interpretation *(5)*.

Table 1 shows the burden of tuberculosis in India (the estimated and reported rates etc.). The Indian scenario about DOTS programme has been discussed in detail in chapter 7.

TABLE 1

Burden of tuberculosis in India (2013)
(Population 1,252 million)

	Number (thousands)	Rate (per 100,000 population)
Estimates of TB burden 2013		
Mortality (excludes HIV+TB)	240 (150–350)	19 (12–28)
Mortality (HIV+TB only)	38 (31–44)	3 (2.5–3.5)
Prevalence (includes HIV+TB)	2,600 (1,800–3,700)	211 (143–294)
Incidence (includes HIV+TB)	2,100 (2,000–2,300)	171 (162–184)
Incidence (HIV+TB only)	120 (100–140)	9.7 (8.3–11)
Case detection, all forms (%)	58 (54–61)	
Estimates of MDR-TB burden 2013		
	New	Retreatment
% of TB cases with MDR-TB	2.2 (1.9–2.6)	15 (11–19)
MDR-TB cases among notified pulmonary TB cases	20,000 (17,000–24,000)	41,000 (30,000–52,000)
TB case notifications 2013		
	New	Relapse
Pulmonary, bacteriologically confirmed	621,762	102,660
Pulmonary, clinically diagnosed	292,926	
Extrapulmonary	226,557	
Total new and relapse	1,243,905	
Previously treated, excluding relapses	171,712	
Total cases notified	1,415,617	
Among 1,243,905 new and relapse cases: 64,726 (5%) cases aged under 15 years.		
Reported cases of RR-/MDR-TB 2013		
		Total
Cases tested for RR-/MDR-TB		248,341
Laboratory-confirmed RR-/MDR-TB cases		35,385
Patients started on MDR-TB treatment		20,763
TB/HIV 2013		
	Number	(%)
TB patients with known HIV status	887,903	(63)
HIV-positive TB patients	44,027	(5)
HIV-positive TB patients on co-trimoxazole preventive therapy (CPT)	41,827	(95)
HIV-positive TB patients on antiretroviral therapy (ART)	38,754	(88)
HIV-positive people screened for TB	1,063,644	
Treatment success rate (%)		
New and relapse cases registered in 2012		88
Previously treated cases, excluding relapse, registered in 2012		74
HIV-positive TB cases, all types, registered in 2012		77
RR-/MDR-TB cases started on second-line treatment in 2011		50

Source : *(1)*

AGE DISTRIBUTION : In India tuberculosis is more prevalent in adults than in children. It affects adults in the most productive age group (15–54 years). More than 80 per cent of TB cases are in this age group, as shown in Table 2.

TABLE 2
Percentage of new smear positive cases in different age groups (2006)

Age group (Years)	No. of cases	Percentage
0–14	11,872	2.0
15–24	1,24,206	20.9
25–34	1,33,389	22.50
35–44	1,20,481	20.32
45–54	96,727	16.32
55–64	66,617	11.24
65 +	39,341	6.63

Source : *(6)*

THE ECONOMIC AND SOCIAL BURDEN OF DISEASE : Besides the disease burden, TB also causes an enormous socio-economic burden to India. TB primarily affects people in their most productive years of life. While two-thirds of the cases are male, TB takes disproportionately larger toll among young females, with more than 50 per cent of female cases occurring before the age of 34 years *(7)*.

Tuberculosis kills more women in reproductive age group than all causes of maternal mortality combined, and it may create more orphans than any other infectious disease. Nearly one-third of female infertility in India, is caused by tuberculosis. The indirect impact of tuberculosis on children is considerable, as nearly 3 lacs children of tuberculosis patients, either leave the school or take up employment to help support their families *(6)*. A patient of tuberculosis takes an average of three to four months to recuperate, losing that much income. The loss is disastrous for those struggling against poverty. They are most likely to be defaulters of treatment. The vast majority (more than 90 per cent) of the economic burden of TB in India is caused by the loss of life rather than morbidity.

In India, tuberculosis is mainly a disease of the poor. The majority of its victims are migrant labourers, slum dwellers, residents of backward areas and tribal pockets. Poor living conditions, malnutrition, shanty housing and overcrowding are the main reasons for the spread of the disease *(6)*.

HIV increases a person's susceptibility to tuberculosis infection, and tuberculosis is one of the earliest opportunistic disease to develop amongst persons infected with HIV. It increases morbidity and mortality in HIV infected persons. HIV is the most potent risk factor for progression of TB infection to disease.

Since death rate is declining and the disease is showing a decline in younger age groups, epidemiologists are beginning to think that perhaps we may have crossed the peak of the secular epidemic curve and are somewhere at the beginning of the declining limb.

Epidemiological indices *(2)*

Indices or parameters are needed to measure the tuberculosis problem in a community as well as for planning and evaluation of control measures. Indices are also required for international comparison. The following epidemiological indices are generally used in tuberculosis problem measurement and programme strategy :

1. **Incidence** is defined as the number of new and recurrent (relapse) episodes of TB (all forms) occurring in a given year. Recurrent episodes are defined as a new episode of TB in people who have had TB in the past and for whom there was bacteriological confirmation of cure and/or documentation that treatment was completed. Relapse cases are referred to as recurrent cases because the term is more useful when explaining the estimation of TB incidence. Recurrent cases may be true relapses or a new episode of TB caused by reinfection. In current case definitions, both relapse cases and patients who require a change in treatment are called 'retreatment cases'. However, people with a continuing episode of TB that requires a treatment change are prevalent cases, not incident cases.

2. **Prevalence** is defined as the number of TB cases (all forms) at a given point in time. It is the best available practical index to estimate the case load in a community. The age-specific prevalence of patients is considered the most relevant index.

3. **Mortality** from TB is defined as the number of deaths caused by TB in HIV-negative people, according to the latest revision of the International Classification of Diseases (ICD-10). TB deaths among HIV-positive people are classified as HIV deaths in ICD-10. For this reason, estimates of deaths from TB in HIV-positive people are presented separately from those in HIV-negative people.

4. The **case fatality rate** is the risk of death from TB among people with active TB disease.

5. The **case notification rate** refers to new and recurrent episodes of TB notified to WHO for a given year, expressed per 100,000 population. The case notification rate for new and recurrent TB is important in the estimation of TB incidence. In some countries, however, information on treatment history may be missing for some cases. When data on treatment history are not available, recurrent cases cannot be distinguished from cases whose treatment was changed, since both are registered and reported in the category "retreatment". Patients reported in the "unknown history" category are considered incident TB episodes (new or relapse). This is a change from previous years in view of past difficulties to estimate with NTPs the proportion of true new, or relapse TB episodes in this category of patients.

6. **Case detection rate** : The case detection rate is calculated as the number of notification of new and relapse cases in a year divided by the estimated incidence of such cases in the same year.

7. **Prevalence of drug-resistant cases :** It is the prevalence of patient excreting tubercle bacilli resistant to anti-tuberculosis drugs. This index is directly related to chemotherapy.

(a) *Prevalence of infection* : It is the percentage of individuals who show a positive reaction to the standard tuberculin test. When the test is done in defined age-groups, it yields age-specific prevalence which is a far superior indicator than the mere percentage of positive reactors in the total population *(8)*. Prevalence represents a cumulative experience of a population to recent and remote infection with Myco. tuberculosis. It may be mentioned that the interpretation of tuberculin test has become complicated in countries with a high coverage of BCG vaccination at birth, since most of the vaccinees become positive reactors to tuberculin test. This presents a problem in identifying true prevalence of infection. Further, cross-sensitivity to atypical mycobacteriae, where it occurred, has also caused the

prevalence to be over-estimated. Despite these limitations, tuberculin-testing is widely used for estimating the prevalence of tuberculous infection in a population.

(b) *Incidence of infection* : (Annual Infection Rate) : It is the percentage of population under study who will be newly infected by Mycobacterium tuberculosis among the non-infected of the preceding survey during the course of one year. It reflects the annual risk of being infected (or reinfected) in a given community. In other words, it expresses the attacking force of tuberculosis in a community *(9)*. In developing countries, every 1% of annual risk of infection is said to correspond to 50 new cases of smear–positive pulmonary tuberculosis, per year for 100,000 general population *(10)*. Also known as "tuberculin conversion" index, this parameter is considered one of the best indicators for evaluating the tuberculosis problem and its trend. The higher the rate, the greater the problem *(9, 11)*. It may be mentioned that a good treatment programme, lowers the risk of tuberculosis infection in the community.

Revised (2013) definitions of tuberculosis cases and treatment *(12)*

WHO has issued updated guidance on definitions of cases and treatment outcomes and associated reporting framework in March 2013. These updates were necessary to accomodate diagnosis using Xpert MTB/RIF and other WHO-endorsed molecular tests, as well as offering an opportunity to improve aspects of the existing (2006) framework, such as inclusion of more comprehensive reporting of TB cases among children. The updated definitions will be used from 2014 in global data collection *(2)*.

Presumptive case: Presumptive TB refers to a patient who presents with symptoms or signs suggestive of TB (previously known as a TB suspect).

A. CASE DEFINITIONS

a. *A bacteriologically confirmed TB case* is one from whom a biological specimen is positive by smear microscopy, culture or WRD (such as Xpert MTB/RIF). All such cases should be notified, regardless of whether TB treatment has started.

b. *A clinically diagnosed TB case* is one who does not fulfil the criteria for bacteriological confirmation but has been diagnosed with active TB by a clinician or other medical practitioner who has decided to give the patient a full course of TB treatment. This definition includes cases diagnosed on the basis of X-ray abnormalities or suggestive histology and extrapulmonary cases without laboratory confirmation. Clinically diagnosed cases subsequently found to be bacteriologically positive (before or after starting treatment) should be reclassified as bacteriologically confirmed.

Bacteriologically confirmed or clinically diagnosed cases of TB are also classified according to:

1. anatomical site of disease;
2. history of previous treatment;
3. drug resistance;
4. HIV status.

1. Classification based on anatomical site of disease

a. *Pulmonary tuberculosis (PTB)* refers to any bacteriologically confirmed or clinically diagnosed case of TB involving the lung parenchyma or the tracheobronchial tree. Miliary TB is classified as PTB because there are lesions in the lungs. Tuberculous intra-thoracic lymphadenopathy (mediastinal and/or hilar) or tuberculous pleural effusion, without radiographic abnormalities in the lungs, constitutes a case of extrapulmonary TB. A patient with both pulmonary and extrapulmonary TB should be classified as a case of PTB.

b. *Extrapulmonary tuberculosis (EPTB)* refers to any bacteriologically confirmed or clinically diagnosed case of TB involving organs other than the lungs, e.g. pleura, lymph nodes, abdomen, genitourinary tract, skin, joints and bones, meninges.

2. Classification based on history of previous TB treatment (patient registration group)

Classifications based on history of previous TB treatment are slightly different from those previously defined. They focus only on history of previous treatment and are independent of bacteriological confirmation or site of disease.

New patients: Patients who have never been treated for TB or have taken anti-TB drugs for less than 1 month.

Previously treated patients: Patients who received 1 month or more of anti-TB drugs in the past. They are further classified by the outcome of their most recent course of treatment as follows:

a. *Relapse patients* have previously been treated for TB, were declared cured or treatment completed at the end of their most recent course of treatment, and are now diagnosed with a recurrent episode of TB (either a true relapse or a new episode of TB caused by reinfection).

b. *Treatment after failure patients* are those who have previously been treated for TB and whose treatment failed at the end of their most recent course of treatment.

c. *Treatment after loss to follow-up patients* have previously been treated for TB and were declared lost to follow-up at the end of their most recent course of treatment. (These were previously known as treatment after default patients.)

d. *Other previously treated patients* are those who have previously been treated for TB but whose outcome after their most recent course of treatment is unknown or undocumented.

e. *Patients with unknown previous TB treatment history* do not fit into any of the categories listed above. New and relapse cases of TB are incident TB cases.

3. Classification based on drug resistance

Cases are classified in categories based on drug susceptibility testing (DST) of clinical isolates confirmed to be M. tuberculosis:

a. *Monoresistance:* resistance to one first-line anti-TB drug only.

b. *Polydrug resistance:* resistance to more than one first-line anti-TB drug (other than both isoniazid and rifampicin).

c. *Multidrug resistance:* resistance to at least both isoniazid and rifampicin.

d. *Extensive drug resistance:* resistance to any fluoroquinolone and at least one of three second-line injectable drugs (capreomycin, kanamycin and amikacin), in addition to multidrug resistance.

e. *Rifampicin resistance:* resistance to rifampicin detected using phenotypic or genotypic methods, with or without resistance to other anti-TB drugs. It includes any resistance to rifampicin, whether monoresistance, multidrug resistance, polydrug resistance or extensive drug resistance.

These categories are not all mutually exclusive. When enumerating rifampicin-resistant TB (RR-TB), for instance, multidrug-resistant TB (MDR-TB) and extensively drug-resistant TB (XDR-TB) are also included. While it has been the practice until now to limit the definitions of monoresistance and polydrug resistance to first-line drugs only, future drug regimens may make it important to classify patients by their strain resistance patterns to fluoroquinolones, second-line injectable agents and any other anti-TB drug for which reliable DST becomes available.

4. Classification based on HIV status

a. *HIV-positive TB patient* refers to any bacteriologically confirmed or clinically diagnosed case of TB who has a positive result from HIV testing conducted at the time of TB diagnosis or other documented evidence of enrolment in HIV care, such as enrolment in the pre-ART register or in the ART register once ART has been started.

b. *HIV-negative TB patient* refers to any bacteriologically confirmed or clinically diagnosed case of TB who has a negative result from HIV testing conducted at the time of TB diagnosis. Any HIV-negative TB patient subsequently found to be HIV-positive should be reclassified accordingly.

c. *HIV status unknown TB patient* refers to any bacteriologically confirmed or clinically diagnosed case of TB who has no result of HIV testing and no other documented evidence of enrolment in HIV care. If the patient's HIV status is subsequently determined, he or she should be reclassified accordingly.

B. TREATMENT OUTCOME DEFINITIONS

The new treatment outcome definitions make a clear distinction between two types of patients:

- patients treated for drug-susceptible TB;
- patients treated for drug-resistant TB using second-line treatment (defined as combination chemotherapy for drug-resistant tuberculosis which includes drugs other than those in Group 1 (see page 187).

The two groups are mutually exclusive. Any patient found to have drug-resistant TB and placed on second-line treatment is removed from the drug-suscepitble TB outcome cohort. This means that management of the standard TB register and of the second-line TB treatment register needs to be coordinated to ensure proper accounting of the outcomes of treatment.

1. Treatment outcomes for TB patients (excluding patients treated for RR-TB or MDR-TB)

All bacteriologically confirmed and clinically diagnosed TB cases should be assigned an outcome from this list except those with RR-TB or MDR-TB, who are placed on a second-line drug regimen.

Outcome	Definition
Cured	A pulmonary TB patient with bacteriologically confirmed TB at the beginning of treatment who was smear or culture-negative in the last month of treatment and on at least one previous occasion.
Treatment completed	A TB patient who completed treatment without evidence of failure BUT with no record to show that sputum smear or culture results in the last month of treatment and on at least one previous occasion were negative, either because tests were not done or because results are unavailable.
Treatment failed	A TB patient whose sputum smear or culture is positive at month 5 or later during treatment.
Died	A TB patient who dies for any reason before starting or during the course of treatment.
Lost to follow-up	A TB patient who did not start treatment or whose treatment was interrupted for 2 consecutive months or more.
Not evaluated	A TB patient for whom no treatment outcome is assigned. This includes cases "transferred out" to another treatment unit as well as cases for whom the treatment outcome is unknown to the reporting unit.
Treatment success	The sum of cured and treatment completed.
Cohort	A group of patients in whom TB has been diagnosed, and who were registered for treatment during a specified time period (e.g. the cohort of new smear-positive cases registered in the calendar year 2011). This group forms the denominator for calculating treatment outcomes. The sum of the treatment outcomes, plus any case for which no outcome is recorded (eg. still on treatment) should equal the number of cases registered *(2)*.

Patients found to have an RR-TB or MDR-TB strain at any point in time should be started on an adequate second-line drug regimen. These cases are excluded from the main TB cohort when calculating treatment outcomes and included only in the second-line TB treatment cohort analysis. If treatment with a second-line drug regimen is not possible, the patient is kept in the main TB cohort and assigned an outcome from above table.

2. Outcomes for RR-TB/MDR-TB/XDR-TB patients treated using second-line treatment

Outcome	Definition
Cured	Treatment completed as recommended by the national policy without evidence of failure AND three or more consecutive cultures taken at least 30 days apart are negative after the intensive phase.[a]
Treatment completed	Treatment completed as recommended by the national policy without evidence of failure BUT no record that three or more consecutive cultures taken at least 30 days apart are negative after the intensive phase.[a]
Treatment failed	Treatment terminated or need for permanent regimen change of at least two anti-TB drugs because of: – lack of conversion[b] by the end of the intensive phase,[a] or – bacteriological reversion[b] in the continuation phase after conversion[b] to negative, or – evidence of additional acquired resistance to fluoroquinolones or second-line injectable drugs, or – adverse drug reactions (ADRs).
Died	A patient who dies for any reason during the course of treatment.
Lost to follow-up	A patient whose treatment was interrupted for 2 consecutive months or more.
Not evaluated	A patient for whom no treatment outcome is assigned. (This includes cases "transferred out" to another treatment unit and whose treatment outcome is unknown)
Treatment success	The sum of cured and treatment completed

Cohort	A group of patients where RR-TB has been diagnosed (including MDR-TB and XDR-TB), and who were started on a full course of a second-line MDR-TB drug regimen during a specified time period (e.g. the cohort of MDR-TB cases registered in the calendar year 2010). This group forms the denominator for calculating treatment outcomes. With the revised definitions, any patient found to have drug-resistant TB and placed on second-line treatment is removed from the drug-susceptible TB outcome cohort. This means that management of the basic management unit TB register and of the second-line TB treatment register needs to be coordinated to ensure proper accounting of the outcomes of treatment *(2)*.

[a] For *Treatment failed*, lack of conversion by the end of the intensive phase implies that the patient does not convert within the maximum duration of intensive phase applied by the programme. If no maximum duration is defined, an 8-month cut-off is proposed. For regimens without a clear distinction between intensive and continuation phases, a cut-off 8 months after the start of treatment is suggested to determine when the criteria for Cured, Treatment completed and Treatment failed start to apply.

[b] The terms "conversion" and "reversion" of culture as used here are defined as follows:

Conversion (to negative) : culture is considered to have converted to negative when two consecutive cultures, taken at least 30 days apart, are found to be negative. In such a case, the specimen collection date of the first negative culture is used as the date of conversion.

Reversion (to positive) : culture is considered to have reverted to positive when, after an initial conversion, two consecutive cultures, taken at least 30 days apart, are found to be positive. For the purpose of defining treatment failed, reversion is considered only when it occurs in the continuation phase.

The revised definitions should be applied by the NTP at a set changeover date (e.g. 1 January): all cases on treatment on that date should be assigned outcomes according to the revised definitions. This means that patients started on treatment in the previous year may be assigned outcomes according to two different definitions of cured or treatment failed, depending on whether they completed treatment before or after the changeover date. This may be the most practical option for the transition period, given that retrospective reassignment of outcomes is not always feasible.

NATURAL HISTORY OF TUBERCULOSIS

Agent factors

(a) AGENT : *M. tuberculosis* is a facultative intracellular parasite, i.e., it is readily ingested by phagocytes and is resistant to intracellular killing *(13)*. Of importance to man are the human and bovine strains. The human strain is responsible for the vast majority of cases. The bovine strain affects mainly cattle and other animals. Regarding virulence, the Indian tubercle bacillus is said to be less virulent than the European bacillus. In recent years, a number of "atypical" mycobacteria have been isolated from man *(14)*. These have been classified into four groups – (i) photochromogens (e.g., *M. Kansasii*); (ii) scotochromogens (e.g., *M. scrofulaceum*); (iii) non–photochromogens (e.g., *M. intercellulare*)) and, (iv) rapid growers (e.g., *M. fortuitum*). All these are mainly saprophytic. Diseases attributed to them have resembled pulmonary tuberculosis and chronic cervical lymphadenitis.

(b) SOURCE OF INFECTION : There are two sources of infection – human and bovine. (i) *Human source :* The most common source of infection is the human case whose sputum is positive for tubercle bacilli and who has either received no treatment or has not been treated fully. An estimated annual average of 10–15 persons contract the infection from one case of infectious pulmonary TB. Such sources can discharge the bacilli in their sputum for years. The tubercle bacilli in a human case are usually a mixed group – some multiply very rapidly and some slowly. The more rapidly a bacillary strain multiplies the more susceptible it is to the bactericidal action of chemotherapeutic drugs. The slow multipliers are the source of persister or dormant bacilli; they can remain alive for years without causing harm to the host, but when conditions are favourable they may start multiplying again and cause active disease. That is, they are the seeds of a future relapse *(15)*. (ii) *Bovine source:* The bovine source of infection is usually infected milk. There is no definite evidence that bovine tuberculosis is a problem in this country because of the practice of boiling milk before consumption.

(c) COMMUNICABILITY : Patients are infective as long as they remain untreated. Effective anti–microbial treatment reduces infectivity by 90 per cent within 48 hours *(16)*.

Host factors

(a) AGE : Tuberculosis affects all ages. Developing countries show a sharp rise in infection rates from childhood to adolescence. In India, from an average of 2 per cent in the "0–14 years age group", the infection rate climbs to about 20 per cent at age 15–24 years age group (Table 2). In the developed countries, the disease is now more common in the elderly. (b) SEX : More prevalent in males than in females. (c) HEREDITY : Tuberculosis is not a hereditary disease. However, twin studies *(17)* indicate that inherited susceptibility is an important risk factor. (d) NUTRITION : Malnutrition is widely believed to predispose to tuberculosis. As malnutrition is widely prevalent in developing world, it will continue to affect the development of active disease, out- come of treatment and spread of the disease. (e) IMMUNITY : Man has no inherited immunity against tuberculosis. It is acquired as a result of natural infection or BCG vaccination. Past infection with atypical mycobacteria is also credited with certain amount of naturally acquired immunity. It is now known that both delayed hypersensitivity and acquired resistance to tuberculosis are cell–mediated responses. In most cases, the cellular immunity proves adequate to limit further multiplication and spread of bacilli.

Social factors

Tuberculosis is a social disease with medical aspects. It has also been described as a barometer of social welfare. The social factors include many non-medical factors such as poor quality of life, poor housing, and overcrowding, population explosion, undernutrition, smoking, alcohol abuse, lack of education, large families, early marriages, lack of awareness of causes of illness, etc. All these factors are interrelated and contribute to the occurrence and spread of tuberculosis. In fact, tuberculosis began to decline in the western world long before the advent of chemotherapeutic drugs. This has been attributed to improvements in the quality of life.

Mode of transmission

Tuberculosis is transmitted mainly by droplet infection and droplet nuclei generated by sputum-positive patients with pulmonary tuberculosis. To transmit infection, the particles must be fresh enough to carry a viable organism. Coughing generates the largest number of droplets of all sizes. The frequency and vigour of cough and the ventilation of the environment influence transmission of infection.

Tuberculosis is not transmitted by fomites, such as dishes and other articles used by the patients. Sterilization of these articles is therefore of little or no value. Patients with extrapulmonary tuberculosis or smear-negative tuberculosis constitute a minimal hazard for transmission of infection

Incubation period

The time from receipt of infection to the development of a positive tuberculin test ranges from 3 to 6 weeks, and thereafter, the development of disease depends upon the closeness of contact, extent of the disease and sputum positivity of the source case (dose of infection) and host–parasite relationship. Thus the incubation period may be weeks, months or years.

THE CONTROL OF TUBERCULOSIS

Tuberculosis control means reduction in the prevalence and incidence of disease in the community.

Since tuberculosis is an infectious disease, the basic principles of prevention and control are the same as for any other infectious disease. The control measures consist of a **curative** component – namely case finding and treatment; and a **preventive** component – namely BCG vaccination. These are the two fundamental components of a national tuberculosis programme. The most powerful weapon, however, is the combination of case-finding and treatment.

Case-finding

a. THE CASE

The first step in a tuberculosis control programme is early detection of sputum-positive cases. This should be an intensive, on-going programme.

b. TARGET GROUP

An overwhelming majority of patients of pulmonary tuberculosis have one or more of the symptoms referable to chest, such as persistent cough and fever, and many of them (over 60 per cent) seek medical advice on their own initiative. The chest symptoms often develop early, that is before the disease has gone on to an advanced stage. This is the most fertile group for case-finding.

c. CASE-FINDING TOOLS

(i) **Sputum examination :** Sputum smear examination by direct microscopy is now considered the method of choice. The reliability, cheapness and ease of direct microscopic examination has made it number one case-finding method all over the world. It enables us to discover the epidemiologically most important cases of pulmonary tuberculosis, i.e., those excreting tubercle bacilli in their sputum. This is the group which contributes most of the new cases to the "pool of infection" every year.

Collection of sputum samples

A pulmonary tuberculosis suspect should submit two sputum samples for microscopy. The chances of finding TB bacilli are greater with two samples than with one sample. Secretions build up in the airways overnight. So an early morning sputum sample is more likely to contain TB bacilli than one taken later in the day. It may be difficult for an out-patient to provide two early morning sputum samples. Therefore in practice an out-patient usually provides sputum samples as follows:

day 1	sample 1	Patient provides an "on-the-spot" sample under supervision when presenting to the health facility. Give the patient a sputum container to take home for an early morning sample the following morning.
day 2	sample 2	Patient brings an early morning sample.

If the patient is coming from a long distance or there is likelihood that the patient may default to give a second sample, 2 spot specimens are collected with a gap of one hour *(18)*.

Ziehl-Neelsen acid-fast stain

This simple stain detects acid fast bacilli. The procedure is as follows:

1. Fix the smear on the slide by passing the slide with the smear up about three times slowly through a flame. It can also be done by covering the smear with alcohol and letting this evaporate.
2. Cover with carbol fuchsin, steam gently for 5 minutes over direct flame (or for 20 minutes over a water bath). Do not permit slide to boil or dry out.
3. Wash with deionized water.
4. Decolourize in 3.0 per cent acid–alcohol (95 per cent ethanol and 3.0 per cent hydrochloric acid) until only a faint pink colour remains.
5. Wash with water.
6. Counter stain for 1 minute with Loeffler's methylene blue.
7. Wash with deionized water and let it dry.

Slide reporting *(19)*

The number of bacilli seen in a smear reflects disease severity and patient infectivity. Therefore, it is important to record the number of bacilli seen on each smear. The table below shows the standard method of reporting using 1000 X magnification.

Number of bacilli			Result reported
No	AFB	per 100 oil immersion fields	0
1-9	AFB	per 100 oil immersion fields	scanty (or number AFB seen)
10-99	AFB	per 100 oil immersion fields	+ (1+)
1-10	AFB	per oil immersion field	++ (2+)
> 10	AFB	per oil immersion field	+++ (3+)

Laboratory technicians should examine both the sputum samples from each TB suspect. They must record the result of each sputum sample with the laboratory reference number in the laboratory register and on the sputum request form. Results as indicated above are made available to the clinician who can then categorize the patient. It is advised that the smear examined by one microscopist should not exceed 20 per day as visual fatigue leads to a deterioration of reading quality *(20)*.

One positive specimen out of the two is enough to declare a patient as smear positive TB. Smear positive TB is further classified as new or retreatment cases, based on their previous treatment history, and appropriate therapy is prescribed. Patients in whom both specimens are smear negative should be prescribed symptomatic treatment and broad-spectrum antibiotic for 10–14 days. In such cases

antibiotics such as fluoroquinolones (ciprofloxacin, ofloxacin, etc.), rifampicin or streptomycin, which are active against TB, should not be used. Most patients are likely to improve with antibiotics if they are not suffering from TB. If the symptoms persist after a course of broad-spectrum antibiotic, repeat sputum smear examination (2 samples) must be done for such patients. If one or more smears are positive, the patient is diagnosed as having smear-positive pulmonary TB. If none of the repeat sputum specimen is positive, a chest X-ray is taken, and if findings of the X-ray are consistent with pulmonary TB, the patient is diagnosed as a case of sputum-negative pulmonary TB *(7)*.

Sputum smear microscopy for tubercle bacilli is positive when there are at least 10,000 organisms present per ml of sputum. The sputum smear positivity rate in TB/HIV patient depends on the degree of immunocompromise. If the degree of immunocompromise is mild, the likelihood of positive sputum smear is similar to HIV negative patient. If immunocompromise is severe, the likelihood of positive sputum smear is decreased because of decreased inflammation in lungs *(19)*.

False-positive results of sputum smear microscopy

A false-positive result means that the sputum smear result is positive even though the patient does not really have sputum smear-positive PTB. This may arise because of the following: red stain retained by scratches on the slide; accidental transfer of AFBs from a positive slide to a negative one; contamination of the slide or smear by environmental mycobacteria; presence of various particles that are acid-fast (e.g. food particles, precipitates, other microorganisms).

False-negative results of sputum smear microscopy

A false-negative result means that the sputum smear result is negative even though the patient really does have sputum smear-positive PTB. This may arise because of problems in collecting (patient provides inadequate sample, inappropriate sputum container used or sputum stored too long before smear microscopy), processing (faulty sampling of sputum for smear or faulty smear preparation and staining), or interpreting sputum smears (inadequate time spent examining smear or inadequate attention to smear examination), or because of administrative errors (misidentification of patient, incorrect labelling of sample or mistakes in documentation).

Fluorescence microscopy

Fluorescence microscopy is mainly used in industralized countries. It is performed with auramine stain. The advantage of FA microscopy is from the speed of examination. The field of view is 5–10 times bigger. Scanning of one length of smear will require only 1–2 minutes.

Light-emitting diode fluorescence microscopy (LEDs)

LEDs provide a much less expensive light source for fluorescence microscopy. In a recent WHO evaluation, the diagnostic accuracy of LED microscopy was found to be comparable to that of conventional fluorescence microscopy and superior to that of conventional Ziehl-Neelsen microscopy. It is therefore recommended that LED microscopy be phased in as an alternative to conventional Z–N light microscopy in both high and low-volume laboratories *(20)*.

Radiography

Chest X-rays are useful for the diagnosis of smear negative pulmonary TB and TB in children. It is not routinely indicated in smear-postive cases. X-rays are valuable tools for the diagnosis of pleural and pericardial effusion, especially in early stages of the disease when clinical signs are minimal. It is essential in the diagnosis of miliary TB. The other indications are frequent or severe haemoptysis to exclude bronchiectasis or aspergilloma and in patients needing specific treatment for pneumothorax.

Sputum culture *(21)*

Isolation of mycobacteria from clinical samples by culture still represents the corner-stone on which definitive diagnosis of tuberculosis and other mycobacterioses relies. At present, mycobacterial culture can be performed on conventional egg based solid medium such as Lowenstein-Jensen medium and agar based ones, such as Middle brook 7H10 or 7H11 and liquid media such as Kirchner's or Middle brook 7H9 broth. The major constraint of culturing mycobacteria in conventional media is its slow growth which necessitates a mean incubation period of at least 4 weeks. The drug susceptibility tests to anti-tuberculosis drugs require additional 4 weeks. Most of the laboratories in the developing world rely on solid media for culture of mycobacteria. The choice and preparation of specimens by various pretreatment procedures has tremendous influence on the sensitivity of results. The positively of culture largely dependens on the technique of decontamination used by various laboratories, viz the chemicals used for decontamination and the centrifugation method adopted for processing specimens for culturing mycobacteria by inoculating into solid or liquid media.

Although a combination of solid and liquid media is currently the gold standard for the primary isolation of mycobacteria, a few modern, rapid methods are also available. These include micro colony detection on solid media (including the rapid slide culture technique), septi-check AFB method, microscopic observation of in-broth culture (MODS), the BACTEC 460 radiometric system, BACTEC MGIT 960 system (Becton Dickinson), MB/BaCT system (Organon Teknika), and the ESP II culture system.

Micro colony detection on solid media *(21)*

In this method, plates poured with thin layer of middle brook 7H11 agar medium are incubated and examined microscopically on alternate days for the first 2 days and less frequently thereafter. In less than 7 days, micro colonies of *M. tuberculosis* can be detected. Though this method is less expensive and requires about half the time needed for conventional culture, the recovery of mycobacteria is less efficient and it is labour intensive. Since *M. tuberculosis* grows more rapidly in liquid medium forming strings and tangles, which can be observed under the inverted light microscope with 40x magnification, this method is a better alternative for culturing tubercle bacilli.

Radiometric BACTEC 460 TB method *(21)*

This technique is specific for mycobacterial growth, wherein C labeled palmitic acid in 7H12 medium is used. This system detects the presence of mycobacteria based on

their metabolism rather than visible growth. When the C labeled substrate present in the medium is metabolized, CO_2 is produced and measured by the BACTEC system instrument and reported in terms of growth index (GI) value. The BACTEC system is also useful in the identification of *M. tuberculosis* using specific inhibitor, para-nitro-a-acetylamino-b-hydroxypro-piophenone. Using the same system, drug susceptibility tests can also be performed for all the anti-tuberculosis drugs when sufficient GI is observed. Mycobacteria in clinical samples can be detected in half the time compared to conventional culture methods.

MGIT 960 mycobacteria detection system *(21)*

It is an automated system for the growth and detection of mycobacteria with a capacity to incubate and continuously monitor 960 mycobacteria growth indicator tube (MGIT) every 60 minutes for increase in fluorescence. Growth detection is based on the AFB metabolic O_2 utilization and subsequent intensification of an O_2 quenched fluorescent dye contained in a tube of modified MGIT. A series of algorithms are used to determine presumptive positivity and alert the operator to the presence and location of positive tubes.

MB/BaCT system

This is a non-radiometric continuous monitoring system with a computerized database management. The system is based on colorimetric detection of CO_2.

Detection and identification of mycobacteria directly from clinical samples

Both genotypic (molecular) and phenotypic methods are available with newer modifications for the diagnosis of tuberculosis as an alternative for smear microscopy.

Genotypic methods *(21)*

Polymerase chain reaction

The PCR allows sequences of DNA present in only a few copies of mycobacteria to be amplified *in vitro* such that the amount of amplified DNA can be visualized and identified. If appropriate sequences specific for *M. tuberculosis* are selected, 10–1000 organisms can be readily identified. The PCR methodology is rapid; results are available within a day of DNA extraction from the sample. A number of target genes of mycobacterial DNA have been evaluated for diagnosis by PCR and various other genotypic methods. The most common target used in the PCR is IS6110.

A variety of PCR methods have been described in the search for a sensitive and reliable screening test for tuberculosis in clinical specimens. Species-specific and genus-specific PCR methods are being used with various targets and modifications of PCR. The following are some of the methods used for identification of *M. tuberculosis* and non-tuberculous mycobacteria (NTM).

Transcription mediated amplification (TMA) and nucleic acid amplification (NAA)

This approach identifies the presence of genetic information unique to *M. tuberculosis* complex directly from pre-processed clinical specimens. The NAA technique uses chemical, rather than biological amplification to produce nucleic acid, so that within a few hours these tests distinguish between *M. tuberculosis* complex and NTM in an AFB-positive specimen.

Cartridge based nucleic acid amplification test

The second generation NAAT-based TB diagnostics offer the prospect of very high sensitivity, approaching that of liquid culture – the current gold standard for TB diagnosis. In addition, some versions of NAAT also provide information on drug susceptibility to rifampicin, which is a surrogate marker in most countries for identification of patients who are most likely to have MDR-TB, thus allowing the early initiation of standardized 2nd line TB treatment *(4)*.

GeneXpert MTB/RIF

The Xpert MTB/RIF detects DNA sequences specific for Mycobacterium tuberculosis and rifampicin resistance by polymerase chain reaction. It is based on the Cepheid GeneXpert system, a platform for rapid and simple-to-use nucleic acid amplification tests (NAAT). The Xpert MTB/RIF purifies and concentrates *Mycobacterium tuberculosis bacilli* from sputum samples, isolates genomic material from the captured bacteria by sonication and subsequently amplifies the genomic DNA by PCR. The process identifies all the clinically relevant rifampicin resistance inducing mutations in the RNA polymerase beta (rpoB) gene in the *mycobacterium tuberculosis* genome in a real time format using fluorescent probes called molecular beacons. Results are obtained from unprocessed sputum samples in 90 minutes, with minimal biohazard and very little technical training required to operate.

Phenotypic method *(21)*

FAST Plaque TB

This is an original phage based test, which uses the mycobacteriophage to detect the presence of *M. tuberculosis* directly from sputum specimens. It is a rapid, manual test, easy to perform and has an overall higher sensitivity when compared with sputum smear microscopy, in newly diagnosed smear positive TB.

Serological diagnosis of tuberculosis

Most of the serological tests have low turn around time, high negative predictive value and are useful as screening tests. The limitation of these tests is low sensitivity in smear negative patients, HIV positive cases, and in disease endemic countries with a high infection rate. The tests are also expensive, require trained personnel and often have difficulty in distinguishing between *M. tuberculosis* and NTM *(21)*.

TB STAT-PAK

Immunochromatographic test based on the detection of antibodies has been evolved with a capability to differentiate between active or dormant TB infection in whole blood, plasma or serum. Its value in disease endemic countries such as India is yet to be ascertained *(21)*.

Insta test TB *(21)*

It is a rapid *in vitro* assay for the detection of antibody in active TB disease using whole blood or serum. The test employs an antibody binding protein conjugated to a colloidal gold particle and a unique combination of TB antigens immobilized on the membrane.

Some of the other commercially available antibody tests for pulmonary TB are listed below.

Name of the assays	Antigen used
MycoDot (Dot-blot)	Lipo arabino mannan (LAM)
Detect- TB (ELISA)	Recombinant protein peptide
Pathozyme Myco (ELISA)	38 kDa (recombinant Ag) and LAM
Pathozyme TB (ELISA)	38 kDA (recombinant)
Antigen A60 (ELISA)	Antigen-60
ICT diagnostics (membrane based)	38 kDa (recombinant)

Sourcfe : *(21)*

TUBERCULIN TEST

The tuberculin test was discovered by Von Pirquet in 1907. A positive reaction to the test is generally accepted as evidence of past or present infection by *M. tuberculosis*. The tuberculin test is the only means of estimating the prevalence of infection in a population.

Tuberculin : Only two tuberculins have been accepted as standard tuberculin by WHO, i.e., purified protein derivative–S (PPD–S) and PPD–RT 23. PPD is standardized in terms of its biological reactivity as tuberculin units (UT). A standard 5 tuberculin unit (5 TU) dose of PPD-S is defined as delayed skin activity contained in a 0.1 µg/0.1 ml dose of PPD–S. 1 TU of PPD–RT 23 is equivalent to 5 TU of PPD–S. In India PPD–RT 23 with Tween 80 is used. Tween 80 is a detergent added to tuberculin to prevent their adsorption on glass or plastic surface. Use of tuberculin strength of 1 TU is recommended for standard Mantoux test in India.

MANTOUX TEST : The Mantoux test is carried out by injecting 1 TU of PPD in 0.1 ml intradermally on the flexor surface of the left forearm, mid-way between elbow and wrist. The injection should be made with a tuberculin syringe, with the needle bevel facing upward. When placed correctly, injection should produce a pale wheal of the skin, 6 to 10 mm in diameter. The result of the test is read after 48–96 hours but 72 hours (3rd day) is the ideal.

Tuberculin reaction consists of erythema and induration. Since erythema is sometimes difficult to measure, induration alone is measured (horizontal transverse diameter of induration in millimetres, using a transparent plastic ruler or callipers). Reactions exceeding 10 mm are considered "positive". Those less than 6 mm are considered "negative". Those between 6 and 9 mm are considered "doubtful", i.e., the reaction may be due to *M. tuberculosis* or atypical mycobacteria. If there is no induration, the result should be recorded as '0'.

It has been further observed that strong reactors (i.e., those showing 20 mm or more induration) have greater chances of developing tuberculosis than those showing 10 mm induration. Those with less than 5 mm induration have more risk of developing tuberculosis than those with 6–9 mm induration. Studies indicate that 92 per cent of new cases occur in persons who are already tuberculin reactors *(22)*. These findings illustrate the prognostic significance of the test.

Classification of positive tuberculin skin test reaction *(23)*

A tuberculin skin test reaction is considered positive if the transverse diameter of the indurated area reaches the size required for the specific group. All other reactions are considered negative. The classificaiton is as follows:

Induration size	Group
≥ 5 mm	1. HIV-positive persons. 2. Recent contacts of individuals with active tuberculosis. 3. Persons with fibrotic changes on chest films suggestive of prior tuberculosis. 4. Patients with organ transplants and other immunosuppressed patients (receiving the equivalent of > 15 mg/d of prednisone for 1 month or more).
≥ 10 mm	1. Recent immigrants (< 5 years) from countries with a high prevalence of tuberculosis (eg, Asia, Africa, Latin America). 2. HIV-negative injection drug users. 3. Mycobacteriology laboratory personnel. 4. Residents of and employees in the following high-risk congregate settings: correctional institutions; nursing homes and other long-term facilities for the elderly; hospitals and other health care facilities; residential facilities for AIDS patients; and homeless shelters. 5. Persons with the following medical conditions that increase the risk of tuberculosis: gastrectomy, ≥ 10% below ideal body weight, jejunoileal bypass, diabetes mellitus, silicosis, advanced chronic kidney disease, some hematologic disorders, (eg. leukemias, lymphomas) and other specific malignancies (eg, carcinoma of the head or neck and lung). 6. Children < 4 years of age or infants, children and adolescents exposed to adults at high risk.
≥ 15 mm	1. Persons with no risk factors for tuberculosis.

A negative tuberculin test must also be interpreted with caution. For many years, it has been assumed that a negative test constituted strong evidence against the presence of active tuberculous disease in the majority of cases. It has been shown that in the majority of patients with tuberculosis, the cellular immune response may be depressed. It means a negative tuberculin test cannot be relied upon to exclude tuberculosis. The dermal hypersensitivity to tuberculin can also be lost in various states of immune suppression, e.g., malignancy, Hodgkin's disease, HIV infection, malnutrition, severe bacterial infection (including TB itself), viral infections (e.g. measles, chickenpox, glandular fever), recent live-virus vaccination (e.g. measles), immunosuppresive drugs (e.g. steroids) and incorrect injection of PPD. Therefore, too great a diagnostic significance should not be placed on a negative tuberculin test *(13)*.

Two-step testing

Some people who were previously infected with TB may have a negative reaction when tested years after infection, as the immune system response may gradually wane. This initial skin test, though negative, may stimulate (boost) the body's ability to react to tuberculin in future tests. Thus, a positive reaction to a subsequent test may be misinterpreted as a new infection, when in fact it is the result of the boosted reaction to an old infection. Giving a second TST after an initial negative TST reaction is called a two-step testing. Use of two-step testing is recommended for initial skin testing of adults who will be retested periodically (e.g, health care workers).

- The first test is read 48–72 hours after injection.
  - If the first test is positive, consider the person infected.
  - If the first test is negative, give a second test one to three weeks after the first injection.
- The second test is read 48–72 hours after injection.
  - If the second test is positive, consider the person previously infected.

– If the second test is negative, consider the person uninfected.

The validity of tuberculin test, like all medical tests, is subject to variability. It is limited by lack of specificity. Apart from errors associated with the mode of administration, reading of results and the test material used, there are other factors such as cross-reactions due to sensitization by other mycobacteria, which should be taken into account. In countries with a high coverage of BCG, which also produces tuberculin hypersensitivity, tuberculin test has lost its sensitivity as an indicator of the "true" prevalence of infection. The true prevalence rates of infection may be exaggerated by infection with atypical mycobacteria as well as the "boosting effect" of a second dose of tuberculin producing a larger reaction than the first *(24)*.

It is often assumed that delayed hypersensitivity as measured by tuberculin testing is a correlate of the protective immune response. But evidence indicates that this hypersensitivity is irrelevant to the ability of the host to combat the disease. Despite these limitations, the tuberculin test continues to be the only tool for measuring the prevalence of tuberculous infection in a community. It has been aptly said that tuberculin test "must be approached with respect, administered with care, read with deliberation and interpreted with sentient discrimination".

Case-finding should not be an end in itself. It is of little value as a control measure unless followed by chemotherapy. Resources and efforts should be directed towards primary health care, rather than irrational case finding.

Please refer to chapter 7 for the flow chart for diagnosis of tuberculosis in adults, as followed by RNTCP.

Chemotherapy

The development of effective treatment for tuberculosis has been one of the most significant advances during this century. With the evolution of controlled trials (see page 81), the chemotherapy of tuberculosis is now more rationally based, than in the treatment of other infectious diseases.

Chemotherapy is indicated in every case of active tuberculosis. The objective of treatment is cure – that is, the elimination of both the fast and slowly multiplying bacilli (including the persisters) from the patient's body. The effects of chemotherapy are judged not by the anatomic healing of lesions, but mainly by the elimination of bacilli from the patient's sputum. Chemotherapy should be easily available, free of charge to every patient detected. It should be adequate, appropriate and applied to the entire pool of infectors in the community. Patient compliance is critically important; the patient must take the correct drugs at the correct dosage for the correct length of time. Incomplete treatment puts the patient at risk of relapse and the development of bacterial resistance and, importantly, the community at risk of infection with resistant organisms.

Anti-tuberculosis drugs

There are now twelve or thirteen drugs active against ***M. tuberculosis,*** of which, six are considered to be essential. An antitubercular drug should satisfy the following criteria : (a) highly effective (b) free from side-effects (c) easy to administer, and (d) reasonably cheap. The currently used drugs may be classified into two groups : bactericidal and bacteriostatic. The bactericidal drugs kill the bacilli *in vivo*. The bacteriostatic drugs inhibit the multiplication of the bacilli and lead to their destruction by the immune mechanism of the host. A brief review of these drugs is given below.

THE FIRST–LINE DRUGS

BACTERICIDAL DRUGS

Rifampicin (RMP)

RMP is a powerful bactericidal drug. It is a better sterilizing agent than INH. It permeates all tissue membranes including the blood–brain and placental barriers. It is equally effective against intracellular as well as extracellular bacilli. It is the only bactericidal drug active against the "persisters" or dormant bacilli which are found in the solid caseous lesions, all other drugs being inactive *(25)*. In this regard, it has a distinct advantage over INH. Rifampicin is of special value when the bacilli resists other drugs. In combination with INH, it can cure even extensive tuberculosis, in about 9 months.

RMP is used only as oral drug. It is so well absorbed that there is little need for parenteral administration. The dose should be taken at least one hour before or 2 hours after food because absorption is reduced by food. It is never used alone for the treatment of tuberculosis, but always used in combination with INH or another drug.

Many patients develop nausea at the start of treatment, but this passes off. The toxic effects include hepatotoxicity, gastritis, influenza–like illness, purpura, thrombocytopenia and nephrotoxicity. The patient should be told that the drug will turn the urine red; this can be used as test of compliance.

PAS delays its absorption; hence concurrent administration with PAS should be avoided. If RMP is stopped for some reason, it should not be restarted within 3 weeks to avoid hypersensitivity.

INH

INH ranks among the most powerful drugs in the treatment of tuberculosis. It can easily penetrate the cell membrane, and is thus active against intracellular and extracellular bacilli. Its action is most marked on rapidly multiplying bacilli. It is less active against slow multipliers. INH gets widely distributed in the body including CSF. Its ease of administration, freedom from toxicity and low cost makes it an ideal component for any drug regimen.

INH should be given as a single dose. INH reaches its peak level in blood 1 to 2 hours after the dose. It has been found that its peak level in serum is more important than sustained inhibitory level. It is for this reason, INH should not be given in divided doses *(26)*.

Patient may experience gastrointestinal irritation, peripheral neuropathy, blood dyscrasias, hyperglycaemia and liver damage. Those patients who are slow inactivators experience a higher incidence of toxicity. The addition of pyridoxine (10–20 mg daily) helps prevent the occurrence of peripheral neuropathy.

Streptomycin

Streptomycin is bactericidal. It acts entirely on rapidly multiplying bacilli. It has been shown that when bacilli are multiplying rapidly, they come out of the phagocytes and are mostly extracellular and are, therefore, susceptible to streptomycin. Streptomycin is less active against slow multipliers. It has no action on persisters. It does not permeate cell walls or normal biological membranes such as meninges or pleura.

The daily dose of streptomycin is 0.75 g in a single injection. This is a disadvantage because of the organizational problem involved in the long term treatment. It can cause side-

effects which include vestibular damage and nystagmus rather than deafness. Renal damage may also occur.

Pyrazinamide

This drug is bactericidal and is particularly active against the slow-multiplying intracellular bacilli which are unaffected by other drugs. It has been found to increase the sterilizing ability of rifampicin. Therefore, pyrazinamide has been incorporated in short-course chemotherapy regimens.

Complications include hepatotoxicity and hyperuricaemia. Pyrazinamide achieves high levels in CSF and is, therefore, recommended in tuberculous meningitis.

BACTERIOSTATIC DRUGS

Ethambutol

Ethambutol is bacteriostatic and is used in combination to prevent the emergence of resistance to other drugs. It is given orally. Its major side-effect is retrobulbar neuritis; this however does not occur at the usual dosage. Ethambutol has replaced para–aminosalicylic acid (PAS) almost entirely among adults.

THE SECOND–LINE DRUGS

Fluoroquinolones

Ciprofloxacin, ofloxacin, levofloxacin, moxifloxacin and gatifloxacin are active against *M. tuberculosis*, even those resistant to other drugs. They are given orally or IV. They are useful in treating infections resistant to standard drugs and in cases with relapse.

Ethionamide

Ethionamide is structurally related to INH and acts by inhibiting the mycolic acid synthesis. It is effective against bacilli resistant to other drugs and has proved effective in infections due to atypical mycobacteria. It is effective against intracellular as well as extracellular organisms.

Capreomycin

It is bactericidal. Its mechanism of action, pharmacokinetics and adverse reactions are similar to those of streptomycin. It should be administered with caution in presence of renal impairment.

Kanamycin and Amikacin

They are bactericidal and are active against bacilli resistant to streptomycin, INH and cycloserine.

Cycloserine

The drug is mainly bacteriostatic. It is effective against bacilli resistant to INH or streptomycin and against atypical mycobacteria, although antitubercular activity is less than that of these two drugs. It acts by inhibiting the synthesis of the bacterial cell wall.

Thioacetazone

It is a bacteriostatic drug. It rapidly diffuses into various body tissues and also crosses the placenta barrier. It is also secreted in milk. It should never be used in HIV patients as it can cause severe and fatal skin reactions. Side-effects include gastrointestinal disturbances, blurring of vision, haemolytic anaemia and urticaria. The incidence of these side-effects seem to differ in different ethnic groups.

Macrolides

Newer macrolides azithromycin and clarithromycin also have action against tubercular bacilli. They are used to treat atypical mycobacterial infection and cases with relapse.

Antituberculosis drugs can also be grouped according to their efficacy, experience in use and drug class. The different groups are as follows *(27)* :

Alternative method of grouping anti-TB agents

Grouping	Drugs
Group 1 : First-line oral anti-TB agents	Isoniazid (H); Rifampicin (R); Ethambutol (E); Pyrazinamide (Z)
Group 2 : Injectable anti-TB agents	Streptomycin (S); Kanamycin (Km); Amikacin (Am); Capreomycin (Cm); Viomycin (Vm).
Group 3 : Fluoroquinolones	Ciprofloxacin (Cfx); Ofloxacin (Ofx); Levofloxacin (Lvx); Moxifloxacin (Mfx); Gatifloxacin (Gfx)
Group 4 : Oral second-line anti-TB agents	Ethionamide (Eto); Prothionamide (Pto); Cycloserine (Cs); Terizadone (Trd); para-aminosalicylic acid (PAS)
Group 5 : Agents with unclear efficacy (not recommended by WHO for routine use in MDR-TB patients)	Clofazimine (Cfz); Linezolid (Lzd); Amoxicillin/Clavulanate (Amx/Clv); thioacetazone (Thz); imipenem/cilastatin (Ipm/Cln); high-dose isoniazid (high-dose H); Clarithromycin (Clr)

For dosage of different second-line drugs, kindly refer to page 191.

Most TB patients complete their treatment without any significant drug side-effects. However, a few patients do develop major reactions and it is important to monitor clinically all the patients. A patient who develops one of the following reactions must never receive that drug again *(19)* :

Reaction	Drug responsible
a. Severe rash, agranulocytosis	Thioacetazone
b. Hearing loss or disturbed balance	Streptomycin
c. Visual disturbance (poor vision and colour perception)	Ethambutol
d. Renal failure, shock or thrombocytopenia	Rifampicin
e. Hepatitis	Pyrazinamide

Two-phase chemotherapy

It is well recognized that there are two phases in the effective treatment of tuberculosis : (i) the first is a short, aggressive or intense phase, early in the course of treatment, lasting 1–3 months. During this intensive phase, three or more drugs are combined to kill off as many bacilli as possible. The more rapidly the bacilli are killed initially, the less likely are "persisters" to emerge. The risk of relapse is also lessened. (ii) the second or "continuation" phase is aimed at sterilizing the smaller number of dormant or persisting bacilli. In the standard anti-tuberculous therapy, the duration of treatment was not less than 18 months to achieve complete sterilization of the bacilli. With the introduction of rifampicin and pyrazinamide, this period is now successfully reduced to 6–9 months.

DOMICILIARY TREATMENT

The self-administration of drugs (generally oral drugs) by the patients themselves without recourse to hospitalization is called domiciliary or ambulatory treatment. The classical controlled clinical trials *(28)* carried out at the Tuberculosis Chemotherapy Centre, Chennai showed that the incidence of tuberculosis was no greater in the contacts of patients treated at home than in the contacts of patients treated in sanatoria. It is now universally accepted that with good chemotherapy, hospital treatment has no advantage over domiciliary

treatment, and domiciliary treatment is to be preferred because in the long run, it is so much cheaper than hospital treatment, and that it can be managed by the primary health care system and the general health services of the country. It may be mentioned that it was this study, the classical Chennai Study, that prompted a radical departure from the traditional sanatorium to ambulatory or domiciliary treatment.

LONG-COURSE REGIMENS

The classical (long-course) conventional chemotherapeutic regimens depended upon the use of INH along with one or two bacteriostatic or "companion" drugs. The main role of the bacteriostatic drugs was to prevent the emergence of INH-resistant strains. Sterilization of the lesions thus depended entirely on INH, and 18 months of treatment was required to avoid relapses. Two main types of drug regimens were formulated for application in India. These are :

a. daily regimens
b. bi-weekly or intermittent regimens

SHORT-COURSE CHEMOTHERAPY

For a long time, the standard duration of tuberculosis chemotherapy was 18 months. In 1972, Wallace Fox and his colleagues from the British Medical Research Council showed that the addition of rifampicin or of pyrazinamide to regimens containing INH made it possible to reduce the duration of treatment.

There are a number of advantages of short–course chemotherapy, viz. rapid bacteriological conversion, lower failure rates and a reduction in the frequency of emergence of drug–resistant bacilli. Patient compliance is improved, they become non-infectious earlier. The disadvantage is that the high cost of short-term chemotherapy militates against its wider use in developing countries.

There are now a number of short–course regimens of 6 months duration that are highly effective, of low toxicity, and well–tolerated. These potent regimens are based on an initial intensive phase with 4 drugs (INH, rifampicin and pyrazinamide, supplemented by either streptomycin or ethambutol) for a period of 2 months, followed by 2 drugs in the continuation phase, (INH plus rifampicin or thioacetazone) given daily or intermittently. The treatment must be fully supervised and monitored mainly by bacteriological examination.

DIRECTLY OBSERVED TREATMENT, SHORT COURSE (DOTS) CHEMOTHERAPY

DOTS is a strategy to ensure cure by providing the most effective medicine and confirming that it is taken. It is the only strategy which has been documented to be effective world–wide on a programme basis. In DOTS, during the intensive phase of treatment a health worker or other trained person watches as the patient swallows the drug in his presence. During continuation phase, the patient is issued medicine for one week in a multiblister combipack, of which the first dose is swallowed by the patient in the presence of health worker or trained person. The consumption of medicine in the continuation phase is also checked by return of empty multiblister combipack, when the patient comes to collect medicine for the next week. The drugs are provided in patient–wise boxes with sufficient shelf-life. In the programme alternate–day treatment is used.

The cases are divided into two types of categories – category I and category II. Table 3 shows the type of cases included in each kind of category, the treatment regimen and the duration of treatment *(29)*.

TABLE 3

Treatment categories and sputum examination schedule in DOTS chemotherapy in India

TREATMENT REGIMEN			SPUTUM EXAMINATIONS FOR PULMONARY TB			
Category of treatment	Type of patient	Regimen*	Pre-treatment sputum	Test at month	IF : result is	→ THEN :
New cases Category I Red Box	New sputum smear-positive New sputum smear-negative New extra-pulmonary** New others	$2(HRZE)_3$ + $4(HR)_3$	+	2	–	Start continuation phase, test sputum again at 4 and 6 months#
					+	Continue intensive phase for one more month# Complete the treatment in 7 months
Previously Treated Category II Blue Box	Sputum smear-positive Relapse*** Sputum smear-positive Failure*** Sputum smear-positive treatment after default others	$2(HRZES)_3$ + $1(HRZE)_3$ + $5(HRE)_3$	+	3	–	Start continuation phase, test sputum again at 5 months 6 months, completion of treatment#
					+	Continue intensive phase for one more month, test sputum again at 4 months if sputum is positive send sputum for culture and drug sensitivity as it might be a case of MDR-TB#

* The number before the letters refers to the number of months of treatment. The subscript after the letters refers to the number of doses per week. H: Isoniazid (600 mg), R: Rifampicin (450 mg), Z: Pyrazinamide (1500 mg), E: Ethambutol (1200 mg), S: Streptomycin (750 mg). Patients who weigh more than 60 kg receive additional Rifampicin 150 mg. Patients more than 50 years old receive streptomycin 500 mg. Patients in categories I and II, who have a positive sputum smear at the end of the initial intensive phase, receive an additional month of intensive phase treatment.

** Examples of seriously ill extra-pulmonary TB cases are meningitis, disseminated TB, tuberculous pericarditis, peritonitis, bilateral or extensive pleurisy, spinal TB with neurological complications and intestinal and genito-urinary TB.

*** In rare and exceptional cases, patients who are sputum smear-negative or who have extra-pulmonary disease can have Relapse or Failure. This diagnosis in all such cases should always be made by an MO and should be supported by culture or histological evidence of current, active tuberculosis. In these cases, the patient should be categorized as 'Other' and given Category II treatment.

\# Any patient treated with Category I who has a positive smear at 5 months of treatment should be considered a Failure and started on Category II treatment, afresh. If category I sputum smear –ve case fails to improve or if patient develops pulmonary signs and positive smear at the end of intensive phase, it is considered treatment failure. Start category II treatment and confirm failure by culture and perform DST.

Source : *(30, 31)*

MANAGEMENT OF PATIENTS WHO INTERRUPT TREATMENT

Table 4, 5 and 6 show the management of patients who interrupt the treatment under revised national tuberculosis control programme.

Daily self administered non-DOTS regime is followed in exceptional cases when there is adverse reaction to drugs used in short-course chemotherapy or when the patient cannot comply with this regime. The treatment is given as follows :

(1) Non-DOTS regime 1 (ND1) : For new smear positive pulmonary seriously ill patients and extrapulmonary seriously ill patients – 2 (SHE) + 10 (HE)

(2) Non-DOTS regime 2 (ND2) : For smear negative pulmonary not seriously ill patients and extra pulmonary not seriously ill patients – 12 (HE).

Please refer to page 180 for the treatment outcome definitions.

TABLE 4

Management of patients who were smear-negative at diagnosis and who interrupt treatment

Treatment received before interruption	Length of interruption	Do a sputum smear examination	Result of sputum smear examination	Outcome	Re-registration	Treatment
Less than 1 month	Less than 2 months	No	–	–	–	Resume treatment and complete all doses
	2 months or more	Yes	Negative	–	–	Resume treatment
			Positive	Default	New	Begin CAT I afresh
More than 1 month	Less than 2 months	No	–	–	–	Resume treatment and complete all doses
	More than 2 months	Yes	Negative	–	–	Resume treatment and complete all doses
			Positive	Default	Treatment after default	Begin CAT II treatment afresh

Source : *(29)*

TABLE 5

Management of new smear-positive cases who interrupt treatment (Category I)

Treatment received before interruption	Length of interruption	Do a sputum smear examination	Result of sputum smear examination	Outcome	Re-registration	Treatment
Less than 1 month	Less than 2 weeks	No	–	–	–	Continue CAT I*
	2-7 weeks	No	–	–	–	Start again on CAT I**
	8 weeks or more	Yes	Positive	Default	New	Start again on CAT I**
			Negative	–	–	Continue CAT I*
1-2 months	Less than 2 weeks	No	–	–	–	Continue CAT I*
	2-7 weeks	Yes	Positive	–	–	1 extra month of intensive phase of CAT I
			Negative	–	–	Continue CAT I*
	8 weeks or more	Yes	Positive	Default	Treatment After Default	Start on CAT II**
			Negative	–	–	Continue CAT I*
More than 2 months	Less than 2 weeks	No	–	–	–	Continue CAT I*
	2-7 weeks	Yes	Positive	Default***	Other	Start on CAT II**
			Negative	–	–	Continue CAT I*
	8 weeks or more	Yes	Positive	Default	Treatment After Default	Start on CAT II **
			Negative	–	–	Continue CAT I*

* A patient must complete all **24 doses** of the initial intensive phase. For example, if a patient has to continue his previous treatment and he took 1 month of treatment (12 doses) before interrupting, he will have to take 1 more month (12 doses) of the intensive phase treatment. He will then start the continuation phase of treatment.

** A patient who must 'start again' will *restart treatment from the beginning.*

*** Although this patient does not strictly fit the definition of default, default most closely describes the outcome of this patient, although at re-registration they should be categorized as 'Other'.

Source : *(29)*

TABLE 6

Management or retreatment of smear-positive cases who interrupt treatment (Category II)

Treatment received before interruption	Length of interruption	Do a sputum smear examination	Result of sputum smear examination	Outcome	Re-registration	Treatment
Less than 1 month	Less than 2 weeks	No	–	–	–	Continue CAT II*
	2-7 weeks	No	–	–	–	Start again on CAT II**
	8 weeks or more	Yes	Positive	Default	Treatment After Default	Start again on CAT II**
			Negative	–	–	Continue CAT II*
1-2 months	Less than 2 weeks	No	–	–	–	Continue CAT II*
	2-7 weeks	Yes	Positive	–	–	1 extra month of intensive phase of CAT II
			Negative	–	–	Continue CAT II*
	8 weeks or more	Yes	Positive	Default	Treatment After Default	Start again on CAT II**
			Negative	–	–	Continue CAT II*
More than 2 months	Less than 2 weeks	No	–	–	–	Continue CAT II*
	2-7 weeks	Yes	Positive	Default**	Other	Start again on CAT II
			Negative	–	–	Continue CAT II*
	8 weeks or more	Yes	Positive	Default	Treatment After Default	Start again on CAT II
			Negative	–	–	Continue CAT II*

* A patient must complete all **36 doses** of the initial intensive phase.

** Although this patient does not strictly fit the definition of default, default most closely describes the outcome of this patient, although at re-registration they should be categorized as 'Other'.

DOTS–PLUS TREATMENT FOR MDR-TB *(7)*

Recognizing that the diagnosis and treatment of MDR-TB is complex, RNTCP has developed national guidelines based on the WHO recommended international DOTS-Plus guidelines. Drug resistance may be suspected based on history of prior treatment (e.g. smear positive case after repeated treatment courses, category II failure etc.) and/or close exposure to a possible source case confirmed to have drug-resistant TB. Please refer to chapter 7 for diagnostic criteria followed by RNTCP. As per guidelines, the diagnosis of MDR-TB is at the Intermediate Reference laboratories accredited to perform culture and drug sensitivity testing (DST). After diagnosis, the treatment of MDR-TB is initiated at designated DOTS–Plus sites, which are established in tertiary care centres (like medical colleges, large speciality hospitals) at least one in each state. The DOTS–Plus sites have qualified staff available to manage patient; using DOTS–Plus regimen; using the second-line drugs, given under DOT and standardized follow-up protocol; and have system in place to deliver ambulatory DOT after an initial short period of in-patient care to stabilize the patient.

Pre-treatment evaluation *(18)*

Since the drugs used for the treatment of MDR-TB are known to produce adverse effects, a proper pre-treatment evaluation is essential to identify patients who are at increased risk of developing such adverse effects. The pre-treatment evaluation includes the following:

1. Detailed history (including screening for mental illness, drug/alcohol abuse etc.)
2. Weight
3. Height
4. Complete blood count
5. Blood sugar to screen for diabetes mellitus
6. Liver function tests
7. Blood urea and S. creatinine to assess the kidney function
8. TSH levels to assess the thyroid function
9. Urine examination – routine and miscroscopic
10. Pregnancy test (for all women in the child-bearing age group)
11. Chest X-ray

All MDR-TB cases are offered referral for counselling and HIV testing at the nearest centre. Patients should receive counselling on the nature and duration of treatment, need for regular treatment and possible side effects of these drugs and the consequences of irregular treatment or pre-mature cessation of treatment. It is advisable to involve close family members during the counselling, since family support is an essential component in the management. Patients should be advised to report any side-effects experienced by them. Female patients should receive special counselling on family planning.

While the MDR-TB case is undergoing pre-treatment evaluation, the DTO should ensure an initial home visit to verify the address and meet the family members. A DOT provider (who can either be a health care worker, a community worker or a community volunteer), should be identified in consultation with the patient. The DOT centre can be either at the sub-centre of the health system or in the community. The DOT provider should be given training for drug administration, identification of adverse effects during treatment and the frequency of follow up.

Regimen for MDR-TB *(18)*

This regimen comprises of 6 drugs – Kanamycin, Levofloxacin, Ethionamide, Pyrazinamide, Ethambutol and Cycloserine during 6–9 months of the intensive phase and 4 drugs–Levovfloxacin, Ethionamide, Ethambutol and Cycloserine during the 18 months of the continuation phase.

RNTCP regimen for MDR-TB :
6 (9) Km Lvx Eto Cs Z E / 18 Lvx Eto Cs E
(Reserve/substitute drugs : PAS, Mfx, Cm)

Special adjustments to the standard regimen for MDR–TB are as follows:

- In case of intolerance to Kanamycin, then Capreomycin (or PAS if injectable agent not feasible) is the available substitute drug.
- In case of intolerance leading to discontinuation of other oral second-line drug, p-aminosalicylic acid (PAS) is the available substitute drug.
- Baseline Kanamycin mono-resistance should lead to substitution of Kanamycin with Capreomycin.
- Baseline Ofloxacin mono-resistance should lead to substitution of Levofloxacin with the combination of Moxifloxacin and PAS.
- Baseline Ofloxacin and Kanamycin resistance (i.e. XDR-TB) should lead to declaration of outcome, referral to DR-TB Centre for pre-treatment evaluation for regimen for XDR-TB.

Drug dosage and administration

All drugs should be given in a single daily dosage under directly observed treatment (DOT) by a DOT provider. All patients will receive drugs under direct observation on 6 days of the week. On Sunday, the oral drugs will be administered unsupervised whereas injection Kanamycin will be omitted. If intolerance occurs to the drugs, Ethionamide, Cycloserine and PAS may be split into two dosages and the morning dose administered under DOT. The evening dose will be self-administered. The empty blister packs of the self-administered doses will be checked the next morning during DOT. Pyridoxine should be administered to all patients on regimen for MDR-TB.

The drug dosage for MDR-TB cases are decided according to the weight bands as shown in Table 7.

TABLE 7

Regimen for MDR-TB dosage and weight–band recommendations

Drug	16–25 kgs	26–45 kgs	46–70 kgs
Kanamycin	500 mg	500 mg	750 mg
Levofloxacin	250 mg	750 mg	1000 mg
Ethionamide	375 mg	500 mg	750 mg
Ethambutol	400 mg	800 mg	1200 mg
Pyrazinamide	500 mg	1250 mg	1500 mg
Cycloserine	250 mg	500 mg	750 mg
Pyridoxine	50 mg	100 mg	100 mg
Na-PAS (80% weight/vol)	5 gm	10 gm	12 gm
Moxifloxacin (Mfx)	200 mg	400 mg	400 mg
Capreomycin (Cm)	500 mg	750 mg	1000 mg

Source : *(18)*

If a patient gains 5 kgs or more in weight during treatment and crosses the weight-band range, the DR-TB centre committee may consider moving the patient to the higher weight-band drug dosages. Similarly if a patient loses 5 kgs or more in weight during treatment and crosses the weight band the DR-TB centre committee may consider moving the patient to the lower weight band. The new higher/lower dosages are provided whenever the patient is due for the next supply of drugs in the normal course of treatment and not as soon as change of weight is noted.

Large majority of the patients fall into one of the above weight bands. However, there are some cases weighing less than 16 kg and more than 70 kg who may require some alteration in the dosage of the drugs in the MDR-TB regimen.

1. The dosages of 2nd the line drugs for MDR-TB cases in paediatric age group weighing < 16 kg are as shown in Table 8.

TABLE 8

Dosage of regimen for MDR-TB for paediatric age group < 16 kg

Drug	Daily dose - mg/kg body weight
Kanamycin / Capreomycin	15–20 mg/kg
Levofloxacin / Moxifloxacin	7.5–10 mg/kg
Ethionamide	15–20 mg/kg
Cycloserine	15–20 mg/kg
Ethambutol	25 mg/kg
Pyrazinamide	30–40 mg/kg
(Na-PAS)	150 mg/kg

2. The dosages for > 70 kg higher weight patients include use of additional dosages of some 2nd line drugs, taking the dosage to Kanamycin/Capreomycin (1 gm), Ethionamide (1 gm), Cycloserine (1 gm), Ethambutol (1.6 gm) and Pyrazinamide (2 gm). Other drugs dosages would remain the same. All these are well within the maximum permissible dosage for each drug as per the WHO guidelines.

Treatment duration for regimen for MDR-TB (18)

The treatment is given in two phases, the intensive phase (IP) and the continuation phase (CP). The total duration of treatment for regimen for MDR-TB is 24–27 months, depending on the IP duration. IP should be given for at least six months. After 6 months of treatment, the patient will be reviewed and the treatment changed to CP if the 4th or 5th month culture result in solid or liquid culture is negative respectively. If the 4th or 5th month culture result remains positive, the treatment is extended by 1 month. Extension of IP beyond 1 month will be decided on the results of sputum culture of 5th or 6th and 6th or 7th months. If the result of the 4th month culture is still awaited after 6 months of treatment, the IP is extended until the result is available, with further treatment being decided according to the culture result. The IP can be extended upto a maximum of 3 months after which the patient will be initiated on the CP irrespective of the culture result. The recommended duration for CP is 18 months.

Discharge from DR-TB Centres and transition to decentralized supervised treatment

Patients admitted at the DR-TB centre, if clinically appropriate, may be discharged 7 days after treatment

initiation to their district of residence with a maximum of 7 day supply of drugs and arrangement for injections in transit. The respective DTO should be informed of the patients discharge three days prior to the actual time of discharge. The DTO will inform the respective MO-PHI and the identified DOT provider about the expected discharged of the patient. The monthly drug box and the patient records will be passed on to the identified DOT provider from the respective TU. Local arrangements will need to be made for daily injections during the intensive phase.

Regimen for XDR-TB *(18)*

All XDR-TB patients should also be subject to a repeat full pre-treatment evaluation, but also including consultation by a thoracic surgeon for consideration of surgery. MDR-TB patients diagnosed as XDR-TB would be given an outcome of "Switched to regimen for XDR-TB". The decision and initiation of regimen for XDR-TB is to be taken by the concerned DR-TB centre committee.

The *Intensive Phase* (6–12 months) consists of 7 drugs – Capreomycin (Cm), PAS, Moxifloxacin (Mfx), High dose INH, Clofazimine, Linezolid, and Amoxyclav

The *Continuation Phase* (18 months) consists of 6 drugs - PAS, Moxifloxacin (Mfx), High dose INH, Clofazimine, Linezolid, and Amoxyclav.

RNTCP regimen for XDR-TB :

6–12 Cm, PAS, Mfx, High dose-H, Cfz, Lzd, Amx/Clv/
18 PAS, Mfx, High dose-H, Cfz, Lzd, Amx/Clv
(Reserve/Substitute drugs : Clarithromycin, Thiacetazone)

The dosage of the drugs would vary as per the weight of the patient (<45 Kg or >45 Kg). All drugs are to be given on a daily basis. Injections of Capreomycin will be given for 6 days/week (not on sundays). All morning doses are to be supervised by the DOT provider except on sundays. After taking DOT for morning doses on saturday, next day medicines would be given to the patient to be taken at home on sunday. Empty blisters of medicines taken unsupervised in the evening, and on sundays are to be collected by DOT provider.

Regimen for XDR-TB dosage and weight band recommendations are as follows

Drugs	Dosage/day	
	≤ 45 Kgs	> 45 Kgs
Inj. Capreomycin (Cm)	750 mg	1000 mg
PAS	10 gm	12 gm
Moxifloxacin (Mfx)	400 mg	400 mg
High dose INH (High dose-H)	600 mg	900 mg
Clofazimine (Cfz)	200 mg	200 mg
Linezolid (Lzd)	600 mg	600 mg
Amoxyclav (Amx/Clv)	875/125 mg BD	875/125 mg BD
Pyridoxine	100 mg	100 mg
Reserve/Substitute drugs		
Clarithromycin (Clr)	500 mg BD	500 mg BD
Thiacetazone (Thz)#	150 mg	150 mg

Depending on availability, not to be given to HIV positive cases.

Source : *(18)*

The reserve/substitute drugs would be used in the following conditions:

- In case the patient was on PAS, PAS will be replaced with one of the reserve drugs in the regimen for XDR-TB
- If the patient is unable to tolerate one or more of the drugs
- If the patient is found to be resistant to Capreomyicn.

Duration of regimen for XDR-TB (18)

The Regimen for XDR-TB would be of 24–30 months duration, with 6–12 months Intensive Phase (IP) and 18 months Continuation Phase (CP). The change from IP to CP will be done only after achievement of culture conversion i.e. 2 consecutive negative cultures taken at least one month apart. In case of delay in culture conversion, the IP can be extended from 6 months upto a maximum of 12 months. In case of extension, the DR-TR centre committee, which will be responsible for initiating and monitoring the regimen for XDR-TB, can decide on administering Capreomycin injection intermittenly (3 times/week) for the months 7 to 12.

Direct observation of treatment remains even more crucial in XDR-TB as this is the last chance at successful treatment that these patients will have. Because of the use of drugs with different toxicity profiles, XDR-TB requires more intensive monitoring during follow-up.

- Complete blood count with platelets count : weekly in first month, then monthly to rule out bone marrow suppression and anaemia as a side-effect of Linezolid.
- Kidney function test: monthly creatinine and addition of monthly serum electrolytes to the monthly creatinine during the period that Inj. Capreomycin is being administered.
- Lever function tests : monthly in IP and 3 monthly during CP.
- CXR every 6 months.

Management of treatment interruptions and default for M/XDR-TB patients

All efforts should be made to ensure that M/XDR-TB patients do not interrupt treatment or default. Action should be taken to promptly retrieve patients who fail to come for DOT. The following situations may be seen in case of treatment interruption.

1. *Patients in IP/CP who miss doses:* All the missed doses during IP must be completed prior to switching the patient to CP. Similarly all missed doses during CP must be administered prior to ending treatment.

2. *Patients who interrupt treatment for less than 2 months during IP:* When the patient returns to resume treatment the IP should be continued, however the duration of treatment will be extended to complete IP. The follow up cultures should be done as per the revised schedule.

3. *Patients who interrupt treatment for less than 2 months during CP:* When the patient returns to resume treatment, the CP should be continued, however the duration of treatment will be extended to complete the CP. The follow up cultures should be done as per the revised schedule.

4. *Patients who default (interrupt treatment for 2 or more months) and return back for treatment:* Such patients should be given an outcome of "default" and then re-registered for further treatment which is based on the duration of default as shown in Fig. 1 and 2. Re-registration of patients will be done by the DR-TB Centre.

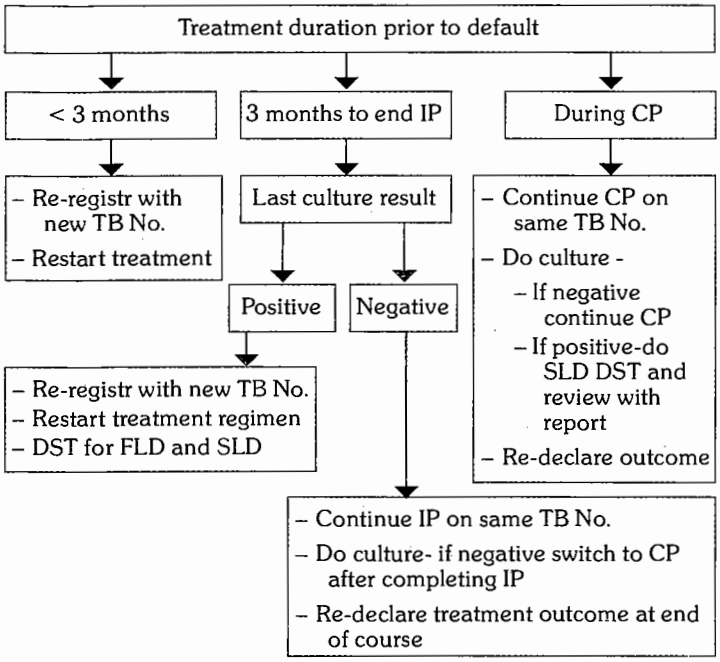

FIG. 1
Algorithm for management of M/XDR patients who default and return for treatment within 6 months of discontinuing regimen for M/XDR–TB

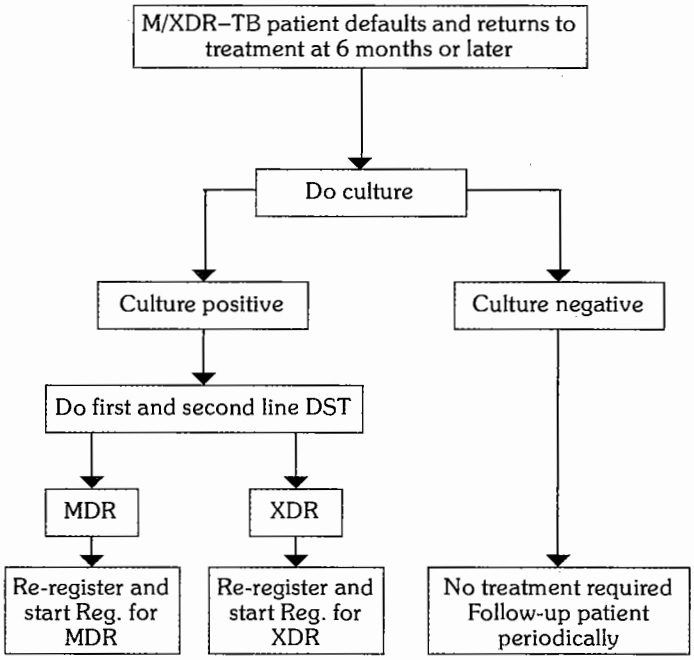

FIG. 2
Algorithm for management of M/XDR patients who default and return for treatment after 6 months.

Follow-up schedule during DR-TB treatment (18)

Schedule for sputum smear microscopy, culture and sensitivity follow up examinations

	IP monthly follow-up examinations				Extension of IP (1–3 months)			CP Quarterly follow-up examination in months						
	1st FU	2nd FU	3rd FU	4th FU				I qtr		II qtr	III qtr	IV qtr	V qtr	VI qtr
No IP extension	3	4	5	6	-	-	-	7	9	12	15	18	21	24
IP extension 1 month	3	4	5	6	7	-	-	8	10	13	16	19	22	25
IP extension 2 months	3	4	5	6	7	8	-	9	11	14	17	20	23	26
IP extension 3 months	3	4	5	6	7	8	9	10	12	15	18	21	24	27

* The number in each cell indicates the month of follow-up examination
** CP will have follow up sputum examination on 7 occasions irrespective of the duration of treatment

The first quarter in the CP will have two examinations and the rest 5 will be in the subsequent quarters till the end of treatment

- Two specimens for AFB at the end of 3, 4, 5, 6, 7, 9, 12, 15, 18, 21, 24 months
- Two specimens for culture at the end of 3, 4, 5, 6, 7, 9, 12, 15, 18, 21, 24 months
- Monthly weight
- Chest radiograph during pre-treatment evaluation, end of IP, end of treatment and whenever clinically indicated
- Physician evaluation including adverse drug reaction monitoring every month for six months, then every three months for two years
- S. Creatinine monthly for first 3 months, then every 3 months during the injectable phase
- Thyroid Function Test during pre-treatment evaluation and when indicated

Please refer to page 180 for the treatment outcome definitions of DOTS-Plus regimen.

CHILDHOOD TUBERCULOSIS

Cases of tuberculosis in children usually represent between 6–8 per cent of all tuberculosis in the age group of under 15 years *(4)*. The source of infection to a child is usually an adult, often a family member with sputum smear-positive tuberculosis. The frequency of childhood TB in a given population depends on : (a) the number of infectious cases; (b) closeness of contact with an infectious case; (c) the age of child when exposed to TB; and the age structure of the population.

Children rarely have sputum smear-positive TB and it is unlikely that they are a powerful source of transmission of TB. Tuberculosis in children is mainly due to failure of TB control in adults. The risk of infection to a child depends on extent of exposure to infectious droplet nuclei. An infant whose mother has sputum smear-positive PTB has a high chance of becoming infected. The chance of developing disease is greatest shortly after infection, and steadily decreases as the time goes by. Because of less-developed immune system, children under 5 years of age are more prone to develop (up

to 20 per cent) the disease mostly within 2 years following infection *(19)*. The commonest age of childhood TB disease is 1 to 4 years. Young age is a risk factor for spread of disease to other parts of the body, i.e. dissemination.

In order to simplify the management of paediatric TB, RNTCP in association with Indian Academy of Paediatrics (IAP) has described criteria for suspecting TB among children, has separate algorithms for diagnosing pulmonary TB and peripheral TB lymphadenitis and a strategy for treatment and monitoring patients who are on treatment. In brief, TB diagnosis is based on clinical features, smear examination of sputum where this is available, positive family history, tuberculin skin testing, chest radiography and histo-pathological examination as appropriate. The treatment strategy comprises of components. First, as in adults, children with TB are classified, categorized, registered and treated with intermittent short-course chemotherapy (thrice-weekly therapy from treatment initiation to completion), given under direct observation of a treatment provider (DOT provider) and the disease status is monitored during the course of treatment. Based on their pre-treatment weight, children are assigned to one of the pre-treatment weight bands and are treated with good quality anti-TB drugs through "ready-to-use" patient-wise boxes containing the patients' complete course of anti-TB drugs, made available to every registered TB patient according to programme guidelines. India is the first country to introduce paediatric patient wise boxes *(4)*.

Diagnosis of Paediatric TB (0–14 years)

A new diagnostic algorithm is developed for pulmonary TB, the commonest type of extra pulmonary TB (Lymph node TB) and for other types of extra-pulmonary TB (Fig. 3 a & b).

a. All efforts should be made to demonstrate bacteriological evidence in the diagnosis of paediatric TB. In cases where sputum is not available for examination or sputum microscopy fails to demonstrate AFB, alternative specimens (gastric lavage, induced sputum, bronco-alveolar lavage) should be collected, depending upon the feasibility, under the supervision of a paediatrician.

b. A positive tuberculin skin test / mantoux positive is defined as 10 mm or more induration. The optimal strength of tuberculin 2 TU (RT 23 or equivalent) is to be used for diagnosis in children.
   - There is no role for inaccurate and inconsistent diagnostics like serology (IgM, IgG, IgA antibodies against MTB antigens), various non-validated commercial PCR tests and BCG test.
   - There is no role of IGRAs in clinical practice for the diagnosis of TB.

c. Loss of weight was defined as a loss of more than 5% of the highest weight recorded in the past three months.

Treatment

The intermittent therapy will remain the mainstay of treating paediatric patients. However, children with severe disseminated disease, neuro-tuberculosis and seriously ill hospitalized children having high likelihood of vomiting and intolerance to oral drugs, an initial daily supervised therapy during their stay in the hospital is needed. After discharge they will be given thrice weekly DOT regimen dosage.

The daily doses (mg per kg of body weight per day) are as follows : Rifampicin 10–12 mg/kg (max 600 mg/day), Isoniazid 10 mg/kg (max 300 mg/day), Ethambutol 20–25 mg/kg (max 1500 mg/day), PZA 30–35 mg/kg (max 2000 mg/day) and Streptomycin 15 mg/kg (max 1 gm/day). Table 9 shows the treatment categories and regimens for paediatric cases.

Drug dosages in children : There will be six weight bands and three generic patient-wise boxes to be used in combination to treat patients in these six weight bands. The newer weight bands are 6–8 kg., 9–12 kg., 13–16 kg., 17–20 kg., 21–24 kg. and 25–30 kg. However, a lead time of at least 2 years is required for the programme to procure and introduce the newer generic patient-wise boxes.

TB preventive therapy : The dose of INH for chemoprophylaxis is 10 mg/kg (instead of earlier recommended dosage of 5 mg/kg) administered daily for 6 months. TB preventive therapy should be provided to:

a. All asymptomatic contacts (under 6 years of age) of a smear positive case, after ruling out active disease and irrespective of their BCG or nutritional status.
b. Chemoprophylaxis is also recommended for all HIV infected children who either had a known exposure to an infectious TB case or are tuberculin skin test (TST) positive (≥5 mm induration) but have no active TB disease.
c. All TST positive children who are receiving immunosuppressive therapy (e.g. children with nephrotic syndrome, acute leukemia, etc).
d. A child born to mother, who was diagnosed to have TB in pregnancy, should receive prophylaxis for 6 months, provided congenital TB has been ruled out. BCG vaccination can be given at birth even if INH chemoprophylaxis is planned.

TABLE 9

Treatment categories and regimens for childhood tuberculosis

Category of treatment	Type of patients	TB treatment regimens	
		Intensive phase	Continuation phase
New cases	– New smear-positive pulmonary tuberculosis (PTB) – New smear-negative PTB – New extra-pulmonary TB.	$2H_3R_3Z_3E_3^*$	$4H_3R_3$
Previously treated cases	– Relapse, failure to respond or treatment after default – Re-treatment others	$2S_3H_3R_3Z_3E_3$ + $1H_3R_3Z_3E_3$	$5H_3R_3E_3$

H=Isoniazid, R=Rifampicin, Z=Pyrazinamide, E=Ethambutol, S=Streptomycin

Source : *(4)*

Treatment during pregnancy *(18)*

Tuberculosis in pregnancy is usually treated with isoniazid, rifampicin and ethambutol for 2 months, followed by isoniazid and rifampicin for an additional 7 months. Ethambutol can be stopped after the first month if isoniazid and rifampicin susceptibility is confirmed. Since the risk of teratogenicity with pyrazinamide has not been clearly defined, pyrazinamide should be used only if resistance to other drugs is documented and susceptibility to pyrazinamide is likely. Streptomycin is contraindicated in pregnancy because it may cause congenital deafness. Pregnant women taking isoniazid should receive pyridoxin (Vitamin B_6), 10–25 mg orally once a day, to prevent peripheral neuropathy.

Pregnancy with MDR-TB

All MDR-TB suspects and patients of child-bearing age should be tested for pregnancy as part of pre-treatment evaluation and while on treatment, if there is a history of amenorrhoea of any duration. They should be advised to use birth control measures because of the potential risk to both mother and foetus. Oral contraceptives should be avoided. Use of barrier methods (condoms/diaphrams), IUDs are recommended, based on individual preference and eligibility. The management of MDR-TB patients with pregnancy is summarized in Fig. 4.

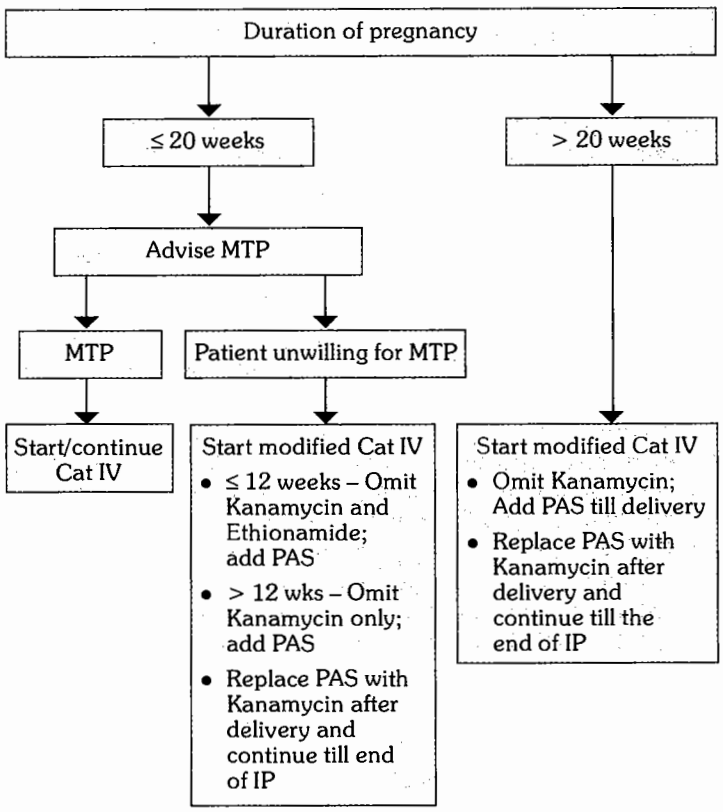

FIG. 4
Management of pregnancy with MDR-TB

In the end it may be stated that the main problem of chemotherapy today is not the need to introduce new regimens or more potent drugs, but to apply the existing ones successfully. The cornerstone of successful chemotherapy is adequate and regular drug intake. Patient compliance is critically important throughout the prescribed period of treatment. All other considerations are secondary.

BCG VACCINATION

Ever since Koch discovered *M. tuberculosis,* attempts have been made to prepare a prophylactic vaccine against tuberculosis using either attenuated or killed tubercle bacilli. Initially BCG was given orally during 1921 to 1925. The first human was vaccinated by the intradermal technique in 1927. Recognition of the value of BCG came in 1948 when it was accepted by tuberculosis workers from all over the world as a safe preventive measure.

(1) AIM : The aim of BCG vaccination is to induce a benign, artificial primary infection which will stimulate an acquired resistance to possible subsequent infection with virulent tubercle bacilli, and thus reduce the morbidity and mortality from primary tuberculosis among those most at risk.

(2) VACCINE : BCG is the only widely used live bacterial vaccine. It consists of living bacteria derived from an attenuated *bovine* strain of tubercle bacilli. The bacilli used for vaccine production are descendants of the original Calmette strain of BCG. Due to different methods of maintenance in various vaccine–production laboratories, many substrains have evolved during the past few decades. The WHO has recommended the "Danish 1331" strain for the production of BCG vaccine. Since January 1967, the BCG Laboratory at Guindy, Chennai, has been using the "Danish 1331" strain for the production of BCG vaccine *(32)*. Emphasis has been laid on regular checking of the quality of vaccines at the International Reference Centre for BCG quality control at Copenhagen.

(3) TYPES OF VACCINE : There are two types of BCG vaccine – the liquid (fresh) vaccine and the freeze-dried vaccine. Freeze-dried vaccine is a more stable preparation than liquid vaccine with vastly superior keeping qualities. Present–day vaccines are distributed in the freeze-dried form.

BCG vaccine is stable for several weeks at ambient temperature in a tropical climate, and for up to 1 year if kept away from direct light and stored in a cool environment preferably refrigerated at a temperature below 10 deg C *(33)*.

The vaccine must be protected from exposure to light during storage (wrapped up in a double layer of red or black cloth) and in the field. Normal saline is recommended as a diluent for reconstituting the vaccine, as distilled water may cause irritation. The reconstituted vaccine may be used up within 3 hours, and the left–over vaccine should be discarded.

(4) DOSAGE : For vaccination, the usual strength is 0.1 mg in 0.1 ml volume *(34)*. The dose to newborn aged below 4 weeks is 0.05 ml. This is because the skin of newborn is rather thin and an intradermal injection with full dose (0.1 ml) in some of them might penetrate into deeper tissue and give rise to local abscess formation and enlarged regional (axillary) lymph nodes.

(5) ADMINISTRATION : The standard procedure recommended by WHO is to inject the vaccine intradermally using a "Tuberculin" syringe (Omega microstat syringe fitted with a 1 cm steel 26 gauge intradermal needle). The syringe and needle technique remains the most precise way of administering the desired dose. All other techniques (e.g., bifurcated needle, dermo–jet) are reported to be less accurate, and do not permit the desired dose to be injected *(35)*. If the vaccine is injected subcutaneously an abscess is more likely to develop *(36)*. The site of injection should be just above the insertion of the left deltoid muscle. If it is injected too high, too forward or too backward, the adjacent lymph nodes may become involved and tender.

A satisfactory injection should produce a wheal of 5 mm in diameter.

The vaccine must not be contaminated with an antiseptic or detergent. If alcohol is used to swab the skin, it must be allowed to evaporate before the vaccine is given.

(6) AGE : The national vaccination policies differ from country to country *(34)*. In countries where tuberculosis is prevalent and the risk of childhood infection is high (as in India), the national policy is to administer BCG very early in infancy either at birth (for institutional deliveries) or at 6 weeks of age simultaneously with other immunizing agents such as DPT and polio. BCG administered early in life provides a high level of protection, particularly against the severe forms of childhood tuberculosis and tuberculous meningitis.

In countries with a low prevalence of tuberculosis, perhaps there is a diminishing need for widespread BCG vaccination. In this situation, it would seem reasonable to restrict BCG vaccination to high risk groups, for example, hospital personnel and tuberculin-negative contacts of known cases of tuberculosis particularly multi-drug resistant TB (MDR-TB) *(33, 37)*.

(7) PHENOMENA AFTER VACCINATION : Two to three weeks after a correct intradermal injection of a potent vaccine, a papule develops at the site of vaccination. It increases slowly in size and reaches a diameter of about 4 to 8 mm in about 5 weeks. It then subsides or breaks into a shallow ulcer, rarely open, but usually seen covered with a crust. Healing occurs spontaneously within 6 to 12 weeks leaving a permanent, tiny, round scar, typically 4–8 mm in diameter. This is a normal reaction *(38)*. However, with overdosage, the local lesion and the later scar may be considerably larger and of irregular size. Normally the individual becomes Mantoux–positive after a period of 8 weeks has elapsed, but sometimes about 14 weeks are needed.

(8) COMPLICATIONS : BCG has been associated with adverse reactions which include : prolonged severe ulceration at the site of vaccination, suppurative lymphadenitis, osteomyelitis, disseminated BCG infection and death. Ulceration and lymphadenitis occur in 1–10 per cent of vaccinations, and disseminated infection occurs in less than one per million vaccinations. The disseminated infection is usually associated with severe abnormalities of cellular immunity. The risk of adverse reactions is related to the BCG strain used by different manufacturers, the dose, the age of the child, the method of immunization and the skill of the vaccinator *(39)*.

If there is a local abscess formation, it should be treated by aspiration, in case it does not clear spontaneously. If this is not successful, it should be incised and treated with local applications daily with PAS or INH powder. There is no need for systemic treatment with INH. The patient should be assured of the harmless nature of the lesion *(40)*. In order to avoid these complications, the vaccination should be strictly intradermal and no other injection should be given for at least 6 months into the arm which received BCG vaccine *(41)*.

(9) PROTECTIVE VALUE : The duration of protection is from 15 to 20 years. The local BCG infection generates an immunity response, which is associated with the development of tuberculin hypersensitivity and with it, possibly, some immunity. The first prospective control trial of BCG showed it to be 80 per cent effective over an observation period of 20 years *(42)*. Since then several well–planned, controlled trials have been conducted in various parts of the world, including the "Tuberculosis Prevention Trial" in South India *(43, 44)*.

Studies have shown that the range of protection offered by BCG varied from 0 to 80 per cent in different parts of the world. The full explanation for the varying degrees of protection has yet to be found *(45, 46)*. One suggestion for which there is an increasing epidemiological support, is that prior exposure to some non-tuberculous environmental mycobacteria (e.g., *M. vaccae, M. non–chromogenicum*) may have conferred partial immunity on the population and thus masked the potential benefit of BCG vaccination *(47)*. There is also evidence that exposure to other species (e.g., *M. kansacii, M. scrofulaceus*) have an antagonistic action against BCG *(48)*. This may be one reason why BCG was not found to be protective in the South Indian trial *(38)*. However, infants and young children, BCG–vaccinated before they had contact with environmental mycobacteria, derived protection.

There is a large body of evidence which supports the conclusion that BCG gives an appreciable degree of protection against childhood tuberculosis *(48)*. The WHO, on the basis of an extended review of BCG including the South Indian trial *(50)* holds that it would seem unreasonable to stop current BCG vaccination programmes *(46)* and recommends that the use of BCG should be continued as an antituberculosis measure *(50)*.

(10) REVACCINATION : The duration of protection conferred by BCG is a matter of dispute. Even 90 years after the development of the vaccine, it is not known whether booster doses are indicated or advisable. In fact, BCG revaccination has not been included in the official immunization schedule in India under the expanded programme on immunization.

(11) CONTRAINDICATIONS : Unless specifically indicated, BCG should not be given to patients suffering from generalized eczema, infective dermatosis, hypogammaglobulinaemia, to those with a history of deficient immunity (symptomatic HIV infection, known or suspected congenital immunodeficiency, leukaemia, lymphoma or generalized malignant diseases), patients under immunosuppressive treatment (corticosteroids, alkylating agents, antimetabolites, radiation), and in pregnancy. The effect of BCG may be exaggerated in these patients.

(12) DIRECT BCG VACCINATION : Direct BCG vaccination, i.e., vaccination without a prior tuberculin test, has been adopted as a national policy in many developing countries, including India. It permits a more rapid and complete coverage of the eligible population, while reducing the cost. No adverse effects have been reported even if BCG is given to tuberculin–positive reactors *(38)*. However, it is sound practice to administer BCG during infancy before the child has had contact with environmental mycobacteria, than to resort to direct BCG at a later date, when the benefits of BCG are doubtful as shown by the South Indian trial *(49)*.

(13) IMPACT : BCG vaccination is less effective in controlling tuberculosis as compared to active case-finding and chemotherapy, as BCG offers only partial protection. In 1982, a WHO Expert Committee *(51)* concluded that although BCG vaccination of uninfected individuals (usually children) can prevent tuberculosis in them, it can have only a relatively small epidemiological effect in that it will not contribute significantly to the reduction in the overall risk of infection in the community as a whole.

(14) BCG VACCINATION AND HIV INFECTION : Following a review of relevant data, the Global Advisory Committee on Vaccine Safety (GACVS) has revised its previous recommendations concerning BCG vaccination of children infected with HIV.

WHO had previously recommended that in countries with a high burden of TB, a single dose of BCG vaccine should be given to all healthy infants as soon as possible after birth unless the child presented with symptomatic HIV infection. However, evidence shows that children who were HIV-infected, when vaccinated with BCG at birth, and who later developed AIDS, were at an increased risk of developing disseminated BCG disease. Among these children, the benefits of potentially preventing severe TB are out weighted by the risks associated with the use of BCG vaccine. GACVS, therefore, advised WHO to change its recommendation such that *children who are known to be HIV-infected, even if asymptomatic, should no longer be immunized with BCG vaccine (52)*. However, population with high prevalence of HIV also have the greatest burden of TB, and in such populations, uninfected children will benefit from the use of BCG vaccine. Furthermore, with the increasing range and coverage of interventions to prevent vertical transmission from mother to child – including early diagonsis of maternal HIV infections; management of sexually transmitted infections; safe delivery practices; maternal and infant preventive antiretroviral medicines or maternal antiretroviral therapy; and safe infant feeding – the majority of infants born to HIV-infected mothers are not infected and would also be expected to benefit from BCG vaccination *(52)*.

Unfortunately, accurate diagnosis of HIV infection in the first year of life relies upon direct demonstration of the HIV virus, as maternal HIV antibody is passively transferred to the infant in utero. Currently available assays that can be used to diagnose HIV in the first year of life are expensive and technically demanding in many countries with generalized HIV epidemics. WHO recommends that these tests are first performed at or around 6 weeks age, yet this is often after BCG vaccination has already been given *(53)*.

(15) COMBINED VACCINATION : BCG may be given at the same time as oral polio vaccine. DPT vaccine may also be given at the same time as BCG, but in different arm without reducing the immune responses or increasing the rate of complications *(43)*. Mixed vaccines containing BCG have not yet been introduced.

An increasing number of industrialized countries are likely to reconsider their BCG vaccination policy during the coming years. To change from general to selective BCG vaccination, an efficient notification system must be in place in addition to the following "low endemicity" criteria : (a) an average annual notification rate of smear-positive pulmonary TB cases below 5 per 100,000; or (b) an average annual notification rate of tubercular meningitis in children aged under five years, below 1 per 10 million population during the previous five years; or (c) an average annual risk of tuberculosis infection below 0.1 per cent *(53)*.

To sum up, BCG vaccination is a fundamental component of a national tuberculosis programme. Despite the contradictory evidence of controlled trials, there is evidence that BCG plays a valuable role in preventing severe forms of childhood tuberculosis, viz meningitis and miliary tuberculosis. Today, BCG vaccination is part of WHO Expanded Programme on Immunization. The greatest need for BCG vaccination today is undoubtedly in the developing countries of the world where tuberculosis is still a major health problem.

CHEMOPROPHYLAXIS

Chemoprophylaxis (now termed preventive treatment) with INH for one year or INH plus ethambutol for 9 months has been tried in contact reactors.

The case against INH chemoprophylaxis rests on three points : (a) First, it is a costly exercise *(54)*; (b) Secondly, it is not strikingly effective. For the majority of tuberculin–reactors, the risk of developing tuberculosis is small and the potential benefit offered by chemoprophylaxis is not great enough to justify its use *(55)*, and (c) INH prophylaxis carries a small risk of drug-induced hepatitis. Chemoprophylaxis is, therefore, not a worthwhile exercise of tuberculosis control, especially in developing countries such as India where resources are limited and a large segment of the population is infected. A WHO expert committee in 1982 *(51)* concluded that chemoprophylaxis with INH can prevent the development of tuberculosis in infected individuals, but its impact on the community will be minimal because it cannot be applied on a mass scale, even in technically advanced countries. An earlier WHO expert committee on tuberculosis *(8)* emphasized that preventive treatment is irrational even for special risk groups, unless case-finding and treatment programme for infectious tuberculosis is widespread and well–organized and achieves a high rate of cure. In this context, BCG gets priority over chemoprophylaxis.

Rehabilitation

In recent years, there has been a good deal of fresh thinking on the subject of rehabilitation, because of the success achieved in treating patients on domiciliary lines without interfering with their normal work and life. The proportion of patients who need rehabilitation and work under sheltered conditions is becoming less and less. The groups that need rehabilitation are those who are chronically ill and are still excreting tubercle bacilli. Some of those who had lung resection may require rehabilitation to suit their physical and mental abilities.

Surveillance

Surveillance is an integral part of any effective tuberculosis programme. It should be concerned with two distinct aspects : (a) surveillance of the tuberculosis situation, for example, by measuring the "annual infection rates" which will guide the epidemiologist and health administrator by indicating whether the TB problem is static, increasing or decreasing; (b) surveillance of control measures applied such as BCG vaccination and chemotherapy.

Role of hospitals

Inspite of effective domiciliary treatment services, there will always be some patients who will be needing hospitalization. The main indications for hospitalization are : (a) emergencies such as massive haemoptysis and spontaneous pneumothorax (b) surgical treatment (c) management of serious types of tuberculosis such as meningeal tuberculosis, and (d) certain social indications, such as when there is no one to look after the patient at home.

DRUG RESISTANCE

All drugs used in the treatment of tuberculosis tend to produce resistant strains. The resistance may be of two types : (a) *PRIMARY OR PRE–TREATMENT RESISTANCE :* It is the resistance shown by the bacteria in a patient, who has not received the drug in question before. That this is not

always due to infection of the individual with drug–resistant bacilli, is well known. It is an accepted fact that when the bacilli are rapidly multiplying, resistant mutants appear irrespective of the administration of any particular drug. According to one hypothesis, drug resistance is induced by transference through what are called "episomes". Episomes are non–chromosomal heritable genes which can pass from one bacterial cell to another. If there is a direct contact between the cell containing episomes, the episomes leave the resistant cell and invade susceptible cells *(56)*. (b) *SECONDARY OR ACQUIRED RESISTANCE* : Here the bacteria were sensitive to the drug at the start of the treatment but became resistant to the particular drug during the course of treatment with it.

Drug resistance means that certain strains of tuberculosis bacilli are not killed by the anti–tuberculosis drugs given during the treatment. Some strains can be resistant to one or more drugs.

Definitions

Please refer to page 179 for classification of cases based on drug resistance.

Causes of drug-resistant tuberculosis *(18)*

Drug-resistant TB has microbial, clinical and programmatic causes. From a microbiological perspective, the resistance is caused by a genetic mutation that makes a drug ineffective against the mutant bacilli. An inadequate or poorly administered treatment regimen allows drug-resistant mutants to become the dominant strain in a patient infected with TB. Table 10 summarizes the common causes of inadequate treatment. However it should be stressed that MDR-TB is man-made phenomenon – poor treatment, poor drugs and poor adherence lead to the development of MDR-TB.

In all countries and especially those where the number of cases of tuberculosis is rising rapidly because of the association with HIV, the development of resistant strains of tuberculosis is a serious concern. In 2012, about 0.45 million people worldwide, are estimated to be infected with strains of drug resistant tuberculosis. An accurate picture of drug resistance is not available because few countries have a reliable drug resistance surveillance system *(2)*.

It is estimated that primary MDR-TB in India is around 2.2 per cent. The drug resistance in re-treatment cases is 15 (11–19) per cent. Although the level of MDR-TB in the country is low in relation to percentage and proportion, it translates into large absolute numbers *(2)*. For details please refer to page 430.

XDR-TB has been reported in India by isolated studies with non-representative and highly selected clinical samples. The magnitude of the problem remains to be determined due to the absence of laboratories capable of conducting quality assured second line drug susceptibility test *(6)*.

It has been observed that resistance to isoniazid alone does not affect the results of treatment so much, if proper regimens for treatment or retreatment are prescribed, but simultaneous resistance to isoniazid and rifampicin limits severely the results of the treatment.

The most serious danger of MDR Tuberculosis is that it is much more difficult to treat, even where second line drugs are available. Treatment of MDR tuberculosis can take at least two years and the results are poor. Second line drugs cost 30 times as much as drugs used in SCC treatment of non–resistant tuberculosis patients. Patients with MDR tuberculosis may need to be hospitalised and isolated which adds to the cost of treatment, to prevent transmission of primary resistant strains to others. Careful precautions are necessary to prevent transmission, especially to health workers caring for MDR tuberculosis patients *(57)*.

DOTS-Plus for MDR-TB is a comprehensive management initiative built upon 5 elements of DOTS strategy. However, DOTS-Plus also takes into account specific issues, such as use of second-line anti-TB drugs. The goal of DOTS-Plus is to prevent further development and spread of MDR-TB. DOTS-Plus is not intended for universal application and is not required in all settings. The aim of implementation of DOTS-Plus in selected areas with significant levels of MDR-TB is to combat an emerging epidemic. The underlying principle is that the first step in controlling MDR-TB is prevention by full implementation of DOTS. An effective DOTS-based TB control programme is a prerequisite for implementation of DOTS-Plus *(19)*.

The emergence of XDR-TB and high case fatality rate in patients with HIV infection was the subject of an emergency consultations held in Johannesburg on 7–8 September, 2006. The issues include strengthening treatment adherence to achieve high levels of completion (≥ 85 per cent) for all TB patients ensuring that second line drugs used to treat MDR-TB and XDR-TB are strictly controlled and properly used according to WHO guidelines. The steps required to limit the impact of MDR-TB and XDR-TB were identified and incorporated into a 7-point plan of action *(58)*.

In the short term, countries should:

1. develop national emergency response plans for MDR-TB and XDR-TB and ensure that basic TB control measures meet international standards for TB care and are fully implemented;
2. conduct rapid surveys of MDR-TB and XDR-TB using a standardized protocol to assess the geographical and

TABLE 10

Causes of inadequate treatment

Providers/programmes : inadequate regimens	Drugs: inadequate supply/quality	Patients: inadequate drug intake
– Absence of guidelines or inappropriate guidelines	– Non-availability of certain drugs (stock-outs or delivery disruptions)	– Poor adherence (or poor DOT)
– Non-compliance with guidelines	– Poor quality	– Lack of information
– Inadequate training of health staff	– Poort storage conditions	– Non-availability of free drugs
– No monitoring of treatment	– Wrong dosages or combination	– Social and economic barriers
– Poorly organized or funded TB control programmes		– Malabsorption – Substance abuse disorders

temporal distribution of XDR-TB in vulnerable populations;

3. strengthen and expand national TB laboratory capacity by addressing all aspects of laboratory procedures and managment;
4. implement infection control precautions in health-care facilities according to WHO guidelines, with special emphasis on those facilities providing care for people living with HIV/AIDS.

In the long term, countries should:

5. establish capacity for clinical and public health managers to respond effectively to MDR-TB and XDR-TB;
6. promote universal access to antiretroviral therapy for all TB patients through close collaboration with treatment and care programmes for people living with HIV/AIDS;
7. support and increase funding for research into the development of new anti-tuberculosis drugs and rapid diagnostic tests for MDR-TB and XDR-TB.

Prevention of Drug Resistance : Since incomplete, inadequate and irregular treatment is the main cause of drug resistance, this can be prevented by (a) treatment with two or more drugs in combination (b) using drugs to which the bacteria are sensitive, and (c) ensuring that the treatment is complete, adequate and regular.

Revised National Tuberculosis Programme

For details of RNTCP activities, refer to chapter 7 page 427.

STOP TB Strategy

In 2006, WHO launched the new Stop TB Strategy. The core of this strategy is DOTS. The strategy is to be implemented over the next 10 years as described in the Global Plan to Stop TB 2006-2015. The targets and indicators for TB control are as defined within the framework of MDGs. These will be used to measure the progress made under the stop TB strategy. It focuses on the five principal indicators that are used to measure the implementation and impact of TB control. They are : case detection, treatment success, incidence, prevalence and deaths. The global targets for case detection and treatment success have been set by WHO's World Health Assembly *(59)*.

Stop TB Partnership targets

By 2015 : The global burden of TB (prevalence and death rates) will be reduced by 50% relative to 1990 levels. This means reducing prevalence to 150 per 100 000 or lower and deaths to 15 per 100 000 per year or lower by 2015 (including TB cases coinfected with HIV). The number of people dying from TB in 2015 should be less than approximately 1 million, including those coinfected with HIV.

By 2050 : The global incidence of TB disease will be less than or equal to 1 case per million population per year.

Components of the strategy and implementation approaches of stop TB strategy are as follows :

1. Pursuing high-quality DOTS expansion and enhancement
   a. Political commitment with increased and sustained financing
   b. Case detection through quality-assured bacteriology
   c. Standardized treatment with supervision and patient support
   d. An effective drug supply and managment system
   e. Monitoring and evaluation system, and impact measurement
2. Addressing TB/HIV, MDR-TB and other challenges
   - Implement collaborative TB/HIV activities
   - Prevent and control MDR-TB
   - Address prisoners, refugees, other high-risk groups and special situations
3. Contributing to health system strengthening
   - Actively participate in efforts to improve system-wide policy, human resources, financing, management, service delivery and information systems
   - Share innovations that strengthen health systems, including the Practical Approach to Lung Health (PAL)
   - Adapt innovations from other fields
4. Engaging all care providers
   - Public-Public and Public-Private Mix (PPM) approaches
   - Implement international standards for tuberculosis care
5. Empowering people with TB, and communities
   - Advocacy, communication and social mobilization
   - Community participation in TB care
   - Patients' charter for tuberculosis care
6. Enabling and promoting research
   - Programme based operational research
   - Research to develop new diagnostics, drugs and vaccines.

TUBERCULOSIS AND HIV

Worldwide the number of people infected with both HIV and tuberculosis is rising. The HIV virus damages the body's natural defences – the immune system – and accelerates the speed at which tuberculosis progresses from a harmless infection to life–threatening condition. The estimated 10 per cent activation of dormant tuberculosis infection over the life span of an infected person, is increased to 10 per cent activation in one year, if HIV infection is superimposed. Tuberculosis is already the opportunistic infection that most frequently kills HIV–positive people.

Even in HIV positive cases, tuberculosis can be cured if diagnosed in time and treated properly. Good TB control programme (DOTS) is the best thing that can be done to cure and extend the lives of HIV positive individuals. With correct TB treatment, the HIV positive person having tuberculosis can gain, on an average two additional years of life *(60)*.

Epidemiological impact

HIV and tuberculosis interact in several ways *(57)* :

1. *Reactivation of latent infection :* People who are infected with both tuberculosis and HIV, are 25–30 times more likely to develop tuberculosis disease, than people infected only with tuberculosis. This is because HIV stops the

immune system working effectively and tuberculosis bacilli are able to multiply rapidly. In developing countries HIV associated tubercular disease is very common.

2. *Primary infection :* New tubercular infection in people with HIV can progress to active disease very quickly. In the USA active tubercular disease in two-thirds of people with both infections is due to recent infection, rather than reactivation of latent infection. People with HIV are at risk of being newly infected, if they are exposed to tuberculosis because their weakened immune system makes them more vulnerable.

3. *Recurring infection :* People with HIV who have been cured of tuberculosis infection may be more at risk of developing tuberculosis again. However, it is not clear whether this is because of reinfection or relapse.

4. *In the community :* There are more new cases of active tuberculosis because more people infected with tuberculosis develop active disease, and those newly infected become ill faster. This means that there are more people in the community who are infectious to others. Larger number of people with active disease mean more people will die from tuberculosis unless they are treated. The association of tuberculosis with HIV means that people suffer additional discrimination. Community education is needed to increase awareness that tuberculosis is curable and, most important, that people are no longer infectious after the first few weeks of treatment.

Diagnosis of tuberculosis in people with HIV

In most people in the early stages of HIV infection, symptoms of tuberculosis are similar as in people without HIV infection. In areas where many people have HIV infection, tuberculosis programmes should continue to focus on identifying infectious sputum–smear–positive cases through microscopy. However, diagnosis of tuberculosis in individual patients using the standard diagnostic tools can be more difficult if they have advanced HIV infection because :

(a) HIV positive people with pulmonary tuberculosis may have a higher frequency of negative sputum smears. Confirming the diagnosis may require sputum culture.

(b) The tuberculin skin test often fails to work in people who are HIV positive because it relies on measuring the response of a person's immune system. If the immune system has been damaged by HIV, it may not respond even though the person is infected with tuberculosis. HIV positive people with tuberculosis, therefore, have a higher frequency of false negative tuberculin skin test results.

(c) Chest radiography may be less useful in people with HIV because they have less cavitation. Cavities usually develop because the immune response to the tubercular bacilli leads to some destruction of lung tissue. In people with HIV, who do not have a fully functioning immune system, there is less tissue destruction and hence less lung cavitation.

(d) Cases of extra–pulmonary tuberculosis seem to be more common in people who are co–infected.

In short–screen for tuberculosis using sputum smear microscopy, if the result is positive, start treatment; if the result is negative, but it is suspected that the patient has tuberculosis, sputum culture should be carried out where feasible to confirm the diagnosis and give treatment to those with positive culture results. Alternatively, where culture cannot be done, treatment can be given to those judged by a doctor to have active tuberculosis on the basis of X-ray and clinical symptoms.

Initiating ART (Anti-Retroviral Therapy) in patients with MDR-TB *(18)*

The use of ART in HIV infected patients with TB improves survival for both drug resistant and susceptible disease cases. However HIV infected MDR patients without the benefit of ART may experience mortality rates exceeding 90%. The likelihood of adverse effects could compromise the treatment of HIV or MDR–TB if both treatments are started simultaneously. On the other hand undue delay in starting ART could result in significant risk of HIV related death amongst MDR patients. Table 11 is based on the WHO guidelines for initiating ART in relationship to treatment for MDR–TB.

TABLE 11

CD 4 cell count	ART recommendation	Timing of ART in relation to treatment for MDR–TB
≤ 350 cells/mm^3	Recommend ART	After 2 weeks, as soon as the treatment for MDR TB is tolerated.
> 350 cells/mm^3	Defer ART	Re-evaluate patient monthly for consideration of ART. CD4 testing is recommended every 3 months during treatment for MDR TB
Not available	Recommend ART	After 2 weeks, as soon as the treatment for MDR TB is tolerated.

For patients who are already on ART at the time of MDR-TB diagnosis be continued on ART when TB therapy is initiated. Occasionally, patients with HIV-related TB may experience a temporary exacerbation of symptoms, signs of radiographic manifestations of TB after beginning TB treatment. This paradoxical reaction occurs in HIV-infected patients with active TB and is thought to be a result of immune restitution due to the simultaneous administration of antiretroviral and tuberculosis medication. Symptoms and signs may include high fever, lymphadenopathy, expanding intra-thoracic lesions and worsening of chest radiographic findings. The diagnosis of paradoxical reaction should be made only after a thorough evaluation has excluded other aetiologies, particularly TB treatment failure. For severe paradoxical reactions prednisone (1–2 mg/kg for 1–2 weeks, then gradually decreasing doses) may be used.

Diagnosis of HIV in TB patients

The diagnosis of HIV relies in serological testing. In areas where there is high prevalence of HIV (>1 per cent in pregnant women), HIV testing should be systemetically offered to all TB patients, including children. Pre-test counselling must be available to all patients so that they understand what the implications of the results might be and make a informed choice. Patients should be counselled on behaviour risk and methods to prevent transmitting or acquiring the infection.

TUBERCULOSIS AND DIABETES

Diabetes has been shown to be an independent risk factor for tuberculosis in community based study from south India and multiple studies globally. It is suggested that diabetes accounts for 14.8 per cent of all tuberculosis and

20.8 per cent of smear positive TB *(3)*. People with weak immune system as in diabetes are at higher risk of progressing from latent to active tuberculosis. The risk is 2–3 times higher than people without diabetes. A large proportion of people with diabetes and TB are diagnosed very late.

It is suggested that all people with TB should be screened for diabetes and screening for TB in diabetes should be considered, particularly in setting with high TB prevalence. People with diabetes and TB have a high risk of death during TB treatment and of TB relapse after treatemt. As diabetes is complicated by presence of other infectious diseases also, it is important to take proper care of diabetes in patients suffering from diabetes/TB *(61)*.

The future

Despite effective case-finding and therapeutic tools and declines in mortality and morbidity rates in some countries, tuberculosis appears to continue as an important communicable disease problem, worldwide, for several decades to come. The chronic nature of the disease, the ability of the tubercle bacilli to remain alive in the human body for years, the concentration of the disease in the older age-groups, the increased expectation of life, the high prevalence of infection rates in some countries, the relatively high reactivation rate, the emergence of drug-resistant strains, association of tuberculosis and HIV infection, and above all, the perpetuation of the "non-specific determinants" of the disease in the third world countries impede a rapid conquest of the disease.

II. INTESTINAL INFECTIONS

POLIOMYELITIS

Poliomyelitis is an acute viral infection caused by an RNA virus. It is primarily an infection of the human alimentary tract but the virus may infect the central nervous system in a very small percentage (about 1 per cent) of cases resulting in varying degrees of paralysis, and possibly death.

Problem statement

In the pre-vaccination era, poliomyelitis was found in all countries of the world. The extensive use of polio vaccines since 1954 eliminated the disease in developed countries. In 1988, the World Health Assembly resolved to eradicate poliomyelitis globally. Since then, implementation of the eradication strategies has reduced the number of polio endemic countries from more than 125 in 1988 to 3 in 2014.

These countries are Afghanistan, Pakistan and Nigeria. India has not reported any polio case since January 2011, and has been declared polio-free since 27th March 2014. This was once considered the most complex challenge to achieve. Four of the six Regions of WHO have been certified as polio-free : the Americas (1994), Western Pacific (2000), Europe (2002) and SEAR (2014). 80 per cent of world's population now lives in polio-free areas *(1)*. During 2013, 406 cases of wild-polio were reported globally. These include only 160 cases from endemic countries; international spread from endemic areas into polio-free areas accounted for the remainder.

Of the 3 strains of wild poliovirus (type 1, type 2 and type 3), wild poliovirus type 2 was eradicated in 1999 and case numbers of type 3 are down to the lowest-ever levels with the last case reported in November 2012 from Nigeria *(1)*.

Recognizing the epidemiological opportunity and the significant risk of potential failure, the new Polio Eradication and Endgame Strategic Plan 2013–2018 has been developed. It is the first plan to eradicate all types of polio disease simultaneously – both due to wild poliovirus and due to vaccine-derived poliovirus.

Polio Eradication and Endgame Strategic Plan, 2013–2018 *(2, 3)*

This programme is a comprehensive long-term strategy that addresses what is needed to deliver a polio free world by 2018. The plan has 4 objectives :

1. *Detect and interrupt all poliovirus transmission:* This objective is to stop all wild polio transmission by the end of 2014 by enhancing global poliovirus surveillance, effectively implementing national emergency plan to improve OPV campaign quality in the remaining endemic countries, and ensuring rapid outbreak response. It also includes stopping any new polio outbreak due to vaccine-derived poliovirus (VDPV) within 6 months of the index case.
2. *Strengthen immunization system and withdraw oral polio vaccine:* This objective will help hasten the interruption of wild poliovirus transmission, reduce the risk of wild and VDPV importation and spread and help build a strong system for the delivery of other life saving vaccines. To eliminate all VDPV risks, in the long-term, all OPV must be removed from routine immunization programmes. As wild poliovirus type 2 was eradicated in 1999, and the main cause of VDPV outbreaks is currently type 2 component of OPV, this component must be removed from the vaccine by mid-2016. Preparation for this removal entails strengthening routine immunization system, especially in areas at highest risk, introducing immunization programme globally and then replacing the trivalent OPV with bivalent OPV in all OPV using countries. This objective affects all 144 countries world-wide which currently use OPV in their immunization programme.
3. *Containment and certification:* This objective encompasses the certification of the eradication and containment of all wild poliovirus in all WHO regions by end of 2018, recognizing that a small number of facilities will need to retain poliovirus stocks in the post-eradication era for the purposes of vaccine production, diagnosis and research. Criteria for the safe handling and biocontainment of such poliovirus, and processes to monitor their application are essential to minimize the risk of poliovirus re-introduction in the post-eradication era.
4. *Legacy planning:* As the polio programme approaches key eradication milestones, successful legacy planning will include the mainstreaming of essential polio functions into on-going public health programmes at national and international levels, ensuring the transfer of learning to other relevant programmes and/or initiatives, and the transition of assets and infrastructure to benefit other development goals and global health priorities *(3)*.

Polio Surveillance *(3)*

Surveillance is the most important part of the whole polio eradication initiative. Without surveillance, it would be impossible to pinpoint where and how wild poliovirus is still circulating, or to verify that the virus has been eradicated. Surveillance identifies new cases and detects importation of wild poliovirus.

Acute flaccid paralysis surveillance

There are four steps of acute flaccid paralysis (AFP) surveillance:

1. *Finding and reporting children with acute flaccid paralysis (AFP) :* The first links in the surveillance chain are staff in all health facilities – from district health centres to large hospitals. They must promptly report every case of acute flaccid paralysis (AFP) in any child under 15 years of age. In addition, public health staff make regular visits to hospitals and rehabilitation centres to search for AFP cases which may have been overlooked or misdiagnosed. The number of AFP cases reported each year is used as an indicator of a country's ability to detect polio – even in countries where the disease no longer occurs. A country's surveillance system needs to be sensitive enough to detect at least one case of AFP for every 100,000 children under 15 – even in the absence of polio.

2. *Transporting stool samples for analysis :* In the early stages, polio may be difficult to differentiate from other forms of acute flaccid paralysis, such as Guillain-Barre Syndrome, transverse myelitis, or traumatic neuritis. All children with acute flaccid paralysis (AFP) should be reported and tested for wild poliovirus within 48 hours of onset, even if doctors are confident on clinical grounds that the child does not have polio. To test for polio, faecal specimens are analyzed for the presence of poliovirus. Because shedding of the virus is variable, two specimens – taken 24–48 hours apart are required. Speed is essential, since the highest concentrations of poliovirus in the stools of infected individuals are found during the first two weeks after onset of paralysis.

Stool specimens have to be sealed in containers and stored immediately inside a refrigerator or packed between frozen ice packs at 4–8°C in a cold box, ready for shipment to a laboratory. Undue delays or prolonged exposure to heat on the way to the laboratory may destroy the virus. Specimens should arrive at the laboratory within 72 hours of collection.

3. *Isolating poliovirus :* In a laboratory, virologists begin the task of isolating poliovirus from the stool samples. If poliovirus is isolated, the next step is to distinguish between wild (naturally occurring) and vaccine-related poliovirus. This is necessary because the oral vaccine consists of attenuated live polioviruses and resembles wild virus in the laboratory. If wild poliovirus is isolated, the virologists identify which of the two surviving types of wild virus is involved. Wild poliovirus type 2 has not been recorded since 1999.

4. *Mapping the virus :* Once wild poliovirus has been identified, further tests are carried out to determine where the strain may have originated. By determining the exact genetic make-up of the virus, wild viruses can be compared to others and classified into genetic families which cluster in defined geographical areas. The newly-found poliovirus sequence is checked against a reference bank of known polioviruses, allowing inferences about the geographical origin of the newly found virus. When polio has been pinpointed to a precise geographical area, it is possible to identify the source of importation of poliovirus – both long-range and cross-border. Appropriate immunization strategies can then be determined to prevent further spread of the poliovirus.

Environmental surveillance

Environmental surveillance involves testing sewage or other environmental samples for the presence of poliovirus. Environmental surveillance often confirms wild poliovirus infections in the absence of cases of paralysis. Systematic environmental sampling (e.g. in Egypt and Mumbai, India) provides important supplementary surveillance data. Ad-hoc environmental surveillance elsewhere (especially in polio-free regions) provides insights into the international spread of poliovirus.

Surveillance indicators (3)

Indicator	Minimum levels for certification standard surveillance
Completeness of reporting	At least 80% of expected routine (weekly or monthly) AFP surveillance reports should be received on time, including zero reports where no AFP cases are seen. The distribution of reporting sites should be representative of the geography and demography of the country.
Sensitivity of surveillance	At least one case of non-polio AFP should be detected annually per 100,000 population aged less than 15 years. In endemic regions, to ensure even higher sensitivity, this rate should be two per 100,000.
Completeness of case investigation	All AFP cases should have a full clinical and virological investigation with at least 80% of AFP cases having 'adequate' stool specimens collected 'Adequate' stool specimens are two stool specimens of sufficient quantity for laboratory analysis, collected at least 24 hours apart, within 14 days after the onset of paralysis, and arriving in the laboratory by reverse cold chain and with proper documentation.
Completeness of follow-up	At least 80% of AFP cases should have a follow-up examination for residual paralysis at 60 days after the onset of paralysis.
Laboratory performance	All AFP case specimens must be processed in a WHO accredited laboratory within the Global Polio Laboratory Network (GPLN).

VACCINE DERIVED POLIOVIRUS (VDPV) (4)

Although OPV is a safe vaccine, on rare occasions adverse events may occur. Vaccine-associated paralytic poliomyelitis (VAPP) is the most important of these rare adverse events. Cases of VAPP are clinically indistinguishable from poliomyelitis caused by WPV, but can be distinguished by laboratory analysis. The incidence of VAPP has been estimated at 4 cases/1000,000 birth cohort per year in countries using OPV. VAPP occurs in both OPV recipients and their unimmunized contacts; it is most frequently associated with Sabin 3 (60% of cases), followed by Sabin 2 and Sabin 1.

VDPVs resemble WPVs biologically and differ from the majority of vaccine-related poliovirus (VRPV) isolates in that they have genetic properties consistent with prolonged replication or transmission, which is substantially longer than the normal period of vaccine virus replication of 4–6 weeks in the OPV recipient *(5)*. All poliovirus isolates are characterized by Global Polio Laboratory Network. The diagnosis is made by real-time reverse transcription-polymerase chain reaction (rRT-PCR) nucleic acid amplification targetted to nucleotide substitution that occur early in VDPV emergence.

VDPVs are divided into three categories as (1) cVDPVs, when evidence of person-to-person transmission in the community exists; (2) immunodeficiency-associated VDPVs (iVDPVs), which are isolates from persons with primary immunodeficiencies, who have prolonged VDPV infections; and (3) ambiguous VDPVs (aVDPVs), which are either clinical isolates from person with no known immunodeficiency or sewage isolates whose source is unknown *(5)*.

The prolonged large outbreak of $cVDPV_2$ in Nigeria and D.R. of Congo, the increased detection of iVDPV infection in developing countries and continued detection of aVDPVs that resemble cVDPV and iVDPV reaffirm the following points *(5)*:

1. The clinical signs and severity of paralysis associated with VDPV and WPV infections are indistinguishable.
2. cVDPVs pose the same public health threat as WPVs and require the same control measures.
3. Surveillance for WPVs and VDPVs should continue to be strengthened.
4. Environmental surveillance to detect VDPVs and WPV infection can serve as an important, sensitive supplement to AFP surveillance in many settings.
5. Persons with prolonged iVDPV infection may transmit poliovirus to others, raising the risk of VDPV circulation in settings of low population immunity to the corresponding poliovirus serotype.
6. Prolonged iVDPV excretion is uncommon among persons with primary immunodeficiencies exposed to OPV.
7. The prevalence of long-term iVDPV excretors may be higher than suggested.

Because of these risks of emergence of vaccine-derived polioviruses, OPV use will be discontinued worldwide once all WPV transmission has been interrupted (i.e. inactivated polio vaccine (IPV) will replace OPV) and strategies to strengthen global polio immunization and surveillance are needed to limit the emergence of VDPVs.

Epidemiological determinants

Agent factors

(a) AGENT : The causative agent is the poliovirus which

has three serotypes 1,2 and 3. Most outbreaks of paralytic polio are due to type–1 virus. Poliovirus can survive for long periods in the external environment. In a cold environment, it can live in water for 4 months and in faeces for 6 months *(6)*. It is, therefore, well–adapted for the faecal–oral route of transmission *(7)*. However, the virus may be rapidly inactivated by pasteurization, and a variety of physical and chemical agents. (b) RESERVOIR OF INFECTION : Man is the only known reservoir of infection. Most infections are subclinical. It is the mild and subclinical infections that play a dominant role in the spread of infection; they constitute the submerged portion of the iceberg. It is estimated that for every clinical case, there may be 1000 subclinical cases in children and 75 in adults *(8)*. There are no chronic carriers. No animal source has yet been demonstrated. (c) INFECTIOUS MATERIAL : The virus is found in the faeces and oropharyngeal secretions of an infected person. (d) PERIOD OF COMMUNICABILITY : The cases are most infectious 7 to 10 days before and after onset of symptoms. In the faeces, the virus is excreted commonly for 2 to 3 weeks, sometimes as long as 3 to 4 months.

Host factors

(a) AGE : The disease occurs in all age groups, but children are usually more susceptible than adults because of the acquired immunity of the adult population. In developed countries, before the advent of vaccination, the age distribution shifted so that most patients were over the age of 5 years, and 25 per cent were over age 15 years *(9)*. In India, polio is essentially a disease of infancy and childhood. About 50 per cent of cases are reported in infancy. The most vulnerable age is between 6 months and 3 years. (b) SEX : Sex differences have been noted in the ratio of 3 males to one female. (c) RISK FACTORS : Several provocative or risk factors have been found to precipitate an attack of paralytic polio in individuals already infected with polio viruses. They include fatigue, trauma, intramuscular injections, operative procedures such as tonsillectomy undertaken especially during epidemics of polio and administration of immunizing agents particularly alum-containing DPT. (d) IMMUNITY : The maternal antibodies gradually disappear during the first 6 months of life. Immunity following infection is fairly solid although reinfection can occur since infection with one type does not protect completely against the other two types of viruses. Type–2 virus appears to be the most effective antigen. Neutralizing antibody is widely recognized as an important index of immunity to polio after infection *(10)*.

Environmental factors

Polio is more likely to occur during the rainy season. Approximately 60 per cent of cases recorded in India were during June to September *(11)*. The environmental sources of infection are contaminated water, food and flies. Polio virus survives for a long time in a cold environment. Overcrowding and poor sanitation provide opportunities for exposure to infection.

Mode of transmission

(a) FAECAL–ORAL ROUTE : This is the main route of spread in developing countries. The infection may spread *directly* through contaminated fingers where hygiene is poor, or *indirectly* through contaminated water, milk, foods, flies and articles of daily use. (b) DROPLET INFECTION : This may occur in the acute phase of disease when the virus occurs in the throat. Close personal contact with an infected person facilitates droplet spread. This mode of transmission may be relatively more important in developed countries where faecal transmission is remote.

Incubation period

Usually 7 to 14 days (range 3 to 35 days).

Clinical spectrum

When an individual susceptible to polio is exposed to infection, one of the following responses may occur (Fig. 1) (a) INAPPARENT (SUBCLINICAL) INFECTION : This occurs approximately in 91–96 per cent of poliovirus infections *(12)*. There are no presenting symptoms. Recognition only by virus isolation or rising antibody titres. (b) ABORTIVE POLIO OR MINOR ILLNESS : Occurs in approximately 4 to 8 per cent of the infections *(13)*. It causes only a mild or self–limiting illness due to viraemia. The patient recovers quickly. The diagnosis cannot be made clinically. Recognition only by virus isolation or rising antibody titre. (c) NON-PARALYTIC POLIO : Occurs in approximately 1 per cent of all infections *(14)*. The presenting features are stiffness and pain in the neck and back. The disease lasts 2 to 10 days. Recovery is rapid. The disease is synonymous with aseptic meningitis. (d) PARALYTIC POLIO : Occurs in less than one per cent of infections. The virus invades CNS and causes varying degrees of paralysis. The predominant sign is asymmetrical flaccid paralysis. A history of fever at the time of onset of paralysis is suggestive of polio. The other associated symptoms are malaise, anorexia, nausea, vomiting, headache, sore throat, constipation and abdominal pain. There might be signs of meningeal irritation, i.e., stiffness of neck and back muscles. Tripod sign may be present, i.e. the child finds difficulty in sitting and sits by supporting hands at the back and by partially flexing the hips and knees. Progression of the paralysis to reach its maximum in the majority of cases occurs in less than 4 days (may take 4–7 days). The paralysis is characterized as descending, i.e. starting at the hip and then moving down to the distal parts

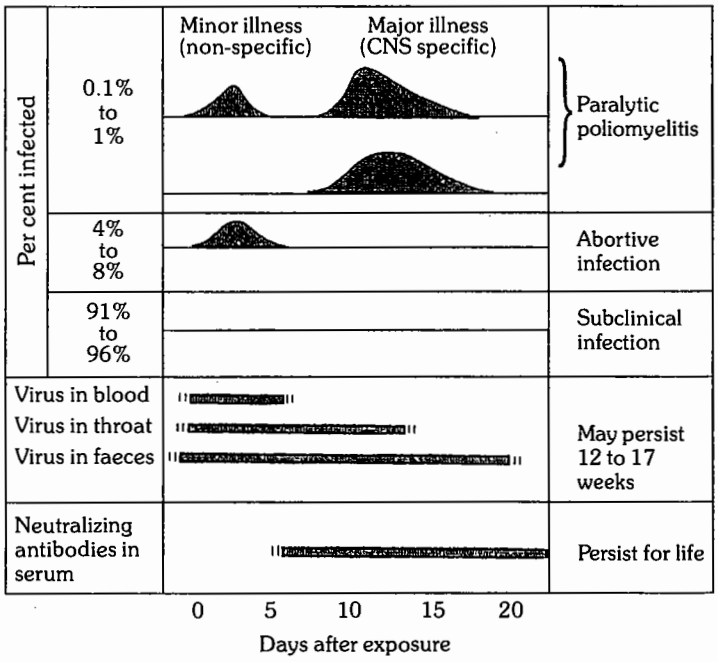

FIG. 1

Time course of events in infection with poliovirus.

Source : *(16)*

of the extremity. As it is asymmetrical patchy paralysis, muscle strength varies in different muscle groups of different limbs. However, proximal muscle groups are more involved as compared to distal ones. Deep tendon reflexes (DTRs) are diminished before the onset of paralysis. There is no sensory loss. Cranial nerve involvement is seen in bulbar and bulbospinal forms of paralytic poliomyelitis. There might be facial asymmetry, difficulty in swallowing, weakness or loss of voice. Respiratory insufficiency can be life–threatening and is usually the cause of death. After the acute phase, atrophy of the affected muscles lead to a life with residual paralysis which is typical and relatively easy to identify as poliomyelitis *(15)*.

Progressive paralysis, coma or convulsions usually indicate a cause other than polio, as does a very high case fatality rate *(14)*.

There is no specific treatment for polio. Good nursing care from the beginning of illness can minimize or even prevent crippling. Physiotherapy is of vital importance. It can be initiated in the affected limb immediately. It helps the weakened muscles to regain strength. Very probably, the child may have to put on metal callipers.

PREVENTION

Immunization is the sole effective means of preventing poliomyelitis. Both killed and live attenuated vaccines are available and both are safe and effective when used correctly. It is essential to immunize all infants by 6 months of age to protect them against polio. Two types of vaccines are used throughout the world; they are :

1. Inactivated (Salk) polio vaccine (IPV).
2. Oral (Sabin) polio vaccine (OPV).

1. Inactivated (Salk) polio vaccine

IPV is usually made from selected WPV strains – namely, Mahoney (Salk type-1), MEF-1 (Salk type-2) and Saukett (Salk type-3) – that are grown in Vero cell culture or in human diploid cells. Harvested viral components are inactivated with formaldehyde. The final vaccine mixture is formulated to contain at least 40 units of type-1, 8 units of type-2 and 32 units of type-3 D-antigen (D-antigen, which is expressed only on intact poliovirus particles, is used to adjust the concentration of the individual viruses included in the trivalent IPV). All versions of IPV have higher antigenicity than the first-generation vaccines, and they are sometimes referred to as IPVs of enhanced potency. IPV may contain trace amounts of formaldehyde, streptomycin, neomycin or polymyxin B; some versions of IPV contain the preservative phenoxy-ethanol (0.5%), but neither thiomersal (incompatible with IPV antigenicity) nor adjuvants are used *(4)*.

IPV is administered by intramuscular injection (preferred) or subcutaneous injection. The vaccine is stable at ambient temperature, but should be refrigerated to ensure no loss of potency. Freezing should be avoided as it could diminish potency. IPV is available either as a stand-alone product or in combination with ≥1 other vaccine antigens including diphtheria, tetanus, whole-cell or acellular pertussis, hepatitis B, or *Haemophilus influenzae* type b. In the combination vaccines, the alum or the pertussis vaccine, or both, have an adjuvant effect.

The primary or initial course of immunization consists of 4 inoculations. The first 3 doses are given at intervals of 1–2 months and 4th dose 6–12 months after the third dose. First dose is usually given when the infant is 6 weeks old. Additional doses are recommended prior to school entry and then every 5 years until the age of 18. Alternatively, one or two doses of live vaccine (OPV) can be given safely as boosters after an initial course of immunization with inactivated vaccine.

IPV induces, humoral antibodies (IgM, IgG and IgA serum antibodies) but does not induce intestinal or local immunity (Fig. 2). The circulating antibodies protect the individual against paralytic polio, but do not prevent reinfection of the gut by wild viruses. For the individual, it gives protection from paralysis and nothing more; for the community, it offers nothing because the wild viruses can still multiply in the gut and be a source of infection to others. This is a major drawback of IPV. Further, in the case of an epidemic, IPV is unsuitable because : (i) immunity is not rapidly achieved, as more than one dose is required to induce immunity, and (ii) injections are to be avoided during epidemic times as they are likely to precipitate paralysis *(17)*. Therefore, IPV is not efficacious in combating epidemics of polio.

Advantages : Inactivated polio vaccine, because it does not contain living virus, is safe to administer (i) to persons with immune deficiency diseases (ii) to persons undergoing corticosteroid and radiation therapy (iii) to those over 50 years who are receiving vaccine for the first time, and (iv) during pregnancy.

Associated risks : No serious adverse reactions to IPV vaccines currently in use have been reported except minor local erythema (0.5–1 per cent), induration (3–11 per cent) and tenderness (14–29 per cent).

2. Oral (Sabin) polio vaccine (OPV)

Oral polio vaccine (OPV) was described by Sabin in 1957. It contains live attenuated virus (types 1,2 and 3) grown in primary monkey kidney or human diploid cell cultures. Ideally each virus type should be given separately as monovalent vaccine, but for administrative convenience, rather than efficacy, it is given as *trivalent* (TOPV) vaccine. The vaccine contains (i) over 3,00,000 TCID 50 of type 1 poliovirus (ii) over 1,00,000 TCID 50 of type 2 virus, and (iii) over 3,00,000 TCID 50 of type 3 virus per dose.

National Immunization Schedule

The WHO Programme on Immunization (EPI) and the National Immunization Programme in India recommend a primary course of 3 doses of OPV at one–month intervals, commencing the first dose when infant is 6 weeks old (see page 123). It is recommended that a dose of OPV (zero-dose) is required to be given to all children delivered in health institutions before their discharge from the hospital. The vaccine should be given in maternity wards, the newborn should not be taken to regular immunization sessions to avoid infection. OPV is given concurrently with DPT; BCG can be given simultaneously with the first dose of OPV. It is very important to complete vaccination of all infants before 6 months of age. This is because most polio cases occur between the ages of 6 months and 3 years. One booster dose of OPV is recommended 12 to 18 months later.

Dose and mode of administration

The dose is 2 drops or as stated on the label. WHO recommends that vaccinators use dropper supplied with the vial of oral polio vaccine. This is the most direct and effective way to deliver the correct drop size. Tilt the child's

back, and gently squeeze the cheeks or pinch the nose to make the mouth open. Let the drops fall from the dropper onto the child's tongue. Repeat the process if the child spits out the vaccine. If the vaccine is spoon–fed there is a chance that it will not all be licked up by the child *(18)*.

Development of immunity

On administration, the live vaccine strains infect intestinal epithelial cells. After replication, the virus is transported to the Peyer's patches where a secondary multiplication with subsequent viraemia occurs. The virus spreads to other areas of the body, resulting in the production of circulating antibodies which prevent dissemination of the virus to the nervous system and prevent paralytic polio. Intestinal infection stimulates the production of IgA secretory antibodies which prevent subsequent infection of the alimentary tract with wild strains of poliovirus, and thus is effective in limiting virus transmission in the community. Thus OPV induces both local and systemic immunity as shown in Fig. 2.

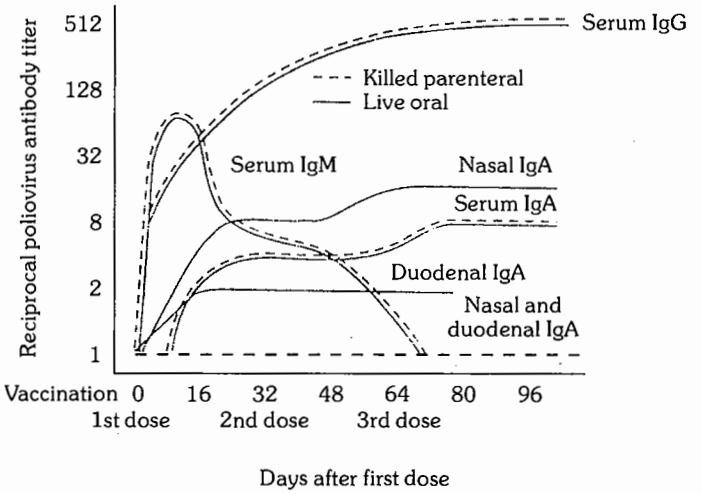

FIG. 2

Serum and secretory antibody response to 3 doses of OPV or 3 doses of IPV

Source : *(16)*

The vaccine progeny is excreted in the faeces and secondary spread occurs to household contacts and susceptible contacts in the community. Non-immunized persons may therefore, be immunized. Thus widespread "herd immunity" results, even if only approximately 66 per cent of the community is immunized *(7)*. This property of OPV has been exploited in controlling epidemics of polio by administering the vaccine simultaneously in a short period to all susceptibles in a community. This procedure virtually eliminates the wild polio strains in the community and replaces them by attenuated strains *(19)*. The duration of immunity produced by the OPV is not known, it may possibly even be lifelong *(20)*.

Colostrum produced in the first three days after child birth contains secretory IgA antibody, which might interfere with the immune response to OPV. Nevertheless, several studies show that among breast-fed infants who are fed OPV in the first three days of life, 20–40 per cent develop serum antibodies and 30–60 per cent excrete vaccine virus. Lower levels of secretory IgA are present in breast milk produced after the fourth day. There is no significant effect of breast-feeding on the response of older infants to OPV *(16)*.

Advantages

The advantages of OPV are : (i) since given orally, it is easy to administer and does not require the use of highly trained personnel (ii) induces both humoral and intestinal immunity. (iii) antibody is quickly produced in a large proportion of vaccinees, even a single dose elicits (except in tropical countries) substantial immunity (iv) the vaccinee excretes the virus and so infects others who are also immunized thereby (v) useful in controlling epidemics, and (vi) relatively inexpensive.

Complications

OPV is remarkably free from complications. However, being living viruses, the vaccine viruses, particularly type 3 do mutate in the course of their multiplication in vaccinated children, and rare cases of vaccine–associated paralytic polio have occurred in (a) recipients of the vaccine, and (b) their contacts. For details please refer to page 204.

Contraindications

It is recommended that diarrhoea should not be considered a contraindication to OPV. However, to ensure full protection, a dose of OPV given to a child with diarrhoea should not be counted as part of the series and the child should receive another dose at the first available opportunity. Live vaccines are not usually given to immunocompromised individuals *(16)*. Patients suffering from leukaemias and malignancy and those receiving corticosteroids may not be given OPV. IPV is an alternative to OPV for immunization of children with HIV infection *(16)*. There is as yet no indication that polio immunization may pose any danger to a pregnant mother or developing foetus. However, OPV should be delayed until after pregnancy unless immediate protection is required, when IPV is indicated *(7)*.

Storage

(a) Stabilized vaccine : Recent oral polio vaccines are heat stabilized by adding magnesium chloride. They can be kept without losing potency for a year at 4 deg. C, and for a month at 25 deg. C temperature *(9)*. *(b) Non-stabilized vaccine :* The vaccine should be stored at –20 deg C in a deep freeze until used. In case a deep freeze is not available, it might be stored temporarily in the freezing chamber of the refrigerator. During transport, the vaccine must be kept either on dry ice (solid carbon dioxide) or a freezing mixture (equal quantities of wet ice and ammonium chloride) *(21)*.

At the vaccination clinic, the bottle containing the OPV should not be frozen and thawed repeatedly, since repeated freezing and thawing has a deleterious effect on the potency of live polio vaccine. It would be preferable to keep the vials of the vaccine in ice during its administration to children *(21)*.

Recent studies indicate that breast-feeding does not impede the effectiveness of oral poliovirus vaccine *(22)*. Breast milk can be given whenever the child is hungry. However, hot water, hot milk or hot fluids should be withheld for about half an hour after the administration of the vaccine. The vaccine should be administered preferably in a cool room, rather than in a hot, humid and crowded room.

The problems with OPV may be summarized as follows (a) A primary problem is the instability of the vaccine at high ambient temperatures. The vaccine has to be kept frozen during storage, and kept cold during transportation, right up

to the point of administration. (b) A second problem is the frequent vaccine failures even with fully potent vaccines. (c) A third problem is the very small residual neurovirulence in OPV.

Sequential administration of IPV and OPV

Over the past decade, a number of countries in central and eastern Europe, the Middle East, the Far East, and southern Africa have adopted sequential schedules of 1–2 doses of IPV followed by ≥ 2 doses of OPV. Combined schedules of IPV and OPV appear to reduce or prevent VAPP while maintaining the high levels of intestinal mucosal immunity conferred by OPV. In addition, such schedules economize on limited resources by reducing the number of doses of IPV, and may optimize both the humoral and mucosal immunogenicity of polio vaccination. The effectiveness of this approach in preventing polio caused by WPV as well as VAPP has been documented by 2 large studies *(4)*.

The difference between IPV and OPV are given in Table 1.

TABLE 1

Differences between IPV and OPV

	IPV (Salk type)	OPV (Sabin type)
1	Killed formolised virus	Live attenuated virus
2	Given subcutaneously or IM	Given orally
3	Induces circulating antibody, but no local (intestinal) immunity	Immunity is both humoral and intestinal. Induces antibody quickly
4	Prevents paralysis, but does not prevent reinfection by wild polio viruses	Prevents not only paralysis, but also intestinal reinfection
5	Not useful in controlling epidemics	Can be effectively used in controlling epidemics. Even a single dose elicits substantial immunity (except in tropical countries)
6	More difficult to manufacture	Easy to manufacture
7	The virus content is 10,000 times more than OPV. Hence costlier	Cheaper
8	Does not require stringent conditions during storage and transportation. Has a longer shelf–life	Requires to be stored and transported at sub-zero temperatures, unless stabilized

Human Normal Ig

The current widespread practice of immunization has virtually eliminated the need for passive immunization. Normal human Ig in a dose of 0.25–0.3 ml per kg of body weight has been found to be protective for a few weeks against paralytic disease but does not prevent sub-clinical infections. Immuneglobulin is effective only if given shortly before infection, it is of no value after clinical symptoms develop *(10)*. The subject shall be actively immunized against polio after a few weeks.

Epidemiological Investigations

The occurrence of a single case of polio is now considered as an epidemic, and should prompt an immediate epidemiological investigation, including an active search for other cases. Samples of faeces from all cases or suspected cases of polio should be collected and forwarded to the laboratory for virus isolation. In addition, where possible, paired sera should be collected, the first specimen at the clinical suspicion of paralytic polio and the second at the period of convalescence. A rising titre of poliovirus neutralizing antibody provides useful confirmatory evidence. The Indian Council of Medical Research has set up National Enterovirus Units at Mumbai, Coonoor, Chennai, Delhi and Kasauli where samples may be sent for examination.

The following check-list indicates the essential data to be collected when investigating an outbreak *(23, 24)*.

1. Name of the administrative area and locality
2. Date first case reported from locality
3. Period of field investigation
   From.....to.....(dates)
4. No.of paralytic polio cases detected
   - 4.1 Clinical diagnosis only
   - 4.2 Laboratory confirmed
   - 4.3 Type(s) of virus isolated
5. No. of deaths from paralytic polio
6. No.of paralytic cases of polio by age

–1 year	10–14 years
1–4 years	15–19 years
5–9 years	20+ years

7. No.of contacts of paralytic polio examined :
   Household contacts
   Other. (specify)
8. Brief description of field investigation
9. History of previous vaccination practice in the locality including the dates of the last community vaccination programme, and the type of vaccine used.
10. Name of the principal investigator and laboratory.

Within an epidemic area, OPV should be provided for all persons over 6 weeks of age who have not been completely immunized or whose immune status is unknown.

Under the International Health Regulations, polio is subject to international surveillance. The WHO should be notified as soon as possible of the occurrence of paralytic polio and to supplement reports on such outbreaks with additional epidemiological information such as the type of virus, and the number of cases and deaths reported. In addition a quarterly report (on prescribed form) should be sent to WHO, Geneva. The WHO has prepared guidelines to poliovirus isolation and serological techniques for polio surveillance.

Strategies for polio eradication in India

(a) Conduct Pulse Polio Immunization days every year until poliomyelitis is eradicated.
(b) Sustain high levels of routine immunization coverage.
(c) Monitor OPV coverage at district level and below.
(d) Improve surveillance capable of detecting all cases of AFP due to polio and non-polio aetiology.
(e) Ensure rapid case investigation, including the collection of stool samples for virus isolation.
(f) Arrange follow-up of all cases of AFP at 60 days to check for residual paralysis.
(g) Conduct outbreak control for cases confirmed or suspected to be poliomyelitis to stop transmission.

Even a single case is treated as an outbreak and preventive measures are initiated, usually within 48 hours of notification of the case. The complete and timely reporting

of cases of poliomyelitis is an important element for the eradication of poliomyelitis. Reporting of all cases of acute flaccid paralysis in children under 15 years of age is mandatory, and line lists of all reported cases of poliomyelitis are maintained. Since 1992, the active surveillance has been extended to all cases of acute flaccid paralysis, including causes other than poliomyelitis.

Line listing of cases

Line listing of reported cases was started in the year 1989 to check for duplication (same case reported more than once if the child visited more than one health facility), year of onset of illness (to screen children with residual paralysis who developed poliomyelitis prior to the year of reporting), identification of high risk pockets (by analysis of residential status) and documentation of high-risk age groups.

Line listing of cases made it possible to take appropriate follow-up action in areas from where the cases had been reported. The line lists have also provided useful epidemiological data for programme purposes. For example, it provided information on the age at onset of illness and to understand the urgency for the early completion of the OPV immunization schedule.

All cases of acute flaccid paralysis must be reported immediately to the chief medical officer/district immunization officer with the following details :

- Name, age and sex of the patient
- Father's name and complete address
- Vaccination status
- Date of onset of paralysis and date of reporting
- Clinical diagnosis
- Doctor's name, address and phone number

Mopping Up

Mopping up activities are usually the last stage in polio eradication. The strategy of "mopping up" involves door–to–door immunization in high-risk districts, where wild polio virus is known or suspected to be still circulating. This strategy is being implemented in India.

Pulse Polio Immunization

In India NIDs have become the largest public health campaigns ever conducted in a single country. Government of India conducted the first round of PPI consisting of two immunization days 6 weeks apart on 9th December 1995 and 20th January 1996. The first PPI conducted targeted all children under 3 years of age irrespective of their immunization status. Later on, as recommended by WHO, it was decided to increase the age group from under 3 to under 5 years.

The term "pulse" has been used to describe this sudden, simultaneous, mass administration of OPV on a single day to all children 0–5 years of age, regardless to previous immunization. PPIs occur as two rounds about 4 to 6 weeks apart during low transmission season of polio, i.e. between November to February. In India, the peak transmission is from June to September. The dose of OPV during PPIs are **extra** doses which supplement, and **do not** replace the doses received during routine immunization services. The children including 0–1 year old infants should receive all their scheduled doses and PPI doses. There is no minimum interval between PPI and scheduled OPV doses *(25)*.

An important improvement in PPI during 1998 has been the use of vaccine vial monitor. Colour monitors or labels are put on vaccine bottles. Each label has a circle of deep blue colour. Inside it is a white square which changes colour and gradually becomes blue, if vaccine bottle is exposed to higher temperature. When the colour of the white square becomes blue like that of surrounding circle, the vaccine should be considered ineffective. Thereby, the health worker can easily ascertain that the vaccine being given is effective or not. This mechanism has been made mandatory in all vaccine procurements since 1998. This quality assurance will ensure that the children will have better protection against polio in 1999 and thereafter.

Following recommendations from the India Expert Advisory Group on Polio Eradication (IEAG), several strategies were utilized during 2005 and early 2006 to improve the impact of SIAs : (i) development and licensure of monovalent OPV1 (mOPV1) and mOPV3 for targeted use during SIAs based on surveillance data; (ii) deployment of additional peronnel to assist with intensified SIAs in the States of Bihar and UP and in Mumbai City; (iii) social mobilization targeted at reaching population groups missed during previous SIAs; (iv) use of mobile teams to vaccinate children at transit points (e.g. railway and bus stations) and on moving trains; and (v) increased engagement and accountability of political leaders and of health staff at all levels. To further improve population immunity in the most critical age group, the IEAG added a specific recommendation at its May 2006 meeting to identify and target all neonates in high-risk areas of UP with a "birth dose" of mOPV1 *(26)*.

The last case of polio in the country was reported from Howrah of West Bengal with date of onset of disease on 13th January 2011. Thereafter no polio case has been reported in the country. On 27th March 2014, India was declared as non-endemic country for polio.

The steps taken by the Government to achieve the target of polio eradication and maintain the polio-free state are as follows *(27)* :

1. All states and union territories in the country have developed a Rapid Response Team (RRT) to respond to any polio outbreak in the country. An Emergency Preparedness and Response Plan (EPRP) has also been developed by all states indicating steps to be undertaken in case of detection of a polio case.
2. In the states of UP and Bihar every new born child is being identified and vaccinated during the polio immunization campaigns and is being tracked for 8 subsequent rounds.
3. In order to reach every eligible child during the pulse polio round, apart from the strategy of vaccinating children at fixed booths and house to house visit, efforts in vaccinating children in transit at railway stations, inside long distance trains, major bus stops, marker places, religious congregations, major road crossings etc. throughout the country have been intensified. Special booths are established in areas bordering neighbouring countries like Wagah border and Attari train station in Punjab and Munabo train station in Barmer district of Rajasthan, to ensure that all children under 5 years of age coming from across the border are given polio drops.
4. An extremely high level of vigilance through surveillance across the country for any importation or circulation of poliovirus and Vaccine Derived Polio Virus (VDPV) is being maintained. Environmental surveillance is continuing at four sites with establishment of two new sites in 2012.

5. Government of India has identified 107 high risk blocks for polio where a multi-pronged strategy is being implemented to ensure sanitation, hygiene and clean drinking water in addition to vaccinating each and every child oral polio vaccine (OPV).
6. Migratory population from UP and Bihar are being identified in the states of Punjab, Haryana, Gujarat and West Bengal and these migratory children are being covered during the Sub National Immunization Day (SNID) in UP and Bihar.
7. Social mobilization activities are being intensified by involving the local influencers, community and religious leaders to improve community participation and acceptance of polio vaccine.
8. A rolling emergency stock of oral polio vaccine (OPV) is being maintained to respond to any wild polio vaccine (WPV) or circulating vaccine derived polio virus (cVDPV) detection. An expert sub-group will be established to discuss issues related to trivalent oral polio vaccine (tOPV) to bivalent oral polio vaccine (bOPV) switch in routine immunization and possibility of injectable polio vaccine (IPV) introduction in the country along with India specific timelines for these activities.

AFP SURVEILLANCE : PPI is supported by AFP surveillance system since 1997. It is being conducted through a network of surveillance medical officers (SMOs), who are specially trained and are responsible for a defined area. A national surveillance team is positioned in Delhi. The SMOs are located at the state headquarters and at regional places in case of larger states. A regular weekly reporting system has been established. As a result of more meticulous search/ reporting, the number of reported cases of AFP increased from 1005 in 1996 to 54,674 and the completeness of stool specimen collection improved markedly from 59 per cent in 1998 to 86 per cent at the end of 2013 *(28)*.

VIRAL HEPATITIS

Viral hepatitis may be defined as infection of the liver caused by any of half dozen viruses. Twenty years ago, hepatitis A virus (HAV) and hepatitis B virus (HBV) were the only known aetiological agents of viral hepatitis. Today, in addition to HAV and HBV hepatitis viruses C, D, E and G have also been identified and are recognized as aetiological agents of viral hepatitis. It is known that many other viruses may be implicated in hepatitis such as cytomegalovirus (CMV), Epstein–Barr virus, yellow fever virus and rubella virus. Viruses of herpes simplex, varicella and adenoviruses can also cause severe hepatitis in immunocompromised individuals, but are rare.

HEPATITIS A

Hepatitis A (formerly known as "infectious" hepatitis or epidemic jaundice) is an acute infectious disease caused by hepatitis A virus (HAV). The disease is heralded by non–specific symptoms such as fever, chills, headache, fatigue, generalized weakness and aches and pains, followed by anorexia, nausea, vomiting, dark urine and jaundice. The disease spectrum is characterized by the occurrence of numerous subclinical or asymptomatic cases. The disease is benign with complete recovery in several weeks. The case fatality rate of icteric cases is less than 0.1 per cent, usually from acute liver failure and mainly affects older adults. Although the disease has, in general, a low mortality (0.1%), patients may be incapacitated for many weeks.

Problem statement

Being an enterovirus infection like poliomyelitis, hepatitis A is endemic in most developing countries, with frequent outbursts of minor or major outbreaks. The exact incidence of the disease is difficult to estimate because of the high proportion of asymptomatic cases. However, based on an ongoing reassessment of the global burden of hepatitis A, WHO estimates suggest that about 1.4 million cases occur every year world-wide *(1)*.

Geographical areas can be characterized as having high, intermediate or low levels of hepatitis A infection *(2)*.

Areas with high levels of infection

In developing countries with very poor sanitary conditions and hygienic practices, most children (90%) have been infected with the hepatitis A virus before the age of 10 years. Those infected in childhood do not experience any noticeable symptoms. Epidemics are uncommon because older children and adults are generally immune. Symptomatic disease rates in these areas are low and outbreaks are rare.

Areas with intermediate levels of infection

In developing countries, countries with transitional

economies, and regions where sanitary conditions are variable, children often escape infection in early childhood. Ironically, these improved economic and sanitary conditions may lead to a higher susceptibility in older age groups and higher disease rates, as infections occur in adolescents and adults, and large outbreaks can occur. Thus, paradoxically, with the transition from high to intermediate endemicity, the incidence of clinically significant hepatitis A increases.

Areas with low levels of infection

In developed countries with good sanitary and hygienic conditions, infection rates are low. Disease may occur among adolescents and adults in high-risk groups, such as injecting-drug users, homosexual men, people travelling to areas of high endemicity, and in isolated populations such as closed religious communities.

The exact incidence of HAV in India is not known. The Indian literature is replete with numerous reports of sporadic and epidemic occurrence of this disease in various cities, residential colonies and campuses. Epidemics of hepatitis A often evolve slowly, involve wide geographic areas and last many months, but, common source epidemics (e.g., faecal contamination of drinking water) may evolve explosively.

Epidemiological determinants

Agent factors

(a) AGENT : The causative agent, the hepatitis A virus, is an enterovirus (type 72) of the Picornaviridae family *(3)*. It multiplies only in hepatocytes. Faecal shedding of the virus is at its highest during the later part of the incubation period and early acute phase of illness. Only one serotype is known. (b) RESISTANCE : The virus is fairly resistant to low pH, heat and chemicals. It has been shown to survive more than 10 weeks in well water *(4)*. It withstands heating to 60 deg C for one hour, and is not affected by chlorine in doses usually employed for chlorination. Formalin is stated to be an effective disinfectant. The virus is inactivated by ultraviolet rays and by boiling for 5 minutes or autoclaving. In short the virus survives for long periods under variable conditions and resists many procedures that eliminate or inactivate most bacterial agents. (c) RESERVOIR OF INFECTION : The human cases are the only reservoir of infection. The cases range from asymptomatic infections to severe ones. Asymptomatic (anicteric) infections are especially common in children. These cases play an important role in maintaining the chain of transmission in the community. There is no evidence of a chronic carrier state. (d) PERIOD OF INFECTIVITY : The risk of transmitting HAV is greatest from 2 weeks before to 1 week after the onset of jaundice. Infectivity falls rapidly with the onset of jaundice *(5)*. (e) INFECTIVE MATERIAL : Mainly man's faeces. Blood, serum and other fluids are infective during the brief stage of viraemia. (f) VIRUS EXCRETION : HAV is excreted in the faeces for about 2 weeks before the onset of jaundice and for up to 2 weeks thereafter. There is little evidence for HAV transmission by exposure to urine or naso-pharyngeal secretions of infected patients. Haemodialysis plays no role in the spread of hepatitis A infections to either patients or the staff *(6)*.

Host factors

(a) AGE : Infection with HAV is more frequent among children than in adults. However, people from all ages may be infected if susceptible. In young children, infections tend to be mild or subclinical; the clinical severity increases with age. The ratio of anicteric to icteric cases in adults is about 1:3; in children, it may be as high as 12:1. However, faecal excretion of HAV antigen and RNA persists longer in the young than in adults *(6)*. In India, by the age of 10 years, 90 per cent of healthy persons have serological evidence of HAV infection *(7)*. (b) SEX : Both sexes are equally susceptible. (c) IMMUNITY : Immunity after attack probably lasts for life; second attacks have been reported in about 5 per cent of patients. Most people in endemic areas acquire immunity through subclinical infection. The IgM antibody appears early in the illness and persists for over 90 days. IgG appears more slowly, and persists for many years.

Environmental factors

Cases may occur throughout the year. In India the disease tends to be associated with periods of heavy rainfall *(8)*. Poor sanitation and overcrowding favour the spread of infection, giving rise to water-borne and food-borne epidemics. Paradoxically, when standards of hygiene and sanitation are improved, morbidity from infection with enteric viruses may increase. This is what happened with hepatitis A *(9)*.

Modes of transmission

(a) *FAECAL–ORAL ROUTE :* This is the major route of transmission. It may occur by direct (person-to-person) contact or indirectly by way of contaminated water, food or milk. Water-borne transmission, is not a major factor in developed countries, where food-borne outbreaks are becoming more frequent. For example, consumption of salads and vegetables, and of raw or inadequately cooked shellfish and oyesters cultivated in sewage polluted water is associated with epidemic outbreaks of hepatitis A *(6)*. Direct transmission comprises an array of routes such as contaminated hands or objects such as eating utensils. Direct infection occurs readily under conditions of poor sanitation and overcrowding.

(b) *PARENTERAL ROUTE :* Hepatitis A is rarely, if ever, transmitted by the parenteral route (i.e., by blood and blood products or by skin penetration through contaminated needles). This may occur during the stage of viraemia. This mode of transmission is of minor importance as viraemic stage of infection occurs during prodromal phase and there is no carrier state *(6)*.

(c) *SEXUAL TRANSMISSION :* As a sexually transmitted infection hepatitis A may occur mainly among homosexual men because of oral–anal contact *(10)*.

Food handlers are not at increased risk for hepatitis A because of their occupation, but are noteworthy because of their critical role in common-source food-borne HAV transmission. Health care personnel do not have an increased prevalence of HAV infection and nosocomial HAV transmission is rare. Children play an important role in HAV transmission as they generally have asymptomatic or unrecognized illness *(11)*.

Incubation period

10 to 50 days (usually 14–28 days). The length of the incubation period is proportional to the dose of the virus ingested *(4)*.

Clinical spectrum

The onset of jaundice is often preceded by gastrointestinal symptoms such as nausea, vomiting,

anorexia, and mild fever. Jaundice may appear within a few days of the prodromal period, but anicteric hepatitis is more common. Hepatitis A resolves completely in 98 per cent of cases but relapse of symptoms are noted in 3–20 per cent cases *(12)*. The outcome of infection with HAV is as shown in Table 1.

TABLE 1

Outcomes of infection with hepatitis A virus

Outcome	Children	Adults
Inapparent (sub-clinical) infection	80-95%	10-25%
Icteric disease	5-20%	75-90%
Complete recovery	>98%	>98%
Chronic disease	None	None
Mortality rate	0.1%	0.3-2.1%

Source : *(6)*

Diagnosis

Tests for abnormal liver function, such as serum alanine aminotransferase (ALT) and bilirubin, supplement the clinical, pathologic, and epidemiologic findings.

A specific laboratory diagnosis of hepatitis A can be obtained by :

a. Demonstration of HAV particles or specific viral antigens in the faeces, bile and blood. HAV is detected in the stool from about 2 weeks prior to the onset of jaundice, up to 2 weeks after.

b. Anti-HAV appears in the IgM fraction during the acute phase, peaking about 2 weeks after elevation of liver enzymes. Anti-HAV IgM usually declines to non–detectable levels within 3–6 months. Anti-HAV IgG appears soon after the onset of disease and persists for decades. Thus, detection of IgM-specific anti-HAV in the blood of an acutely infected patient confirms the diagnosis of hepatitis A. ELISA is the method of choice for measuring HAV antibodies *(6)*.

The clinical, virologic and serological events following exposure to HAV are as shown in Fig. 1.

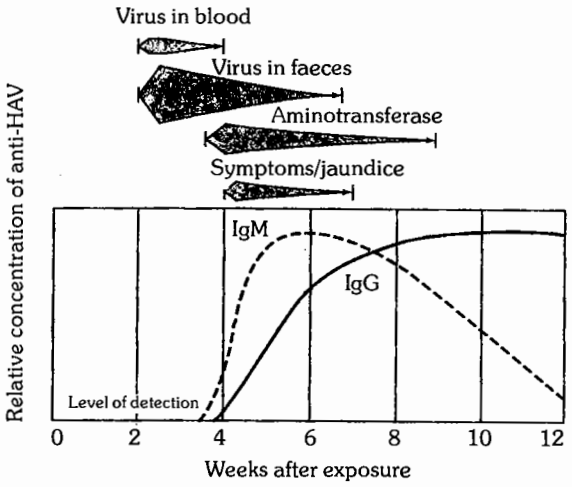

FIG. 1
Immunologic and biologic events associated with human infection with hepatitis A virus.

Prevention and containment

a. Control of reservoir

Control of reservoir is difficult because of the following factors: (a) faecal shedding of the virus is at its height during the incubation period and early phase of illness (b) the occurrence of large number of subclinical cases (c) absence of specific treatment, and (d) low socio-economic profile of the population usually involved. Strict isolation of cases is not a useful control measure because of (a) and (b). However, attention should be paid to the usual control measures such as complete bed rest and disinfection of faeces and fomites. The use of 0.5 per cent sodium hypochlorite has been strongly recommended as an effective disinfectant *(13)*.

b. Control of transmission

The best means of reducing the spread of infection is by promoting simple measures of personal and community hygiene, e.g., hand washing before eating and after toilet; the sanitary disposal of excreta which will prevent contamination of water, food and milk; and purification of community water supplies by flocculation, filtration and adequate chlorination. A question is often asked how much chlorine is needed to inactivate the virus. Studies indicated that 1 mg/L of free residual chlorine can cause destruction of the virus in 30 minutes at pH values of 8.5 or less *(14)*. The water treatment and distribution system should be improved. During epidemics, boiled water should be advocated for drinking purposes. Several countries of the world have achieved control of water-borne HAV infection. Other control measures include proper disposal of sewage within communities. If all these measures are properly implemented, a substantial reduction of HAV infection can be expected.

c. Control of susceptible population

Targeted protection of high-risk groups should be considered in low and very low endemicity, settings. Groups at increased risk of hepatitis A include travellers to areas of intermediate or high endemicity, those requiring life-long treatment with blood products, men having sex with men, workers in contact with non-human primates, and injection drug users. In addition, patients with chronic liver disease are at increased risk for fulminant hepatitis A and should be vaccinated *(12)*. Use of hepatitis A vaccine rather than passive prophylaxis with immune globuline should be considered for pre-exposure prophylaxis (e.g. for travellers) and post-exposure prophylaxis (e.g. for close contacts of acute cases of hepatitis A.

1. *Vaccines* : Two types of hepatitis A vaccines are currently used worldwide:

(a) Formaldehyde inactivated vaccines – produced in several countries and which are most commonly used worldwide.

(b) Live attenuated vaccinces – which are manufactured in China and are available in several countries.

Inactivated hepatitis A vaccine are licensed for use in persons ≥ 12 months of age. The complete vaccination schedule consists of 2 dose administration into the deltoid muscle. The interval between the first (primary) dose and second (booster) dose is commonly 6–12 months; however, the interval between the doses is flexible and can be extended to 18–36 months. It can be administered simulteneously with other vaccines. Following 2 doses of vaccine the protective efficacy is about 94 per cent.

The live attenuated vaccine is administered as a single subcutaneous dose.

Both inactivated and live attenuated hepatitis A vaccines are highly immunogenic and immunization will generate long-lasting, possibly life-long, protection against the disease in children and adults.

Recommendations for hepatitis A vaccination in outbreak situation depend on the epidemiologic features of disease in the community and the feasibility of rapidly implementing a widespread vaccination programme. National immunization programmes may consider inclusion of single-dose inactivated hepatitis A vaccine in immunization schedule *(12)*.

Combination of hepatitis A and B, or hepatitis A and typhoid vaccines have been developed, mainly intended for use in adult travellers.

2. *Human immunoglobulin* : The protective efficacy of immune globulin (Ig) against HAV infection is well documented. The duration of protection is, however, limited to approximately 1–2 months and 3–5 months following administration of IgG at dose of 0.02 and 0.06 ml/kg body weight, respectively. Prophylaxis is achieved within hours of injection and is 80 to 90 per cent effective when administered before or no later than 14 days after exposure. The use of Ig worldwide is now declining because of insufficient concentration of anti–HAV IgG in non-specific Ig preparations, the high cost of specific HAV IgG preparations, the limited duration of protection following passive IgG prophylaxis against HAV infection, and because hepatitis A vaccines have been shown to induce rapid protection against HAV after first dose *(12)*.

HEPATITIS B

Hepatitis B (formerly known as "serum" hepatitis) is an acute systemic infection with major pathology in the liver, caused by hepatitis B virus (HBV) and transmitted usually by the parenteral route. It is clinically characterized by a tendency to a long incubation period (4 weeks to 6 months) and a protracted illness with a variety of outcomes. Usually, it is an acute self-limiting infection, which may be either subclinical or symptomatic. In approximately 5 to 15 per cent of cases, HBV infection fails to resolve and the affected individuals then become persistent carriers of the virus. Persistent HBV infection may cause progressive liver disease including chronic active hepatitis and hepatocellular carcinoma. There is also evidence of a close association between hepatitis B and primary liver cancer *(11)*. Hepatitis B virus can form a dangerous alliance with delta virus and produce a new form of virulent hepatitis which is considered to be a widespread threat for much of the world.

Problem statement

WORLD

Hepatitis B is endemic throughout the world, especially in tropical and developing countries and also in some regions of Europe *(11)*. Its prevalence varies from country to country and depends upon a complex mix of behavioural, environmental and host factors. In general, it is lowest in countries or areas with high standards of living.

The HBV infection is a global problem, with 66 per cent of all the world's population living in areas where there are high levels of infection.

More than 2 billion people worldwide have evidence of past or current HBV infection and 350 million are chronic carriers of the virus, which is harboured in the liver, and causes an estimated 780,000 deaths from cirrhosis of liver and hepatocellular carcinoma *(15)*. The virus causes 60–80 per cent of all primary liver cancer. Between 5 per cent and 10 per cent of adults, and upto 90 per cent of infants infected with HBV become carriers. Among these, 25 per cent, in the long term, develop serious liver disease.

Hepatitis B is endemic in China and other parts of Asia. In these regions most people become infected in childhood and 8–10 per cent of the adult population are chronically infected. In the Middle East and Indian sub-continent, an estimated 2–5 per cent of the general population is chronically infected. In Western Europe and North America less than 1 per cent population is infected.

Based on the different HBsAg carrier rates, countries can be divided into three categories : high endemicity ($\geq$ 8 per cent), intermediate ($\geq$ 2–8 per cent), and low endemicity ($<$ 2 per cent). Countries of the Region can be divided into three epidemiological patterns. The Type 1 occurs in Nepal and Sri Lanka and is characterized by a low HBsAg carrier rate of 0.9 to 1.0 per cent. The second pattern (Type 2) can be found in Bhutan, India, Indonesia and Maldives where carrier rate is high in the general population (5 to 7 per cent). In India alone there are an estimated 43 to 45 million HBsAg carriers and, among them 10 to 12 million also have HBeAg. Type 3 is observed in Bangladesh, DPR Korea, Myanmar and Thailand, where the carrier rate is very high and ranges from 9 per cent to 12 per cent.

Transmission of HBV infection by blood transfusion and in other medical interventions in both modern and traditional health practices is also common in the Region. In India, the carrier rate of HBsAg in hospital staff has been found to be higher (10.87 per cent) than in voluntary blood donors (6 per cent) and in the general population (5 per cent). In India there are only 806 licensed blood banks and the incidence of post transfusion hepatitis in multiple–transfused patients is as high as 18 to 30 per cent *(16)*.

Epidemiological determinants

Agent factors

(a) AGENT : Hepatitis B virus was discovered by Blumberg in 1963. Efforts to grow this virus have been so far unsuccessful *(17)*. HBV is a complex, 42–nm, double–shelled DNA virus, originally known as the **"Dane particle".** It replicates in the liver cells. HBV occurs in three morphological forms in the serum of a patient: (a) small spherical particles with an average diameter of 22–nm. These particles are antigenic and stimulate production of surface antibodies; (b) tubules of varying length and diameter, and (c) the Dane particle which corresponds morphologically to hepatitis B virus. A person who is serologically positive for the surface antigen is circulating all morphological forms, of which 22–nm particles constitute the bulk. Of the three morphological forms, only the Dane particle is considered infectious, the other circulating morphological forms are not infectious.

(b) RESERVOIR OF INFECTION : Man is the only reservoir of infection which can be spread either from **carriers** or from **cases.** The continued survival of infection is due to the large number of individuals who are carriers of the virus. The persistent carrier state has been defined as the presence of HBsAg (with or without concurrent HBeAg) for more than 6 months. Cases may range from inapparent to symptomatic cases.

(c) INFECTIVE MATERIAL : Contaminated blood is the main source of infection, although the virus has been found in body secretions such as saliva, vaginal secretions and semen of infected persons.

(d) RESISTANCE : The virus is quite stable and capable of surviving for at least 7 days on environmental surfaces. It can be readily destroyed by sodium hypoclorite, as is by heat sterilization in an autoclave for 30 to 60 minutes.

(e) PERIOD OF COMMUNICABILITY : The virus is present in the blood during the incubation period (for a month before jaundice) and acute phase of the disease. Period of communicability is usually several months (occasionally years in chronic carriers) or until disappearance of HBsAg and appearance of surface antibody.

Host factors

(a) AGE : The outcomes of HBV infection are age-dependent. Acute hepatits B occurs in approximately 1 per cent of perinatal, 10 per cent of early childhood (1–5 years of age), and 30 per cent of late (> 5 years age) HBV infections. Mortality from fulminant hepatitis B is approximately 70 per cent. The development of chronic HBV infection is inversely related to age and occurs in approximately 80–90 per cent of persons infected perinatally, in 30 per cent infected in early childhood (less than 6 years of age) and in 5 per cent infected after 6 years of age *(17)*.

(b) HIGH-RISK GROUPS : Certain groups carry higher risks. The annual incidence of HBV infection in surgeons is estimated to be 50 times greater than that in the general population, and is more than twice that of other physicians. Other high risk groups comprise recipients of blood transfusions, health care and laboratory personnel, homosexuals, prostitutes, percutaneous drug abusers, infants of HBV carrier mothers, recipients of solid organ transplants and patients who are immunocompromised. Serological screening and vaccination of high-risk groups is highly recommended.

(c) HEPATITIS B AND HIV INFECTION : It is estimated that 10 per cent of the 40 million people infected with HIV worldwide are coinfected with HBV. Although HBV infection appears to have a minimal effect on the progression of HIV, the presence of HIV markedly increases the risk of developing HBV-associated liver cirrhosis and hepatocellular carcinoma. The mortality rate increases among HIV-positive people due to HBV coinfection both before and after commencement of highly active anti-retroviral therapy *(17)*.

(d) HUMORAL AND CELLULAR RESPONSES *(18)*: Hepatitis B virus has three distinct antigens – a surface antigen, also known as "Australia antigen" (HBsAg), a core antigen (HBcAg), and an "e" antigen (HBeAg). They stimulate the production of corresponding antibodies e.g., surface antibody (anti-HBs), core antibody (anti-HBc) and "e" antibody (anti-HBe). These antibodies and their antigens constitute very useful markers of HBV infection. Patients with HBV infection are expected to have one or more HBV markers. The course of a typical acute hepatitis is outlined in Fig. 1.

Modes of transmission

a. *Parenteral route*

Hepatitis B is essentially a blood-borne infection. It is transmitted by infected blood and blood products through transfusions, dialysis, contaminated syringes and needles, pricks of skin, handling of infected blood, accidental inoculation of minute quantities of blood such as may occur

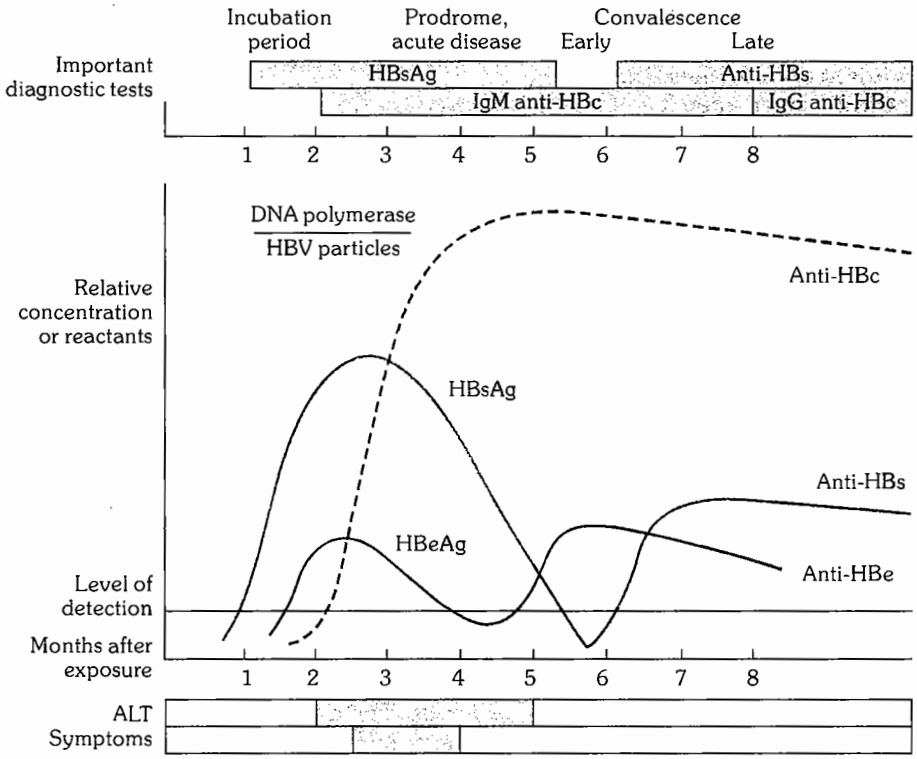

FIG. 1
Course of a typical acute hepatitis

ALT – alanine aminotransferase; anti-HBc – antibody to hepatitis B core antigen; anti-HBe – antibody to hepatitis B e antigen; anti-HBs – antibody to hepatitis B surface antigen; HBeAg – hepatitis B e antigen; HBsAg – hepatitis B surface antigen; HBV – hepatitis B virus; IgG – immunoglobulin G; IgM – immunoglobulin M.

Source : *(6)*

during surgical and dental procedures, immunization, traditional tattooing, ear piercing, nose piercing, ritual circumcision, accupuncture, etc. Accidental percutaneous inoculations by shared razors and tooth brushes have been implicated as occasional causes of hepatitis B *(8)*.

b. *Perinatal transmission*

Spread of infection from HBV carrier mothers to their babies appears to be an important factor for the high prevalence of HBV infection in some regions, particularly China and SE Asia. The risk of infection varies from country to country and unless vaccinated at birth, the majority of children born to mothers who are HBeAg–positive become chronically infected. The mechanism of perinatal infection is uncertain. Although HBV can infect the foetus in utero, this rarely happens and most infections appear to occur at birth, as a result of a leak of maternal blood into the baby's circulation, or ingestion or accidental inoculation of blood *(19)*. Infection of the baby is usually anicteric and is recognized by the appearance of surface antigen between 60–120 days after birth *(8)*.

c. *Sexual transmission*

There is ample evidence for the spread of infection by intimate contact or by sexual route. The sexually promiscuous, particularly male homosexuals, are at very high risk of infection with hepatitis B.

d. *Other routes*

Transmission from child–to–child, often called horizontal transmission, is responsible for a majority of HBV infections and carriers in parts of the world other than Asia. The researchers believe that the spread occurs through physical contact between children with skin conditions such as impetigo and scabies, or with cuts or grazes. Often transmission occurs when children play together or share the same bed *(20)*.

In short, transmission occurs in a wide variety of epidemiological settings. It can spread either from carriers or from people with no apparent infection, or during the incubation period, illness or early convalescence.

Incubation period

30 to 180 days. Lower doses of the virus result often in longer incubation period. The average incubation period is about 75 days *(17)*.

Clinical picture

The symptoms and manifestations of hepatitis B are similar to those of the other types of viral hepatitis. But the picture is complicated by the carrier state and by chronic liver disease, which may follow the infection. Chronic liver disease may be severe, and may progress to primary liver cancer which, in some parts of the world, is one of the commonest human cancers, particularly in men *(21)*. The clinical course of hepatitis B in adults is as shown in Fig. 2.

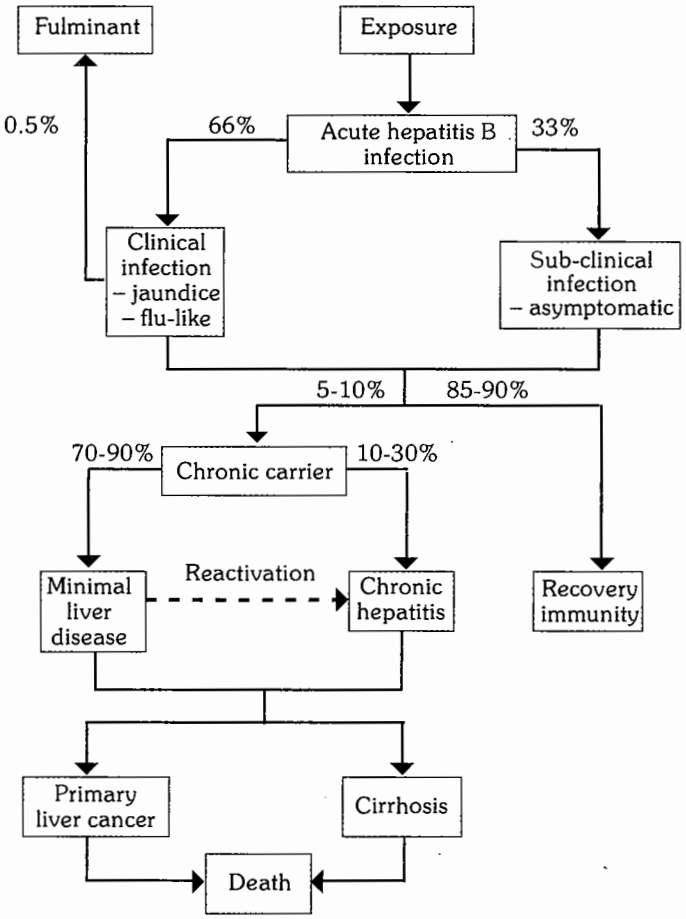

FIG. 2

Clinical course of hepatitis B in adults

Source : *(22)*

There are three distinct antigen antibody systems that relate to HBV infection and a variety of circulating makers that are useful in diagnosis. Interpretation of common serological patterns is as shown in Table 1.

TABLE 1

Common serologic patterns in hepatitis B virus infection and their interpretation

HBsAg	Anti-HBs	Anti-HBc	HBeAg	Anti-HBe	Interpretation
+	–	IgM	+	–	Acute hepatitis B
+	–	IgG[1]	+	–	Chronic hepatitis B with active viral replication
+	–	IgG	–	+	Chronic hepatitis B with low viral replication
+	+	IgG	+ or –	+ or –	Chronic hepatitis B with heterotypic anti-HBs (about 10% of cases)
–	–	IgM	+ or –	–	Acute hepatitis B
–	+	IgG	–	+ or –	Recovery from hepatitis B (immunity)
–	+	-	–	–	Vaccination (immunity)
–	–	IgG	–	–	False-positive, less commonly, infection in remote past

[1] Low levels of IgM anti-HBc may also be detected.

Source : *(18)*

PREVENTION AND CONTAINMENT

Since there is no specific treatment, prevention has been the major aim in managing viral hepatitis B. The following measures are available :

a. Hepatitis B vaccine

The recombinant hepatitis B vaccine was introduced in 1986 and has gradually replaced the plasma–derived hepatitis B vaccine. The active substance in recombinant hepatitis B vaccine is HBsAg.

Hepatitis B vaccine is available as monovalent formulation, or in fixed combination with other vaccines, including DPT, Hib, hepatitis A and inactivated polio. The immune response and safety of these combinations of vaccines are comparable to those observed when the vaccines are administered separately. When immunizing against HBV at birth, only monovalent hepatitis B vaccine should be used. Internationally marketed hepatitis B vaccines are considered immunologically comparable and can be used interchangeably *(23)*.

The dose for adults is 10–20 micrograms initially (depending on the formulation) and again at 1 and 6 months. Children under 10 years of age should be given half of the adult dose at the same time intervals. For greatest reliability of absorption, the deltoid muscle is preferred for injection as gluteal injection often results in deposition of vaccine in fat rather than muscle, with fewer serologic conversion. For infants and children under 2 years, anterolateral aspect of thigh is used as vaccination site. Intradermal administration is not recommended because the immune response is less reliable particularly in children. The hepatitis B vaccine does not interfere with immune response to any other vaccine and vice-versa. The birth dose of hepatitis B can be given safely together with BCG vaccine. However, the vaccines should be given at different sites.

There are multiple options for incorporating the hepatitis B vaccine into national immunization programmes. The choice of schedule depends on the local epidemiological situation and programme considerations. The recommended schedule for vaccination can be divided into those that include a birth-dose and those that do not. Schedules with a birth-dose call for the first dose at birth, followed by a second dose and third dose at the time of the first and third dose of DPT vaccination respectively. Alternatively, a four-dose schedule may be used (as in India) where the dose at birth is followed by three additional doses at 6, 10 and 14 weeks with DPT vaccination. These doses may be given either as monovalent vaccine or as a combination (eg. with DPT and/or Hib) following the schedules commonly used for these vaccines. The minimum recommended interval between the doses is four weeks. Longer dose intervals may increase the final anti-HBs titres but not the sero-conversion rates. These schedules will prevent most perinatally acquired infection. In countries where a high proportion of HBV infection is acquired perinatally, specifically in countries where the prevalence in the general population of chronic HBV infection is more than 8 per cent, the first dose of hepatitis B vaccine should be given within 24 hours after birth to prevent perinatal transmission *(24)*.

The complete vaccine series induces protective antibody levels in more than 95 per cent of infants, children and young adults. After the age of 40 years, protection following the primary vaccination series drops below 90 per cent; by 60 years, protective antibody levels are achieved in only 65–75 per cent of the vaccinees. The duration of protection is at least 15 years and based on current scientific evidence, life long *(24)*. Some infants born prematurely with low birth weight (< 2000 g) may not respond well to vaccination at birth. However, by one month of chronological age, all premature infants, regardless of initial birth weight or gestational age, are likely to respond adequately. In such cases the vaccine dose given at birth should not be counted towards the primary series and 3 additional doses should be given according to the national immunization schedule *(17)*. Immunosuppressive illness such as advanced HIV infection, chronic liver disease, chronic renal failure, and diabetes are associated with reduced immunogenicity of the vaccine.

Data on immunogenecity suggest that in any age group, interruption of the vaccination schedule does not require restarting of the vaccine series. If the primary series is interrupted after the first dose, the second dose should be administered as soon as possible and the second and the third doses separated by a minimum interval of 4 weeks; if only the third dose is delayed, it should be administered as soon as possible *(17)*.

Immunization in adults : Routine pre-exposure vaccination should be considered for groups of adults who are at increased risk of HBV infection. Adults 20 years of age and older should receive 1 ml of adult formulation. The usual schedule for adults is two doses separated by no less than 4 weeks, and a third dose 4 to 6 months after the second dose. If an accelerated schedule is needed, the minimum interval between first and second dose is 4 weeks and the minimum interval between the second and third dose is 8 weeks. However, the first and the third doses should be separated by no less than 16 weeks. Doses given at less than these minimum intervals should not be counted as part of the vaccination series. It is not necessary to restart the series or add doses because of an extended interval between doses *(11)*.

The high-risk persons for whom the vaccination is recommended are persons with high-risk sexual behaviour, partners and household contacts of HBsAg–positive persons, injecting drug users, persons who frequently require blood or blood products, recipients of solid organ transplantation, those at occupational risk of HBV infection, including health care workers, as well as for international travellers to HBV endemic countries.

Hepatitis B vaccine is contraindicated for individuals with a history of allergic reactions to any of the vaccine's components. Neither pregnancy nor lactation is a contraindication for use of this vaccine *(24)*.

The vaccine should be stored at 2–8°C. Freezing must be avoided as it dissociates antizen from the alum adjuvant.

Serological testing in vaccine recipients *(11)*

Prevaccination serological testing: Prevaccination serological testing is not indicated before routine vaccination of infants and children. It is recommended for all persons born in Africa, Asia, the Pacific Islands, and other regions with HBsAg prevalence of 2 per cent or higher; household, sex and needle sharing contacts of HBsAg–positive persons; homosexuals; injecting drug users; certain persons receiving cytotoxic or immunosuppressive therapy.

Postvaccination serological testing: Not routinely recommended following vaccination of infants, children, adolescents, or most adults. It is recommended for – chronic haemodialysis patients; other immunocompromised

persons; persons with HIV infection; sex partners of HBsAg+ persons; infants of HBsAg+ women; and certain health workers.

Vaccine nonresponse: Several factors have been associated with nonresponse to hepatitis B vaccine. These include vaccine factors (e.g., dose, schedule, injection site) and host factors. Older age (40 years and older), male gender, obesity, smoking and chronic illness have been independently associated with non-response to hepatitis B vaccine. Further vaccination of persons who fail to respond to a primary vaccinaton series, administered in the deltoid muscle, produces adequate response in 15 to 25 per cent of vaccinees after one additional dose and in 30 per cent to 50 per cent after three additional doses *(11)*. The second vaccine series should be given on the usual 0, 1 and 6 month schedule. Revaccinated personnel should be tested 1–2 months later after completion of the second vaccine series.

Fewer than 5 per cent persons receiving six doses of hepatitis B vaccine fail to develop detectable anti-HBs antibody. One reason for persistant nonresponse is that the person is chronically infected with HBV. They should be tested for HBsAg. Persons who fail to respond to two three-dose series and who are HBsAg negative should be considered susceptible to HBV infection and should be counselled regarding precautions to prevent HBV infection *(11)*.

b. Hepatitis B immunoglobulin (HBIG)

For immediate protection, HBIG is used for those acutely exposed to HBsAg–positive blood, for example (a) surgeons, nurses or laboratory workers (b) newborn infants of carrier mothers (c) sexual contacts of acute hepatitis B patients, and (d) patients who need protection against HBV infection after liver transplantation. The HBIG should be given as soon as possible after an accidental inoculation (ideally within 6 hours and preferably not later than 48 hours). At the same time the victim's blood is drawn for HBsAg testing. If the test is negative, vaccination should be started immediately and a full course given. If the test is positive for surface antibody, no further action is needed *(25)*.

The recommended dose is 0.05 to 0.07 ml/kg of body weight *(26)*; two doses should be given 30 days apart *(26, 27)*. HBIG provides short-term passive protection which lasts approximately 3 months. Since the median incubation period is said to be lower than 100 days *(28)*, two doses of HBIG given one month apart should suffice. The general use of HBIG for long-term prophylaxis has not been recommended because of its limited availability, its high cost and risk (although remote) of complications through repeated use over a long period of time *(29)*.

c. Passive–active immunization

The simultaneous administration of HBIG and hepatitis B vaccine is more efficacious than HBIG alone. HBIG does not interfere with the antibody response to the hepatitis B vaccine. This combined procedure is ideal both for prophylaxis of persons accidentally exposed to blood known to contain hepatitis B virus, and for prevention of the carrier state in the newborn babies of carrier mothers. HBIG (0.05–0.07 ml/kg) should be given as soon as possible and within 24 hours, if possible. Hepatitis B virus vaccine 1.0 ml (20 mcg/1.0 ml) should be given intramuscularly within 7 days of exposure, and second and third doses should be given one and six months, respectively, after the first dose.

d. Other measures

All blood donors should be screened for HBV infection, and those positive for Australia antigen should be rejected. Voluntary blood donation should be encouraged because purchased blood has shown a higher risk of post–transfusion hepatitis *(8)*. Health personnel should be alerted to the importance of adequate sterilization of all instruments and to the practice of simple hygienic measures. Carriers should be told not to share razors or tooth brushes and use barrier methods of contraception; they should not donate blood.

HEPATITIS C

Hepatitis C is a contagious liver disease that results from infection with the hepatitis C virus. It can range in severity from a mild illness lasting a few weeks to a serious, lifelong illness. It is among the most common virus that infect the liver and it has been shown to be a major cause of parenterally transmitted hepatitis.

Every year, 3–4 million people are infected with the hepatitis C virus. About 130–150 million people are chronically infected and are at risk of developing liver cirrhosis and/or liver cancer. More than 500,000 people die from hepatitis C – related liver diseases every years.

Transmission

The hepatitis C virus is most commonly transmitted through exposure to infectious blood. This can occur through: (a) receipt of contaminated blood transfusions, blood products and organ transplants; (b) injections given with contaminated syringes and needle-stick injuries in health-care settings; (c) injection drug use; and (d) being born to a hepatitis C-infected mother.

Hepatitis C may be transmitted through sex with an infected person or sharing of personal items contaminated with infectious blood, but these are less common. Hepatitis C is not spread through breast milk, food or water, or by casual contact such as hugging, kissing and sharing food or drinks with an infected person.

Incubation period

The incubation period for hepatitis C is 2 weeks to 6 months.

Symptoms

Following initial infection, approximately 80% of people do not exhibit any symptoms. Those people who are acutely symptomatic may exhibit fever, fatigue, decreased appetite, nausea, vomiting, abdominal pain, dark urine, grey-coloured faeces, joint pain and jaundice. About 75–85% of newly infected persons develop chronic disease and 60–70% of chronically infected people develop chronic liver disease; 5–20% develop cirrhosis and 1–5% die from cirrhosis or liver cancer. In 25% of liver cancer patients, the underlying cause is hepatitis C.

Diagnosis *(31)*

Diagnosis of acute infection is often missed because a majority of infected people have no symptoms. Common methods of antibody detection cannot differentiate between acute and chronic infection. The presence of antibodies against the hepatitis C virus indicates that a person is or has been infected. The hepatitis C virus recombinant immunoblot assay (RIBA) and hepatitis C virus RNA testing

are used to confirm the diagnosis. Diagnosis of chronic infection is made when antibodies to the hepatitis C virus are present in the blood for more than six months. Similar to acute infections, diagnosis is confirmed with an additional test. Specialized tests are often used to evaluate patients for liver disease, including cirrhosis and liver cancer.

Early diagnosis can prevent health problems that may result from infection and prevent transmission to family members and other close contacts. Some countries recommend screening for people who may be at risk for infection. These include: (a) people who recevied blood, blood products or organs before screening for hepatitis C virus was implemented, or where screening was not yet widespread. (b) current or former injecting drug users (even those who injected drugs once many years ago); (c) people on long-term haemodialysis; (d) health–care workers; (e) people living with HIV; (f) people with abnormal liver tests or liver disease, and (g) infants born to infected mothers.

Treatment *(32)*

Hepatitis C does not always require treatment. There are 6 genotypes of hepatitis C and they may respond differently to treatment. Careful screening is necessary before starting the treatment to determine the most appropriate approach for the patient. Combination antiviral therapy with interferon and ribavirin has been the mainstay of hepatitis C treatment. Unfortunately, interferon is not widely available globally, it is not always well tolerated, some virus genotypes respond better to interferon than others, and many people who take interferon do not finish their treatment. This means that while hepatitis C is generally considered to be a curable disease, for many people this is not a reality. Scientific advances have led to the development of new antiviral drugs for hepatitis C, which may be more effective and better tolerated than existing therapies. Two new therapeutic agents telaprevir and boceprevir have recently been licensed in some countries. Much needs to be done to ensure that these advances lead to greater access and treatment globally.

Prevention

Primary prevention

There is no vaccine for hepatitis C. The risk of infection can be reduced by avoiding.

- unnecessary and unsafe injections;
- unsafe blood products;
- unsafe sharps waste collection and disposal;
- use of illicit drugs and sharing of injection equipment;
- unprotected sex with hepatitis C-infected people;
- sharing of sharp personal items that may be contaminated with infected blood;
- tattoos, piercings and acupuncture performed with contaminated equipment.

Secondary and tertiary prevention

For people infected with the hepatitis C virus, WHO recommends:

- education and counselling on options for care and treatment;
- immunization with the hepatitis A and B vaccines to prevent coinfection from these hepatitis viruses to protect their liver,
- early and appropriate medical management including antiviral therapy if appropriate; and
- regular monitoring for early diagnosis of chronic liver disease.

For a number of technical reasons, the development of a vaccine to prevent HCV infection is unlikely for many years.

The epidemiologic and clinical features of hepatitis A, hepatitis B and hepatitis C are summarized in Table 2.

HEPATITIS E

The infection caused by the hepatitis E virus (HEV) which was discovered in 1980, is essentially a water-borne disease. Formerly termed enterically transmitted hepatitis non–A, non–B (HNANB), HEV is a 29–nm to 32–nm RNA virus with 4 genotypes (type 1, 2, 3 and 4).

Hepatitis E is found worldwide and different genotypes of the hepatitis E virus determine differences in epidemiology. For example, genotype 1 is usually seen in developing countries and causes community-level outbreaks while genotype 3 is usually seen in the developed countries, and does not cause outbreaks. Hepatitis E prevalence is highest in East and South Asia with genotype 1 most commonly found in India. Countries with limited resources, i.e., limited access to essential water, sanitation, hygiene and health services are frequently affected. In recent years, some of these outbreaks have occurred in areas of conflict and humanitarian emergencies, such as war zones, and in camps for refugees or internally displaced populations. An estimated 20 million infections and 3.3 million acute cases occur annually worldwide with an estimated 56,600 deaths. Over 60 per cent of all hepatitis E infections and 65 per cent of hepatitis deaths occur in East and South Asia, where seroprevalence rate of 25 per cent are common in some age groups *(1)*.

Transmission

The hepatitis E virus is transmitted mainly through the faecal-oral route, due to faecal contamination of drinking water. Other transmission routes have been identified, which include : (a) food-borne transmission from ingestion of products derived from infected animals; (b) transfusion of infected blood products; and (c) vertical transmission from a pregnant woman to her foetus.

Incubation period

The incubation period following exposure to the hepatitis E virus ranges from three to eight weeks, with a mean of 40 days. The period of communicability is unknown.

Symptoms

Symptomatic infection is more common in young adults aged 15–40 years. Although infection is frequent in children, the disease is mostly asymptomatic or causes a very mild illness without jaundice that goes undiagnosed. The typical symptoms are jaundice, loss of appetite, abdominal pain and tenderness, nausea and vomiting, fever and enlarged and tender liver. The symptoms are largely indistinguishable from those experienced during any acute phase of hepatic illness and last for one or two weeks.

TABLE 2

Epidemiologic and clinical features of viral hepatitis types A, B and C

	Viral Hepatitis Type A	Viral Hepatitis Type B	Viral Hepatitis Type C
Incubation period	10-50 days (avg. 25-30)	50-180 days (avg. 60-90)	2 weeks-6 months (avg. 40-120 days
Principal age distribution	Children,[1] young adults	15-29 years[2]	Adults[2]
Seasonal incidence	Throughout the year but tends to peak in autumn	Throughout the year	Throughout the year
Route of infection	Predominantly faecal-oral	Predominantly parenteral	Predominantly parenteral
Occurrence of virus :			
Blood	2 weeks before to ≤ 1 week after jaundice	Months to years	Months to years
Stool	2 weeks before to 2 weeks after jaundice	Absent	Probably absent
Urine	Rare	Absent	Probably absent
Saliva, semen	Rare (saliva)	Frequently present	Unknown
Clinical and laboratory features :			
Onset	Abrupt	Insidious	Insidious
Fever > 38°C (100.4°F)	Common	Less common	Less common
Duration of aminotransferase elevation	1-3 weeks	1-6+ months	1-6+ months
Immunoglobulins (IgM levels)	Elevated	Normal to slightly elevated	Normal to slightly elevated
Complications	Uncommon, no chronicity	Chronicity in 5-10%	Chronicity in 50% or more
Mortality rate (icteric cases)	< 0.5%	< 1–2%	0.5–1%
HBsAg	Absent	Present	Absent
Immunity :			
Homologous	Yes	Yes	?
Heterologous	No	No	No
Duration	Probably lifetime	Probably lifetime	?
Immune globulin intramuscular (IG, gammaglobulin, ISG)	Regularly prevents jaundice	Prevents jaundice only if immunoglobulin is of sufficient potency against HBV	?

[1] Non-icteric hepatitis is common in children.

[2] Among the age group 15-29 years, hepatitis B and C are often associated with drug abuse or promiscuous sexual behaviour. Patients with transfusion-associated HBV or HCV are generally over age 29.

Source : *(6)*

In rare cases, acute hepatitis E can result in fulminant hepatitis (acute liver failure) and death. Fulminant hepatitis occurs more frequently during pregnancy. Pregnant women are at greater risk of obstetrical complications and mortality from hepatitis E, which can induce a mortality rate of 20% among pregnant women in their third trimester.

Cases of chronic hepaitits E infection have been reported in immunosuppressed people. Reactivation of hepatitis E infection has also been reported in immunocompromised people.

Diagnosis

Cases of hepatitis E are not clinically distinguishable from other types of acute viral hepatitis. Diagnosis of hepatitis E infection is, therefore, usually based on the detection of specific IgM and IgG antibodies to the virus in the blood. Additional tests include reverse transcriptase polymerase chain reaction (RT-PCR) to detect the hepatitis E virus RNA in blood and/or stool, but this assay may require specialized laboratory facilities.

Treatment

Hepatitis E is usually self-limiting. Prevention is the most effective approach against the disease as there is no specific treatment for altering the course of acute hepatitis. Hospitalization is required for fulminant cases and in symptomatic pregnant women. Recovery from disease is always complete. No specific immunoglobulin prophylaxis is available.

Prevention

The risk of infection and transmission can be reduced by maintaining quality standards for public water supplies and establishing proper disposal systems to eliminate sanitary waste. On an individual level, infection risk can be reduced by : (a) maintaining hygienic practices such as hand washing with safe water, particularly before handling food; (b) avoiding drinking water and/or ice of unknown purity; and (c) adhering to WHO safe food practices.

In 2011, the first vaccine to prevent hepatitis E infection was registered in China, although it is not available globally.

HEPATITIS D *(6)*

HDV is found throughout the world but with a non–uniform distribution. Its highest prevalence has been reported in Italy, the Middle East, Central Asia, West Africa and South America. HDV infects all ages. Persons who have received multiple transfusions, intravenous drug abusers, and their close contacts are at high-risk.

The primary route of transmission are believed to be similar to those of HBV, though HDV does not appear to be sexually transmitted disease. Infection is dependent on HBV replication, as HBV provides an HBsAg envelop for HDV.

The incubation period varies from 2–12 weeks, being shorter in HBV carriers who are superinfected with the agent, than in susceptible persons who are simultaneously infected with both HBV and HDV.

HDV has been transmitted perinatally, but fortunately it is not prevalent in regions of the world, such as Asia, where perinatal transmission of HBV occurs frequently.

Two epidemiological patterns of HDV infection have been identified. In Mediterranean countries, HDV infection is endemic among persons with hepatitis B, and most infections are thought to be transmitted by intimate contact. In non endemic areas, such as United States and northern Europe, HDV infection is confined to persons exposed frequently to blood and blood products, drug addicts and haemophiliacs.

HDV can be prevented by vaccinating HBV susceptible persons with hepatitis B vaccine. However, vaccination does not protect hepatitis B carriers from superinfection by HDV.

HEPATITIS G

Hepatitis G virus HGV was discovered in 1996. The prevalence of this infection is still not known. A few publications provide information on the association of this infection with blood transfusion in India *(16)*.

The nomenclature and definitions used in the disease are shown in Table 3.

TABLE 3

Nomenclature and definitions of hepatitis viruses, antigens and antibodies

Disease	Component of system	Definition
Hepatitis A	HAV	Hepatitis A virus. Etiologic agent of infectious hepatitis. A *picornavirus*, the prototype of a new genus, *Hepatovirus*.
	Anti-HAV	Antibody to HAV. Detectable at onset of symptoms; lifetime persistence.
	IgM Anti-HAV	IgM class antibody to HAV. Indicates recent infection with hepatitis A; positive up to 4-6 months after infection.
Hepatitis B	HBV	Hepatitis B virus. Etiologic agent of serum hepatitis. A *hepadnavirus*.
	HBsAg	Hepatitis B surface antigen. Surface antigen(s) of HBV detectable in large quantity in serum; several sub-types identified.
	HBeAg	Hepatitis Be antigen. Soluble antigen ; associated with HBV replication, with high titers of HBV in serum, and with infectivity of serum.
	HBcAg	Hepatitis B core antigen.
	Anti-HBs	Antibody to HBsAg. Indicates past infection with and immunity to HBV, presence of passive antibody from HBIG, or immune response from HBV vaccine.
	Anti-HBe	Antibody to HBeAg. Presence in serum of HBsAg carrier suggests lower titer of HBV.
	Anti-HBc	Antibody to HBcAg. Indicates infection with HBV at some undefined time in the past.
	IgM Anti-HBc	IgM class antibody to HBcAg. Indicates recent infection with HBV ; positive for 4-6 months after infection.
Hepatitis C	HCV	Hepatitis C virus, a common etiologic agent of post-transfusion hepatitis. A flavivirus, genus *Hepacivirus*.
	Anti-HCV	Antibody to HCV.
Hepatitis D	HDV	Hepatitis D virus. Etiologic agent of delta hepatitis ; causes infection only in presence of HBV.
	HDAg	Delta antigen (delta-Ag). Detectable in early acute HDV infection.
	Anti-HDV	Antibody to delta-Ag (anti-delta). Indicates past or present infection with HDV.
Hepatitis E	HEV	Hepatitis E virus. Enterically transmitted hepatitis virus. Causes large epidemics in Asia and North Africa ; faecal–oral or waterborne transmission. Perhaps a *calicivirus*.
Hepatitis G	HGV	Hepatitis G virus, a *flavivirus*.
Immune globulins	IG	Immune globulin USP. Contains antibodies to HAV ; no antibodies to HBsAg, HCV, or HIV.
	HBIG	Hepatitis B immune globulin. Contains high titers of antibodies to HBV.

ACUTE DIARRHOEAL DISEASES

Diarrhoea is defined as the passage of loose, liquid or watery stools. These liquid stools are usually passed more than three times a day. However, it is the recent change in consistency and character of stools rather than the number of stools that is more important.

The term "diarrhoeal diseases" should be considered only as a convenient expression – not as a nosological or epidemiological entity – for a group of diseases in which the predominant symptom is diarrhoea.

CLINICAL TYPES OF DIARRHOEAL DISEASE *(1)*

It is most practical to base treatment of diarrhoea on the clinical type of illness, which can easily be determined. Four clinical types of diarrhoea can be recognized, each reflecting the basic underlying pathology and altered physiology :

(1) *Acute watery diarrhoea* – which lasts several hours to days; the main danger is dehydration, weight loss also occurs if feeding is not continued. The pathogens that usually cause acute diarrhoea include *V. cholerae* or *E. coli* bacteria, as well as rotavirus.

(2) *Acute bloody diarrhoea* – which is also called dysentery – the main dangers are damage of the intestinal mucosa, sepsis and malnutrition; other complications including dehydration, may also occur. It is marked by visible blood in the stools. The most common cause of bloody diarrhoea is *shigella*, a bacteria that is also a most common cause of severe cases.

(3) *Persistent diarrhoea* – which lasts 14 days or longer. The main danger is malnutrition and serious non-intestinal infection, dehydration may also occur. Persons with other illness, such as AIDS, are more likely to develop persistent diarrhoea.

(4) *Diarrhoea with severe malnutrition (marasmus and Kwashiorkor)* – The main dangers are severe systemic infection, dehydration, heart failure, and vitamin and mineral deficiency.

Problem statement

Acute diarrhoea is rivalled in importance only by respiratory infection, as a cause of morbidity on a worldwide scale. When the WHO initiated the Diarrhoeal Diseases Control Programme in 1980, approximately 4.6 million children used to die each year of the dehydration caused by diarrhoea. Diarrhoea is still a major killer of children under 5, although its toll has dropped by a third over the past decade. It killed more than 1,600 chileren under 5 years of age every day in 2012. It accounts for 9 per cent of all under-five deaths – a loss of more than 0.6 million child lives in 2012. Most of these deaths occur among children less than 2 years of age *(2)*.

Comparing estimates of the current global burden of diarrhoeal disease with previously published estimates, highlights that the incidence of diarrhoea have not changed much, although overall diarrhoeal mortality has declined. For children aged under 5 years, a median of 3 episodes of diarrhoea occurred per child-year, which is similar to that reported previously. The current estimates in under-five children suggest that there are about 1.4 billion episodes of diarrhoea per year with 123 million clinic visits annually and 9 million hospitalizations worldwide, with a loss of 62 million disability-adjusted life years (DALYs) *(3)*.

In India, acute diarrhoeal disease accounts for about 8 per cent of deaths in under-5 years age group. During the year 2013, about 10.7 million cases with 1,535 deaths were reported in India *(4)*.

Diarrhoea is a leading cause of death during complex emergencies and natural disasters. Displacement of population into temporary, overcrowded shelters is often associated with polluted water sources, inadequate sanitation, poor hygiene practices, contaminated food and malnutrition – all of which affect the spread and severity of diarrhoea. At the same time, the lack of adequate health services and transport reduces the likelihood of prompt and appropriate treatment of diarrhoea cases.

Diarrhoeal disease causes a heavy economic burden on the health services. Much attention has been given to acute diarrhoeal disease and its management over the last decade, which is dominated by advances in oral rehydration technique and through integrated management of childhood

illness. The treatment recommendations reflect a better understanding of what works to reduce child death from diarrhoea, as well as new insights into treatment feasibility. These changes in treatment recommendations and preventive measures have subsequently led to monitorable treatment and diarrhoea prevention indicators. They are as follows *(5)* :

The Indian data generated by demography and health survey 2005–2006 is given in bracket with each indicator.

(A) *Diarrhoea prevention indicators*

(1) Percentage of population using :

(a) improved drinking water sources (urban, rural, total); (For India – urban 97%, rural 90% and total 92%)

(b) improved sanitation facilities (urban, rural, total); (For India – urban 58%, rural 23% and total 34%)

(2) Percentage of one year old immunized against measles; (India–74%)

(3) Percentage of children who are :

- under-weight (moderate and severe) (India–43%) – 0 to 59 months age
- stunted (moderate and severe) (India–48%) – 0 to 59 months age
- exclusively breast-fed (India–46%) – 0 to 5 months age
- breast-fed with complementary food (India–57%) – 6 to 9 months age
- still breast-feeding (India–77%) – 20 to 23 months age

(4) Vitamin A supplementation coverage rate (per cent full coverage) – 6 to 59 months (India–53%)

(B) *Diarrhoea treatment Indicators*

Percentage of children under five years with diarrhoea receiving :

(1) ORT with continuous feeding (India 33%)

(2) ORS packet (India 26%)

(3) Recommended home made fluids (India 20%)

(4) Increased fluids (India 10%)

(5) Continued feeding (India 70%)

(C) *Use of oral rehydration therapy*

Percentage of children under five years with diarrhoea receiving oral rehydration therapy (ORS packet or recommended home-made fluids or increased fluids with continued feeding)

(1) Gender – male, female (India – male 34%, female 31%)

(2) Residence – Urban, rural (India – urban 38%, rural 31%)

(3) Wealth index quintiles – poorest, second, middle, fourth, richest (India – 29%, 29%, 31%, 35% and 45%).

Epidemiological determinants

Agent factors

In developing countries, diarrhoea is almost universally infectious in origin. A wide assortment of organisms cause acute diarrhoea, and many of them have been discovered only in recent years such as rotaviruses and campylobacters (Table 1).

TABLE 1

Infections causing diarrhoea

1. Viruses :	3. Others :
Rotaviruses	E. histolytica
Astroviruses	Giardia intestinalis
Adenoviruses	Trichuriasis
Calciviruses	Cryptosporidium SPP
Coronaviruses	Intestinal worms
Norwalk group viruses	*Cyclospora*
Enteroviruses	
Cytomegalovirus	
2. Bacteria :	
Campylobacter jejuni	
Enterotoxigenic Escherichia coli	
Shigella	
Salmonella	
Vibrio cholerae	
Vibrio parahaemolyticus	
Bacillus cereus	
Staphylococcus aureus	
Clostridium perfringens	
Enterohaemorrhagic E. coli	
Clostridium difficile	
Enteroinvasive E. coli	
Aeromonas	
Yersinia enterocolitica	
Chlamydia	
Neisseria gonorrhoeae	

Source : *(6)*

Until recent years, the identification of pathogens in the stool was only feasible in about 25 per cent of patients with acute diarrhoea. At present, new techniques enable competent laboratories to identify these pathogens in about 75 per cent of cases. The infectious agents most often connected with diarrhoea in young children, in developing countries, are as shown in Table 2.

TABLE 2

Pathogens frequently identified in children with acute diarrhoea in treatment centres in developing countries

Pathogen		% of cases
Viruses	Rotavirus	15–25
Bacteria	Enterotoxigenic *Escherichia coli*	10–20
	Shigella	5–15
	Campylobacter jejuni	10–15
	Vibrio cholerae 01	5–10
	Salmonella (non-typhoid)	1–5
	Enteropathogenic *Escherichia coli*	1–5
Protozoans	*Cryptosporidium*	5–15
No pathogen found	–	20–30

Source : *(7)*

(a) *VIRUSES*

A great many diarrhoeal diseases are caused by viruses (Table 1).

ROTAVIRUSES : The rotavirus, first discovered in 1973, has emerged as the leading cause of severe, dehydrating diarrhoea in children aged <5 years globally, with an estimated more than 25 million out-patient visits and more than 2 million hospitalizations attributable to rotavirus infections each year. In developing countries, three-quarters of children acquire their first episode of rotavirus diarrhoea before the age of 12 months, whereas in developed countries the first episode is frequently delayed until the age of 2–5 years. Severe rotavirus gastroenteritis is largely limited to children aged 6–24 months. Fatal outcomes in children, estimated to be approximately 420,000–494,000 in 2008 *(8)*, occur predominantly in low-income countries. Rotavirus reinfection is common, although the primary infection is usually the most significant clinically. In temperate climates, the incidence of rotavirus gastroenteritis typically peaks during the winter season, whereas in tropical settings rotavirus occurs year round and a marked seasonality may be masked by high background levels *(9)*.

Rotaviruses are shed in very high concentrations ($>10^{12}$ particles/gram) and for many days in the stools and vomit of infected individuals. Transmission occurs primarily by the faecal-oral route, directly from person to person or indirectly *via* contaminated fomites. The universal occurrence of rotavirus infections shows that clean water supplies and good hygiene are unlikely to have a substantial effect on virus transmission *(9)*.

(b) *BACTERIAL CAUSES*

Besides the well–known bacterial causes of enteric infections and diarrhoeal diseases such as *V. cholerae* 01, Salmonella, *Shigella*, enterotoxigenic *E.coli* and *Campylobacter jejuni* are the most frequent cause of diarrhoea. They produce a potent enterotoxin similar to that produced by *V. cholerae*. The less–known pathogens which cause diarrhoea are *Yersinia enterocolitica*, and *V. parahaemolyticus*.

Enterotoxigenic *Escherichia coli* (ETEC) is an important cause of acute watery diarrhoea in adults and children in developing countries causing annually 280–400 million diarrhoeal episodes in children under 5 years of age, and an additional 100 million episodes in children aged 5–14 years. In adults it causes substantial disease (about 400 million cases per year). It is also the most common cause of traveller's diarrhoea. Being responsible for one-third to one-half of all diarrhoeal episodes in travellers to Africa, Asia and Latin America, the illness results in 0.3 to 0.5 million deaths per year mostly in young children *(10)*. ETEC does not invade the bowel mucosa and the diarrhoea it causes is mediated by toxins. There are two ETEC toxins, heat labile (LT) and heat stable (ST). Some strains produce only one type of toxin, some both. The LT toxin is closely related to cholera toxin. ETEC is spread mostly by means of contaminated food and water.

Salmonella cause inflammation of the bowel epithelium; *Vibrio cholerae* O1 do not. Both are endemic diseases in India. In cholera–endemic areas, cholera probably accounts for not more than 5 to 10 per cent of all acute diarrhoeas yearly, and in more than 90 per cent of instances is clinically indistinguishable from other acute diarrhoeas. *Campylobacters* are slim, highly motile, S-shaped, gram-negative rods, formerly classed as vibrios. They are one of the commonest causes of enteritis. They do not seem to produce any toxin. It is not clear how they cause diarrhoea *(11)*.

Shigella accounts for a high percentage of mortality due to diarrhoeal disease. The estimates suggest that it causes about 1 million deaths every year in children aged under 5 years, mostly in the developing countries. In addition about 164.7 million *Shigella* episodes are estimated worldwide, with 69 per cent of all episodes in young children *(12)*. It is a major cause of diarrhoea in India.

(c) *OTHERS*

Amoebiasis, giardiasis and other intestinal parasitic infections are associated with diarrhoea *(13)*. Giardiasis is a recognized cause of diarrhoea. It flourishes in the duodenum and jejunum. The organisms can be present in very large numbers, the lumen of the intestine teeming with them and the epithelial surfaces almost smothered with them *(14)*.

Cryptosporidium is a coccidian parasite that causes diarrhoea in infants, immunodeficient patients, and a variety of domestic animals. In developing countries most episodes of illness occur in the first year of life. Thereafter, infections are usually asymptomatic. Diarrhoea is usually neither severe nor prolonged, except in immunodeficient patients, such as those with severe malnutrition or AIDS. In such individuals cryptosporidium is an important cause of persistent diarrhoea with wasting *(14)*.

The enumeration of the germs causing the enteric infections which lead to acute diarrhoea should not overshadow the fact that diarrhoea may be caused by a parenteral infection (non-digestive origin) and particularly so in younger children. These include ENT infections, respiratory or urinary infections, malaria, bacterial meningitis, or even simple teething *(7)*.

Besides the above causes, malnutrition may lead to certain nutritional diseases such as kwashiorkor, sprue, coeliac disease and pellagra which are all associated with diarrhoea. In the developed countries, the causes of diarrhoea may be slightly different. Diarrhoea in the newborn is unusual and may be due to inborn errors of metabolism such as congenital enzyme deficiencies. It may also be associated with severe infections like septicaemia or necrotizing enterocolitis *(15)*.

Persistent diarrhoea is one of the main clinical signs of AIDS in the tropics (an episode of diarrhoea lasting more than 30 days, according to the WHO definition of AIDS in children). This is associated with one or several other signs of the disease. Children with measles or who have had measles recently, run a high risk of developing severe or fatal diarrhoea *(7)*.

Reservoir of infection

For some enteric pathogens, man is the principal reservoir and thus most transmission originates from human factors ; examples are enterotoxigenic *E. coli*, *shigella spp.*, *V. cholerae, Giardia lamblia* and *E. histolytica*. For other enteric pathogens, animals are important reservoirs and transmission originates from both human and animal faeces; examples are *Campylobacter jejuni*, *Salmonella spp* and *Y. enterocolitica*. For viral agents of diarrhoea, the role of animal reservoirs in human disease remains uncertain.

Host factors

Diarrhoea is most common in children especially those between 6 months and 2 years. Incidence is highest in the age group 6–11 months, when weaning occurs. It reflects the combined effects of declining levels of maternally acquired antibodies, the lack of active immunity in the infant, the introduction of contaminated food, and direct contact with human or animal faeces when the infant starts to crawl. It is also common in babies under 6 months of age fed on cow's milk or infant feeding formulas *(16)*. Diarrhoea is more common in persons with malnutrition. Malnutrition leads to infection and infection to diarrhoea which is a well known vicious circle. Poverty, prematurity, reduced gastric acidity, immunodeficiency, lack of personal and domestic hygiene and incorrect feeding practices are all contributory factors.

Environmental factors

Distinct seasonal patterns of diarrhoea occur in many geographical areas. In temperature climates, bacterial diarrhoea occur more frequently during the warm season, whereas viral diarrhoea, particularly diarrhoea caused by rotavirus peak during the winter. In tropical areas, rotavirus diarrhoea occurs throughout the year, increasing in frequency during the drier, cool months, whereas bacterial diarrhoeas peak during the warmer, rainy season. The incidence of persistent diarrhoea follows the same seasonal patterns as that of acute watery diarrhoea *(14)*.

Mode of transmission

Most of the pathogenic organisms that cause diarrhoea and all the pathogens that are known to be major causes of diarrhoea in many countries, are transmitted primarily or exclusively by the **faecal–oral route**. Faecal–oral transmission may be water-borne; food-borne, or direct transmission which implies an array of other faecal–oral routes such as *via* fingers, or fomites, or dirt which may be ingested by young children *(17)*.

CONTROL OF DIARRHOEAL DISEASES

It is now obvious that many different organisms – some known, probably many unknown – cause diarrhoea. It is also clear that they do not act in the same way to cause diarrhoea. But from an epidemiological point of view, they are considered together because of the common symptom, diarrhoea. It is now firmly established that regardless of the causative agent or the age of the patient, the sheet anchor of treatment is oral rehydration therapy such as the one advocated by WHO/UNICEF.

The Diarrhoeal Diseases Control (DDC) Programme of WHO has since its inception in 1980, advocated several intervention measures to be implemented simultaneously with mutually reinforcing and complementary impacts. These measures centre round the widespread practice of "oral rehydration therapy".

Components of a Diarrhoeal Diseases Control Programme

The intervention measures recommended by WHO *(15)* may be classified as below :

1. Short-term

a. Appropriate clinical management.

2. Long-term

b. Better MCH care practices.

c. Preventive strategies.

d. Preventing diarrhoeal epidemics.

a. Appropriate clinical management

(I) ORAL REHYDRATION THERAPY : With introduction of oral rehydration by WHO it is now firmly established that oral rehydration treatment can be safely and successfully used in treating acute diarrhoeas due to all aetiologies, in all age groups, and in all countries. The aim of oral fluid therapy is to prevent dehydration and reduce mortality. It has been the experience of workers at Kolkata that as many as 90–95 per cent of all cases of cholera and acute diarrhoea can be treated by oral fluids alone *(18)*. Oral fluid therapy is based on the observation that glucose given orally enhances the intestinal absorption of salt and water, and is capable of correcting the electrolyte and water deficit.

At first the composition of oral rehydration salt (ORS) recommended by WHO was sodium bicarbonate based. Inclusion of trisodium citrate in place of sodium bicarbonate made the product more stable and it resulted in less stool output especially in high-output diarrhoea as in cholera, probably because of direct effect of trisodium citrate in increasing intestinal absorption of sodium and water.

More recently an improved ORS formulation has been developed which is as safe and effective as the original in preventing and treating diarrhoeal dehydration but also reduced stool output or offers additional clinical benefit or both. It is focussed on reducing the osmolarity of ORS solution to avoid possible adverse effects of hypertonicity on net fluid absorption by reducing the concentration of glucose and sodium chloride in the solution. Decreasing the sodium concentration of ORS solution to 75 mOsm/l improved the efficacy of the ORS regimen for children with acute non-cholera diarrhoea. The need for unscheduled supplemental intravenous therapy in children given the new ORS fell by 33 per cent, the stool output decreased by 20 per cent and vomiting was reduced by 30 per cent. The reduced osmolarity (245 mOsm/l) solution also appears to be as safe and effective as standard ORS for use in children with cholera *(19)*.

Recommended formulation : Because of the improved effectiveness of reduced osmolarity ORS solution, WHO and UNICEF are recommending that countries manufacture and use the following formulation in place of the previously recommended ORS solution. Since January 2004, the new ORS formulation is the only one procured by UNICEF. India was the first country in the world to launch this ORS formulation since June 2004.

Composition of reduced osmolarity ORS

Reduced osmolarity ORS	**grams / litre**
Sodium chloride	2.6
Glucose, anhydrous	13.5
Potassium chloride	1.5
Trisodium citrate, dihydrate	2.9
Total weight	20.5
Reduced osmolarity ORS	**mmol / litre**
Sodium	75
Chloride	65
Glucose, anhydrous	75
Potassium	20
Citrate	10
Total osmolarity	245

Source : *(19)*

Guidelines for assessing dehydration and oral rehydration : The guidelines for assessing dehydration and oral rehydration are given in Tables 3 and 4 *(20, 21)*.

TABLE 3
Assessment of dehydration

	DEHYDRATION	
	Mild	Severe
(1) Patient's appearance	Thirsty; alert, restless	Drowsy; limp, cold, sweaty; may be comatose
(2) Radial pulse	Normal rate and volume	Rapid, feeble, sometimes impalpable
(3) Blood pressure	Normal	Less than 80 mm Hg; may be unrecordable
(4) Skin elasticity	Pinch retracts immediately	Pinch retracts very slowly (more than 2 seconds)
(5) Tongue	Moist	Very dry
(6) Ant. fontanelle	Normal	Very sunken
(7) Urine flow	Normal	Little or none
% body weight loss	4–5%	10% or more
Estimated fluid deficit	40–50 ml/kg	100–110 ml/kg

When obvious signs of dehydration exist, the water deficit is somewhere between 50 and 100 ml per kg of body weight. If the child's weight is known, the amount of ORS solution required for rehydration during the first four hours may be calculated by setting the deficit at approximately 75 ml/kg. If the child's weight is not known, the approximate deficit may be determined on the basis of age, although this procedure is less accurate. The guidelines for oral rehydration are given in Table 4.

TABLE 4
Guidelines for oral rehydration therapy (for all ages) during the first four hours

Age (*)	under 4 months	4–11 months	1–2 yrs.	2–4 yrs.	5–14 yrs.	15 yrs or over
Weight (kg)	under 5	5–7.9	8–10.9	11–15.9	16–29.9	30 or over
ORS solution (ml)	200–400	400–600	600–800	800–1200	1200–2200	2200–4000

(*) The patient's age should only be used if weight is not known. The approximate amount of ORS required in ml. may also be calculated by multiplying the patient's weight (expressed in kg) by 75.

Source : *(1)*

The actual amount given will depend on the patients desire to drink and by surveillance of signs of dehydration, keeping in mind the fact that greater amounts should be given to heavier patients, those with greater signs of dehydration and those who still have watery diarrhoea during rehydration. The general rule is that patients should be given as much ORS solution as they want, and that signs of dehydration should be checked until they subside.

Older children and adults should be given as much water as they want, in addition to the ORS solution.

Mothers should be taught how to administer ORS solution to their children. It is best for a demonstration to be given by a nurse or by a health worker following which the mother feeds the solution to her child under their supervision respecting the following rules :

- for children under age 2 years, give a teaspoon every 1 to 2 minutes, and offer frequent sips out of a cup for older children. Adults may drink as much as they like. Try to give the estimated required amount within a 4–hour period. As a general guide, after each loose stool, give – children under 2 years of age : 50–100 ml (a quarter to half a large cup) of fluid; children aged 2 up to 10 years : 100–200 ml (a half to one large cup); and older children and adults : as much fluid as they want.
- if the child vomits, wait for 10 minutes, then try again, giving the solution slowly – a spoonful every 2 to 3 minutes.
- if the child wants to drink more ORS solution than the estimated amount, and does not vomit, there can be no harm in feeding him/her more. If the child refuses to drink the required amount and signs of dehydration have disappeared, rehydration is completed. The treatment plan for non-dehydrated diarrhoeic children is then resumed.
- if the child is breast-fed, nursing should be pursued during treatment with ORS solution.

The introduction of oral rehydration fluid has not only reduced the cost of treatment, but also made possible treatment of patients in their own homes by primary health workers or relatives of patients. The ingredients required for the preparation of oral fluid are inexpensive and readily available, and the solution can be prepared with ordinary drinking water and needs no sterilization. The development of oral rehydration therapy is a major breakthrough in the fight against cholera and other diarrhoeal diseases.

Packets of "oral rehydration mixture" are now freely available at all primary health centres, sub-centres, hospitals and chemist shops. The contents of the packet are to be dissolved in one litre of drinking water. The solution should be made fresh daily and used within 24 hours. It should not be boiled or otherwise sterilized.

If the WHO mixture of salts is not available, a simple mixture consisting of table salt (one level teaspoon) and sugar (6 level teaspoon) dissolved in one litre of drinking water may be safely used until the proper mixture is obtained. The earlier the treatment is instituted the better it is for the patient.

Many countries have designated recommended house fluids. Wherever possible these should include at least one fluid that contains salt. Fluids that do not contain salt are water in which a cereal has been cooked e.g. rice water; unsalted soup, yoghurt drinks, green coconut water, weak tea etc. The mothers should be taught to add salt about 3 g/litre to an unsalted drink or soup during diarrhoea. A few fluids are potentially dangerous and should be avoided during diarrhoea. Especially important are drinks sweetened with sugar, which can cause osmotic diarrhoea and hypernatraemia. Examples are commercial carbonated beverages, commercial fruit juices and sweetened tea. Other fluids to be avoided are those with stimulant diuretic or purgative effect, e.g. coffee and some medicinal tea or infusions *(1)*.

The infant's usual diet of cereals, vegetables and other foods should be continued during diarrhoea, and increased afterwards. Food should never be witheld and the child's usual food should never be diluted. The aim is to give as

much nutrient rich food as the child will accept. Most children with watery diarrhoea regain their appetite after dehydration is corrected, whereas those with bloody diarrhoea often eat poorly until the illness resolves. These children should be encouraged to resume normal feeding as soon as possible.

Please refer to Chapter 9, Annexure A for plan A, Plan B and Plan C for the management of dehydration due to diarrhoea.

(II) INTRAVENOUS REHYDRATION

Intravenous infusion is usually required only for the *initial* rehydration of severely dehydrated patients who are in shock or unable to drink. Such patients are best transferred to the nearest hospital or treatment centre.

The solutions recommended by WHO for intravenous infusion are: (a) *Ringer's lactate solution* (also called Hartmann's solution for injection) : It is the best commercially available solution. It supplies adequate concentrations of sodium and potassium and the lactate yields bicarbonate for correction of the acidosis. It can be used to correct dehydration due to acute diarrhoeas of all causes. (b) *Diarrhoea Treatment Solution (DTS):* Also recommended by WHO as an ideal polyelectrolyte solution for intravenous infusion. It contains in one litre, sodium chloride 4 g sodium acetate 6.5 g potassium chloride 1 g and glucose 10 g *(21)*. It must meet purity and sterility requirements of fluid for injection.

If nothing else is available, *normal saline* can be given because it is often readily available. Normal saline is the poorest fluid because it will not correct the acidosis and will not replace potassium losses. It should be replaced by the above solutions as early as possible. Plain glucose and dextrose solutions should not be used as they provide only water and glucose.

The recommended dose of the IV fluid to be given is 100 ml/kg, divided as follows (Table 5) :

TABLE 5

Treatment plan for rehydration therapy

Age	First give 30 ml/kg in	Then give 70 ml/kg in
Infants (under 12 months)	1 hour	5 hours
Older	30 minutes	$2^1/_2$ hours

The initial rehydration should be fast until an easily palpable pulse is present. Reassess the patient every 1–2 hours. If dehydration is not improving give the IV drip more rapidly. The use of large-bore needle (No.18) will permit rapid infusion. After infusing 1–2 litres of fluid, rehydration should be carried out at a somewhat slower rate until pulse and blood pressure return to normal. When the patient can drink the oral fluids give ORS about 5 ml/kg/hour.

The patient must be examined at intervals during rehydration. After 4–6 hours of satisfactory treatment, all signs of dehydration should have disappeared except that the urine flow may not have yet started. Sometimes if too much rehydration fluid is given, the eyelids become puffy; if this occurs, IV fluid should be stopped. It is most helpful to examine skin elasticity and pulse strength, both of which should be normal. Rehydration must continue until all signs of dehydration have disappeared.

(III) MAINTENANCE THERAPY

After the initial fluid and electrolyte deficit has been corrected (i.e., the signs of dehydration (Table 3) have gone) oral fluid should be used for maintenance therapy. In adults and older children, thirst is an adequate guide for fluid needs; they can be told to drink as much as they want to satisfy their thirst. The guidelines for maintenance therapy are given in Table 6. The general principle is that the oral fluid intake should equal the rate of continuing stool loss, which should be measured. Diarrhoea usually lasts for 1 or 2 days.

TABLE 6

Maintenance therapy

Amount of diarrhoea	Amount of oral fluid
Mild diarrhoea (not more than one stool every 2 hours or longer, or less than 5 ml stool per kg per hour)	100 ml/kg body weight per day until diarrhoea stops
Severe diarrhoea (more than one stool every 2 hours, or more than 5 ml of stool per kg per hour)	Replace stool losses volume for volume; if not measurable give 10–15 ml/kg body weight per hour

(IV) APPROPRIATE FEEDING : Medical profession has reeled for centuries under the mistaken assumption that it is important to "rest the gut" during diarrhoea. The current view is that during episodes of diarrhoea, normal food intake should be promoted as soon as the child whatever its age, is able to eat. This is especially relevant for the exclusively breast-fed infants. Newborn infants with diarrhoea who show little or no signs of dehydration can be treated by breast-feeding alone. Those with moderate or severe dehydration should receive oral rehydration solution. Breast-feeding is continued along with oral rehydration solution given after each liquid stool. Not only breast milk helps the infant to recover from an attack of diarrhoea both in terms of the nutrients it supplies, and its rehydrating effect, but it helps to prevent further infection because it has protective properties.

(V) CHEMOTHERAPY : Unnecessary prescription of antibiotics and other drugs will do more harm than good in the treatment of diarrhoea. Antibiotics should be considered where the cause of diarrhoea has been clearly identified as shigella, typhoid or cholera. The symptomatic differential diagnosis of *shigella* and cholera are as shown in Table 7.

TABLE 7

Symptomatic differential diagnosis of *shigella* and cholera

Symptoms	Cholera	*Shigella*
Diarrhoea	Acute watery diarrhoea	Acute bloody diarrhoea
Fever	No	Yes
Abdominal cramps	Yes	Yes
Vomiting	Yes	No
Rectal pain	No	Yes
Stool	> 3 loose stools per day, watery like rice water	> 3 stools per day, with blood or pus

For diarrhoea due to cholera the drug of choice is doxicycline, tetracycline, TMP-SMX and erythromycin. For diarrhoea due to *shigella*, the drug of choice is ciprofloxacin as *shigella* is usually resistant to ampicillin and TMP-SMX.

The medicines that should not be uesd in the treatment of diarrhoea are as follows *(16)* :

- neomycin (damages the intestinal mucosa and can cause malabsorption);
- purgatives (worsen diarrhoea and dehydration);
- tincture of opium or atropine (dangerous for children and dysentery patients because of decreased intestinal transit time);
- cardiotonics such as Coramine; shock in diarrhoea must be corrected by intravenous fluids and not by drugs;
- steroids (expensive, useless, and may cause adverse effects);
- oxygen (expensive, unnecessary);
- charcoal, kaolin, pectin, bismuth (no value);
- mexaform (no value and can be dangerous).

(VI) ZINC SUPPLEMENTATION : When a zinc supplement is given during an episode of acute diarrhoea, it reduces the episode's duration and severity. In addition, zinc supplements given for 10 to 14 days lower the incidence of diarrhoea in the following 2 to 3 months. WHO and UNICEF therefore recommend daily 10 mg of zinc for infants under 6 months of age, and 20 mg for children older than 6 months for 10–14 days *(19)*.

b. Better MCH care practices

(a) MATERNAL NUTRITION : Improving prenatal nutrition will reduce the low birth weight problem. Prenatal and postnatal nutrition will improve the quality of breast milk.

(b) CHILD NUTRITION : *(i) Promotion of breast-feeding :* Any measures to promote breast-feeding are likely to reduce the diarrhoeal diseases in infants. The breast-fed child is at very much less risk of severe diarrhoea and death than the bottlefed child. Promotion of breast-feeding should include strong efforts to limit the use of commercial and artificial formulas. Breast-feeding should be continued as long as possible. *(ii) Appropriate weaning practices :* Poor weaning practices are a major risk factor for diarrhoea. The child should be weaned neither too soon, nor too late, in any case not earlier than the sixth month of life using nutritious and locally available foods, and the foods should be hygienically prepared and given. *(iii) Supplementary feeding :* This is necessary to improve the nutritional status of children aged 6–59 months. As soon as the supplementary food is introduced, the child enters the high-risk category. *(iv) Vitamin A supplementation :* Vitamin A supplementation is a critical preventive measure, and studies have shown mortality reductions ranging from 19 per cent to 54 per cent in children receiving supplements. This reduction is associated in large part with decline in deaths due to diarrhoeal diseases and measles. It also reduces the duration, severity and complications associated with diarrhoea *(2)*.

c. Preventive strategies

(i) SANITATION : Measures to reduce transmission emphasize the traditional improved water supply, improved excreta disposal and improved domestic and food hygiene. Without an adequate supply of clean water close to their homes, it is extremely difficult to promote personal and domestic hygiene. Simple hygienic measures like hand washing with soap before preparing food, before eating, before feeding a child, after defecation, after cleaning a child who has defecated, and after disposing off a child's stool should be promoted. All families should have a clean and functioning latrine. The latrine should be kept clean by regular washing of dirty surface. If there is no latrine, family members should defecate at a distance from the house, paths or areas where children play and at least 10 metres away from the water supply source. It should be recognized that in many communities, young children are often permitted to defecate indiscriminately. Because diarrhoea attack rates are higher among children, it is the defecation in this age group that deserves the most attention. Contaminated foods of all sorts have been identified as major vehicles for the transmission of faecal pathogens during early infancy, e.g., diluted milk, cereal gruels, etc. Delays in consumption add to the problem.

(ii) HEALTH EDUCATION : Environmental sanitation measures require educational support, to ensure their proper use and maintenance of such facilities. An important part of health worker's job is to help prevent diarrhoea by convincing and helping community members to adopt and maintain certain preventive practices such as breast-feeding, improved weaning, clean drinking water, use of plenty of water for hygiene, use of latrine, proper disposal of stools of young children etc.

(iii) IMMUNIZATION : Immunization against measles is a potential intervention for diarrhoea control. When administered at the recommended age, the measles vaccine can prevent upto 25 per cent of diarrhoeal deaths in children under 5 years of age.

Rotavirus vaccine *(9)*

Two live, oral, attenuated rotavirus vaccines were licensed in 2006 : the monovalent human rotavirus vaccine (Rotarix™) and the pentavalent bovine-human, reassortant vaccine (Rota Teq™). Both vaccines have demonstrated very good safety and efficacy profiles in large clinical trials. The rotavirus vaccines are now introduced for routine use in a number of industrialized and developing countries.

The Rotarix™ vaccine is administered orally in a 2-dose schedule to infants of approximately 2 and 4 months of age. The first dose can already be administered at the age of 6 weeks and should be given no later than at the age of 12 weeks. The interval between the 2 doses should be at least 4 weeks. The 2-dose schedule should be completed by age 16 weeks, and no later than by 24 weeks of age.

For RotaTeq™, the recommended schedule is 3 oral doses at ages 2, 4 and 6 months. The first dose should be administered between ages 6–12 weeks and subsequent doses at intervals of 4–10 weeks. Vaccination should not be initiated for infants aged >12 weeks. All 3 doses should be administered before the age of 32 weeks.

There is a potentially higher risk of intussusception when the first dose of these vaccines is given to infants aged >12 weeks; consequently, current rotavirus vaccines should not be used in catch-up vaccination campaigns, where the exact age of the vaccinees may be difficult to ascertain.

(iv) FLY CONTROL : Flies breeding in association with human or animal faeces should be controlled.

d. Control and/or prevention of diarrhoeal epidemics

This requires strengthening of epidemiological surveillance systems.

e. The Integrated Global Action Plan for the Prevention and Control of Pneumonia and Diarrhoea

Please refer to page 174 for details.

PRIMARY HEALTH CARE

The concept of primary health care involves the delivery of a package of curative and preventive services at the community level. An intersectoral approach centred upon primary health care involving activities in the fields of water supply and excreta disposal, communicable disease control, mother and child health, nutrition and health education is regarded as essential for the ultimate control of diarrhoeal diseases.

Diarrhoeal Diseases Control Programme in India

The Diarrhoeal Disease Control Programme was started in 1978 with the objective of reducing the mortality and morbidity due to diarrhoeal diseases. Since 1985–86, with the inception of the National Oral Rehydration Therapy Programme, the focus of activities has been on strengthening case management of diarrhoea for children under the age of 5 years and improving maternal knowledge related to use of home available fluids, use of ORS and continued feeding. For details, refer to chapter 7 and 9.

CHOLERA

Cholera is an acute diarrhoeal disease caused by *V. Cholerae* O1 (classical or El Tor) and O139. It is now commonly due to the El Tor biotype and O139. Cases range from symptomless to severe infections. The majority of infections are mild or asymptomatic. Typical cases are characterized by the sudden onset of profuse, effortless, watery diarrhoea followed by vomiting, rapid dehydration, muscular cramps and suppression of urine. Unless there is rapid replacement of fluid and electrolytes, the case fatality may be as high as 30 to 40 per cent.

Problem statement

The number of cholera cases reported to WHO continues to rise. For 2013 alone, a total of 129,060 cases were notified from 47 countries, including 2,102 deaths. Many more cases were unaccounted for due to limitations in surveillance systems and fear of trade and travel sanctions. The true burden of the disease is estimated to be 1.4–4.3 million cases and 28,000–142,000 deaths annually *(1, 2)*.

Two serogroups of *V. cholerae* – O1 and O139 – cause outbreaks. *V. cholerae* O1 causes the majority of outbreaks, while O139 – first identified in Bangladesh in 1992 – is confined to South–East Asia. Non–O1 and non–O139 *V. cholerae* can cause mild diarrhoea but do not generate epidemics. Recently, new El Tor variant strains have been detected in several parts of Asia and Africa. Observations suggest that these strains cause more severe cholera with higher case fatality rates. Careful epidemiological monitoring of circulating strains is recommended *(1)*.

Recent studies indicate that global warming creates a favourable environment for the bacteria.

Cholera transmission is closely linked to inadequate environmental management. Typical at-risk areas include peri-urban slums, where basic infrastructure is not available and in areas, where as a consequence of a disaster, disruption of water and sanitation system takes place, or the displacement of population to inadequate and overcrowded camps. Risk of cholera transmission increases, should the bacteria be present or introduced. Epidemics have never arisen from dead bodies *(1)*.

Cholera remains a global threat to public health and a key indicator of lack of social development.

The dynamics of cholera occurrences since 2005, combined with the emergence of new strains that lead to a more severe clinical presentation; increased antimicrobial resistance and climate change, suggest that cholera may well return to the forefront of the global public health agenda *(3)*.

INDIA

Since the introduction of Cholera El Tor biotype in 1964, the geographic distribution of cholera in India has considerably changed. West Bengal has lost its reputation as the "home" of cholera. Many of the States which never had cholera or were free from it for a long time, got infected and became endemic foci of El Tor infection. In several of the recently invaded areas, the disease is seen persisting as a smouldering infection. The classical severe epidemics with high mortality are now uncommon. Explosive outbreaks, particularly following large fairs and festivals are also now rare.

The bacteriology of cholera also presents a changed

picture. For reasons that are not known, there has been no large scale epidemic of classical cholera since 1964. In short, the El Tor biotype of *V. Cholerae* O1 has rapidly replaced the classical biotype in all parts of the country. Most of the El Tor biotype isolated today belong to the serotype Ogawa.

During 2013, about 1,127 cholera cases were reported in India with 5 deaths. The majority cases were reported from Gujarat (327) followed by Maharashtra (247). Karnataka reported 105 cases, Tamil Nadu 93, and West Bengal 120 cases *(4)*.

Epidemiological features

Cholera is both an epidemic and endemic disease. The epidemicity and endemicity of a disease will depend on the *characteristics* of the agent, and those of the *system* (environment). Characteristics of the agent which influence its distribution include its ability to survive in a given environment, its virulence, the average number of organisms required to cause infection, etc. Characteristics of the system which affect the distribution of the agent include the number of susceptibles, and the opportunities it provides for transmission of the infection. Global experience has shown that the introduction of cholera into any country cannot be prevented, but cholera can create a problem only in areas where sanitation is defective.

Epidemics of cholera are characteristically abrupt and often create an acute public health problem. They have a high potential to spread fast and cause deaths. The epidemic reaches a peak and subsides gradually as the "force of infection" declines. Often–times, by the time control measures are instituted the epidemic has already reached its peak and is waning. Thus, cholera epidemic in a community is self–limiting. This is attributed to the acquisition of temporary immunity, as well as due to the occurrence of a large number of subclinical cases.

The "force of infection" is composed of 2 components, namely the force of infection through water and the force of infection through contacts *(5)*. It is well-known that the elimination of contaminated water does not immediately bring an outbreak to an end, but a so-called "tail" of the epidemic is produced. This is due to the continuation of transmission through contacts *(5)*.

In areas where cholera is endemic, it does not show a stable endemicity like typhoid fever *(5)*. It undergoes seasonal fluctuations as well as epidemic outbreaks. The seasonal variation differs between countries and even between regions of the same country. The seasonal incidence is also subject to change. For example, the disease used to be most common in the summer in Kolkata and in the early winter in Bangladesh; now in both places, it is most frequent in the autumn *(6)*. In some parts of India, the peak incidence is in August.

The El Tor biotype, wherever it has spread, has become endemic with periodic outbreaks. It appears to have greater "endemic tendency" than its classical counterpart in that it causes a higher infection–to–case ratio (i.e., inapparent infections and mild cases).

Cholera occurs at intervals even in endemic areas. A question that is frequently asked is about the fate of *V. cholerae* in the inter–epidemic periods. Three explanations are offered : (a) the existence of long-term carriers *(7)*; (b) the existence of diminished but continuous transmission involving asymptomatic cases *(8)*, and (c) the persistence of the organism in a free–living, perhaps altered form in the environment *(9, 10)*. The existence of a free–living cycle may explain why cholera became endemic for varying periods in certain areas after introduction of the current pandemic strains *(9, 10)*. Atypical non-toxigenic *V. cholerae* O1 of the El Tor biotype have sometimes been found in surface waters in endemic and non-endemic areas without any related human infection or disease *(11)*. A question of considerable epidemiological significance is whether "transmission" of somatic antigen can occur in the natural environment, i.e., can non–O1 *V. cholerae* become *V. cholerae* O1? *(12)*. Such "transformation" has been claimed by many workers *(13)*.

Epidemiological determinants

Agent factors

(a) AGENT : The organism that causes cholera is labelled as *V. cholerae* O Group 1 or *Vibrio cholerae* O1 and O139. The term "epidemic strain" has also been used for these vibrios. Vibrios that are biochemically similar to the epidemic strains (*V. cholerae* O1 and O139) but do not agglutinate in *V. cholerae* O1 and O139 antiserum have been referred to in the past as non–agglutinating (NAG) vibrios or as non–cholera vibrios (NCV). These are now included in the species *V. cholerae* and are referred to as non–O Group 1V/ O139 *cholerae* (non-epidemic strains). It is now recognized that the NCV/NAG vibrios include some species that are pathogenic for humans (e.g., *Vibrio parahaemolyticus*) which have caused outbreaks of cholera-like diarrhoea. It is, therefore, necessary to identify *V. cholerae* O1 and O139 for specific diagnosis of cholera. Within the O–Group 1, two biotypes – classical and El Tor, have been differentiated. It may be mentioned that the El Tor biotype was first isolated at the El Tor quarantine station in Egypt in 1905. Cholera is now caused mostly by the El Tor biotype and O139. Classical and El Tor vibrios are further divided each into 3 serological types namely Inaba, Ogawa and Hikojima. Most of the El Tor vibrios isolated in India belong to the Ogawa serotype. The El Tor biotype which are known for their haemolytic property, lost this property as the pandemic progressed. They may be distinguished from classical vibrios by the following tests :

(1) El Tor vibrios agglutinate chicken and sheep erythrocytes
(2) they are resistant to classical phage lV
(3) they are resistant to polymyxin B–50–unit disc, and
(4) the VP reaction and haemolytic test do not give consistent results.

(b) RESISTANCE : *V. cholerae* are killed within 30 minutes by heating at 56 deg.C or within a few seconds by boiling. They remain in ice for 4–6 weeks or longer. Drying and sunshine will kill them in a few hours. They are easily destroyed by coal tar disinfectants such as cresol. Bleaching powder is another good disinfectant which kills vibrios instantly at 6 mg/litre. The El Tor biotype tends to be more resistant than do classical vibrios. (c) TOXIN PRODUCTION : The vibrios multiply in the lumen of the small intestine and produce an exotoxin (enterotoxin). This toxin produces diarrhoea through its effect on the adenylate cyclase–cyclic AMP system of mucosal cells of the small intestine. The exotoxin has no effect on any other tissue except the intestinal epithelial cells. (d) RESERVOIR OF INFECTION: The human being is the only known reservoir of cholera infection. He may be a case or carrier. *(i) Cases :* Cases

range from inapparent infections to severe ones. About 75 per cent of people infected with *V. cholerae* do not develop any symptoms, although the bacteria are present in their faeces for 7–14 days after infection and are shed back into the environment, potentially infecting other people. Among people who develop symptoms, about 20 per cent develop acute watery diarrhoea with severe dehydration. People with low immunity, e.g., malnourished children and people living with HIV are at a greater risk of death if infected *(1)*. It is the mild and asymptomatic cases that play a significant role in maintaining endemic reservoir. *(ii) Carriers* : The carriers are usually temporary, rarely chronic. They also make an important contribution to the reservoir of infection. Since carriers excrete fewer vibrios than clinical cases, carriers are best detected by bacteriological examination of the purged stool induced by the administration of 30–60 gram of magnesium sulphate in 100 ml of water by mouth. (e) INFECTIVE MATERIAL : The immediate sources of infection are the stools and vomit of cases and carriers. Large numbers of vibrios (about 10^7–10^9 vibrios per ml of fluid) are present in the watery stools of cholera patients; and an average patient excretes 10–20 litres of fluid. Carriers excrete fewer vibrios than cases, 10^2–10^5 vibrios per gram of stools. (f) INFECTIVE DOSE : Cholera is dose–related. Infection occurs when the number of vibrios ingested exceeds the dose that is infective for the individual. Experimental work suggests that in the normal person a very high dose–something like 10^{11} organisms – is required to produce the clinical disease *(14)*. (g) PERIOD OF COMMUNICABILITY : A case of cholera is infectious for a period of 7–10 days. Convalescent carriers are infectious for 2–3 weeks. The chronic carrier state may last from a month up to 10 years or more.

Carriers in cholera *(15)*

A cholera carrier may be defined as an apparently healthy person who is excreting *V. cholerae* O1 (classical or El Tor) in stools. Four types of cholera carriers have been described *(16)* : (a) PRECLINICAL OR INCUBATORY CARRIERS : Since the incubation period of cholera is short (1–5 days), incubatory carriage is of short duration. The incubatory carriers are potential patients. (b) CONVALESCENT CARRIER : The patient who has recovered from an attack of cholera may continue to excrete vibrios, during his convalescence for 2–3 weeks. Convalescent state has been found to occur in patients who have not received effective antibiotic treatment. The convalescent carriers can often become chronic or long-term carriers. (c) CONTACT OR HEALTHY CARRIER : This is the result of subclinical infection contracted through association with a source of infection, be it a case or infected environment. The duration of contact carrier state is usually less than 10 days; the gall bladder is not infected, and the stool culture is frequently positive for *V. cholerae* O1. Contact carriers probably play an important role in the spread of cholera. (d) CHRONIC CARRIER : A chronic carrier state occurs infrequently. The longest carrier state was found to be over 10 years *(16)*. Studies indicate that gall bladder is infected in chronic carriers. Since carriers excrete fewer vibrios than cases, selective media and proper enrichment are important for their diagnosis. In carriers, the antibody titre against *V. cholerae* O1 rises and remains positive as long as the person harbours the organism. This method may be used to detect long-term carriers along with bacteriological examination of stools.

Host factors

(a) AGE AND SEX : Cholera affects all ages and both sexes. In endemic areas, attack rate is highest in children. (b) GASTRIC ACIDITY : An effective barrier. The vibrio is destroyed in an acidity of pH 5 or lower. Conditions that reduce gastric acidity may influence individual susceptibility *(19)*. (c) POPULATION MOBILITY : Movement of population (e.g., pilgrimages, marriages, fairs and festivals) results in increased risk of exposure to infection. In this jet age, cases and carriers can easily transfer infection to other countries. (d) ECONOMIC STATUS : The incidence of cholera tends to be the highest in the lower socio-economic groups, and this is attributable mainly to poor hygiene. (e) IMMUNITY : An attack of cholera is followed by immunity to reinfection, but the duration and degree of immunity are not known. In experimental animals specific IgA antibodies occur in the lumen of the intestine. Similar antibodies in serum develop after the infection but only last a few months. Vibriocidal antibodies in serum (titer $\geq$ 1:20) have been associated with protection against colonization and disease. The presence of antitoxin antibodies has not been associated with protection *(17)*. Vaccination gives only temporary, partial immunity for 3–6 months.

Environmental factors

Vibrio transmission is readily possible in a community with poor environmental sanitation. The environmental factors of importance include contaminated water and food. Flies may carry *V. cholerae* but not vectors of proven importance. Numerous social factors have also been responsible for the endemicity of cholera in India. These comprise certain human habits favouring water and soil pollution, low standards of personal hygiene, lack of education and poor quality of life.

Mode of transmission

Transmission occurs from man to man *via* (a) FAECALLY CONTAMINATED WATER : Uncontrolled water sources such as wells, lakes, ponds, streams and rivers pose a great threat. (b) CONTAMINATED FOOD AND DRINKS : Ingestion of contaminated food and drinks have been associated with outbreaks of cholera. Bottle–feeding could be a significant risk factor for infants. Fruits and vegetables washed with contaminated water can be a source of infection. After preparation, cooked food may be contaminated through contaminated hands and flies. There is growing opinion that El Tor cholera may in some instances be transmitted through a complex interaction of contaminated food, water and environment rather than through public drinking water supplies *(18)*. (c) DIRECT CONTACT : In developing countries, a considerable proportion of cases may result from secondary transmission, i.e., person to person transmission through contaminated fingers while carelessly handling excreta and vomit of patients and contaminated linen and fomites.

Incubation period

From a few hours up to 5 days, but commonly 1–2 days.

Pathogenesis

The main symptom of cholera is diarrhoea. Diarrhoea in cholera was attributed in the past to such factors as increased permeability of the intestinal epithelial cells, increased peristalsis, mucosal damage, an increase in mesenteric blood flow and failure of the "sodium pump", i.e., interference with

the passage of sodium from the lumen to the plasma. None of these theories stood the test of time *(19)*.

According to current concepts, the cholera vibrio get through the mucus which overlies the intestinal epithelium. It probably secretes mucinase, which helps it move rapidly through the mucus. Then it gets attached or *adhered* to the intestinal epithelial cells, and this it probably does by an adherence factor on its surface. When the vibrio becomes *adherent* to the mucosa, it produces its enterotoxin which consists of 2 parts – the light or L toxin and the heavy or H toxin. The L toxin combines with substances in the epithelial cell membrane called *gangliosides* and this binds the vibrio to the cell wall. Binding is irreversible. The mode of action of H toxin is not fully clear. What we know is that there is a substance called "adenyl cyclase" in the intestinal epithelial cells, and H toxin activates this substance. The activated adenyl cyclase causes a rise in another substance, called 3, 5–adenosine monophosphate, better known as cyclic or cAMP (A physiologist got Noble Prize for describing this substance). cAMP provides energy which drives fluid and ions into the lumen of the intestine. This fluid is isotonic and is secreted by all segments of small intestine. The increase in fluid is the cause of diarrhoea, and not increased peristalsis. There is no evidence that *V. cholerae* invades any tissue, nor the enterotoxin to have any direct effect on any organ other than the small intestine *(19)*.

Clinical features

The severity of cholera is dependent on the rapidity and duration of fluid loss. Epidemiological studies have shown that more than 90 per cent of El Tor cholera cases are mild and clinically indistinguishable from other acute diarrhoeas *(20)*. However, a typical case of cholera shows 3 stages : (a) STAGE OF EVACUATION : The onset is abrupt with profuse, painless, watery diarrhoea followed by vomiting. The patient may pass as many as 40 stools in a day. The stools may have a "rice water" appearance. (b) STAGE OF COLLAPSE : The patient soon passes into a stage of collapse because of dehydration. The classical signs are : sunken eyes, hollow cheeks, scaphoid abdomen, sub–normal temperature, washerman's hands and feet, absent pulse, unrecordable blood pressure, loss of skin elasticity, shallow and quick respirations. The output of urine decreases and may ultimately cease. The patient becomes restless, and complains of intense thirst and cramps in legs and abdomen. Death may occur at this stage, due to dehydration and acidosis resulting from diarrhoea. (c) STAGE OF RECOVERY : If death does not occur, the patient begins to show signs of clinical improvement. The blood pressure begins to rise, the temperature returns to normal, and urine secretion is re-established. If anuria persists, the patient may die of renal failure. The classical form of severe cholera occurs in only 5–10 per cent of cases. In the rest, the disease tends to be mild characterized by diarrhoea with or without vomiting or marked dehydration. As a rule, mild cases recover in 1–3 days.

Epidemiologically, cholera due to El Tor biotype differs from classical cholera in the following respects : (a) a higher incidence of mild and asymptomatic infection. This implies that the characteristic picture of rice–water stools and other signs of classical cholera described above may not be seen often; (b) fewer secondary cases in the affected families; (c) occurrence of chronic carriers, and (d) since El Tor vibrios are more resistant than classical cholera vibrios, they survive longer in the extra–intestinal environment.

Laboratory diagnosis of cholera *(21)*

The diagnosis of cholera can never be made with certainty on clinical grounds. Laboratory methods of diagnosis are required to confirm the diagnosis : (a) COLLECTION OF STOOLS : A fresh specimen of stool should be collected for laboratory examination. Sample should be collected before the person is treated with antibiotics. Collection may be made generally in one of the following ways : *(i) Rubber catheter :* Collection by the catheter is the best method but is complicated under field conditions. Soft rubber catheter (No.26–28) sterilized by boiling should be used. The catheter is introduced (after lubrication with liquid paraffin) for at least 4–5 cm into the rectum. The specimen voided may be collected directly into a transport (holding) media, e.g., Venkatraman–Ramakrishnan (VR) medium, alkaline peptone water. *(ii) Rectal swab :* Swabs consisting of 15–20 cm long wooden sticks, with one end wrapped with absorbent cotton, sterilized by autoclaving have been found to be satisfactory. Rectal swabs should be dipped into the holding medium before being introduced into the rectum. (iii) If no transport medium is available, a cotton–tipped rectal swab should be soaked in the liquid stool, placed in a sterile plastic bag, tightly sealed and sent to the testing laboratory *(22)*. (b) VOMITUS : This is practically never used as the chances of isolating vibrios are much less and there is no advantage. (c) WATER : Samples containing 1–3 litres of suspect water should be collected in sterile bottles (for the filter method), or 9 volumes of the sample water added to 1 volume of 10 per cent peptone water, and despatched to the laboratory by the quickest method of transport. (d) FOOD SAMPLES : Samples of food suspected to be contaminated with *V. cholerae* (or other enteric bacteria) amounting to 1 to 3 g are collected in transport media and sent to the laboratory. (e) TRANSPORTATION : (i) The stools should be transported in sterilized McCartney bottles, 30 ml capacity containing alkaline peptone water or VR medium. VR medium can be used if larger stool specimens can be collected. The specimen should be transported in alkaline peptone water or Cary–Blair medium if it is collected by a rectal swab. One gram or one ml of faeces in 10 ml of the holding medium will suffice. Rectal swabs should have their tops broken off so that caps of the containers can be replaced (ii) If suitable plating media are available (e.g., bile salt agar) at the bed-side, the stools should be streaked on to the media and forwarded to the laboratory with the transport media. (f) DIRECT EXAMINATION : If a microscope with dark field illumination is available, it may be possible to diagnose about 80 per cent of the cases within a few minutes, and more cases after 5–6 hours of incubation in alkaline peptone water. In the dark field, the vibrios evoke the image of many shooting stars in a dark sky. If motility ceases on mixing with polyvalent anti–cholera diagnostic serum, the organisms are presumed to be cholera vibrios. A presumptive diagnosis of cholera can thus be established. (g) CULTURE METHODS : On arrival at the laboratory, the specimen in holding fluid is well shaken, and about 0.5 to 1.0 ml of material is inoculated into Peptone Water Tellurite (PWT) medium for enrichment. After 4 to 6 hours incubation at 37 deg. C, a loopful of the culture from the surface is subcultured on Bile Salt Agar medium (BSA, pH 8.6). After overnight incubation, the plates are screened under oblique light illumination for vibrio colonies. (h) CHARACTERIZATION : *V. cholerae* usually appears on bile salt agar (BSA) as translucent, moist, raised, smooth and easily emulsifiable colonies about 1 mm in diameter. The typical colonies are picked up and tested as follows : *(i) Gram's stain and motility :* Gram negative and curved rods

with characteristic scintillating type of movement in hanging drop preparations are very characteristic of *V. cholerae (ii) Serological test:* Slide agglutination test is done by picking up suspected colonies and making a homogeneous suspension in 0.85 per cent sterile saline and adding one drop of polyvalent anti–cholera diagnostic serum. If agglutination is positive, the test is repeated with *Inaba* and *Ogawa* antisera, to determine the subtype. (i) BIOCHEMICAL TESTS : Serologically positive colonies should be subcultured in one tube each of the sugar broths (mannose, sucrose, arabinose) and a tube of peptone water pH 7.2 for the cholera red reaction. Production of acid in sucrose and mannose, but not arabinose is characteristic of *V. cholerae.* (j) FURTHER CHARACTERIZATION : For further characterization of biotypes of *V. cholerae* organisms are identified by slide agglutination tests using anti – O1 or group 139 antisera and by biochemical reaction patterns.

Suspicious colonies that do not agglutinate with anticholera sera are tested further by the oxidase and string tests *(19).*

CONTROL OF CHOLERA

It is now considered that the best way to control cholera is to develop and implement a national programme for the control of ALL diarrhoeal diseases because of similarities in the epidemiology, pathophysiology, treatment and control of cholera and other acute diarrhoeal diseases *(23).* The following account is based on the "Guidelines for Cholera Control" proposed by the WHO *(11).*

1. Verification of the diagnosis

It is important to have confirmation of the outbreak as quickly as possible. All cases of diarrhoea should be investigated even on the slightest suspicion. For the specific diagnosis of cholera, it is important to identify *V. cholerae* O1 in the stools of the patient. Once the presence of cholera has been proved, it is not necessary to culture stools of all cases or contacts. Bacteriological diagnosis of cholera envisages a well–organized system of laboratory services in the community.

2. Notification

Cholera is a notifiable disease locally and nationally. Since 2005 cholera notification is no longer mandatory internationally. Health workers at all levels (particularly those who are closest to the community such as the community health workers and the multi-purpose workers) should be trained to identify and notify cases immediately to the local health authority. Under the International Health Regulations, cholera is notifiable to the WHO within 24 hours of its occurrence by the National Government; the number of cases and deaths are also to be reported daily and weekly till the area is declared free of cholera. An area is declared free of cholera when twice the incubation period (i.e., 10 days) has elapsed since the death, recovery or isolation of the last case *(24).*

3. Early case-finding

An aggressive search for cases (mild, moderate, severe) should be made in the community to be able to initiate prompt treatment. Early detection of cases also permits the detection of infected household contacts and helps the epidemiologist in investigating the means of spread for deciding on specific intervention.

4. Establishment of treatment centres

In the control of cholera, no time should be lost in providing treatment for the patients. To achieve this objective, it is necessary to establish easily accessible treatment facilities in the community.

The *mildly dehydrated* patients (which account for over 90 per cent of cases) should be treated at home with oral rehydration fluid. *Severely dehydrated* patients, requiring intravenous fluids, should be transferred to the nearest treatment centre or hospital; if possible, they should receive oral rehydration on the way to the hospital or treatment centre. If there is no hospital or treatment centre within a convenient distance, a local school or public building should be taken over and converted into a temporary treatment centre, as close to the site of epidemic as possible. Transportation of cases over long distances is not desirable; it has been linked with the spread of the disease.

In areas where peripheral health services are poor and cholera is endemic or threatening, mobile teams should be established at the district level. When needed, these teams should be brought promptly into the epidemic area to assist the local workers.

5. Rehydration therapy

Cholera is now the most effectively treated disease. Mortality rates have been brought down to less than 1 per cent by effective rehydration therapy. The rehydration may be oral or intravenous. The guidelines for ORT and intravenous rehydration are discussed in detail on page 224, 225.

6. Adjuncts to therapy

Antibiotics should be given as soon as vomiting has stopped, which is usually after 3 to 4 hours of oral rehydration. Injectable antibiotics have no special advantages. The commonly used antibiotics for the treatment of cholera are flouroquinolones, tetracycline, Azithromycin, ampicilline and Trimethoprim TMP-Sulfamethoxazole (SMX). No other medication should be given to treat cholera, like antidiarrhoeals, antiemetics, antispasmodics, cardiotonics and corticosteroids. In regions where cholera is present, it is important to identify those antibiotics to which the vibrio cholerae 01 is resistant. If diarrhoea persists after 48 hours of treatment, resistance to antibiotic should be suspected.

7. Epidemiological investigations

General sanitation measures must be applied at the onset of an outbreak (see under sanitation measures). At the same time, epidemiological studies must be undertaken to define the extent of the outbreak and identify the modes of transmission so that more effective and specific control measures can be applied. The epidemiologist must maintain contact with all health and civic units in his area to ensure detection of new foci of disease.

There are certain institutions which are able to assist in investigating outbreaks. These include the National Institute of Communicable Diseases, Delhi and the All India Institute of Hygiene and Public Health, Kolkata, where epidemiological teams are available for investigating epidemics. In addition, stools for phage typing may be sent to the National Institute of Cholera and Enteric Diseases, 3, Dr Isaque Road, Kolkata–700016, where the WHO International Centre for Vibrios is located.

8. Sanitation measures

(a) *WATER CONTROL* : As water is the most important vehicle of transmission of cholera, all steps must be taken to provide properly treated or otherwise safe water to the community for all purposes (drinking, washing and cooking).

Various approaches have been described for supplying safe water quickly and with limited resources *(25)*. Facilities selected and installed should be appropriate and acceptable to the community. The ultimate aim should be provision of piped water supply on a permanent basis and elimination of alternative unsafe water sources. Because of financial limitations and other competitive priorities, this measure cannot be applied immediately on a large scale in developing countries, such as India. As an emergency measure, in urban areas, properly treated drinking water containing free residual chlorine should be made available to all families; this water should be stored in the household in narrow-mouthed, covered containers. In rural areas, water can be made safe by boiling or by chlorination. The emergency measures should be followed by the development of more permanent facilities.

(b) *EXCRETA DISPOSAL* : Provision of simple, cheap and effective excreta disposal system (sanitary latrines) is a basic need of all human settlements. When cholera appears in a community, the need for these facilities becomes vital. With the cooperation of the community, sanitary system should be selected and constructed *(25)*, taking into consideration the customs and practices of the population, the existing terrain and geology, and the available resources. Simultaneously, health education messages should stress the proper use of such facilities, the dangers involved in depositing faeces on the ground, and in or near water, and the importance of handwashing with soap after defecation.

(c) *FOOD SANITATION* : Since food may be an important vehicle of infection, steps should be taken to improve food sanitation, particularly sale of foods under hygienic conditions. Health education must stress the importance of eating cooked hot food and of proper individual food handling techniques. Cooking utensils should be cleaned and dried after use.

The housefly plays a relatively small role in transmitting cholera, but its prevalence is a general indicator of the level of sanitation.

(d) *DISINFECTION* : Disinfection should be both concurrent and terminal. The most effective disinfectant for general use is a coal tar disinfectant with a Rideal-Walker (RW) coefficient of 10 or more such as cresol. A disinfectant with a RW coefficient of less than 5 should not be used *(26)*. Bleaching powder, if used, should be of good quality. For disinfection, attention should be paid to the following : patient's stools and vomit; clothes and other personal items that may have been contaminated; the latrine, if any; the patient's house and neighbourhood.

9. Chemoprophylaxis

Studies have shown that approximately 10–12 per cent of close household contacts of a cholera case may be bacteriologically positive, and some of these develop clinical illness. In contrast, a very small proportion (0.6–1 per cent) in the community may be excreting vibrios. Mass chemoprophylaxis is not advised for the total community because in order to prevent one serious case of cholera, some 10,000 persons must be given the drug. Further, the drug's effect is only short-lived for a few days. Whenever mass chemoprophylaxis was attempted, it failed to stop the spread of cholera. Because of these reasons, chemoprophylaxis is advised only for household contacts or of a closed community in which cholera has occurred.

Tetracycline is the drug of choice for chemoprophylaxis. It has to be given over a 3-day period in a twice-daily dose of 500 mg for adults, 125 mg for children aged 4–13 years, and 50 mg for children aged 0–3 years. Alternatively, the long-acting tetracycline (doxycycline) may be used for chemoprophylaxis, if the prevailing strains are not resistant. A single oral dose of doxycycline (300 mg for adults and 6 mg/kg for children under 15 years) has proved to be effective.

10. Vaccination

ORAL VACCINE (27)

Two types of oral cholera vaccines are available : (a) Dukoral (WC-rBS) and (b) Sanchol and mORCVAX. The live attenuated single-dose vaccine (CVD103-HgR) is no longer produced.

(a) Dukoral (WC-rBS)

Dukoral is a monovalent vaccine based on formalin and heat-killed whole cells (WC) of *V. cholerae* O1 (classical and El Tor, Inaba and Ogawa) plus recombinant cholera toxin B subunit. The vaccine is provided in 3 ml single-dose vials together with the bicarbonate buffer (effervescent granules in sachets to protect the toxin B subunit from being destroyed by gastric acid). Vaccine and buffer are mixed in 150 ml of water (chlorinated or not) for persons aged >5 years and in 75 ml of water for children aged 2–5 years. The vaccine has a shelf life of 3 years at 2–8°C and remains stable for 1 month at 37°C.

Vaccine schedule and administration

According to the manufacturer, primary immunization consists of 2 oral doses given ≥7 days apart (but <6 weeks apart) for adults and children aged ≥6 years. Children aged 2–5 years should receive 3 doses ≥7 days apart (but <6 weeks apart). Intake of food and drink should be avoided for 1 hour before and after vaccination. If the interval between the primary immunization doses is delayed for >6 weeks, primary immunization should be restarted. Protection may be expected about 1 week after the last scheduled dose.

Provided there is continued risk of *V. cholerae* infection, 1 booster dose is recommended by manufacturer, after 2 years for adults and children aged ≥6 years. If the interval between the primary series and booster immunization is >2 years, primary immunization must be repeated. For children aged 2–5 years 1 booster dose is recommended every 6 months, and if the interval between primary immunization and the booster is >6 months, primary immunization must be repeated.

Dukoral is not licensed for children aged <2 years.

(b) Sanchol and mORCVAX

The closely related bivalent oral cholera vaccines are based on serogroups O1 and O139. Unlike Dukoral, these vaccines do not contain the bacterial toxin B subunit therefore it does not require buffer. According to the manufacturer, vaccine should be administered orally in 2 liquid doses 14 days apart for individuals aged ≥1 year. A booster dose is recommended after 2 years *(27)*.

11. Health education

The most effective prophylactic measure is perhaps health education. It should be directed mainly to (a) the effectiveness and simplicity of oral rehydration therapy (b) the benefits of early reporting for prompt treatment (c) food hygiene practices (d) hand washing after defecation and before eating, and (e) the benefit of cooked, hot foods and safe water. Since cholera is mainly a disease of the poor and ignorant, these groups should be tackled first.

Diarrhoeal Diseases Control Programme

The incidence of cholera cases and deaths has decreased in recent years. During the year 1980–81, strategy of the National Cholera Control Programme has undergone changes *(28)*. It is now termed as Diarrhoeal Diseases Control Programme *(29)*. Oral Rehydration Therapy Programme was started in 1986–87 in a phased manner. The main objective of the programme is to prevent diarrhoea–associated deaths in children due to dehydration. The training programme and health education material highlight the rational management of diarrhoea in children, including increased intake of home available fluids and breast feeding. ORS is promoted as first line of treatment. ORS is being supplied as a part of the sub-centre kits *(30)*.

TYPHOID FEVER

Typhoid fever is the result of systemic infection mainly by *S. typhi* found only in man. The disease is clinically characterized by a typical continuous fever for 3 to 4 weeks, relative bradycardia with involvement of lymphoid tissues and considerable constitutional symptoms. The term ***"enteric fever"*** includes both typhoid and paratyphoid fevers. The disease may occur sporadically, epidemically or endemically.

Problem statement

WORLD

Typhoid fever occurs in all parts of the world where water supplies and sanitation are sub-standard. The disease is now uncommon in the developed countries where most of the cases that occur are either acquired abroad or imported by immigrants *(1)*. Improved living conditions and the introduction of antibiotics in the late 1940s resulted in drastic reduction of typhoid fever morbidity and mortality in industrialized countries. In developing areas of Asia, Africa, Latin America, however, the disease continues to be a public health problem, albeit with incidence rate that vary considerably between and within countries. In 2004, WHO estimated the global typhoid fever disease burden at 21 million cases annually, resulting in an estimated 216,000-600,000 deaths per year, predominantly in children of school age or younger. Majority of this burden occurs in Asia *(2)*.

Since 1950, the organism's resistance to antibiotics has also been a growing problem; by 1989 resistance was reported in a number of countries, particularly in Asia and Middle East. Resistant strains have caused outbreaks of the disease in India and Pakistan in recent years. In South–East Asia, 50 per cent or more of the strains of the bacteria may already be resistant to several antibiotics *(3)*. Typhoid fever caused by multidrug-resistant (MDR) strains of *S. typhi* – that is resistant to all 3 of the first line of antibiotics (chloramphenicol, ampicillin and cotrimoxazole) – is associated with more severe illness and higher rates of complications and death, especially in children aged less than 2 years. Also, compared with typhoid fever caused by sensitive strains, a ten-fold higher rate of post-treatment symptomatic bacterial carriers has been reported with MDR *S. typhi* infection *(2)*. Without effective treatment, typhoid fever kills almost 10 per cent of those infected *(3)*.

The socio-economic impact of the disease is huge, because typhoid survivors may take several months to recover and resume work.

INDIA

Typhoid fever is endemic in India. Reported data for the year 2013 shows 1.53 million cases and 361 deaths. Maximum cases were reported from Bihar (261,791 cases with 2 deaths) followed by Andhra Pradesh (233,212 cases with 5 deaths). The other states having large number of cases are, Uttar Pradesh (223,066 cases and 161 deaths), Madhya Pradesh (114,578 cases and 28 deaths), West Bengal (108,695 cases and 39 deaths), Maharashtra (82,852 cases and 1 death), Odisha (53,743 cases and 35 deaths) *(5)*.

Epidemiological determinants

Agent factors

(a) AGENT : *S. typhi* is the major cause of enteric fever. *S. para A and S. para B* are relatively infrequent *(6)*. *S. typhi* has three main antigens – O, H and Vi and a number of phage types (at least 80). Phage typing has proved a useful epidemiological tool in tracing the source of epidemics. *S. typhi* survives intracellularly in the tissues of various organs. It is readily killed by drying, pasteurization, and common disinfectants. The factors which influence the onset of typhoid fever in man are the infecting dose and virulence of the organism.

(b) RESERVOIR OF INFECTION : Man is the only known reservoir of infection, viz cases and carriers. (i) CASES : The case may be mild, missed or severe. A case (or carrier) is infectious as long as bacilli appear in stools or urine. (ii) CARRIERS : The carriers may be temporary (incubatory, convalescent) or chronic. *Convalescent carriers* excrete the bacilli for 6 to 8 weeks, after which their numbers diminish rapidly. By the end of three months, not more than 4 per cent of cases are still excreting the organisms; and by the end of one year, the average carrier rate is around 3 per cent *(7)*. Persons who excrete the bacilli for more than a year after a clinical attack are called chronic carriers. In most chronic carriers, the organisms persist in the gall bladder and in the biliary tract. A chronic carrier state may be expected to develop in 2 to 5 per cent of cases. A chronic carrier may excrete the bacilli for several years (may be as long as 50 years) either continuously or intermittently. The famous case of "Typhoid Mary" who gave rise to more than 1300 cases in her life time is a good example of a chronic carrier. Faecal carriers are more frequent than urinary carriers. Chronic urinary carrier state is often associated with some abnormality of the urinary tract.

(c) SOURCE OF INFECTION : The primary sources of infection are faeces and urine of cases or carriers; the secondary sources contaminated water, food, fingers and flies. There is no evidence that typhoid bacilli are excreted in sputum or milk.

Host factors

(a) Age : Typhoid fever may occur at any age. Highest incidence of this disease occurs in the 5–19 years of age group. Prospective population-based surveillance in some Asian urban slum areas has shown that in the age group 5–15 years, the annual incidence of blood culture-confirmed typhoid fever may reach 180–494 per 100,000. In some of these areas, pre-school-age children less than 5 years, show incidence rates similar to those of school-age children *(2)*. After the age of 20 years, the incidence falls probably due to acquisition of immunity from clinical or subclinical infection. *(b) Sex :* More cases are reported among males than females, probably as a result of increased exposure to infection. But carrier rate is more in females. *(c) Immunity:* All ages are susceptible to infection. Antibody may be stimulated by the infection or by immunization; however, the antibody to the somatic antigen (O) is usually higher in the patient with the disease, and the antibody to the flagellar antigen (H) is usually higher in immunized individuals. Serum antibodies are not the primary defences against infection; *S. typhi* being an intracellular organism, cell–mediated immunity plays a major role in combating the infection. Natural typhoid fever does not always confer solid immunity; second attacks may occur when challenged with a large oral dose. Among the host factors that contribute to resistance to *S. typhi are* gastric acidity and local intestinal immunity.

Environmental and social factors

Enteric fevers are observed all through the year. The peak incidence is reported during July–September *(8)*. This period coincides with the rainy season and an increase in fly population.

Outside the human body, the bacilli are found in water, ice, food, milk and soil for varying periods of time. Typhoid bacilli do not multiply in water; many of them perish within 48 hours, but some may survive for about 7 days. They may survive for over a month in ice and icecream. They may survive for up to 70 days in soil irrigated with sewage under moist winter conditions, and for half that period under drier summer conditions *(9)*. Food being a bad conductor of heat, provides shelter to the bacilli which may multiply and survive for sometime in food. Typhoid bacilli grow rapidly in milk without altering its taste or appearance in anyway. Vegetables grown in sewage farms or washed in contaminated water are a positive health hazard. These factors are compounded by such social factors as pollution of drinking water supplies, open air defecation and urination, low standards of food and personal hygiene and health ignorance. Typhoid fever may therefore be regarded as an index of general sanitation in any country.

Incubation period

Usually 10–14 days. But it may be as short as 3 days or as long as three weeks depending upon the dose of the bacilli ingested.

Modes of transmission

Typhoid fever is transmitted *via* the faecal–oral route or urine–oral routes. This may take place *directly* through soiled hands contaminated with faeces or urine of cases or carriers, or *indirectly* by the ingestion of contaminated water, milk and/or food, or through flies.

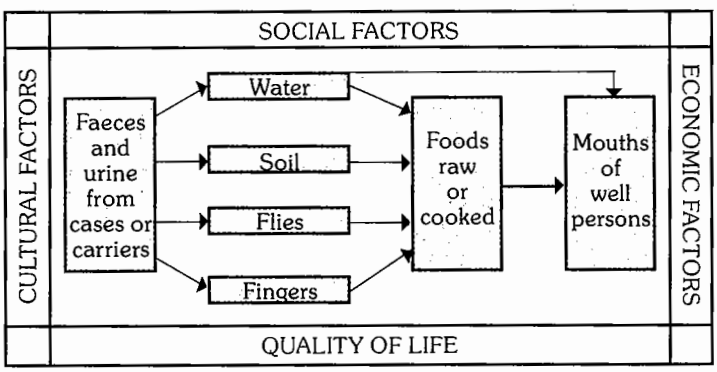

FIG.1
Dynamics of typhoid fever transmission

Fig. 1 shows the dynamics of transmission. There are numerous sources of infection and many vehicles of transmission, each making its own contribution to the total magnitude of the problem. The situation is rendered more complex by the web of social, cultural and economic factors which determine the quality of life of the people.

Clinical features

The onset is usually insidious but in children may be abrupt, with chills and high fever. During the prodromal

stage, there is malaise, headache, cough and sore throat, often with abdominal pain and constipation. The fever ascends in a step–ladder fashion. After about 7–10 days, the fever reaches a plateau and the patient looks toxic, appearing exhausted and often prostrated. There may be marked constipation, especially in early stage or "pea soup" diarrhoea. There is marked abdominal distention. There is leukopenia and blood, urine and stool culture is positive for salmonella. If there are no complications the patient's condition improves over 7–10 days. However, relapse may occur for up to 2 weeks after termination of therapy.

During the early phase, physical findings are few. Later, splenomegaly, abdominal distension and tenderness, relative bradycardia, dicrotic pulse, and occasionally meningismus appear. The rash (rose spots) commonly appears during the second week of disease. The individual spot, found principally on the trunk, is a pink papule 2–3 mm in diameter that fades on pressure. It disappears in 3–4 days.

Serious complications occur in up to 10 per cent of typhoid fever patients, especially in those who have been ill longer than 2 weeks, and who have not received proper treatment. Intestinal haemorrhage is manifested by a sudden drop in temperature and signs of shock, followed by dark or fresh blood in the stool. Intestinal perforation is most likely to occur during the third week. Less frequent complications are urinary retention, pneumonia, thrombophlebitis, myocarditis, psychosis, cholecystitis, nephritis and osteomyelitis.

Estimates of case-fatality rates of typhoid fever range from 1 per cent to 4 per cent; fatality rates in children aged less than 4 years being 10 times higher (4.0%) than in older children (0.4%). In untreated cases, the fatality rates may rise to 10–20 per cent *(2)*.

Laboratory diagnosis of typhoid *(3)*

(a) MICROBIOLOGICAL PROCEDURES : The definitive diagnosis of typhoid fever depends on the isolation of *S. typhi* from blood, bone marrow and stools. Blood culture is the mainstay of diagnosis of this disease.

(b) SEROLOGICAL PROCEDURE : Felix-Widal test measures agglutinating antibody levels against O and H antigens. Usually, O antibodies appear on day 6–8 and H antibodies on day 10–12 after the onset of disease. The test is usually performed on an acute serum (at first contact with the patient). The test has only moderate sensitivity and specificity. It can be negative in up to 30 per cent of culture – proven cases of typhoid fever. This may be because of prior antibiotic therapy that has blunted the antibody response. On the other hand, *S. typhi* shares O and H antigens with other *salmonella* serotypes and has cross-reacting epitopes with other Enterobacteriacae, and this can lead to false-positive results. Such results may also occur in other clinical conditions, e.g. malaria, typhus, bacteraemia caused by other organisms, and cirrhosis.

(c) NEW DIAGNOSTIC TESTS : The recent advances for quick and reliable diagnostic tests for typhoid fever as an alternative to the Widal test include the IDL Tubex® test marketed by a Swedish company, which reportedly can detect IgM09 antibodies from patient within a few minutes. Another rapid serological test, Typhidot®, takes three hours to perform. It was developed in Malaysia for the detection of specific IgM and IgG antibodies against a 50 kD antigen of *S. typhi*. A newer version of the test, Typhidot-M®, was recently developed to detect specific IgM antibodies only. The dipstick test, developed in the Netherlands, is based on the binding of *S. typhi* – specific IgM antibodies in samples to *S. typhi lipopolysaccharide* (LPS) antigen and the staining of bound antibodies by an anti-human IgM antibody conjugated to colloidal dye particles.

CONTROL OF TYPHOID FEVER

The control or elimination of typhoid fever is well within the scope of modern public health. This is an accomplished fact in many developed countries. There are generally three lines of defence against typhoid fever :

1. control of reservoir
2. control of sanitation, and
3. immunization.

The weakest link in the chain of transmission is sanitation which is amenable to control.

1. Control of reservoir

The usual methods of control of reservoir are their identification, isolation, treatment and disinfection.

a. CASES

(i) Early diagnosis : This is of vital importance as the early symptoms are non-specific. Culture of blood and stools are important investigations in the diagnosis of cases. *(ii) Notification:* This should be done where such notification is mandatory. *(iii) Isolation :* Since typhoid fever is infectious and has a prolonged course, the cases are better transferred to a hospital for proper treatment, as well as to prevent the spread of infection. As a rule, cases should be isolated till three bacteriologically negative stools and urine reports, are obtained on three separate days. *(iv) Treatment :* The fluoroquinolones are widely regarded as the drug of choice for the treatment of typhoid fever. They are relatively inexpensive, well tolerated and more rapidly and reliably effective than the former first-line drugs, viz. chloramphenicol, ampicillin, amoxicillin and trimethoprim – sulfamethoxazole (TMP-SMX). The antibiotics used in uncomplicated typhoid fever are as shown in Table 1. Patients seriously ill and profoundly toxic may be given an injection of hydrocortisone 100 mg daily for 3 to 4 days. *(v) Disinfection :* Stools and urine are the sole sources of infection. They should be received in closed containers and disinfected with 5 per cent cresol for at least 2 hours. All soiled clothes and linen should be soaked in a solution of 2 per cent chlorine and steam–sterilized. Nurses and doctors should not forget to disinfect their hands. *(vi) Follow-up :* Follow-up examination of stools and urine should be done for *S. typhi* 3 to 4 months after discharge of the patient, and again after 12 months to prevent the development of the carrier state. With early diagnosis and appropriate treatment, mortality has been reduced to about 1 per cent as compared to about 30 per cent in untreated cases.

(b) CARRIERS

Since carriers are the ultimate source of typhoid fever, their identification and treatment is one of the most radical ways of controlling typhoid fever. The measures recommended are : *(i) Identification :* Carriers are identified by cultural and serological examinations. Duodenal drainage establishes the presence of salmonella in the biliary tract in carriers. The Vi antibodies are present in about 80 per cent of chronic carriers. *(ii) Treatment :* The carrier should be given an intensive course of ampicillin or

TABLE 1

Treatment of uncomplicated typhoid fever

Susceptibility	Optimal therapy: Antibiotic	Daily dose mg/kg	Days	Alternative effective drugs: Antibiotic	Daily dose mg/kg	Days
Fully sensitive	Fluoroquinolone e.g. ofloxacin or ciprofloxacin	15	5-7 [a]	Chloramphenicol	50-75	14-21
				Amoxicillin	75-100	14
				TMP-SMX	8-40	14
Multidrug resistance	Fluoroquinolone or cefixime	15 15-20	5-7 7-14	Azithromycin Cefixime	8-10 15-20	7 7-14
Quinolone resistance [b]	Azithromycin or ceftriaxone	8-10 75	7 10-14	Cefixime	20	7-14

[a] Three-day courses are also effective and are particularly so in epidemic containment.
[b] The optimum treatment for quinolone-resistant typhoid fever has not been determined. Azithromycin, the third-generation cephalosporins, or a 10-14 days course of high-dose fluoroquinolones, is effective. Combinations of these are now being evaluated.

Source : *(10)*

amoxycillin (4–6 g a day) together with Probenecid (2 g/day) for 6 weeks. These drugs are concentrated in the bile and may achieve eradication of the carrier state in about 70 per cent of carriers. Chloromycetin is considered worthless for clearing the carrier state. *(iii) Surgery :* Cholecystectomy with concomitant ampicillin therapy has been regarded as the most successful approach to the treatment of carriers. Cure rate may be as high as 80 per cent. Urinary carriers are easy to treat, but refractory cases may need nephrectomy when one kidney is damaged and the other healthy. *(iv) Surveillance :* The carriers should be kept under surveillance. They should be prevented from handling food, milk or water for others. *(v) Health education :* Health education regarding washing of hands with soap, after defecation or urination, and before preparing food is an essential element. In short, the management of carriers continues to be an unsolved problem. This is the crux of the problem, in the elimination of typhoid fever.

2. Control of sanitation

Protection and purification of drinking water supplies, improvement of basic sanitation, and promotion of food hygiene are essential measures to interrupt transmission of typhoid fever. For instance, typhoid fever is never a major problem where there is a clean domestic water supply. Sanitary measures, not followed by health education may produce only temporary results. However, when sanitation is combined with health education, the effects tend to be cumulative, resulting in a steady reduction of typhoid morbidity *(11)*.

3. Immunization

While ultimately, control of typhoid fever must take the form of improved sanitation and domestic and personal hygiene, these are long-term objectives in many developing countries. A complementary approach to prevention is immunization, which is the only specific preventive measure, likely to yield the highest benefit for the money spent. Immunization against typhoid does not give 100 per cent protection, but it definitely lowers both the incidence and seriousness of the infection. It can be given at any age upwards of two years. It is recommended to : (i) those living in endemic areas (ii) household contacts (iii) groups at risk of infection such as school children and hospital staff (iv) travellers proceeding to endemic areas, and (v) those attending *melas* and *yatras*.

ANTI-TYPHOID VACCINES *(2)*

The old parenteral killed whole-cell vaccine was effective but produced strong side-effects. Two safe and effective vaccines are now licensed and available. One is based on defined subunit antigens, the other on whole-cell live attenuated bacteria.

The Vi polysaccharide vaccine

This subunit vaccine was first licensed in the United States in 1994. It is composed of purified Vi capsular polysaccharide from the Ty2 S. Typhi strain and elicits a T-cell independent IgG response that is not boosted by additional doses. The vaccine is administered subcutaneously or intramuscularly. The target value for each single human dose is about 25µg of the antigen. The vaccine is stable for 6 months at 37°C, and for 2 years at 22°C. The recommended storage temperature is 2–8°C. The Vi vaccine does not elicit adequate immune responses in children aged less than 2 years.

Schedule

The vaccine is licensed for individuals aged ≥ 2 years. Only 1 dose is required, and the vaccine confers protection 7 days after injection. To maintain protection, revaccination is recommended every 3 years. The Vi polysaccharide vaccine can be co-administered with other vaccines relevant for international travellers, such as yellow fever and hepatitis A, and with vaccines of the routine childhood immunization programmes.

Safety

No serious adverse events and a minimum of local side-effects are associated with Vi vaccination. There are no contraindications to the use of this vaccine other than previous severe hypersensitivity reaction to vaccine components. Although the Vi polysaccharide vaccine is safe for HIV-infected individuals, the induction of protective antibodies is directly correlated to the levels of CD4 positive T-cells.

The Ty21a vaccine

This vaccine, which was first licensed in Europe in 1983 and in the USA in 1989, is an orally administered, live-attenuated Ty2 strain of S. Typhi in which multiple genes, including the genes responsible for the production of Vi,

have been mutated chemically. The lyophilized vaccine is available as enteric coated capsules. Protection is markedly influenced by the number of doses and their spacing. There are currently no field trials to document the efficacy of Ty21a vaccine in children aged <3 years. Ty21a requires storage at 2–8°C; it retains potency for approximately 14 days at 25°C.

Schedule

The capsules are licensed for use in individuals aged ≥ 5 years. The vaccine is administered every other day; on 1, 3, and 5th day; a 3-dose regimen is recommended. With the 3-dose regimen, protective immunity is achieved 7 days after the last dose. The recommendation is to repeat this series every 3 years for people living in endemic areas, and every year for individuals travelling; from non-endemic to endemic countries. The Ty21a vaccine may be given simultaneously with other vaccines, including live vaccines against polio, cholera, and yellow fever, or the measles, mumps and rubella (MMR) combination.

Safety and precautions

Proguanil and antibacterial drugs should be stopped from 3 days before until 3 days after giving Ty21a, as such drugs may harm live bacterial vaccines. The vaccine is unlikely to be efficacious if administrated at the time of ongoing diarrhoea. It is not known whether this live attenuated vaccine may cause foetal harm when administered to pregnant women. Ty21a can be administered to HIV-positive, asymptomatic individuals as long as the T-cell count (CD4) is >200/mm^3.

Ty21a is remarkably well tolerated and has low rates of adverse events.

The vaccine is not recommended in congenital or acquired immunodeficiency including treatment with immuno-suppressive and antimitotic drugs, acute febrile illness and acute intestinal infection.

FOOD POISONING

Food poisoning is an acute gastroenteritis caused by ingestion of food or drink contaminated with either living bacteria or their toxins or inorganic chemical substances and poisons derived from plants and animals. The condition is characterized by: (a) history of ingestion of a common food (b) attack of many persons at the same time, and (c) similarity of signs and symptoms in the majority of cases.

Types of food poisoning

Food poisoning may be of two types : non-bacterial and bacterial. *(a) Non-bacterial :* Caused by chemicals such as arsenic, certain plant and sea foods. In recent years, there has been a growing concern about contamination of food by chemicals, e.g., fertilizers, pesticides, cadmium, mercury etc. *(b) Bacterial :* Caused by the ingestion of foods contaminated by living bacteria or their toxins. The conventional classification of bacterial food poisoning into toxic and infective types is becoming increasingly blurred with the knowledge that in some types, both multiplication and toxin production are involved *(1)*. Bacterial food poisoning may be of the following types :

1. Salmonella food poisoning

An extremely common form of food poisoning. Five reasons have been given for its increase in recent years : (a) an increase in community feeding (b) increase in international trade in human food (c) a higher incidence of salmonellosis in farm animals (d) widespread use of household detergents interfering with sewage treatment, and (e) wide distribution of "prepared foods" *(2)*.

(a) AGENT(S) : The species most often incriminated in human outbreaks are *S. typhimurium, S. cholera–suis* and *S. enteritidis*, besides many others. (b) SOURCE : Salmonellosis is primarily a disease of animals. Man gets the infection from *farm animals* and *poultry* – through contaminated meat, milk and milk products, sausages, custards, egg and egg products. Rats and mice are another source; they are often heavily infected and contaminate foodstuffs by their urine and faeces. Temporary human carriers can also contribute to the problem. (c) INCUBATION PERIOD : 12 to 24 hours commonly. (d) MECHANISM OF FOOD POISONING : The causative organisms, on ingestion, multiply in the intestine and give rise to acute enteritis and colitis. The onset is generally sudden with chills, fever, nausea, vomiting, and a profuse watery diarrhoea which usually lasts 2–3 days. Mortality is about 1 per cent. A convalescent carrier state lasting for several weeks may occur *(1)*.

Salmonellosis is described in detail separately, (Page 298).

2. Staphylococcal food poisoning

It is about as common as salmonella food poisoning. (a) AGENT : Enterotoxins of certain strains of coagulase–positive *Staphylococcus aureus*. At least 5 different enterotoxins have been identified, and a sixth may exist *(3)*. Toxins can be formed at optimum temperatures of 35 deg. to 37 deg. C. These toxins are relatively heat stable and resist boiling for 30 minutes or more. (b) SOURCE : Staphylococci are ubiquitous in nature, and are found on the skin and in the nose and throat of men and animals. They are a common agent of boils and pyogenic infections of man and animals. Cows suffering from mastitis have been responsible for outbreaks of food poisoning involving milk and milk products. The foods involved are salads, custards, milk and milk products which get contaminated by staphylococci. (c) INCUBATION PERIOD : 1–8 hours. The incubation period is short because of "preformed" toxin. (d) MECHANISM OF FOOD POISONING : Food poisoning results from ingestion of toxins preformed in the food in which bacteria have grown ("intradietetic" toxins). Since the

toxin is heat–resistant, it can remain in food after the organisms have died. The toxins act directly on the intestine and CNS. The illness becomes manifest by the sudden onset of vomiting, abdominal cramps and diarrhoea. In severe cases, blood and mucus may appear. Unlike salmonella food poisoning, staphylococcal food poisoning rarely causes fever. Death is uncommon.

Botulism

Most serious but rare. It kills two-thirds of its victims. (a) AGENT : Exotoxin of *Clostridium botulinum* generally Type A, B or E. (b) SOURCE : The organism is widely distributed in soil, dust and the intestinal tract of animals and enters food as spores. The foods most frequently responsible for botulism are home preserved foods such as home–canned vegetables, smoked or pickled fish, home–made cheese and similar low acid foods. In fact, botulism derives its name from the Latin word for sausage (botulus). (c) INCUBATION PERIOD : 18 to 36 hours. (d) MECHANISM OF FOOD POISONING : The toxin is preformed in food ("intradietetic") under suitable anaerobic conditions. It acts on the parasympathetic nervous system. Botulism differs from other forms of food poisoning in that the gastrointestinal symptoms are very slight. The prominent symptoms are dysphagia, diplopia, ptosis, dysarthria, blurring of vision, muscle weakness and even quadriplegia. Fever is generally absent, and consciousness is retained. The condition is frequently fatal, death occurring 4–8 days later due to respiratory or cardiac failure. Patients who recover do not develop antitoxin in the blood. Since the toxin is thermolabile, the heating of food which may be subjected to 100 deg. C for a few minutes before use will make it quite safe for consumption *(4)*.

Botulism occurring in infants is called "infant botulism". It is due to infection of the gut by *Cl. botulinum* with subsequent in vivo production of toxin *(5)*.

Antitoxin is of considerable value in the prophylaxis of botulism. When a case of botulism has occurred, antitoxin should be given to all individuals partaking of the food. The dose varies from 50,000 to 100,000 units IV *(6)*. The antitoxin will be of no avail if the toxin is already fixed to the nervous tissue. Guanidine hydrochloride given orally in doses of 15 to 40 mg/kg of body weight has been shown to reverse the neuromuscular block of botulism. When combined with good medical and nursing care, the drug can be a useful adjunct in the treatment of botulism *(7)*. Active immunization with botulinum toxoid to prevent botulism is also available *(8)*.

Cl. perfringens food poisoning

(a) AGENT : *Clostridium (Cl.) perfringens (welchii)*. (b) SOURCE : The organism has been found in faeces of humans and animals, and in soil, water and air. The majority of outbreaks have been associated with the ingestion of meat, meat dishes and poultry. The usual story is that the food has been prepared and cooked 24 hours or more before consumption, and allowed to cool slowly at room temperature and then heated immediately prior to serving. (c) INCUBATION PERIOD : 6 to 24 hours, with a peak from 10 to 14 hours (d) MECHANISM OF FOOD POISONING : The spores are able to survive cooking, and if the cooked meat and poultry are not cooled enough, they will germinate. The organisms multiply between 30 deg. and 50 deg. C and produce a variety of toxins, e.g., alpha toxin, theta toxin, etc. Prevention consists either by cooking food just prior to its consumption or, if it has to be stored, by rapid and adequate cooling *(10)*. (e) CLINICAL SYMPTOMS : The most common symptoms are diarrhoea, abdominal cramps and little or no fever, occurring 8 to 24 hours after consumption of the food. Nausea and vomiting are rare. Illness is usually of short duration, usually 1 day or less. Recovery is rapid and no deaths have been reported.

B. cereus food poisoning

Bacillus cereus is an aerobic, spore–bearing, motile, gram positive rod. It is ubiquitous in soil, and in raw, dried and processed foods. The spores can survive cooking and germinate and multiply rapidly when the food is held at favourable temperatures. *B. cereus* has been recognized as a cause of food poisoning, with increasing frequency in recent years.

Recent work has shown that *B. cereus* produces at least 2 distinct enterotoxins, causing 2 distinct forms of food poisoning. One, the *emetic form* with a short incubation period (1–6 hours) characterized by predominantly upper gastro-intestinal tract symptoms, rather like staphylococcal food poisoning. The other, the *diarrhoeal* form, with a longer incubation period (12–24 hours) characterized by predominantly lower intestinal tract symptoms like *Cl. perfringens* food poisoning (diarrhoea, abdominal pain, nausea with little or no vomiting and no fever. Recovery within 24 hours is usual). The toxins are preformed and stable.

Diagnosis can be confirmed by isolation of 10^5 or more *B. cereus* organisms per gram of epidemiologically incriminated food. Treatment is symptomatic.

Differential diagnosis

Food poisoning may be mistaken for cholera, acute bacillary dysentery and chemical (arsenic) poisoning. The differentiating points between cholera and food poisoning are given in Table 1.

INVESTIGATION OF FOOD POISONING

(a) Secure complete list of people involved and their history : All the people who have shared part of the food should be interviewed. They may be supplied questionnaires concerning the foods eaten during the previous 2 days, and place of consumption; time of onset of symptoms; symptoms of illness (e.g., nausea, vomiting, diarrhoea, abdominal pain, headache, fever, prostration, etc.) in order of occurrence; personal data such as age, sex, residence, occupation, and any other helpful information. Questionnaires may be administered to kitchen employees and those working in the dining halls. *(b) Laboratory investigations :* An important part of the investigation. The object is not only to incriminate the causative agent from stool, vomit or remnants of food by inoculating into appropriate media, but also to determine the total number of bacteria and the relative numbers of each kind involved. This will give a better indication of the organism involved. Stool samples of the kitchen employees and food handlers should also be investigated. The samples should be examined aerobically and anaerobically. Phage typing of the organisms should be done to complete the laboratory investigation. *(c) Animal experiments :* It may be

TABLE 1

Differential diagnosis of cholera and food poisoning

		Cholera	Food poisoning
1.	Epidemiology	Occurs often in epidemic form associated with other cases in the neighbourhood	Often a single group of persons who shared a common meal
		Secondary cases occur	No secondary cases
2.	Incubation	From a few hours upto 5 days	1 to 24 hours
3.	Onset	With purging	With vomiting
4.	Nausea and retching	None	Present
5.	Vomiting	Projectile, effortless, watery and continuous	Often single, severe vomit, mucus and blood streaked
6.	Stools	Copious rice watery, inoffensive	Frequent, may contain mucus and blood, offensive
7.	Tenesmus	None	Yes
8.	Abdominal tenderness	None	Yes
9.	Dehydration	Very marked	Distinct
10.	Muscular cramps	Constant and severe	Less constant
11.	Surface temperature	Subnormal	Often upto 100–102 deg.F.
12.	Headache	None	Often
13.	Urine	Suppressed	Seldom suppressed
14.	Blood	Leucocytosis	Normal

necessary to feed rhesus monkeys with the remnants of food. Protection tests are useful in the case of botulism; in this, a saline filtrate of food-stuff is injected subcutaneously into mice protected with antitoxic sera, keeping suitable controls. *(d) Blood for antibodies :* This is useful for retrospective diagnosis. *(e) Environmental study :* This includes inspection of the eating place(s), kitchen(s), and questioning of food handlers regarding food preparation. *(f) Data analysis :* The data should be analyzed according to the descriptive methods of time, place and person distribution. Food–specific attack rates should be calculated. A case control study may be undertaken to establish the epidemiologic association between, illness and the intake of a particular food.

PREVENTION AND CONTROL

(a) FOOD SANITATION : *(i) Meat inspection :* The food animals must be free from infection. This can be ensured by their examination by veterinary staff, both before and after slaughter. *(ii) Personal hygiene :* A high standard of personal hygiene among individuals engaged in the handling, preparation and cooking of food is needed. *(iii) Food handlers :* Those suffering from infected wounds, boils, diarrhoea, dysentery, throat infection, etc should be excluded from food handling. The medical inspection of food handlers is required in many countries; this is of limited value in the detection of carriers, although it will remove some sources of infection *(12). (iv) Food handling techniques :* The handling of ready-to-eat foods with bare hands should be reduced to a minimum. Time between preparation and consumption of food should be kept short. The importance of rapid cooling and cold storage must be stressed. Milk, milk products and egg products should be pasteurized. Food must be thoroughly cooked. The heat must penetrate the centre of the food leaving thereby no cool spots. Most food poisoning organisms are killed at temperatures over 60 deg. C. *(v) Sanitary improvements :* Sanitization of all work surfaces, utensils and equipments must be ensured. Food premises should be kept free from rats, mice, flies and dust. *(vi) Health education :* Food handlers should be educated in matters of clean habits and personal hygiene, such as frequent and thorough hand washing.

(b) REFRIGERATION : In the prevention of bacterial food poisoning, emphasis must be placed on proper temperature control. Food should not be left in warm pantries; a few germs can multiply to millions by the next morning. Foods not eaten immediately should be kept in cold storage to prevent bacterial multiplication and toxin production. "Cook and eat the same day" is a golden rule. When foods are held between 10 deg. C (50 deg. F) and 49 deg. C (120 deg.F) they are in the danger zone for bacterial growth. Cold is bacteriostatic at temperature below 4 deg. C (40 deg.F), and refrigeration temperature should not exceed this level.

SURVEILLANCE : Food samples must be obtained from the food establishments periodically and subjected to laboratory analysis if they were unsatisfactory. Continuing surveillance is necessary to avoid outbreaks of food-borne diseases.

AMOEBIASIS

The term "amoebiasis" has been defined by WHO *(1)* as the condition of harbouring the protozoan parasite *Entamoeba histolytica* with or without clinical manifestations. The symptomatic disease occurs in less than 10 per cent of infected individuals *(2)*. The symptomatic group has been further subdivided into intestinal and extraintestinal amoebiasis. Only a small percentage of those having intestinal infection will develop invasive amoebiasis. The intestinal disease varies from mild abdominal discomfort and diarrhoea to acute fulminating dysentery. Extraintestinal amoebiasis includes involvement of liver (liver abscess), lungs, brain, spleen, skin, etc. Amoebiasis is a potentially lethal disease. It carries substantial morbidity and mortality.

Problem statement

WORLD : Amoebiasis is a common infection of the human gastro-intestinal tract. It has a worldwide distribution. It is a major health problem in the whole of China, South East and West Asia and Latin America, especially Mexico. Globally it is estimated that 500 million people carry *E. histolytica* in their intestinal tract and approximately one-tenth of infected people suffer from invasive amoebiasis. It is probable that invasive amoebiasis, accounted for about 100,000 deaths in the world *(3)*. Prevalence rates vary from as low as 2 per cent to 60 per cent or more in areas devoid of sanitation *(4)*. In areas of high prevalence, amoebiasis occurs in endemic forms as a result of high levels of transmission and constant reinfection. Epidemic water-borne infections can occur if there is heavy contamination of drinking water supply.

INDIA : It is generally agreed that amoebiasis affects about 15 per cent of the Indian population *(5)*. Amoebiasis has been reported throughout India : the prevalence rate is about 15% ranging from 3.6 to 47.4 per cent in different areas *(4)*. The reported variations in prevalence are attributed to variations in clinical diagnostic criteria *(6)* and to technical difficulties in establishing a correct diagnosis and lack of sampling criteria *(7)*.

Epidemiological determinants

Agent factors

(a) AGENT : Amoebiasis is caused by potentially pathogenic strains of *E. histolytica*. Recent studies *(8)* have shown that *E. histolytica* can be differentiated into at least 18 zymodemes (a zymodeme is a population of organisms differing from similar population in the electrophoretic mobilities of one or more enzymes). It has furthermore been shown that pathogenic strains are all from particular zymodemes; that non-invasive strains are from quite distinct zymodemes; that invasive strains can give rise to faecal cysts, and the organisms breed true *(8)*. The iso-enzyme characteristics do not, however, determine why a particular zymodeme is able to invade. Isoenzyme electrophoretic mobility analysis have so far identified 7 potentially pathogenic and 11 non-pathogenic zymodems *(9)*.

E. histolytica exists in two forms – vegetative (trophozoite) and cystic forms. Trophozoites dwell in the colon where they multiply and encyst. The cysts are excreted in stool. Ingested cysts release trophozoites which colonize the large intestine. Some trophozoites invade the bowel and cause ulceration, mainly in the caecum and ascending colon; then in the rectum and sigmoid. Some may enter a vein and reach the liver and other organs.

The trophozoites are short-lived outside the human body; they are not important in the transmission of the disease. In contrast the cysts are infective to man and remain viable and infective for several days in faeces, water, sewage and soil in the presence of moisture and low temperature. The cysts are not affected by chlorine in the amounts normally used in water purification, but they are readily killed if dried, heated (to about 55 deg C) or frozen.

(b) RESERVOIR OF INFECTION : Man is the only reservoir of infection. The immediate source of infection is the faeces containing the cysts. Most individuals infected with *E. Histolytica* remain symptom free and are healthy carriers of the parasite *(12)*. The carriers can discharge upto 1.5×10^7 cysts daily *(6)*. The greatest risk is associated with carriers engaged in the preparation and handling of food *(6)*.

(c) PERIOD OF COMMUNICABILITY : As long as cysts are excreted; the period may be several years, if cases are unrecognized and untreated.

Host factors

Amoebiasis may occur at any age. There is no sex or racial difference in the occurrence of the disease. Amoebiasis is frequently a household infection. When an individual in a family is infected, others in the family may also be affected. Specific antiamoebic antibodies are produced when tissue invasion takes place. There is strong evidence that cell-mediated immunity plays an important part in controlling the recurrence of invasive amoebiasis *(10)*.

Environmental factors

Amoebiasis is more closely related to poor sanitation and socio-economic status than to climate. The use of nightsoil for agricultural purposes favours the spread of the disease. In countries with marked wet–dry seasons, infection rates are higher during rains, presumably since cysts may survive longer and the potential for transmission is thereby increased. Epidemic outbreaks are usually associated with sewage seepage into the water supply.

Mode of transmission

(i) Faecal–oral route : This may readily take place through intake of contaminated water or food. Epidemic water-borne infections can occur if there is heavy contamination of drinking water supply. Vegetables, especially those eaten raw, from fields irrigated with sewage polluted water can readily convey infection. Viable cysts have been found on the hands and under finger nails. This may lead to direct hand to mouth transmission. **(ii) Sexual transmission:** by oral–rectal contact is also recognized, especially among male homosexuals. **(iii) Vectors :** such as flies, cockroaches and rodents are capable of carrying cysts and contaminating food and drink.

Incubation period

About 2 to 4 weeks or longer.

PREVENTION AND CONTROL

1. Primary prevention

The measures aimed at primary prevention centre round preventing contamination of water, food, vegetables and fruits with human faeces. (a) **Sanitation :** Safe disposal of human excreta coupled with the elementary sanitary

practice of washing hands after defecation and before eating is a crucial factor in the prevention and control of amoebiasis. But there are too many hurdles (both social and economic) in enforcing it in many developing countries. With the cooperation of the local community, the sanitary systems should be selected and constructed *(14)* taking into consideration the customs and practices of the population and the available resources. (b) **Water supply :** The protection of water supplies against faecal contamination is equally important because amoebic cysts may survive for several days and weeks in water. The cysts are not killed by chlorine in amounts used for water disinfection. Sand filters are quite effective in removing amoebic cysts. Therefore water filtration and boiling are more effective than chemical treatment of water against amoebiasis. (c) **Food hygiene :** Environmental measures should also include the protection of food and drink against faecal contamination. Uncooked vegetables and fruits can be disinfected with aqueous solution of acetic acid (5–10 per cent) or full strength vinegar *(1)*. In most instances, thorough washing with detergents in running water will remove amoebic cysts from fruits and vegetables. Since food handlers are major transmitters of amoebiasis, they should be periodically examined, treated and educated in food hygiene practices such as hand washing. (d) **Health education :** In the long-term, a great deal can be accomplished through health education of the public.

2. Secondary prevention

(a) **Early diagnosis :** Demonstration of trophozoites containing red cells is diagnostic. They are most readily seen in fresh mucus passed per rectum. Microscopy should be performed immediately before its cooling results. The absence of pus cells in the stool may be helpful in the differential diagnosis with shigellosis. Serological tests are often negative in intestinal amoebiasis, but if positive, they provide a clue to extraintestinal amoebiasis. Indirect haemagglutination test (IHA) is regarded as the most sensitive serological test. Newer techniques include counter immuno-electrophoresis (CIE) and ELISA technique *(11)*.

(b) **Treatment :** *(i) Symptomatic cases :* At the health centre level, symptomatic cases can be treated effectively with metronidazole orally and the clinical response in 48 hours may confirm the suspected diagnosis. The dose is 30 mg/kg of body weight/day, divided into 3 doses after meals, for 8–10 days. Tinidazole can be used instead of metronidazole. Suspected cases of liver abscess should be referred to the nearest hospital. *(ii) Asymptomatic infections :* In an endemic area, the consensus is not to treat such persons because the probability of reinfection is very high *(10)*. They may, however, be treated, if the carrier is a food handler. In non-endemic areas they are always likely to be treated. They should be treated with oral diiodohyroxyquin, 650 mg TDS (adults) or 30–40 mg/kg of body weight/day (children) for 20 days, or oral diloxanide furoate, 500 mg TDS for 10 days (adults) *(3)*.

At present there is no acceptable chemoprophylaxis for amoebiasis. Mass examination and treatment cannot be considered a solution for the control of amoebiasis *(10)*.

SOIL-TRANSMITTED HELMINTHIASIS

Soil-transmitted helminth (STHs) infections refer to a group of parasitic diseases in humans caused by intestinal roundworms (ascariasis), hookworms (*Necator americanus* and *Ancylostoma duodenale*) and whipworm (*Trichuris trichiura*). They are the most common infections worldwide. More than 1.5 billion people, or about 24 per cent of the world's population are infected. Infections are widely distributed in tropical and subtropical areas, with the greatest numbers occurring in sub-Saharan Africa, the Americas, China and east Asia *(1)*. Over 270 million pre-school children and over 600 million school-age children live in areas where these parasites are intensively transmitted and are in need of treatment and preventive interventions.

Mode of transmission

Soil-transmitted helminths are transmitted by eggs that are passed in the faeces of infected people, as adult worms live in the intestine where they produce thousands of eggs each day. In areas that lack adequate sanitation, these eggs contaminate the soil. This can happen in several ways : (a) eggs that are attached to vegetables and salads are ingested when the vegetables are not carefully cooked, washed or peeled; (b) eggs are ingested from contaminated water sources; and (c) eggs are ingested by children who play in soil and then put their hands in their mouth without washing them.

In addition, hookworm eggs hatch in the soil, releasing larvae that mature into a form that can actively penetrate the skin. People become infected with hookworm primarily by walking barefoot on contaminated soil.

There is no direct person-to-person transmission, or infection from fresh faeces, because eggs passed in faeces need about three weeks to mature in the soil before they become infective. Since these worms do not multiply in the human host, reinfection occurs only as a result of contact with infective stages in the environment.

ASCARIASIS

An infection of the intestinal tract caused by the adult, *Ascaris lumbricoides* and clinically manifested by vague symptoms of nausea, abdominal pain and cough. Live worms are passed in the stool or vomited. Occasionally, they may produce intestinal obstruction or may migrate into the peritoneal cavity.

Geographic distribution and prevalence

Ascaris is cosmopolitan in distribution. It is the most

common helminthic infestation. It is estimated that about one billion (807–1121 million) people are infected worldwide annually with about 12 million acute cases and 20,000 or more deaths. Heavy infection is common in children aged 3–8 years *(2)*.

Epidemiological features

(a) AGENT : *Ascaris lumbricoides* lives in the lumen of small intestine, where it moves freely. Sexes are separate. The female measures 20–35 cm in length, and the male 12–30 cm. Egg production is very heavy – an estimated 2,40,000 eggs per day by each female, which counterbalances the heavy losses in the environment. The eggs are excreted in the faeces. They become embryonated in the external environment and become infective in 2–3 weeks. On ingestion by man, the embryonated eggs hatch in the small intestine. The resulting larvae penetrate the gut wall and are carried to the liver and then to the lungs *via* the blood stream. In the lungs, they moult twice. They break through the alveolar walls and migrate into the bronchioles. They are coughed up through the trachea and then swallowed by the human host. On reaching the intestine, they become mature into adults in 60–80 days. The life span of an adult is between 6–12 months, maximum reported being 1.5 years. (b) RESERVOIR OF INFECTION : Man is the only reservoir. (c) INFECTIVE MATERIAL : Faeces containing the fertilized eggs. (d) HOST : Infection rates are high in children; they are the most important disseminators of infection. Adults seem to acquire some resistance. There is a high degree of host–parasite tolerance. Roundworms rob man of his food and may possibly compete for vitamin A in the intestine *(1)*. They contribute to malnutrition especially in children who may show growth retardation. (e) ENVIRONMENT : Ascaris is a "soil–transmitted" helminth. The eggs remain viable in the soil for months or years under favourable conditions. Of the various ecological factors regulating the population of *Ascaris* eggs, the most important ones are the temperature, moisture, oxygen pressure and ultra-violet radiation from the sunlight *(3)*. A low temperature inhibits the development of eggs. Clay soils are most favourable for the development of ascariasis eggs, in contrast to moist porous soils for those of hookworms. (f) HUMAN HABITS : Seeding of the soil by ascariasis eggs takes place by the human habit of indiscriminate open air defecation. It is the most important factor responsible for the widespread distribution of ascariasis in the world *(3)*. Soil pollution is usually concentrated around houses where small children who have no regular habits pollute the house and surrounding areas. Infective eggs can then easily reach other children who play on the ground and contaminate their hands and food *(3)*. (g) PERIOD OF COMMUNICABILITY: Until all fertile females are destroyed and stools are negative.

Incubation period

18 days to several weeks.

Symptoms

The symptoms are related to the number of the worms harboured. People with light infection usually have no symptoms. Heavier infections can cause a range of symptoms including intestinal manifestations like diarrhoea, abdominal pain; general malaise, weakness, impaired cognitive and physical development. The WHO definition of heavy infection of roundworm is ≥ 50,000 eggs per gram of faeces *(4)*.

The larvae migration may cause fever, cough, sputum formation, asthma, skin rash, oesinophilia. The adult roundworm aggregate masses can cause volvulus, intestinal obstruction or intessusception; and wandering worm can cause bowel perforation in the ileococcal region, blocking of common bile duct or may come out with vomit *(4)*.

HOOKWORM INFECTION

Hookworm infection is defined as "any infection caused by *Ancylostoma duodenale* or *Necator americanus" (5)*. They may occur as single or mixed infections in the same person.

Problem statement

Ancylostoma duodenale and *Necator americanus* are the main nematodes causing hookworm infection in man. Almost eradicated from Europe and the USA *(3)*, hookworm infection is still seen in warm, moist climates in tropical and subtropical regions between 45°N and 30°S of the equator (e.g., Asia, Africa, Central and South America and the South Pacific). The geographic distribution of these two hookworms used to be regarded as relatively distinct, the former being more prevalent in Europe and South–western Asia, and the latter in tropical Africa and in the Americas. However, over the past decades both parasites have become widely distributed throughout the tropics and subtropics, and rigid demarcations are no longer tenable *(6)*.

It is estimated that, during 2010, the global prevalence of hookworm was about 576–740 million cases, of these about 80 million were severely affected *(6)*.

Epidemiological determinants

Agent factors

(a) AGENT : Adult worms live in the small intestine, mainly jejunum where they attach themselves to the villi. Males measure 8 to 11 mm, and females 10 to 13 mm in length with dorsally curved anterior end. Eggs are passed in the faeces in thousands; one female *A. duodenale* produces about 10,000–30,000 eggs and one female *N. americanus* about 5,000–10,000 eggs per day *(6)*. High egg production ensures constant exposure to infection.

When deposited on warm, moist soil, a larva rapidly develops in the egg and hatches after 1 to 2 days. The newly hatched larva (rhabditiform larva) moults twice in the soil and becomes a skin–penetrating third stage infective larva within 5 to 10 days. These lie in wait in the soil to pierce the skin of the human host. They move very little horizontally, but migrate upwards on blades of grass *(3)*. They can survive in shaded, moist soil for up to one month. Infection occurs when the larva enters the body through the skin, most commonly through the feet. Larvae of *A. duodenale* are also infective by mouth. Once inside the body, they migrate via lymphatics and blood stream to the lungs. They break into the alveoli, ascend the bronchi and trachea and are coughed up and swallowed to reach the small intestine, where they become sexually mature. Adult *A. duodenale* and *N. americanus* are believed to be capable of surviving for an average about 1 and 4 years, respectively *(5)*. (b) RESERVOIR : Man is the only important reservoir of human hookworm infection. (c) INFECTIVE MATERIAL : Faeces containing the ova of hookworms. However, the immediate source of infection is the soil contaminated with infective larvae. (d) PERIOD OF INFECTIVITY : As long as the person harbours the parasite.

Host factors

(a) AGE AND SEX : All ages and both sexes are susceptible to infection. In endemic areas, the highest incidence is found in the age group, 15 to 25 years. (b) NUTRITION : Studies indicate that malnutrition is a predisposing factor; the chronic disabling disease does not occur in the otherwise healthy individual who is well–nourished and whose iron intake is adequate. (c) HOST–PARASITE BALANCE : In endemic areas, the inhabitants develop a host–parasite balance in which the worm load is limited. They harbour the parasite without manifesting clinical signs and symptoms. In some areas, the infection rate may be 100 per cent, but most infections are light and only a small proportion of the people are heavily infected *(5)*. This delicate balance may be upset by malnutrition and intercurrent infections. Little is known about host immunity. (d) OCCUPATION : It is to be expected that hookworm infection will have a higher prevalence in agricultural than in town workers, and in many tropical countries, it is an occupational disease of the farming community.

Environmental factors

Hookworm larvae live in the upper half-inch (1.2 cm.) of the soil. Favourable environmental conditions are, therefore, crucial for the survival of the hookworm larvae in the soil. These are : (a) SOIL : The soil must be suitable for the eggs and larvae. The type of soil that favours the survival of hookworm larvae is a damp, sandy or friable soil with decaying vegetation. In general, sandy soil is more favourable than clay soil. (b) TEMPERATURE : A temperature of 24 to 32 deg. C is considered favourable for the survival of the larvae. The eggs fail to develop at temperatures below 13 deg. C. Larvae are killed at 45 to 50 deg. C. (c) OXYGEN : This is required for the growth and development of the larvae. (d) MOISTURE : Moisture is necessary for survival; dryness is rapidly fatal. (e) RAINFALL : A rainfall of 40 inches (100 cm) and above is considered a favourable environmental factor. More important than the total annual rainfall is the number of rainy days spread out evenly throughout the year to keep up the moisture content of the soil. Flooding is an unfavourable factor. (f) SHADE : Direct sunlight kills the larvae whereas shade protects them. (g) HUMAN HABITS : The habits of the human host not only determine the mode and extent of soil pollution, but also the mode and extent of contact between infected soil and skin or mouth *(3)*. These include indiscriminate defecation, using the same places for defecation, going barefoot, farming practices using untreated sewage, children wading in the infected mud with bare–feet and hands. These habits are compounded by social factors such as illiteracy, ignorance and low standard of living.

Incubation period (prepatent period)

Following infection, the prepatent period for *N. americanus* is 7 weeks while that for *A. duodenale* is unpredictable, ranging from 5 weeks to 9 months *(5)*. This is because the invading larva of *A. duodenale* is capable of remaining arrested or dormant in the tissues of the host for as long as 9 months and then again resume development and migration.

Effects of the disease

(a) INDIVIDUAL : Hookworm infection causes chronic blood loss and depletion of body's iron stores leading to iron–deficiency anaemia. This has implications for child health in terms of retarded physical growth and development; for the health of mothers in terms of increased morbidity, low birth weight babies, abortion, stillbirths and impaired lactation; and for the health of adults in terms of diminished capacity for sustained hard work. Hookworm infection also causes a loss of blood plasma into the small intestine which can lead to hypoalbuminaemia in some subjects. (b) COMMUNITY : Hookworm infection exerts a significant and harmful effect on various aspects of the economy and quality of life of a community, especially in three major areas. These are nutrition, growth and development; work and productivity, and medical care costs.

WHIPWORM

Whipworm is the third most common soil-transmitted helminthiasis in the humans. According to current estimate, nearly 800 million people are infected, and majority of cases are children 4–10 years age. Heavy infection could lead to acute symptoms such as diarrhoea and anaemia, and chronic symptoms such as growth retardation and impaired cognitive development. It is quite common in United States, South-East Asia, to a lesser extent equatorial Africa, Central and South America *(4)*.

Agent Factor

Whipworms live in the large intestine, Male worm measures about 30–45 mm long while female is about 30–35 mm long. Female worm produces about 200–10,000 eggs per day for more than 5 years. Embryonization takes 21 days. It can withstand cold temperatures but not desiccation. The infection is directly from the faeces. Eggs hatch after being swallowed in the intestine, where shell is digested by intestinal juices and the larva emerges in the small intestine. It penetrates the villi and develops for a week until it re-emerges and passes to the cecum and colorectum where it attaches itself to the mucosa and becomes adult *(4, 6)*.

Incubation period

Period from ingestion of egg to appearance of egg in stool is 60–90 days *(4, 6)*.

Effect of the disease

Majority of infections are mild or asymptomatic. It causes epigestric pain, nausea, vomiting, distension flatulence, weight loss. Moderate infection causes growth deficit and anaemia. Severe infection causes severe chronic diarrhoea or dysentery with blood and mucous in stool, dehydration, rectal prolapse, colonic obstruction, hypoproteinaemia, chronic iron deficiency, anaemia etc. *(4)*.

PREVENTION AND CONTROL OF SOIL-TRANSMITTED HELMINTHS

Primary prevention

Methods based on primary prevention are the most effective in interrupting transmission. These are : sanitary disposal of human excreta to prevent or reduce faecal contamination of the soil, provision of safe drinking water, food hygiene habits, and health education of the community in the use of sanitary latrines, personal hygiene and changing behavioural patterns, measures of personal

protection such as wearing protective footwear and making use of health facilities for diagnosis and treatment. Prevention, to be effective, must take into consideration the life cycle of the parasite and the peculiar ecological, social and cultural circumstances that prevail in a community.

Secondary prevention

Effective drugs are available for the treatment of the human reservoir. These are piperazine, mebendazole, levamisole and pyrantel; the last two drugs are effective in a single dose. (a) *Albendazole :* The usual dose for adults and children over 2 years is 400 mg as a single dose. Contraindicated in children below 2 years and in pregnancy. (b) *Mebendazole :* The usual dose is 100 mg twice daily for 3 days for all ages above 2 years. (c) *Levamisole :* It is the levorotatary form of tetramisole and is more active than the parent compound. For many it is now the drug of choice. A single oral dose of 2.5 mg/kg of body weight (maximum 150 mg) has been recommended. There are usually no side effects. It has been used successfully in the mass treatment of ascariasis.(d) *Pyrantel :* Effective in a single dose of 10 mg/kg of body weight *(7)* with a maximum of 1g.

Treatment of anaemia and other complications

Anaemia should be treated with iron and folic acid. Patient should be treated for hypoproteinaemia and hypereosinophilia.

Preventive chemotherapy *(1)*

The WHO strategy for control of soil-transmitted helminth infection is to control morbidity through periodic treatment of at-risk people living in endemic areas. The people at risk are : (a) preschool-aged children; (b) school aged children; (c) women of childbearing age including pregnant women in second and third trimesters and breast-feeding mothers; and (d) adults in certain high-risk occupations, such as tea-pickers or miners.

WHO recommends periodic deworming without previous individual diagnosis to all at-risk people living in endemic areas. Treatment should be given once a year when prevalence of soil-transmitted helminth infection in the community is over 20 per cent and twice a year if the prevalence is over 50 per cent. This reduces the morbidity by reducing the worm burden. Periodic deworming can easily be integrated with child health days or supplementation programmes for pre-school children, or can be integrated with school health programmes. Schools provide a particularly good entry point for deworming activities, as they allow easy provision of the health and hygiene education component – such as promotion of hand washing and improved sanitation.

The recommended medicines are albendazole (400 mg) and mebendazole (500 mg). They are effective and can be easily administered by non-medical persons. The drugs are donated by WHO. In 2011, over 300 million pre-school aged and school-aged children were treated with anthelmintic medicines, corresponding to 30 per cent of the children at risk *(1)*.

The global target is to eliminate morbidity due to soil-transmitted helminthiasis in children by year 2020. This will be achieved by regularly treating at least 75 per cent of the children in endemic areas – an estimated 873 million children *(1)*.

DRACUNCULIASIS

Dracunculiasis or guineaworm disease is a vectorborne parasitic disease, mainly of the subcutaneous tissues (usually leg and foot) caused by the nematode parasite, *Dracunculus medinensis.* Although not lethal, this parasitic disease can disable its victim temporarily.

Problem Statement

Progress towards the elimination of dracunculiasis in the past decade has been spectacular, with the number of cases falling world-wide from an estimated 892,005 in 1989 (when most endemic countries began to report monthly cases from each endemic village) to a total of 148 cases in 2013. Compared with 2012 (542 cases), the largest decline in the number of cases occurred in South Sudan. At present only Ethiopia, Mali, Chad, Sudan and South Sudan are reporting cases *(1)*.

In India, the last reported case was in July 1996. On completion of three years of zero incidence, India was declared free of guineaworm disease *(2)*.

Natural history

(a) AGENT : The adult parasite inhabits the subcutaneous tissue mainly of the legs but also of other parts of the body, including the head and neck. The female grows to a length of 55 to 120 cm, and the male is very short (2–3 cm). The gravid female makes it's way down to the infected person's lower limbs near the skin surface. There it penetrates into the dermis and induces an inflammatory reaction and subsequent blister formation. Upon contact with water, the blister soon ruptures and the parasite releases up to one million, microscopic, free–swimming larvae into water. The larvae may remain active in water for 3–6 days. They are picked up by small fresh–water crustaceans called cyclops. The larvae require a period of about 15 days for development in cyclops, which is the intermediate host.

Man acquires infection by drinking water containing infected cyclops. In the human body, digested by gastric juice, the parasites are released. They penetrate the duodenal wall. Subsequently they migrate through the viscera to the subcutaneous tissues of various parts of the body. They grow into adults in 10–14 months.

(b) RESERVOIR OF INFECTION : An infected person harbouring the gravid female. The possibility of an animal reservoir exists but not proved *(3)*.

(c) HOST FACTORS : Host susceptibility is universal. Multiple and repeated infections may occur in the same individual. The habit of washing and bathing in surface water and using step–wells is important.

(d) ENVIRONMENTAL FACTORS : The main link in the

transmission of guineaworm disease is water infested with cyclops. The risk of transmission exists where such cyclops–infested water–sources are frequented by infected persons. *Season :* The seasonal variations in the incidence of the disease are marked. Where the step-wells are the source of water supply, peak transmission occurs during the dry season (March–May) when the contact between open cases of gunieaworm disease and the drinking water is the greatest; and there is little transmission when the wells are full during and after rains. Where the ponds are used, transmission appears to be confined to June–September, when the ponds contain water *(4, 5). Temperature :* The larvae develop best between 25 and 30 deg C, and will not develop below 19 deg C. Therefore, the disease is limited to tropical and subtropical regions *(6)*.

Mode of transmission

The disease is transmitted entirely through the consumption of water containing cyclops harbouring the infective stages of the parasite. Guineaworm disease is a totally water–based disease and does not have an alternate pathway of transmission.

Treatment

No drug cures the infection but metronidazole and mebendazole are sometimes used to limit inflammation and facilitate worm removal. Wet compresses may relieve discomfort. Occlusive dressings improves hygiene and limit shedding of infectious larvae. Worms are removed by sequentially rolling them out over a small stick. When available simple surgical procedure can be used to remove worm. Topical antibiotics may limit bacterial superinfection.

Eradication

Guineaworm disease is amenable to eradication. The eradication strategy comprises the following elements :

i) Provision of safe drinking water (e.g., piped water, installation of hand pumps).
ii) Control of cyclops (see Chap.12).
iii) Health education of the public in matters relating to boiling or sieving drinking water through a double–thickness cotton cloth for personal protection, and prevention of water contamination by infected persons.
iv) Surveillance : Active search for new cases, and

Guineaworm Eradication Programme

Refer to chapter 7 for details.

III. ARTHROPOD–BORNE INFECTIONS

THE DENGUE SYNDROME

Dengue viruses are arboviruses capable of infecting humans, and causing disease. These infections may be asymptomatic or may lead to (a) "classical" dengue fever, or (b) dengue haemorrhagic fever without shock, or (c) dengue haemorrhagic fever with shock. The manifestations of the dengue syndrome are as shown in Fig. 1.

Dengue fever is a self–limiting disease and represents the majority of cases of dengue infection. A prevalence of *Aedes aegypti* and *Aedes albopictus* together with the circulation of dengue virus of more than one type in any particular area tends to be associated with outbreaks of DHF/DSS *(1)*.

Problem statement

Dengue fever (DF) and its severe forms – dengue haemorrhagic fever (DHF) and dengue shock syndrome (DSS) – have become major international public health concerns. Over the past three decades, there has been dramatic global increase in the frequency of dengue fever, DHF and DSS and their epidemics. It is found in tropical and subtropical regions around the world, predominantly in urban and semi-urban areas, and are now spreading to rural areas.

Some 2.5 billion people i.e. two fifth of the world's population in tropical and subtropical countries are at risk of the disease. An estimated 50 million dengue infections occur worldwide annually and about 500,000 people with DHF require hospitalization each year. Approximately 90 per cent of them are children aged less than five years, and about 2.5 per cent of those affected die. Epidemics of dengue are increasing in frequency. During epidemics, infection rate among those who have not been previously exposed to the virus are often 40 to 50 per cent, but can also reach 80 to 90 per cent *(2)*. Cocirculation of multiple serotypes/genotypes is evident.

Dengue and DHF is endemic in more than 100 countries in the WHO regions of Africa, the Americas, Eastern Mediterranean, South-East Asia and Western Pacific. The South-East Asia and Western Pacific regions are most seriously affected. Detection of all four serotypes has now rendered the countries hyperendemic. The countries of South-East Asia region are divided into 3 categories *(2)*.

Category A (Bangladesh, India, Indonesia, Maldives, Myanmar, Sri Lanka, Thailand and Timor-Leste)

a. Major public health problem;
b. Leading cause of hospitalization and death among children;
c. Hyperendemicity with all 4 serotypes circulating in urban areas; and
d. Spreading to rural areas.

Category B (Bhutan, Nepal)

a. Endemicity uncertain;
b. Bhutan reported first outbreak in 2004; and
c. Nepal reported first indigenous case in 2004.

Category C (DPR Korea)

No evidence of endemicity.

INDIA

In India, the risk of dengue has shown an increase in recent years due to rapid urbanization, lifestyle changes and deficient water management including improper water storage practices in urban, peri-urban and rural areas, leading to proliferation of mosquito breeding sites. The disease has a seasonal pattern i.e. the cases peak after monsoon, and it is not uniformly distributed throughout the year. However, in the southern states and Gujarat the transmission is perennial *(3)*.

Dengue is endemic in 31 states/UTs. During 2013, about 74,168 cases were reported with 168 deaths. The case fatality rate was 0.22 per cent. As seen from Table 1, the highest number of cases were reported from Punjab followed by Tamil Nadu, Gujarat, Kerala and Andhra Pradesh *(5)*.

All the four serotypes i.e. dengue 1, 2, 3 and 4 have been isolated in India but at present DENV-1 and DENV-2 serotypes are widespread *(4)*.

Epidemiological determinants

Agent factors

(a) AGENT : The dengue virus form a distinct complex within the genus *flavivirus* based on antigenic and biological characteristics. There are four virus serotypes which are designated as DENV-1, DENV-2, DENV-3 and DENV-4. Infection with any one serotype confers lifelong immunity to that virus serotype *(6)*. Although all four serotypes are antigenically similar, they are different enough to elicit cross-protection for only a few months after infection by any one of them. Secondary infection with dengue serotype 2 or multiple infection with different serotypes lead to severe form dengue DHF/DSS *(2)*. The first infection probably sensitizes the patient, while the second infection with different serotype appears to produce immunological catastrophy.

The pathogenesis of severe syndrome involves pre-existing dengue antibody. It is postulated that virus antibodies are formed within a few days of the second dengue infection and that the non-neutralizing enhancing antibodies promote infection of higher numbers of mononuclear cells, followed by the release of cytokines, vasoactive mediators, and procoagulants, leading to the disseminated intravascular coagulation seen in the haemorrhagic fever syndrome *(7)*.

All four serotypes have been associated with epidemics of dengue fever (with or without DHF) with varying degree of severity.

(b) VECTOR : *Aedes aegypti* and *Aedes Albopictus* are the two most important vectors of dengue. They both carry high vectorial competency for dengue virus, i.e., high susceptibility to infecting virus, ability to replicate the virus and ability to transmit the virus to another host. *Aedes aegypti* is a highly domesticated, strongly anthropophilic, nervous feeder (i.e., it bites more than one host to complete one blood meal) and is a discordant species (i.e., it needs more than one feed for the completion of the gonotropic cycle). This habit results in the generation of multiple cases and the clustering of dengue cases in the cities. On the contrary, *Ae. albopictus* partly invades peripheral areas of urban cities. It is an aggressive feeder and concordant species, i.e., the species can complete its blood meal in one go on one person and also does not require a second blood meal for the completion of the gonotropic cycle.

Transmission of disease

The *Aedes* mosquito becomes infective by feeding on a patient from the day before onset to the 5th day (viraemia stage) of illness. After an extrinsic incubation period of 8 to 10 days, the mosquito becomes infective, and is able to transmit the infection. Once the mosquito becomes infective, it remains so for life. The genital tract of the mosquito gets infected and transovarian transmission of dengue virus occurs when virus enters fully developed eggs at the time of oviposition.

Environmental factors

The population of *Aedes aegypti* fluctuates with rainfall and water storage. Its life span is influenced by temperature and humidity, survives best between 16°C–30°C and a relative humidity of 60–80 per cent. It breeds in the containers in and around the houses. Being a domestic breeder, it is a endophagic and endophilic. However, even with a 2°C increase in temperature the extrinsic incubation period of DENV will be shortened and more infected mosquitoes are available for a longer duration. Besides that the mosquitoes will bite more frequently because of dehydration and thus increase man–mosquito contact *(2, 4)*.

The failure of urban authorities to provide civil amenities and poor public health infrastructure raises the potential for

Source : *(5)*

the vector to breed at high level and makes the environment transmission conducive. The rural spread of the vector is relatively recent occurrence associated with the development of rural water supply schemes, improved transport systems, scarcity of water and lifestyle changes *(4)*.

Dengue in the community *(2)*

A number of factors that contribute to initiation and maintenance of an epidemic include: (i) the strain of the virus, which may influence the magnitude and duration of the viraemia in humans; (ii) the density, behaviour and vectorial capacity of the vector population; (iii) the susceptibility of the human population (both genetic factors and pre-existing immune profile); and (iv) the introduction of the virus into a receptive community.

DF/DHF syndrome

DF/DHF is characterized by the "iceberg" or pyramid phenomenon. At the base of the pyramid, most of the cases are symptomless, followed by DF,DHF and DSS. Clusters of cases have been reported in particular households or neighbourhoods due to the feeding behaviour of the vector.

Affected population

The population affected varies from one outbreak to another. Actual estimates can be made by obtaining clinical/ subclinical ratios during epidemics. In a well-defined epidemic study in North Queensland, Australia, with primary infection, 20% to 50% of the population was found affected.

Severity of the disease

The serotype that produces the secondary infection and, in particular, the serotype sequence are important to ascertain the severity of the disease. All the four serotypes are able to produce DHF cases. However, during sequential infections, only 2% to 4% of individuals develop severe disease.

Studies in Thailand have revealed that the DENV-1/ DENV-2 sequence of infection was associated with a 500 fold risk of DHF compared with primary infection. For the DENV-3/DENV-2 sequence the risk was 150-fold, and a DENV-4/DENV-2 sequence had a 50-fold risk of DHF. There is no time-limit to sensitization after a primary infection. The 1997 Santiago de Cuba epidemic clearly demonstrated that with the introduction of DENV-2, DHF had occurred 16–20 years after the primary infection with DENV-1.

High risk patients *(2)*

The following host factors contribute to more severe disease and its complications :

1. infants and elderly ;
2. obesity;
3. pregnancy;
4. peptic ulcer disease;
5. women who are in menstruation or have abnormal bleeding;
6. haemolytic disease such as G–6PD, thalassemia and other haemoglobinopathies;
7. congenital heart disease;
8. chronic diseases such as diabetes mellitus, hypertension, asthma, ischaemic heart disease, chronic renal failure, liver cirrhosis; and
9. patients on steroid or NSAID treatment.

Clinical mainfestations

Dengue virus infection may be asymptomatic or may cause undifferientiated febrile illness (viral syndrome), dengue fever(DF), or dengue haemorrhagic fever (DHF) including dengue shock syndrome (DSS) as shown in Fig.1

1. Undifferentiated fever

Infants, children and adults who have been infected with denuge virus, especially for the first time (i.e. primary dengue infection), may develop a simple fever indistinguishable from other viral infection. Maculopapular rashes may accompany the fever or may appear during

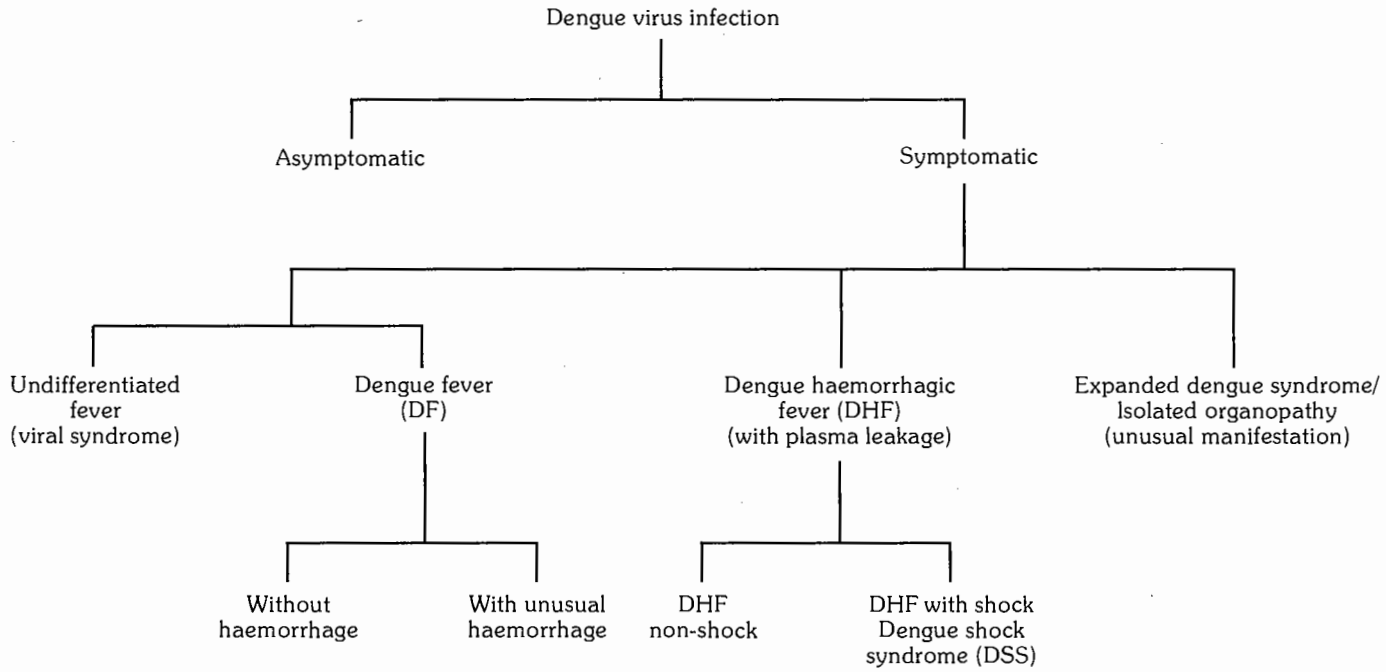

FIG. 1

Manifestations of the dengue virus infection

Source : *(2)*

defervescence. Upper respiratory and gastrointestinal symptoms are common.

2. Classical dengue fever

All ages and both sexes are susceptible to dengue fever. Children usually have a milder disease than adults. The illness is characterized by an incubation period of 3 to 10 days (commonly 5–6 days). The onset is sudden, with chills and high fever, intense headache, muscle and joint pains, which prevent all movement. Within 24 hours retroorbital pain, particularly on eye movements or eye pressure and photophobia develops. Other common symptoms include extreme weakness, anorexia, constipation, altered taste sensation, colicky pain and abdominal tenderness, dragging pain in inguinal region, sore throat and general depression. Fever is usually between 39°C and 40°C. Fever is typically but not inevitably followed by a remission of a few hours to 2 days (biphasic curve). The skin eruptions appear in 80 per cent of cases during the remission or during second febrile phase, which lasts for 1–2 days. The rash is accompanied by similar but milder symptoms. The rash may be diffuse flushing, mottling or fleeting pin–point eruptions on the face, neck and chest during the first half of the febrile period and a conspicuous rash, that may be maculopapular or scarlatiniform on 3rd or 4th day. It starts on the chest and trunk and may spread to the extremities and rarely to the face. It may be accompanied by itching and hyperaesthesia. The rash lasts for 2 hours to several days and may be followed by desquamation *(1)*. Fever lasts for about 5 days, rarely more than 7 days after which recovery is usually complete although convalescence may be protracted *(8)*. The case fatality is exceedingly low.

3. Dengue haemorrhagic fever

Dengue haemorrhagic fever (DHF) is a severe form of dengue fever. The course of dengue illness can be divided into three phases–febrile phase, critical phase and recovery phase, as shown in Fig. 2 *(9)*.

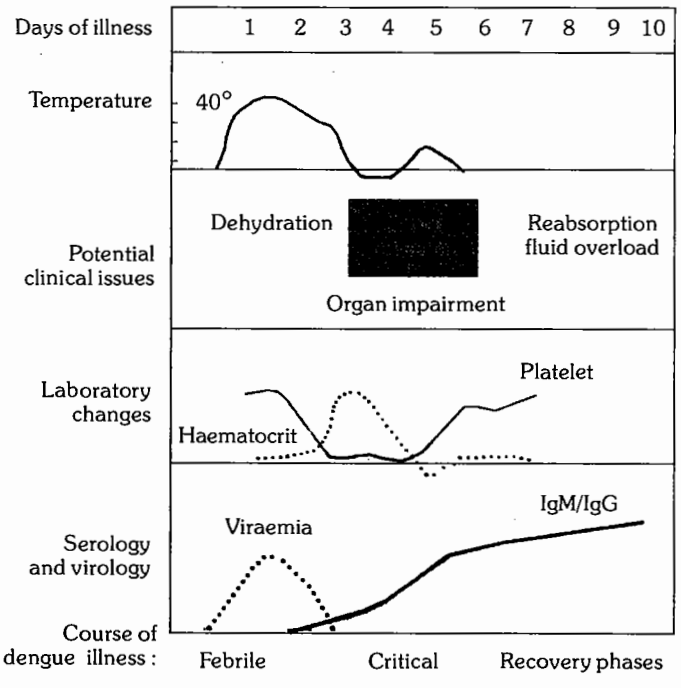

FIG. 2
The course of dengue illness

Source : *(9)*

1. Febrile phase

Following an incubation period of four to six days, the illness commonly begins abruptly with high fever accompanied by facial flushing and headache. Anorexia, vomiting, epigastric discomfort, tenderness at the right costal margin and generalized abdominal pain are common. During the first few days the illness usually resembles classical DF, but maculopapular rash usually rubelliform type, is less common. It may appear early or late in the course of the illness. Occasionally, the temperature may be 40°C to 41°C and febrile convulsions may occur particularly in infants *(1)*.

The major pathophysiologic changes that determine the severity of disease in DHF and differentiate it from DF are plasma leakage and abnormal haemostasis, as manifested by a rising haematocrit value and moderate to marked thrombocytopenia. These two clinical laboratory changes are distinctive and constant findings.

A positive tournicate test is the most common haemorrhagic phenomenon. The test is performed by inflating a blood pressure cuff to a a mid point between systolic and diastolic pressure for 5 minutes. The test is considered positive when 10 or more petechiae per 2.5 × 2.5 cm (1 inch square) are observed. In DHF, the test usually gives a definite positive with 20 petechiae or more *(4)*.

2. Critical phase (9)

Around the time of defervescence, when the temperature drops to 37.5–38°C or less, and remains below this level, usually on days 3–7 of illness, an increase in capillary permeability in parallel with increasing haematocrit levels may occur. This marks the beginning of the critical phase. The period of clinically significant plasma leakage usually lasts 24–48 hours.

Progressive leukopenia followed by a rapid decrease in platelet count usually precedes plasma leakage. At this point patients without an increase in capillary permeability will improve, while those with increased capillary permeability may become worse as a result of lost plasma volume. The degree of plasma leakage varies. Pleural effusion mostly on right side and ascites may be clinically detectable depending on the degree of plasma leakage and the volume of fluid therapy. Gall bladder oedema has been found to precede plasma leakage. Hence chest X-ray and abdominal ultrasound can be useful tools for diagnosis. The degree of increase above the baseline haematocrit often reflects the severity of plasma leakage.

Shock occurs when a critical volume of plasma is lost through leakage. It is often preceded by warning signs of abdominal pain or tenderness, persistent vomiting, clinical fluid accumulation, mucosal bleeding, lethargy, restlessness, liver enlargement more than 2 cm. and oliguria. The body temperature may be subnormal when shock occurs. With prolonged shock, the consequent organ hypoperfusion results in progressive organ impairment, metabolic acidosis and disseminated intravascular coagulation. This in turn leads to severe haemorrhage causing the haematocrit to decrease in severe shock. Instead of the leukopenia usually seen during this phase of dengue, the total white cell count may increase in patients with severe bleeding. In addition, severe organ impairment such as severe hepatits, encephalitis or myocarditis and/or severe bleeding may also develop without obvious plasma leakage or shock.

Those who improve after defervescence are said to have

non-severe dengue. Some patients progress to the critical phase of plasma leakage without defervescence and, in these patients, changes in the full blood count should be used to guide the onset of the critical phase and plasma leakage. Those who deteriorate will manifest with warning signs. This is called dengue with warning signs. Cases of dengue with warning signs will probably recover with early intravenous rehydration. Some cases will deteriorate to severe dengue.

3. Recovery phase

If the patient survives the 24–48 hour critical phase, a gradual reabsorption of extravascular compartment fluid takes place in the following 48–72 hours. General well-being improves, appetite returns, gastrointestinal symptoms abate, haemodynamic status stabilizes and diuresis ensues. Some patients may have a rash of "isles of white in the sea of red". Some may experience generalized pruritus. Bradycardia and electrocardiographic changes are common during this stage.

The haematocrit stabilizes or may be lower due to the dilutional effect of reabsorbed fluid. White blood cell count usually starts to rise soon after defervescence but the recovery of platelet count is typically later than that of white blood cell count.

Respiratory distress from massive pleural effusion and ascites will occur at any time if excessive intravenous fluids have been administered. During the critical and/or recovery phases, excessive fluid therapy is associated with pulmonary oedema or congestive heart failure.

4. Severe dengue

Severe dengue is defined by one or more of the following : (i) plasma leakage that may lead to shock (dengue shock) and/or fluid accumulation, with or without respiratory distress, and/or (ii) severe bleeding, and/or (iii) severe organ impairment.

As dengue vascular permeability progresses, hypovolaemia worsens and results in shock. It usually takes place around defervescence, usually on day 4 or 5 (range days 3–7) of illness, preceded by the warning signs. During the initial stage of shock, the compensatory mechanism which maintains a normal systolic blood pressure also produces tachycardia and peripheral vasoconstriction with reduced skin perfusion, resulting in cold extremities and delayed capillary refill time. Uniquely, the diastolic pressure rises towards the systolic pressure and the pulse pressure narrows as the peripheral vascular resistance increases. Patients in dengue shock often remain conscious and lucid. The inexperienced physician may measure a normal systolic pressure and misjudge the critical state of the patient. Finally, there is decompensation and both pressures disappear abruptly. Prolonged hypotensive shock and hypoxia may lead to multi-organ failure and an extremely difficult clinical course.

The patient is considered to have shock if the pulse pressure is ≤20 mm Hg in children or he/she has signs of poor capillary perfusion (cold extremities, delayed capillary refill, or rapid pulse rate). In adults, the pulse pressure of ≤20 mm Hg may indicate a more severe shock. Hypotension is usually associated with prolonged shock which is often complicated by major bleeding.

Patients with severe dengue may have coagulation abnormalities, but these are usually not sufficient to cause major bleeding. When major bleeding does occur, it is almost always associated with profound shock since this, in combination with thrombocytopenia, hypoxia and acidosis, can lead to multiple organ failure and advanced disseminated intravascular coagulation. Massive bleeding may occur without prolonged shock in instances when acetylsalicylic acid (aspirin), ibuprofen or corticosteriods have been taken.

Unusual manifestations, including acute liver failure and encephalopathy, may be present, even in the absence of severe plasma leakage or shock. Cardiomyopathy and encephalitis are also reported in a few dengue cases. However, most deaths from dengue occur in patients with profound shock, particularly if the situation is complicated by fluid overload.

CRITERIA FOR CLINICAL DIAGNOSIS *(2, 4)*

A summary of clinical diagnosis of DF and DHF is as follows :

Dengue fever

Probable diagnosis

Acute febrile illness with two or more of the following;

- headache,
- retro-orbital pain,
- myalgia,
- arthralgia/bone pain,
- rash,
- haemorrhagic manifestations,
- leucopenia (wbc ≤ 5000 cells/mm^3),
- thrombocytopenia (platelet count <150,000 cells/mm^3),
- rising haematocrit (5–10%);

and at least one of following :

- supportive serology on single serum sample: titre ≥ 1280 with haemagglutination inhibition test, comparable IgG titre with enzyme-linked immunosorbent assay, or testing positive in IgM antibody test, and
- occurrence at the same location and time as confirmed cases of dengue fever.

Confirmed diagnosis

Probable case with at least one of the following :

- isolation of dengue virus from serum, CSF or autopsy samples.
- fourfold or greater increase in serum IgG (by haemagglutination inhibition test) or increase in IgM antibody specific to dengue virus.
- detection of dengue virus or antigen in tissue, serum or cerebrospinal fluid by immunohistochemistry, immunofluorescence or enzyme-linked immunosorbent assay.
- detection of dengue virus genomic sequences by reverse transcription-polymerase chain reaction.

Dengue haemorrhagic fever

All of following :

- acute onset of fever of two to seven days duration.
- haemorrhagic manifestations, shown by any of the following; positive tourniquet test, petechiae, ecchymoses or purpura, or bleeding from mucosa, gastrointestinal tract, injection sites, or other locations.
- platelet count ≤ 100,000 cells/mm^3

- objective evidence of plasma leakage due to increased vascular permeability shown by any of the following :
  - Rising haematocrit/haemoconcentration ≥ 20% from baseline or evidence of plasma leakage such as pleural effusion, ascites or hypoproteinaemia/ albuminaemia.

Dengue shock syndrome

Criteria for dengue haemorrhagic fever as above with signs of shock including :

- tachycardia, cool extremities, delayed capillary refill, weak pulse, lethargy or restlessness, which may be a sign of reduced brain perfusion.
- pulse pressure ≤ 20 mmHg with increased diastolic pressure, e.g. 100/80 mmHg.
- hypotension by age, defined as systolic pressure <80 mmHg for those aged <5 years, or 80 to 90 mmHg for older children and adults.

Laboratory diagnosis *(2, 4)*

Rapid and accurate dengue diagnosis is of a paramount importance for : (1) clinical management; (2) epidemiological surveillance; (3) research; and (4) vaccine trials. Epidemiological surveillance requires early determination of dengue virus infection during the outbreak for urgent public health action towards control, as well as at sentinel sites for detection of circulating serotypes/genotypes during the inter-epidemic period for use in forecasting possible outbreak. The following laboratory tests are available to diagnose dengue fever and DHF :

1. *Virus isolation :* Isolation of dengue virus from clinical specimens is possible provided the specimen is taken during the first six days of illness and processed without delay. Specimen that are suitable for virus isolation are – acute phase serum, plasma or washed buffy coat from the patient,autopsy tissue from fatal case (especially liver, spleen, lymph nodes and thymus), and mosquitoes collected from the affected areas.

2. *Viral nucleic acid detection :* Dengue viral genome, which consists of RNA, can be detected by reverse transcriptase polymerase chain reaction (RT–PCR) assay and real time RT–PCR. In recent years, a number of RT–PCR assays have been reported for detecting dengue virus. They offer better specificity and sensitivity compared to virus isolation with a much more rapid turnaround time.

3. *Immunological response and serological tests :* Following tests are available for diagnosis of dengue infection :

a. Haemagglutination - inhibition assay (HIA);
b. Complement Fixation (CF);
c. Neutralization test (NT);
d. IgM capture enzyme-linked immunosorbent assay (MAC-ELISA);
e. Indirect IgG- ELISA, and
f. IgM/IgG ratio

4. *Viral antigen detection :* ELISA and dot blot assays directed against the envelop/membrane (EM) antigens and nonstructural protein 1 (NS1) can be detected in both patients with primary and secondary dengue infection upto 6 days after the onset of the illness. Commercial kits for the detection of NS1 antigens are now available; however, these kits do not differentiate between the serotypes. Besides providing an early diagnostic marker for clinical management, it may also facilitate the improvement of epidemiological surveys of dengue infection.

5. *Rapid diagnostic test (RDT) :* A number of commercial rapid format serological test-kits for anti-dengue IgM and IgG antibodies have become available in the past few years, some of these producing results within 15 minutes. Unfortunately, the accuracy of most of these tests is uncertain since they have not yet been properly validated.

6. *Analysis of haematological parameters :* Standard haematological parameters such as platelet count and haematocrit are important and are part of the diagnosis of dengue infection. They should be closely monitored.

The diagnostic tests are summarized in Table 2.

TABLE 2
Dengue diagnostics and sample characteristics

	Clinical sample	Diagnostic method	Methodology	Time to results
Virus detection and its components	Acute serum (1–5 days of fever) and necropsy tissues	Viral isolation	Mosquito or mosquito cell culture inoculation	One week or more
		Nucleic acid detection	RT-PCR and real time RT-PCR	1 or 2 days
		Antigen detection	NS1 Ag rapid tests	Minutes
			NS1 Ag ELISA	1 day
			Immuno-histochemistry	2–5 days
Serological response	Paired sera (acute serum from 1–5 days and second serum 15–21 days after)	IgM or IgG seroconversion	ELISA HIA	1–2 days
			Neutralization test	Minimum 7 days
	Serum after day 5 of fever	IgM detection (recent infection)	ELISA	1 or 2 days
			Rapid tests	Minutes
		IgG detection	IgG ELISA HIA	1 or 2 days

ELISA = enzyme-linked immunosorbent assay; HIA = haemagglutination inhibition assay; IgG = immunoglobulin G; IgM = immunoglobulin M; NS1 Ag = non-structural protein 1 antigen; RT-PCR = reverse transcriptase polymerase chain reaction.

CLINICAL MANAGEMENT

Grading of the severity of dengue infection

To decide where to treat the patient, it is important to classify the severity of dengue infection. The presence of thrombocytopenia with concurrent haemoconcentration differentiates grade I and grade II DHF from DF. Table 3 shows grading of dengue infection.

Guidelines for treatment

A full blood count of the patient should be done at the first visit. A haematocrit test in the early febrile phase establishes the patient's own baseline haematocrit. A rapidly decreasing platelet count in parallel with a rising haematocrit compared to the baseline is suggestive of progress to the plasma leakage/critical phase of the disease. In the absence of the patients baseline, age specific population haematocrit levels could be used as a surrogate during the critical phase.

1. Management of dengue fever

These are patients who are able to tolerate adequate volumes of oral fluids and pass urine at least once every six hours, and do not have any of the warning signs, particularly when fever subsides. Those with stable haematocrit can be sent home after being advised to return to the hospital immediately if they develop any of the warning signs, and to adhere to the following action plan :

(1) Encourage intake of oral rehydration solution (ORS), fruit juice and other fluids containing electrolytes and sugar to replace losses from fever and vomiting. Adequate oral fluid intake may be able to reduce the number of hospitalizations. (Caution : fluids containing sugar/glucose may exacerbate hyperglycaemia of physiological stress from dengue and diabetes mellitus.)

(2) Give paracetamol for high fever if the patient is uncomfortable. The interval of paracetamol dosing should not be less than six hours. Tepid sponge if the patient still has high fever. Do not give acetylsalicylic acid (aspirin), ibuprofen or other non-steroidal anti-inflammatory agents (NSAIDs) as these drugs may aggravate gastritis or bleeding. Acetylsalicylic acid (aspirin) may be associated with Reye's Syndrome.

(3) Instruct the care-givers that the patient should be brought to hospital immediately if any of the following occur; no clinical improvement, deterioration around the time of defervescence, severe abdominal pain, persistent vomiting, cold and clammy extremities, lethargy or irritability/ restlessness, bleeding (e.g. black stools or coffee–ground vomiting), not passing urine for more than 4–6 hours.

Patients who are sent home should be monitored daily by health care providers for temperature pattern, volume of fluid intake and losses, urine output (volume and frequency), warning signs, signs of plasma leakage and bleeding, haematocrit, and white blood cell and platelet counts.

2. Management of DHF (Febrile Phase) *(4)*

The management of febrile phase is similar to that of DF. Paracetamol is recommended to keep the temperature below 39°C. Copious amount of fluid should be given orally, to the extent the patient tolerates, oral rehydration solution (ORS), such as those used for the treatment of diarrhoeal disesases and/or fruit juices are preferable to plain water. IV fluid may be administered if the patient is vomiting persistently or refusing to feed.

Patients should be closely monitored for the initial signs of shock. The critical period is during the transition from the febrile to the afebrile stage and usually occurs after the third day of illness. Serial haematorcrit determinations are essential guide for treatment, since they reflect the degree of plasma leakage and need for intravenous administration of fluids. Haematocrit should be determined daily from the third day until the temperature has remained normal for one or two days. If haematocrit determination is not possible, haemoglobin determination may be carried out as an alternative. The details of IV treatment when required for patients are given in Fig. 3.

TABLE 3

WHO classification and grading of the severity of dengue infection

DF/DHF	Grade	Symptoms/signs	Laboratory findings
DF		Fever with two or more of following – Headache – Retro-orbital pain – Myalgia – Arthralgia – Rash – Haemorrhagic manifestations – No evidence of plasma leakage	– Leucopenia (WBC ≤ 5000 cells/cu.mm), – Thrombocytopenia (platelet count < 150,000 cells/cu.mm), – Rising haematocrit (5-10 per cent)
DHF	I	Above criteria for DF and haemorrhagic manifestaion plus positive tourniquet test, evidence of plasma leakage	Thrombocytopenia : Platelet count < 100,000/cu.mm. Haematorcit rise 20% or more
DHF	II	Above signs and symptoms plus some evidence of spontaneous bleeding in skin or other organs (black tarry stools, epistaxis, bleeding from gums, etc) and abdominal pain	Thrombocytopenia platelet count < 100,000/cu.mm. Haematocrit rise 20% or more
DHF	III	Above signs and symptoms plus circulating failure (weak rapid pulse, pulse pressure ≤ 20 mm Hg or high diastolic pressure, hypotension with the presence of cold clammy skin and restlessness)	Thrombocytopenia : Platelet count < 100,000/cu.mm. Haematocrit rise more than 20%
DHF	IV	Signs as grade III plus profound shock with undetectable blood pressure or pulse	Thrombocytopenia : Platelet count < 100,000/cu.mm. Haemotocrit rise more than 20%
DHF III and IV are Dengue Shock Syndrome

Source : *(4)*

3. Management of DHF Grade I and II

Any person who has dengue fever with thrombocytopenia and haemoconcentration and presents with abdominal pain, black tarry stools, epistaxis, bleeding from the gums and infection etc needs to be hospitalized. All these patients should be observed for signs of shock. The critical period for development of shock is transition from febrile to abferile phase of illness, which usually occurs after third day of illness. A rise of haemoconcentration indicates need for IV fluid therapy. If despite the treatment, the patient develops fall in BP, decrease in urine output or other features of shock, the management for Grade III/IV DHF/ DSS should be instituted.

Oral rehydration should be given along with antipyretics like paracetamol, sponging, etc. as described above. The detailed treatment for patients with DHF Grade I and II is given in Fig. 3.

4. Management of DHF Grade III and IV

Common signs of complication are observed during the afebrile phase of DHF. Immediately after hospitalization, the haematocrit, platelet count and vital signs should be examined to assess the patient's condition and intravenous fluid therapy should be started. The patient requires regular and sustained monitoring. If the patient has already received about 1000 ml of intravenous fluid, it should be changed to colloidal solution preferably Dextran 40/haemaccele or if haematocrit is decreasing, fresh whole blood transfusion 10 ml/kg/hour should be given.

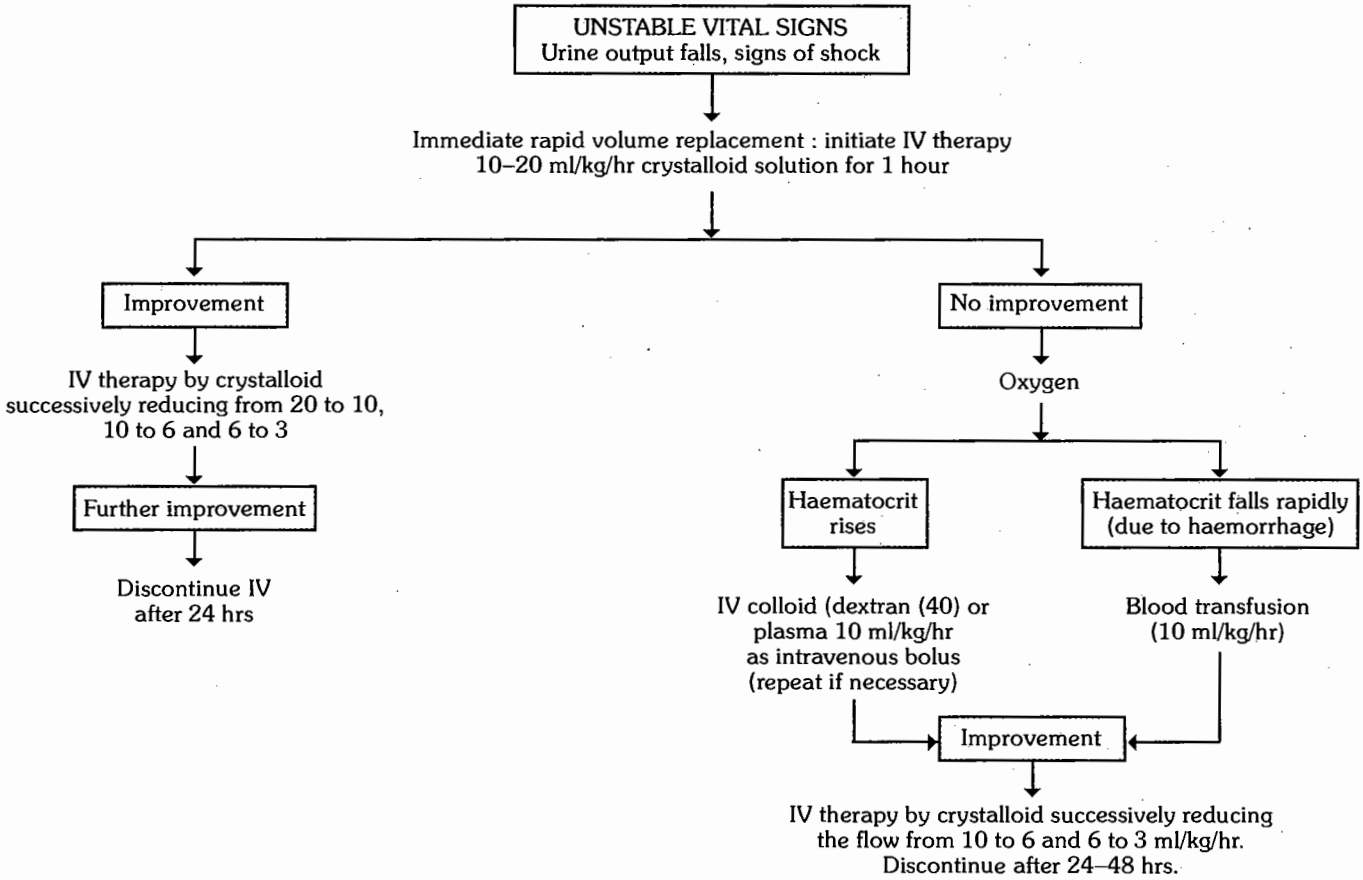
However, in case of persistent shock when, after initial fluid replacement and resuscitation with plasma or plasma expanders, the haematocrit continues to decline, internal bleeding should be suspected. It may be difficult to recognize and estimate the degree of internal blood loss in the presence of haemoconcentration. It is thus recommended to give fresh whole blood in small volumes of 10 ml/kg/hour for all patients in shock as a routine precaution. Oxygen should be given to all patients in shock. The detailed graphical presentation of the treatment for patients with DHF Grades III and IV is given in Fig. 4.

Indications of red cell transfusion

1. Loss of blood (overt blood) – 10 per cent or more of total blood volume – preferably give whole blood or components to be used.
2. Refractory shock despite adequate fluid administration and declining haematocrit.
3. Replacement volume should be 10 ml/kg body weight at a time and coagulogram should be done.
4. If fluid overload is present packed cells are to be given.

Indications of platelet transfusion

In general there is no need to give prophylactic platelet even at < 20,000/cu.mm.



- Serial platelet and haematocrit determinations : drop in platelets and rise in haematrocrit are essential for early dignosis of DHF.
- Cases of DHF should be observed every hour for vital signs and urinary output.

FIG. 4

Volume replacement flow chart for patients with DHF Grades III & IV

Source : *(4)*

1. Prophylactic platelet transfusion may be given at level of < 10,000/cu.mm.
2. Prolonged shock; with coagulopathy and abnormal coagulogram.
3. In case of systemic massive bleeding, platelet transfusion may be needed in addition to red cell transfusion.

Criteria for discharge of patients

1. Absence of fever for atleast 24 hours without the use of anti-pyretic drugs.
2. Return of appetite.
3. Visible clinical improvement.
4. Good urine output.
5. Minimum of 2–3 days after recovery from shock.
6. No respiratory distress from pleural effusion or ascites.
7. Platelet count > 50,000/cu.mm.

Disease notification

In dengue-endemic countries, cases of suspected, probable and confirmed dengue should be notified as soon as possible so that appropriate health measures can be initiated.

CONTROL MEASURES

1. Mosquito control

The vectors of DF and DHF (e.g., *A. aegypti*) breed in and around houses and, in principle can be controlled by individual and community action, using antiadult and antilarval measures. These measures are outlined in chapter 12.

2. Vaccines

So far, there is no satisfactory vaccine and no immediate prospect of preventing the disease by immunization.

3. Other measures

Isolation of the patient under bed-nets during the first few days; individual protection against mosquitoes.

The personal prophylactic measures are wearing of full sleeves shirts and full pants; use of mosquito repellent creams, liquids, coils, mats etc.; use of bed-nets for sleeping infants and young children during day time to prevent mosquito bite.

The environmental measurements are detection and elimination of mosquito breeding places, management of roof tops, porticos and sunshades, proper covering of stored water, observation of weekly dry day.

Global strategy for dengue prevention and control 2012–2020 *(11)*

Dengue is a global threat that requires a global response involving all possible partners. The global strategy promotes co-ordination and collaboration among multisectoral partners on integrated vector management approach and sustained control measures at all levels. The goals are :

a. to reduce dengue mortality by at least 50 per cent by 2020;
b. to reduce dengue morbidity by at least 25 per cent by 2020; and
c. to estimate the true burden of the disease by 2015.

MALARIA

Malaria is a protozoal disease caused by infection with parasites of the genus **Plasmodium** and transmitted to man by certain species of infected female Anopheline mosquito. A typical attack comprises three distinct stages : cold stage, hot stage and sweating stage. The clinical features of malaria vary from mild to severe, and complicated, according to the species of parasite present, the patient's state of immunity, the intensity of the infection and also the presence of concomitant conditions such as malnutrition or other diseases. The febrile paroxysms occur with definite intermittent periodicity repeating every third or fourth day depending upon the species of the parasite involved.

Problem statement

WORLD

According to the latest estimates, there were about 198 million (124–283 million) cases of malaria in the year 2013 and an estimated 584,000 deaths (367,000–755,000). Malaria mortality rates have fallen by 47 per cent globally since year 2000, and by 54 per cent in the WHO African Region. Most deaths occur among children living in Africa, where a child dies every minute from malaria *(1A)*.

Approximately half of the world's population is at risk of malaria. Most malaria cases and deaths occur in sub-Saharan Africa. However, Asia, Latin America, and to a lesser extent the Middle East and parts of Europe are also affected. In 2013, 97 countries and territories had ongoing malaria transmission.

The specific risk groups for malaria includes the following population *(1)* :

1. young children in stable transmission areas who have not yet developed protective immunity against the most severe forms of the disease;
2. non-immune pregnant women as malaria causes high rates of miscarriage and can lead to maternal death;
3. semi-immune pregnant women in areas of high transmission. Malaria can result in miscarriage and low birth weight, especially during first and second pregnancies;
4. semi-immune HIV-infected pregnant women in stable transmission areas, during all pregnancies. Women with malaria infection of the placenta also have a higher risk of passing HIV infection to their newborns;
5. people with HIV/AIDS;
6. international travellers from non-endemic areas because they lack immunity.
7. immigrants and their children living in non-endemic areas and returning to their home countries to visit friends and relatives are similarly at risk because of waning or absent immunity.

Malaria affects mainly poor, underserved and marginalized populations in remote rural areas which are characterized by inadequate control measures and limited access to health care. Higher malaria prevalence has been reported among ethnic and tribal groups living in remote forested and border areas, as well as among mobile and migrant populations.

The childhood deaths result mainly from cerebral malaria and anaemia. Fatality rates of 10–30 per cent have been reported among children referred to hospital with severe malaria. However, these rates are even higher in rural and remote areas where patients have restricted access to adequate treatment. Malaria also contributes indirectly to illness and deaths from respiratory infections, diarrhoeal disease and malnutrition. Deaths from malaria in countries outside Sub-Saharan Africa occur principally in non-immune people who become infected with *P. falciparum.*

Underreporting of malaria cases and deaths remain a major challenge. Drug-resistant parasites, poor treatment-seeking behaviour and the presence of counterfeit antimalarial drugs further hinder control efforts. Resistance of *P. falciparum* to the 4–aminoquinolines and sulfadoxine–pyrimethamine is widespread in almost all countries of SEAR, with varying levels of severity. Resistance to mafloquine was reported from Myanmar and Thailand. Quinine has reduced susceptibility in Thailand. With progress from mono-to-multidrug resistance, all malaria-endemic countries that have *falciparum* malaria adopted the highly effective artemisinin – based combination therapy (ACT).

The coverage of indoor residual spraying with insecticides (IRS) remains low (42 per cent). Insecticide-treated nets have been introduced in almost all countries to supplement IRS efforts, but the coverage remains extremely low.

INDIA

Malaria continues to pose a major public health threat in India, particularly due to *Plasmodium falciparum* which is prone to complications. In India about 21.98 per cent population lives in malaria high transmission

(≥ 1 case/1000 population) areas and about 67 per cent in low transmission (0–1 case/1000 population) areas *(2)*. About 92 per cent of malaria cases and 97 per cent of deaths due to malaria is reported from North-eastern states, Chhattisgarh, Jharkhand, Madhya Pradesh, Orissa, Andhra Pradesh, Maharashtra, Gujarat, Rajasthan, West Bengal and Karnataka. However, the other states are also vulnerable with local and focal outbreaks of malaria. Much of these areas are remote and inaccessible, forest or forest fringed with operation difficulties and predominantly inhabited by tribal population *(3)*.

The countrywide malaria surveillance data for the period from 1995 to 2013 is as shown in Table 1.

The API has been steadily declining in India from 3.29 in 1995 to 0.88 in 2012. When interpreting API, it is important to evaluate the level of surveillance activity indicated by the Annual Blood Examination Rate (ABER). At low levels of surveillance, the Slide Positivity Rate (SPR) is a better indicator. The SPR has also shown a decline in the country from 3.51 in 1995 to 0.51 in 2013. The *Pf* cases have declined from 1.14 million in 1995 to 0.44 million cases in 2013. However *Pf* % has gradually increased from 38.8% in 1995 to nearly 66.9% in 2013, which may indicate increasing resistance to chloroquine *(4)*.

India is predominantly characterized by unstable malaria transmission. Transmission is seasonal with increased intensity related to rains. Due to the low and unstable transmission dynamics, most of the population has no or little immunity toward malaria. As a result, the majority of Indians living in malarious areas are at risk of infection with all age groups affected. However, surveys have shown that in some foci, mainly in forested areas, transmission is intense and the disease burden is to a large extent concentrated in children.

There are six primary vectors of malaria in India : (1) *An. culicifacies* is the main vector of rural and peri-urban areas and is widespread in peninsular India. It is found in a variety of natural and man-made breeding sites. It is highly zoophilic. Species A is an established vector for *P. Vivax* and *P. falciparum*, whereas species B is completely refractory to *P. Vivax* and partially refractory to *P. falciparum*. It has been demonstrated that species B, however, may play a role as a vector of *P. falciparum* in areas where the cattle population is very low or absent; (2) *An. stephensi* is responsible for malaria in urban and industrial areas. The type form is found in urban areas; intermediate form in urban and semi-urban localities and *mysorensis* form is present in rural areas (it is not a vector); (3) *An. fluviatilis* is the main vector in hilly areas, forests and forest fringes in many states, especially in the east; (4) *An. minimus* is the vector in the foot hills of North-Eastern states; (5) *An. dirus* is an important forest vector in the North-East; and (6) *An. epiroticus* is now restricted to the Andaman and Nicobar Islands *(5)*.

Prevalent major epidemiological types of malaria in India *(6)*

In the course of the stratification exercise, various problems and constraints responsible for the slow progress of malaria control have been identified. An analysis of these factors has resulted in the identification of malaria priority areas.

TRIBAL MALARIA : The population of tribal areas are contributing about 50 per cent of *P. falciparum* cases of the country *(5)*. Infants, young children and pregnant women have been identified as malaria high risk groups followed by mobile tribal population engaged in forest–related activities. Limited health infrastructure and lack of drugs at village level are the factors responsible for high morbidity and mortality due to malaria.

RURAL MALARIA : These include irrigated areas of arid and semiarid plains. Malaria is of moderate to low endemicity. *An. culicifacies* is the main vector and *P.vivax* is predominant during lean period and *P.falciparum* during periodic exacerbation. In these the health infrastructure is moderately developed.

URBAN MALARIA : 15 major cities including 4 metropolitans account for nearly 80 per cent of malaria cases covered under urban malaria control scheme. The health infrastructure is well developed. In peri-urban areas malaria situation is influenced by poor sanitary conditions and low socio-economic groups living in unplanned settlements prone to periodical epidemics.

MALARIA IN PROJECT AREAS : Project areas are those areas where construction and developmental activities are taken up and temporary tropical aggregation of labourers takes place bringing in different strains of malaria parasite and non–immune population. This results in disturbance in eco–system, prolific increase in vector breeding places and increased man–mosquito contact favouring high malaria transmission. These pockets contribute a large number of malaria cases which are highly disproportionate to the

TABLE 1

Countrywide malaria surveillance data (1995–April 2014)

Year	Population (in thousands)	BSE (in millions)	Total malaria cases (in millions)	*P. falciparum* cases (in millions)	Pf%	API	SPR	SFR	Deaths due to malaria

Source : *(4)*

relatively small population groups inhabitating the area. One or more major vectors are involved in malaria transmission. Limited health facilities for prompt treatment is invariably associated with chloroquine resistant malaria parasite. Hence specific control strategy is required for such areas.

BORDER MALARIA : These are the high malaria transmission belts along the international borders and state borders. These areas have their own problems in regard to malaria control because of mixing of population and poor administrative control.

Some definitions *(2)*

Malaria control : reducing the malaria disease burden to a level at which it is no longer a public health problem.

Malaria elimination : the interruption of local mosquito-borne malaria transmission; reduction to 'zero' of the incidence of infection caused by human malaria parasites in a defined geographical area as a result of deliberate efforts; continued measures to prevent re-establishment of transmission are required.

Certification of malaria elimination : can be granted by WHO after it has been proven beyond reasonable doubt that the chain of local human malaria transmission by *Anopheles* mosquitoes has been fully interrupted in an entire country for at least 3 consecutive years.

Malaria eradication : permanent reduction to 'zero' of the worldwide incidence of infection caused by a specific agent; applies to a particular malaria parasite species. Intervention measures are no longer needed once eradication has been achieved.

Epidemiological determinants

Agent factors

(a) AGENT

Malaria in man is caused by four distinct species of the malaria parasite – *P. vivax, P. falciparum, P. malariae* and *P. ovale. Plasmodium vivax* has the widest geographic distribution throughout the world. In India, about 50 per cent of the infections are reported to be due to *P. falciparum* and 4–8 per cent due to mixed infection and rest due to *P. vivax*. *P. malariae* has a restricted distribution and is said to be responsible for less than 1 per cent of the infections in India. The largest focus of *P. malariae* in India is reported to be in Tumkur and Hassan districts in Karnataka. *P. ovale* is a very rare parasite of man, mostly confined to tropical Africa. It has also been reported in Vietnam. The severity of malaria is related to the species of the parasite.

Life history

The malaria parasite undergoes 2 cycles of development – the human cycle (asexual cycle) and the mosquito cycle (sexual cycle). Man is the intermediate host and mosquito the definitive host (Fig. 1).

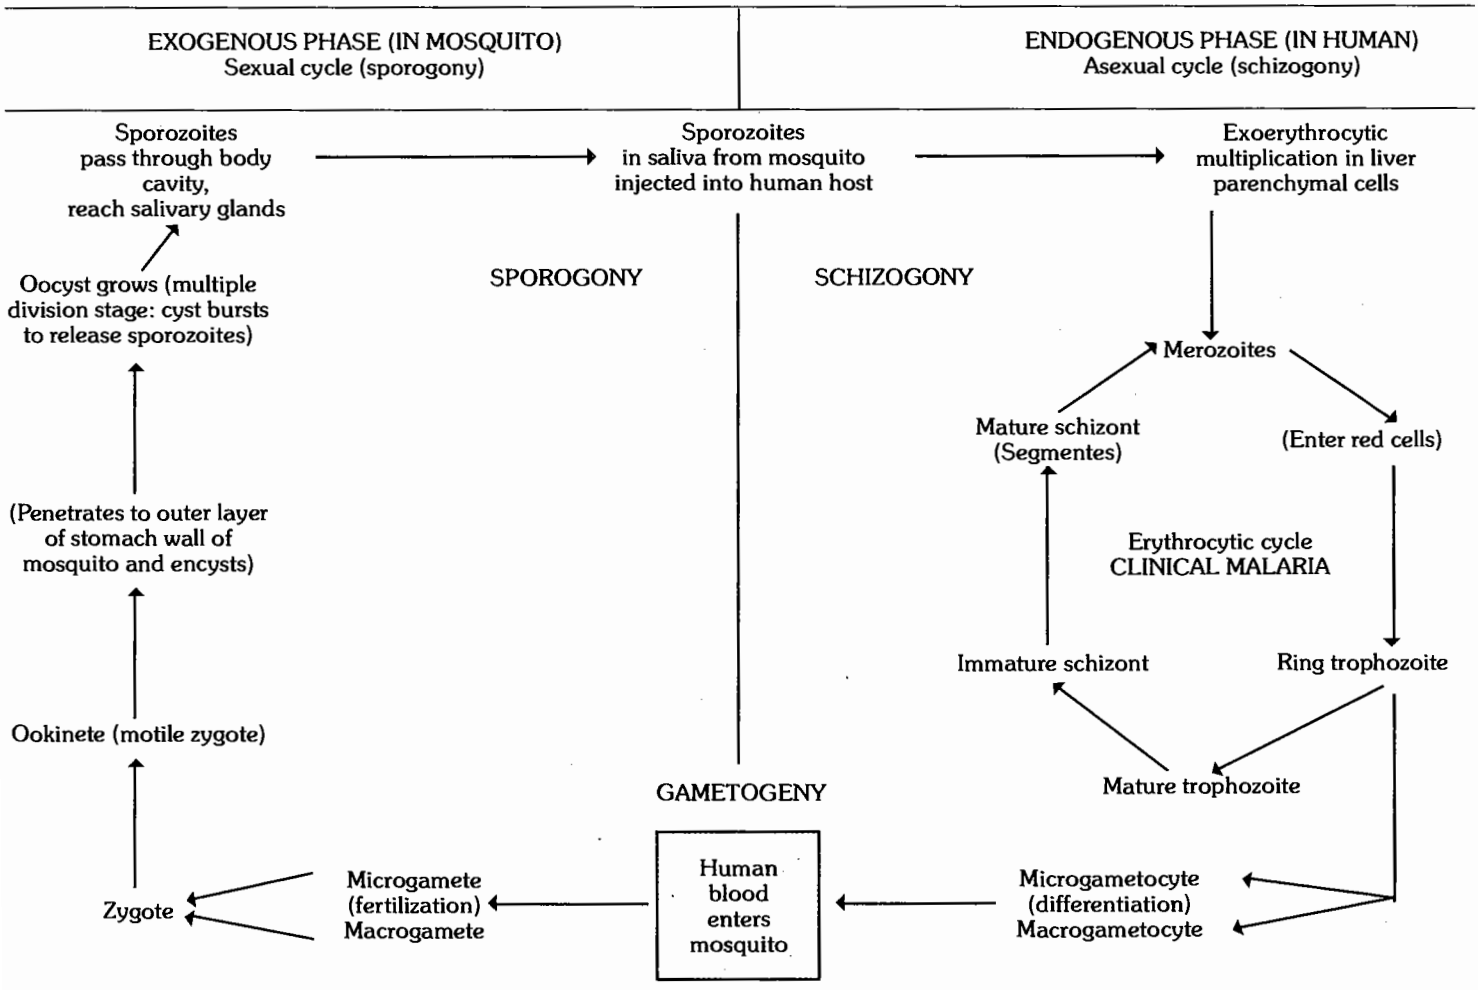

FIG. 1

Lifecycle of the malaria parasite.

Source : *(10)*

(i) *Asexual cycle:* The asexual cycle begins when an infected mosquito bites a person and injects sporozoites. A considerable amount of new knowledge about the parasite's life cycle has become available in recent years, concerning almost all phases of the cycle *(7)*. A brief description is as follows – four phases are described in the human cycle: (a) HEPATIC PHASE: The sporozoites disappear within 60 minutes from the peripheral circulation *(8)*. Many of them are destroyed by phagocytes, but some reach the liver cells. After 1–2 weeks of development (depending upon the species), they become hepatic schizonts, which eventually burst releasing a shower of merozoites. The number of merozoites produced from a single sporozoite varies considerably with the infecting species. A single *P. falciparum* sporozoite may form as many as 40,000 merozoites, whereas sporozoites from other species of plasmodia produce only 2,000 to 15,000 merozoites *(8)*. In the case of *P. falciparum,* the intrahepatic schizonts rupture almost simultaneously and there is no persistent tissue phase (the so-called exo-erythrocytic phase). On the contrary, the intrahepatic schizonts of the other plasmodia do not burst all at the same time. Some hepatic forms persist and remain dormant in the hepatocytes for considerable periods before they begin to grow and undergo pre-erythrocytic schizogony, thus liberating merozoites into the blood stream causing relapses of these infections. *P. vivax* and *P. ovale* may continue to relapse for 2 to 3 years and *P. malariae* may persist for 10 to 20 years or more. Once the parasites enter the RBC, they do not reinvade the liver. (b) ERYTHROCYTIC PHASE: Many of the merozoites are quickly destroyed, but a significant number attach to specific receptor sites on the RBC. The merozoites then penetrate the RBC and pass through the stages of trophozoite and schizont. The erythrocytic phase ends with the liberation of merozoites, which infect fresh red blood cells. The cycle is repeated over and over again until it is slowed down by the immune response of the host *(9)*. The duration of the erythrocytic cycle is constant for each species of malaria parasite– 48 hours for *P. falciparum, P. vivax* and *P. ovale*; and 72 hours for *P. malariae.* (c) GAMETOGENY: In all species of malaria some erythrocytic forms do not divide but become male and female gametocytes. These are the sexual forms of the parasite which are infective to mosquito.

(ii) *Sexual cycle:* The mosquito cycle (sporogony) begins when gametocytes are ingested by the vector mosquito when feeding on an infected person. The gametocytes continue further development in the mosquito. The first event to take place in the stomach of the mosquito is exflagellation of the male gametocyte; 4–8 thread–like filaments called "micro-gametes" are developed. The female gametocyte undergoes a process of maturation and becomes a female gamete or "macrogamete". By a process of chemotaxis, microgametes are attracted towards the female gamete, and one of which (microgamete) causes fertilization of the female gamete. The resulting zygote is at first a motionless body, but within 18–24 hours, it becomes motile. This is known as *Ookinete,* which penetrates the stomach wall of the mosquito and develops into an oocyst on the outer surface of the stomach. The oocyst grows rapidly and develops within it numerous sporozoites. When mature, the oocyst bursts and liberates sporozoites into the body cavity of mosquito. Many of the sporozoites migrate to the salivary glands of the mosquito, and the mosquito now becomes infective to man. The period of time required for the development of the parasite from the gametocyte to sporozoite stage in the body of the mosquito is about 10–20 days depending upon favourable conditions of atmospheric temperature and humidity. This period is also referred to as the "extrinsic incubation period".

(b) RESERVOIR OF INFECTION

With the possible exception of chimpanzees in tropical Africa, which may carry the infection with *P. malariae,* no other animal reservoir of human plasmodia is known to exist *(9)*. A human reservoir is one who harbours the sexual forms (gametocytes) of the parasite. A patient can be a carrier of several plasmodial species at the same time. Children are more likely to be gametocyte carriers than adults. The child is thus epidemiologically a better reservoir than the adult. Certain conditions must be met before a person can serve as a reservoir: (i) the person must harbour both the sexes of the gametocyte in his blood. If the person harbours only male or female gametocytes, further development cannot take place in the mosquito vector, (ii) the gametocytes must be mature; immature forms do not undergo further development. It may take 2–4 days for the gametocytes to attain maturity after their appearance in the blood, (iii) the gametocytes must be viable, i.e., if the patient receives an antimalarial drug, the gametocytes lose their viability or infectivity to mosquitoes (iv) the gametocytes must be present in sufficient density to infect mosquitoes. The number of gametocytes necessary to infect mosquitoes is not definitely known, but it is thought by some that there must be at least 12 per cubic mm of blood.

(c) PERIOD OF COMMUNICABILITY

Malaria is communicable as long as mature, viable gametocytes exist in the circulating blood in sufficient density to infect vector mosquitoes. In vivax infections, gametocytes appear in blood 4–5 days after the appearance of the asexual parasites; in falciparum infections, they do not appear until 10–12 days after the first appearance of asexual parasites. Gametocytes are the most numerous during the early stages of the infection when their density may exceed 1,000 per cubic mm of blood. They also tend to occur in waves in peripheral blood.

RELAPSES: It is usual for vivax and ovale malaria to relapse more than 3 years after the patient's first attack. Recurrences of falciparum malaria usually disappear within 1–2 years. *P. malariae* has a tendency to cause prolonged low–level, asymptomatic parasitaemia *(11)*. The infection is known to persist for 40 years or more. It is probable that persons harbouring such infections are at least occasionally infective to mosquitoes.

It is now considered more likely that vivax and ovale relapses are derived from original, sporozoite–induced, liver schizonts which have lain latent long before bursting. In *P. falciparum* and *P. malariae* infections latent liver schizonts do not appear to occur. Relapses in these species, most authorities maintain, are due to a chronic blood infection, i.e., erythrocytic schizogony persisting at a low level.

Host factors

The main variables of the human element that have an influence on malaria epidemiology include the following :

(a) AGE : Malaria affects all ages. Newborn infants have considerable resistance to infection with *P. falciparum.* This has been attributed to the high concentration of foetal haemoglobin during the first few months of life, which suppresses the development of *P. falciparum (12)*. (b) SEX : Males are more frequently exposed to the risk of acquiring malaria than females because of the outdoor life they lead.

Further, females in India are usually better clothed than males. (c) RACE : Individuals with AS haemoglobin (sickle–cell trait) have a milder illness with falciparum infection than do those with normal (AA) haemoglobin *(8)*. Persons whose red blood cells are "Duffy negative" (a genetic trait) are resistant to *P. vivax* infection. (d) PREGNANCY : Pregnancy increases the risk of malaria in women. Malaria during pregnancy may cause intrauterine death of the foetus; it may also cause premature labour or abortion. Primigravid women are at greatest risk *(13)*. (e) SOCIO-ECONOMIC DEVELOPMENT : Malaria has demonstrated the relationship between health and socio-economic development. It is generally accepted that malaria has disappeared from most developed countries as a result of socio-economic development *(13)*. (f) HOUSING: Housing plays an important role in the epidemiology of malaria. The ill–ventilated and ill–lighted houses provide ideal indoor resting places for mosquitoes. Malaria is acquired in most instances by mosquito–bites within the houses. The site, type of construction, nature of the walls, etc. influence the selection of control measures *(14)*. (g) POPULATION MOBILITY : People migrate for one reason or other from one country to another or from one part of a country to another. Labourers connected with various engineering, irrigation, agricultural and other projects and periodic migration of nomads and wandering tribes are outstanding examples of internal migration. Some of them may import malaria parasites in their blood and reintroduce malaria into areas where malaria has been controlled or eliminated. Imported malaria has become quite a public health problem in Europe, North America, and other temperate parts of the world, owing to the rising tide of air travel, tourism and migration *(10)*. (h) OCCUPATION : Malaria is predominantly a rural disease and is closely related to agriculture practices. (i) HUMAN HABITS : Habits such as sleeping out of doors, nomadism, refusal to accept spraying of houses, replastering of walls after spraying and not using measures of personal protection (e.g. bed nets) influence man–vector contact, and obviously the choice of control measures. (j) IMMUNITY: The epidemic of malaria is influenced by the immune status of the population. Immunity to malaria in humans is acquired only after repeated exposure over several years. Thus in endemic malarious areas a state of collective immunity becomes established slowly, so that infants, young children, migrants and travellers from non–endemic areas suffer most from the disease. Those, however, who survive to the adult age show less evidence of adverse effects to the attenuated infection. Infants born of immune mothers are generally protected during the first 3–5 months by maternal IgG antibody; infants born of semi–immune mothers are only partially protected. Active immunity is species–specific, that is, immunity against one strain does not protect against another. People living in endemic areas exposed continually to malaria develop considerable degree of resistance to clinical disease, but their partial immunity to malaria declines with time after they leave their endemic countries. Semi–immune individuals may harbour malaria parasites without presenting any symptoms of disease. Both humoral and cellular factors play a role in this protection *(1)*.

Environmental factors

India's geographic position and climatic conditions had been, for long, favourable to the transmission of malaria. (a) SEASON : Malaria is a seasonal disease. In most parts of India, the maximum prevalence is from July to November. (b) TEMPERATURE: Temperature affects the life cycle of the malaria parasite. The optimum temperature for the development of the malaria parasite in the insect vector is between 20 deg. to 30 deg.C (68 deg. to 86 deg.F). The parasite ceases to undergo development in the mosquito if the mean temperature is below 16 deg.C (60.8 deg.F). Temperatures higher than 30 deg.C are lethal to the parasite. (c) HUMIDITY: The atmospheric humidity has a direct effect on the length of life of the mosquito, although it has no effect on the parasite. A relative humidity of 60 per cent is considered necessary for mosquitoes to live their normal span of life. When the relative humidity is high, mosquitoes are more active and they feed more voraciously. If the humidity is low, mosquitoes do not live long. (d) RAINFALL : Rain in general provides opportunities for the breeding of mosquitoes and may give rise to epidemics of malaria. Rain increases the atmospheric humidity which is necessary for the survival of mosquitoes. However, heavy rain may have an adverse affect in flushing out the breeding places. Paradoxically in some areas, (e.g., Sri Lanka) severe epidemics of malaria followed years of drought. It was because, the lesser monsoon rains led to the formation of small pools of water in river beds, which served as active breeding places for malaria vectors. The relationship between rainfall (total and its distribution) and mosquito breeding is of fundamental importance *(15)*. (e) ALTITUDE: As a rule, *Anophelines* are not found at altitudes above 2000–2500 metres, due to unfavourable climatic conditions. (f) MAN–MADE MALARIA: Burrow pits, garden pools, irrigation channels and engineering projects like construction of hydroelectric dams, roads, bridges have led to the breeding of mosquitoes and an increase in malaria. Malaria consequent on such human undertakings is called "man–made malaria".

Vector of malaria

Out of about 45 species of anopheline mosquitoes in India, only a few are regarded as the vectors of primary importance. These are: *An. culicifacies*, *An. fluviatilis*, *An. stephensi*, *An. minimus*, *An. philippinensis*, *An. sundaicus*, and *An. maculatus*. The vectors of major importance are *An culicifacies* in rural areas and *An. stephensi* in urban areas.

In the absence of a vaccine, vector control is the only practical approach to malaria control. A knowledge of anopheline biology is essential for understanding the epidemiology of malaria and its prevention. The main factors which determine the vectorial importance of mosquitoes are: (a) DENSITY : To be an effective vector, a species must be present in adequate density in or near human habitations. A sudden increase in density of vectors, may be a cause of epidemic outbreaks. For each vector, there is what is known as "critical density" below which effective transmission cannot be maintained in a community. This level varies with different species. In the case of *An. culicifacies* a high density is required for the propagation of malaria; in the case of *An. fluviatilis* which is very efficient vector, a much lower density would suffice. (b) LIFE SPAN: The key factor in the transmission of malaria is the life span of the vector. The vector mosquito must live for at least 10–12 days after an infective blood meal to become infective. The strategy in malaria eradication is to shorten the life span of mosquitoes to less than 10 days by insecticides. (c) CHOICE OF HOST : Some mosquitoes prefer human blood, some animal blood, and some show great variation in their feeding habits. The percentage of

human blood feeds in the case of *An. culicifacies*, an important vector in India, has been found to vary from 2–80 per cent *(8)*. In contrast, *An. fluviatilis* is a highly anthrophilic species. The anthrophilic species, i.e., those that have a high preference for human blood are better vectors of malaria than zoophilic species. (d) RESTING HABITS : After a blood meal, some mosquitoes rest indoors on the walls for quite sometime. This behaviour pattern is known as "endophily". But there are some species which rest outdoors (exophily). A knowledge of the resting habits (which must be under constant surveillance) is the basis for organizing rational anti-adult measures. In fact, the concept of malaria eradication is based on endophilism (indoor resting habits) of most malarial vectors. (e) BREEDING HABITS: The breeding habits of mosquitoes vary considerably. Some breed in moving water *(An. fluviatilis)*, some in brackish water *(An. sundaicus)* and some in wells, cisterns, fountains and overhead tanks *(An. stephensi)*. A knowledge of the breeding habits is required for conducting anti-larval operations. (f) TIME OF BITING : The majority of Indian mosquitoes bite at night excepting the Aedes mosquitoes. Anophiline mosquitoes have nocturnal feeding habits, between dusk and dawn. (g) VECTORIAL CAPACITY : The term vectorial capacity refers to the combined effect of the density of the vector population, its susceptibility to infection, life span and probability of feeding on man. It is distinct from physiological capacity to transmit infection. (h) RESISTANCE TO INSECTICIDES : A knowledge of the status of vector resistance to insecticides is also necessary. On this depends the choice of insecticides to be used. When an insect vector is resistant to a given insecticide, alternative insecticides have to be used.

Mode of transmission

(a) VECTOR TRANSMISSION: Malaria is transmitted by the bite of certain species of infected, female, anopheline mosquitoes. A single infected vector, during her life time, may infect several persons. The mosquito is not infective unless the sporozoites are present in its salivary glands. (b) DIRECT TRANSMISSION: Malaria may be induced accidentally by hypodermic intramuscular and intravenous injections of blood or plasma, e.g., blood transfusion, malaria in drug addicts *(16, 17)*. Blood transfusion poses a problem because the parasites keep their infective activity for at least 14 days in blood bottles stored at – 4 deg.C *(16)*. Persons who have lived in an endemic area (including those who have been taking antimalarials prophylactically) and anyone who has had malaria should not be accepted as blood donor until 3 years afterwards *(18)*. (c) CONGENITAL MALARIA: Congenital infection of the newborn from an infected mother may also occur, but it is comparatively rare.

Incubation period

This is the length of time between the infective mosquito bite and the first appearance of clinical signs of which fever is most common. This period is usually not less than 10 days.

The duration of the incubation period varies with the species of the parasite, and in natural infections (in mosquito-transmitted malaria) this is 12 (9–14) days for falciparum malaria, 14 (8–17) days for vivax malaria, 28 (18–40) days for quartan malaria and 17 (16–18) days for ovale malaria. With some strains of *P. vivax,* the incubation period may be delayed for as long as 9 months; this may also occur with other species in persons who have been taking suppressive antimalarial drugs *(8)*.

Clinical features

The primary fever is marked by paroxysms which correspond to the development of the parasites in the red blood cells. The peaks of the fever coincide with the release into the blood stream of successive broods of merozites.

The typical attack comprises three distinct stages, i.e., the cold stage, the hot stage and the sweating stage. These are followed by an afebrile period in which the patient feels greately relieved.

COLD STAGE : The onset is with lassitude, headache, nausea and chilly sensation followed in an hour or so by rigors. The temperature rises rapidly to 39–41°C. Headache is often severe and commonly there is vomiting. In early part of this stage, skin feels cold; later it becomes hot. Parasites are usually demonstrable in the blood. The pulse is rapid and may be weak. This stage lasts for 1/4–1 hour.

HOT STAGE : The patient feels burning hot and casts off his clothes. The skin is hot and dry to touch. Headache is intense but nausea commonly diminishes. The pulse is full and respiration rapid. This stage lasts for 2 to 6 hours.

SWEATING STAGE : Fever comes down with profuse sweating. The temperature drops rapidly to normal and skin is cool and moist. The pulse rate becomes slower, patient feels relieved and often falls asleep. This stage lasts for 2–4 hours.

The febrile paroxysms occur with definite intermittent periodicity repeating every third or fourth day depending upon the species of the parasite involved. The classical 3 stages (cold, hot and sweating) may not always be observed due to maturation of generations of parasite at different times. Periods of latency may last several weeks or months *(8, 19)*. The disease has a tendency to relapse and is characterized by enlargement of the spleen and secondary anaemia. Febrile herpes is common in all malarial patients.

In patients with *P. falciparum* infection the primary fever in its first few days is usually irregular or even continuous and then the classical 48 hour periodicity becomes established or the fever may continue to be irregular and the hot and cold stages, so typical of other malarial infections are less clearly separated from one another. In persons with poor immunity the paroxysms are associated with marked prostration. Headache, nausea and vomiting are usually more severe, and there is greater tendency towards the development of delirium, haemolytic jaundice and anaemia. The mortality is much greater than in other forms of malaria.

With *P. vivax* infection, symptoms are same but are usually milder and more regularly divided into "hot" and "cold" stages than in *P. falciparum* infections.

P. ovale infections differ little from that of *P. vivax*. However, they tend to be milder than *P. vivax* and cease after a few paroxysms even if no treatment is given.

Clinically, *P. malariae* attacks resemble those of *P. vivax* but the cycle is of 72 hours instead of 48 hours. The tendency for long-term relapses to occur is marked.

The complications of *P. falciparum* malaria are cerebral malaria, acute renal failure, liver damage, gastro-intestinal symptoms, dehydration, collapse, anaemia, blackwater fever etc. The complications of *P. vivax, P. ovale* and *P. malariae* infections are anaemia, splenomegaly, enlargement of liver, herpes, renal complications etc.

Diagnosis

The diagnosis of malaria depends on demonstration of

the parasite in the blood. Suspicion of the diagnosis is aroused by epidemiological and clinical evidence.

1. Microscopy

Two types of blood films are useful in searching for and identification of malaria parasite. The "thin film" and the "thick film". It is recommended that both types of film be prepared on a single microscope glass slide. The thick film is more reliable in searching for parasite, as large volume of blood is examined under each microscope field. When scanty, parasite may be found about 20 times more rapidly in thick slide than in thin slide. The thin slide is more valuable for identifying the species of the parasite present. In it they are seen more clearly.

The advantage of microscopy are : The sensitivity is high. It is possible to detect malarial parasite at low densities. It also helps to quantify the parasite load; It is possible to distinguish the various species of malaria parasite and their different stages.

2. Serological test

The malarial fluorescent antibody test usually becomes positive two weeks or more after primary infection, by which time the infection may have been cured. A positive test is therefore, not necessarily an indication of current infection. The test is of the greatest value in epidemiological studies and in determining whether a person has had malaria in the past *(20)*.

3. Rapid diagnostic test (RDT)

Rapid Diagnostic Tests are based on the detection of circulating parasite antigens with a simple dipstick format. Several types of RDTs are available. Some of them can only detect *P. falciparum* while others can detect other parasites also. The latter kits are expensive and temperature sensitive. RDTs are produced by different companies, so there may be differences in the contents and in the manner in which the test is done. The users manual should always be read properly to avoid false negative results *(21)*.

Measurement of malaria

PRE-ERADICATION ERA

In the pre-eradication era, the magnitude of the malaria problem in a country used to be determined mostly from the reports of the *clinically diagnosed malaria cases.* The classical malariometric measures are spleen rate, average enlarged spleen, parasite rate etc. In a control programme, the case detection machinery is weak. Therefore, the classical malariometric measures may provide the needed information, i.e. the *trend of the disease.*

(a) SPLEEN RATE : It is defined as the percentage of children between 2 and 10 years of age showing enlargement of spleen. Adults are excluded from spleen surveys, because causes other than malaria frequently operate in causing splenic enlargement in them. The spleen rate is widely used for measuring the endemicity of malaria in a community. (b) AVERAGE ENLARGED SPLEEN : This is a further refinement of spleen rate, denoting the average size of the enlarged spleen *(22)*. It is a useful malariometric index. (c) PARASITE RATE : It is defined as the percentage of children between the ages 2 and 10 years showing malaria parasites in their blood films. (d) PARASITE DENSITY INDEX : It indicates the average degree of parasitaemia in a sample of well–defined group of the population. Only the positive slides are included in the denominator *(8)*. (e) INFANT PARASITE RATE : It is defined as the percentage of infants below the age of one year showing malaria parasites in their blood films. It is regarded as the most sensitive index of recent transmission of malaria in a locality. If the infant parasite rate is zero for 3 consecutive years in a locality, it is regarded as absence of malaria transmission even though, the Anopheline vectors responsible for previous transmission may remain. (f) PROPORTIONAL CASE RATE : Since the morbidity rate is difficult to determine, except in conditions when the diagnosis and reporting of each case is carried to perfection, proportional case rate is used *(8)*. It is defined as the number of cases diagnosed as clinical malaria for every 100 patients attending the hospitals and dispensaries. This is a crude index because the cases are not related to their time/ space distribution.

ERADICATION ERA (current incidence levels)

During the eradication era, the *microscopic diagnosis* of malaria cases became the main method of diagnosis. The parameters used for the measurement of malaria were mostly parasitological in nature; the commonly used parameters were API, ABER, SPR and SFR. The same parameters are being used at the present time. These parameters are unlikely to reveal the true epidemiological picture, unless the case detection machinery is fully supervised and very efficient. The following parameters are in use at present :

a. Annual parasite incidence (API)
b. Annual blood examination rate (ABER)
c. Annual falciparum incidence (AFI)
d. Slide positivity rate (SPR)
e. Slide falciparum rate (SFR).

a. Annual parasite incidence (API)

API is given by the formula :

$$\text{API} = \frac{\text{Confirmed cases during one year}}{\text{Population under surveillance}} \times 1000$$

API is a sophisticated measure of malaria incidence in a community. It is based on intensive active and passive surveillance, and cases are confirmed by blood examination. Areas with API ≥ 2 per 1000 population per year have been classified as high risk areas in India, and thereby eligible for vector control.

b. Annual blood examination rate (ABER)

ABER is given by the formula :

$$\text{ABER} = \frac{\text{Number of slides examined}}{\text{Population}} \times 100$$

ABER is an index of operational efficiency. The annual parasite incidence (API) depends upon the annual blood collection and examination rates. A sufficient number of blood slides must be systematically obtained and examined for malaria parasite to work out accurately annual parasite incidence (API).

At present, about 100 million fever cases are screened every year in India. The aim is to screen 10 per cent of the population even though the disease transmission is expected to reduce. The surveillance system has not undergone any change *(5)*.

c. *Annual falciparum incidence*

Since the emergence of *P. falciparum* problem in India, data are collected separately for total malaria cases and *P. falciparum* cases.

d. Others

The slide positivity rate and slide falciparum rate are useful parameters. They provide information on the trend of malaria transmission.

Slide positivity rate : slide positivity rate is the percentage of slides found positive for malarial parasite, irrespective of the type of species.

Slide falciparum rate : It is the percentage of slides positive for *P. falciparum* parasite.

VECTOR INDICES

A malaria survey is not complete unless it includes investigations relating to the insect vector. Some of the important vector indices are: (a) HUMAN BLOOD INDEX : It is the proportion of freshly-fed female Anopheline mosquitoes whose stomach contains human blood. It indicates the degree of anthrophilism. (b) SPOROZOITE RATE : It is the percentage of female anophelines with sporozoites in their salivary glands. (c) MOSQUITO DENSITY : It is usually expressed as the number of mosquitoes per man-hour-catch. (d) MAN-BITING RATE (Biting density) : It is defined as the average incidence of anopheline bites per day per person. It is determined by standardized vector catches on human bait (e) INOCULATION RATE : The man-biting rate multiplied by the infective sporozoite rate is called the inoculation rate. All these rates are employed in the quantitative assessment of malaria and in building up a composite epidemiological picture of malaria.

APPROACHES AND STRATEGIES OF MALARIA CONTROL

As the concept of control replaces that of eradication in many national programmes, a reordering of priorities in the selection of control methods must occur. These priorities and approaches must be based on epidemiological considerations, adverse effects on health, economy, technical feasibility, functional resources, human resources and community participation. Recently WHO stressed a number of points relevant to future strategy of malaria control. The main emphasis is on the need to base it on an epidemiological approach. These aspects are discussed below.

APPROACHES TO MALARIA CONTROL

Strategic Action Plan for malaria control in India, 2007-2012, and more recently 2012-2017 were developed by Directorate of National Vector Borne Disease Control Programme.

The strategies for prevention and control of malaria and its transmission are *(5)* :

(a) Surveillance and case management
  (1) Case detection (passive and active)
  (2) Early diagnosis and complete treatment
  (3) Sentinel surveillance.

(b) Integrated vector management
  (1) Indoor residual spray (IRS)
  (2) Insecticide treated bed-nets (ITNs) and long lasting insecticidal nets((LLINs)
  (3) Antilarval measures including source reduction.

(c) Epidemic preparedness and early response

(d) Supportive interventions
  (1) Capacity building
  (2) Behavioural change communication
  (3) Intersectoral collaboration
  (4) Monitoring and Evaluation
  (5) Operational research and applied field research.

Early diagnosis and treatment of malaria aims at :

(1) Complete cure;
(2) Prevention of progression of uncomplicated malaria to severe disease;
(3) Prevention of deaths;
(4) Interruption of transmission; and
(5) Minimizing risk of selection and spread of drug resistant malaria parasite.

GUIDELINES FOR DIAGNOSIS AND TREATMENT OF MALARIA IN INDIA–2013 *(23)*

According to the revised drug policy 2013, there is no scope of presumptive treatment in malaria control. The recommended guidelines are as follows :

Treatment of Uncomplicated Malaria

All fever cases diagnosed as malaria by microscopy or RDT should promptly be given effective treatment.

TREATMENT OF P. VIVAX CASES

Positive *P. vivax* cases should be treated with chloroquine in full therapeutic dose of 25 mg/kg divided over three days. Vivax malaria relapses due to the presence of hypnozoites in the liver. The relapse rate in vivax malaria in India is around 30%. For its prevention, primaquine may be given at a dose of 0.25 mg/kg daily for 14 days under supervision. Primaquine is contraindicated in G6PD deficient patients, infants and pregnant women. Caution should be exercised before administering primaquine in areas known to have high prevalence of G6PD deficiency. Primaquine can lead to haemolysis in G6PD deficiency. Patient should be advised to stop primaquine immediately if he develops symptoms like dark coloured urine, yellow conjunctiva, bluish discolouration of lips, abdominal pain, nausea, vomiting etc. and should report to the doctor immediately.

TREATMENT OF P. FALCIPARUM CASES

Artemisinin Combination Therapy (ACT) (Artesunate 3 days + sulphadoxine-pyrimethamine 1 day) should be given to all confirmed *P. falciparum* cases found positive by microscopy or RDT. This is to be accompanied by single dose of primaquine (0.75 mg/kg body weight) on Day 2.

However, considering the reports of resistance to SP drug in North Eastern states, the Technical Advisory Committee has recommended to use the coformulated tablet of Artemether (20 mg) + Lumefantrine (120 mg) as per age-specific dose schedule for the treatment of *Pf* cases in North Eastern states. This drug is not recommended during the first trimester of pregnancy and for children weighing < 5 kg. Production and sale of Artemisinin monotherapy has been banned in India, as it can lead to development of parasite resistance to the drug.

TREATMENT OF MALARIA IN PREGNANCY

ACT should be given for treatment of *P. falciparum*

malaria in second and third trimesters of pregnancy, while quinine is recommended in the first trimester. *P. vivax* malaria can be treated with chloroquine. Primaquine is contraindicated in pregnant woman.

TREATMENT OF MIXED INFECTIONS

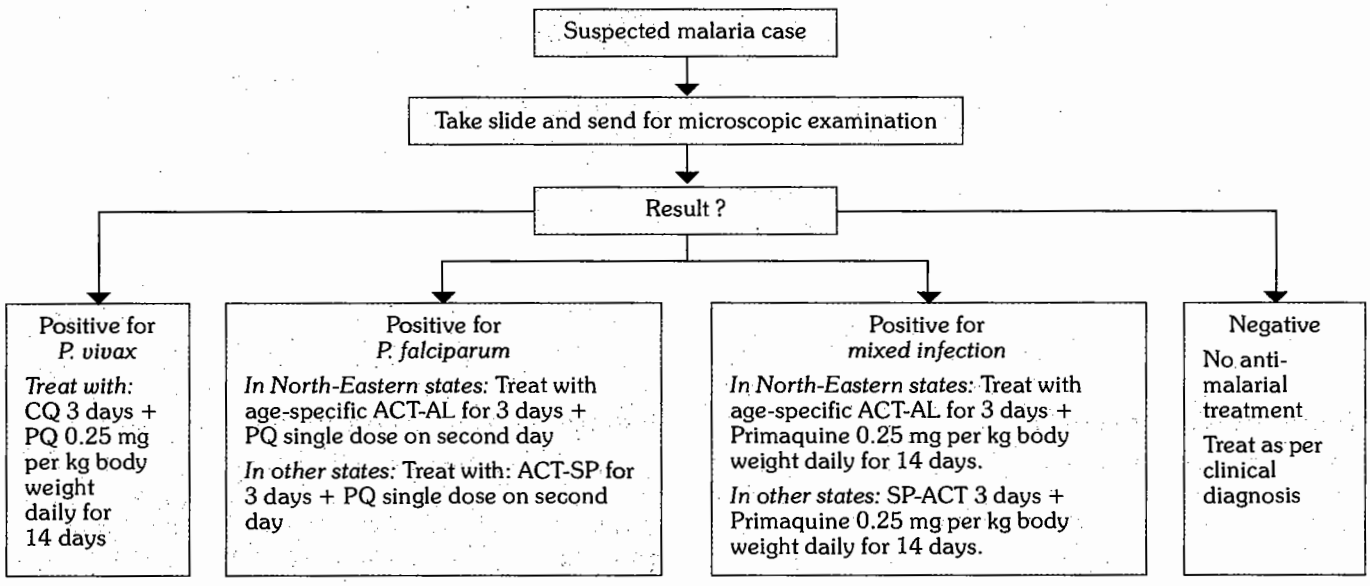
Mixed infections with *P. falciparum* should be treated as falciparum malaria.

Resistance should be suspected if inspite of full treatment with no history of vomiting, diarrhoea, patient does not respond within 72 hours, clinically and parasitologically. Such cases not responding to ACT, should be treated with oral quinine with tetracycline/doxicycline. These instances should be reported to concerned District Malaria/State Malaria Officer/ROHFW for initiation of therapeutic efficacy studies.

Diagnosis and treatment of malaria *(23)*

All fever cases diagnosed as malaria by either RDT or microscopy should be promptly given effective treatment. The medicines chosen will depend upon whether the patient has *vivax* malaria or *falciparum* malaria. The flow charts in different settings for diagnosis and drug selection for the treatment of malaria are shown in Fig. 2, 3 and 4.

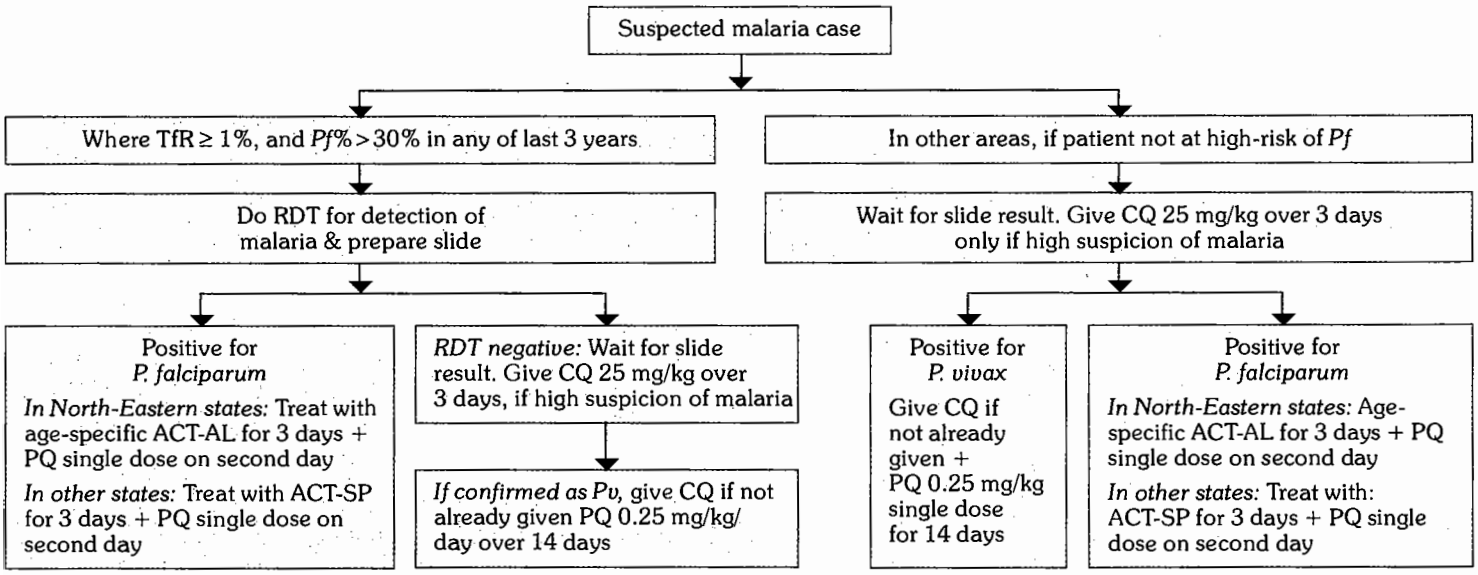
A. *Where microscopy result is available within 24 hours*



ACT-AL – Artemisinin-based combination therapy - Artemether - Lumefantrine
ACT-SP – Artemisinin-based combination therapy (Artesunate + Sulfadoxine-Pyrimethamine)
CQ – Chloroquine
PQ – Primaquine

FIG. 2

B. *Where microscopy result is not available within 24 hours and monovalent RDT is used*

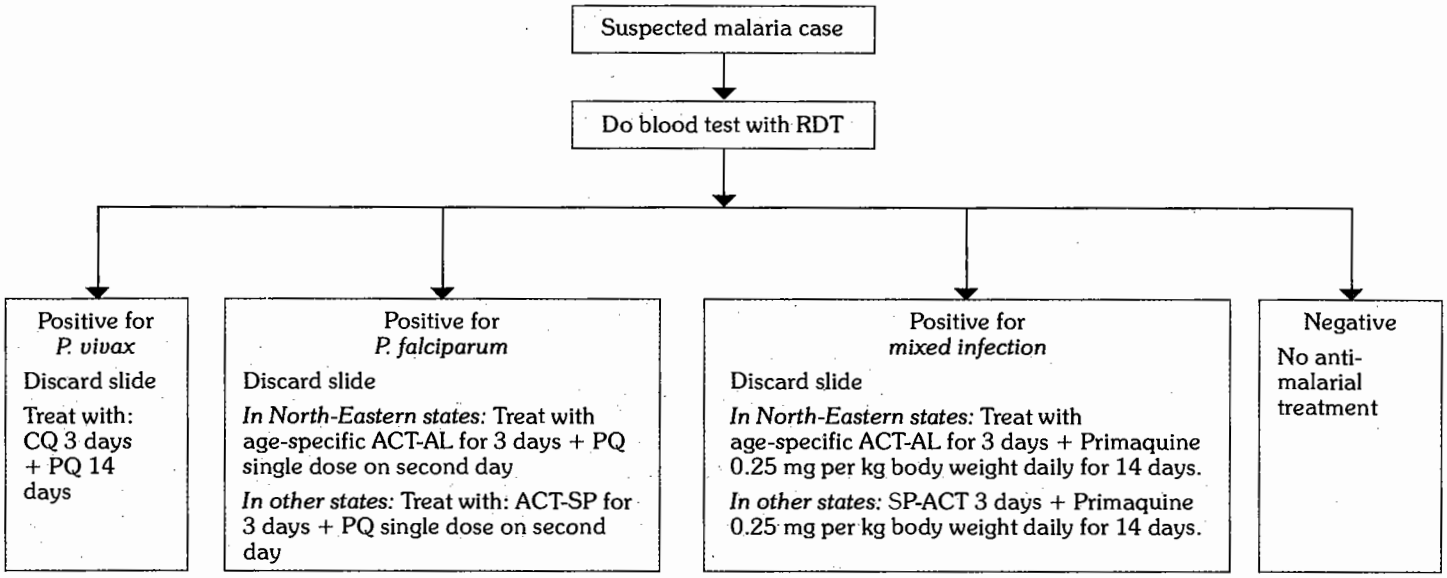


TfR = Test falciparum rate

Note : If a patient has severe symptoms at any stage, then immediately refer to a nearest PHC or other health facility with indoor patient management or a registered medical doctor.

FIG. 3

C. Where microscopy result is not available within 24 hours and bivalent RDT is used



Note : (a) If a patient has severe symptoms at any stage, then immediately refer to a nearest PHC or other health facility with indoor patient management or a registered medical doctor.
(b) PQ is contra-indicated in pregnancy and in children under 1 year (Infant).

FIG. 4

Treatment of *vivax* malaria *(23)*

Diagnosis of vivax malaria may be made by the used of RDT (Bivalent) or microscopic examination of the blood smear. On confirmation, following treatment is to be given :

Drug schedule for treatment of P. vivax malaria:

1. *Chloroquine:* 25 mg/kg body weight divided over three days i.e.

   10 mg/kg on day 1,

   10 mg/kg on day 2 and

   5 mg/kg on day 3.

2. *Primaquine:* 0.25 mg/kg body weight daily for 14 days.

   Primaquine is contraindicated in infants, pregnant women and individuals with G6PD deficiency.

   14 day regimen of Primaquine should be given under supervision.

Dosage chart for treatment of *vivax* malaria

Age	Day 1		Day 2		Day 3		Day 4 to 14
	CQ (150 mg base)	PQ (2.5 mg)	CQ (150 mg base)	PQ (2.5 mg)	CQ (150 mg base)	PQ (2.5 mg)	PQ (2.5 mg)
Less than 1 yr	½	0	½	0	¼	0	0
1–4 years	1	1	1	1	½	1	1
5–8 years	2	2	2	2	1	2	2
9–14 years	3	4	3	4	1½	4	4
15 yrs or more*	4	6	4	6	2	6	6
Pregnancy	4	0	4	0	2	0	0

Note : CQ 250 mg tablet is having 150 mg base

Treatment of *falciparum* malaria *(23)*

Diagnosis of falciparum malaria may be made by the use of RDT (monovalent or bivalent) or microscopic examination of the blood smear. It is imperative to start the treatment for falciparum malaria immediately on diagnosis. The treatment for falciparum malaria is as follows:

In other states (other than North-Eastern states):

1. Artemisinin based combination therapy (ACT-SP)*

   Artesunate (AS), available as 50 mg tablets are given for three days, and Sulfadoxine-Pyrimethamine (S-P) tablets, containing 500 mg Sulfadoxine and 25 mg pyrimethamine are given for one day, as shown in the dosage chart below.

   All tablets for a day should be taken together, swallowed with water.

   In addition, Primaquine (PQ large) tablets should be given on the second day.

Dose schedule for treatment of uncomplicated P. falciparum cases:

1. Artemisinin based combination therapy (ACT-SP) *

   Artesunate 4 mg/kg body weight daily for 3 days, plus

   Sulfadoxine (25 mg/kg body weight) – Pyrimethamine (1.25 mg/kg body weight) on first day.

   * ACT is not to be given in 1st trimester of pregnancy.

2. Primaquine * : 0.75 mg/kg body weight on day 2.

   With the introduction of different coloured blister packs for different age groups, treatment by the field level staff has been made easy. The colour code for different age groups for packing of tablet ACT+SP has been given as follows :

Dosage chart for treatment of *falciparum* malaria with ACT-SP

Age group (Years)	1st day		2nd day		3rd day
	AS	SP	AS	PQ	AS
0–1* Pink blister	1 (25 mg)	1 (250+ 12.5 mg)	1 (25 mg)	Nil	1 25 (mg)
1–4 Yellow blister	1 (50 mg)	1 (500+25 mg each)	1 (50 mg)	1 (7.5 mg base)	1 (50 mg)
5–8 Green blister	1 (100 mg)	1 (750+37.5 mg each)	1 (100 mg)	2 (7.5 mg base each)	1 (100 mg)
9–14 Red blister	1 (150 mg)	2 (500+25 mg each)	1 (150 mg)	4 (7.5 mg base each)	1 (150 mg)
15 & above White blister	1 (200 mg)	2 (750+37.5 mg each)	1 (200 mg)	6 (7.5 mg base each)	1 (200 mg)

* SP is not to be prescribed for children <5 months of age and should be treated with alternate ACT

* ACT-AL is not to be prescribed for children weighing less than 5 kg.

In North-Eastern states (NE states):

1. ACT-AL co-formulated tablet of Artemether (20 mg) – Lumefantrine (120 mg)

   (Not recommended during the first trimester of pregnancy and for children weighing <5 kg)

Recommended regimen by weight and age group
The packing size for different age groups based on Kg body weight.

Co-formulated tablet ACT-AL	5–14 kg (>5 months to <3 years)	15–24 kg (>3 to 8 years)	25–34 kg (>9 to 14 years)	>34 kg (>14 years)
Total dose of ACT-AL	20 mg/ 120 mg twice daily for 3 days	40 mg/ 240 mg twice daily for 3 days	60 mg/ 360 mg twice daily for 3 days	80 mg/ 480 mg twice daily for 3 days
	Pack size			
No. of tablets in the packing	6	12	18	24
Give	1 tablet twice daily for 3 days	2 tablets twice daily for 3 days	3 tablets twice daily for 3 days	4 tablets twice daily for 3 days
Colour of the pack	Yellow	Green	Red	White

2. Primaquine * : 0.75 mg/kg body weight on day 2

Treatment of uncomplicated P. falciparum cases in pregnancy:

1st trimester : Quinine salt 10 mg/kg 3 times daily for 7 days.

Quinine may induce hypoglycaemia; pregnant women should not start taking quinine on an empty stomach and should eat regularly, while on quinine treatment.

2nd and 3rd trimester : Area-specific ACT as per dosage schedule given above i.e. ACT-AL in North-Eastern states, ACT-SP in other states.

Primaquine (PQ) prevents transmission of falciparum malaria to others by its ability to kill gametocytes. PQ tablets should be taken after a meal; not on an empty stomach. Children less than the age of one year and pregnant women should not be given primaquine. As pregnant women having falciparum malaria require different medicines, they should be directed to go to the nearest PHC or hospital immediately, without delay.

Treatment of mixed infections (*P. vivax* + *P. falciparum*) cases *(23)*

All mixed infections should be treated with full course of ACT and Primaquine 0.25 mg per kg body weight daily for 14 days.

In North-Eastern states: Treat with: Age-specific ACT-AL for 3 days + Primaquine 0.25 mg per kg body weight daily for 14 days.

In other states: ACT-SP 3 days + Primaquine 0.25 mg per kg body weight daily for 14 days.

Dosage chart for treatment of mixed (*vivax* and *falciparum*) malaria with ACT-SP

Age	Day 1			Day 2		Day 3		Day 4-14
	AS tablet (50 mg)	SP tablet	PQ (2.5 mg)	AS tablet (50 mg)	PQ (2.5 mg)	AS tablet (50 mg)	PQ (2.5 mg)	PQ (2.5 mg)
Less than 1 year	½	½	0	½	0	½	0	0
1–4 years	1	1	1	1	1	1	1	1
5–8 years	2	1½	2	2	2	2	2	2
9–14 years	3	2	4	3	4	3	4	4
15 years or more	4	3	6	4	6	4	6	6

Treatment of *P. ovale* and *P. malariae*

In India these species are very rarely found in few places. *P. ovale* should be treated as *P. vivax* and *P. malariae* should be treated as *P. falciparum*.

General recommendations for the management of uncomplicated malaria

1. Avoid starting treatment on an empty stomach. The first dose should be given under observation. Dose should be repeated if vomiting occurs within 15 minutes by opening a new blister pack (discard what remains of old pack). If the patient vomits the first dose again, it is considered a severe case of malaria and refer the patient immediately to the nearest Block PHC/CHC/Hospital. Special precaution should be taken in case of a child under-5 years of age, and in pregnant woman.
2. Explain to the patient or caretaker that : (a) if the treatment is not completed as prescribed, the disease may manifest again with more serious features and more difficult to treat; (b) to come back immediately, if there is no improvement after 24 hours, if the situation gets worse or the fever comes back; and (c) that regular use of a mosquito net (preferably insecticide treated net) is the best way to prevent malaria.
3. Patient should also be examined for concomitant illness.

Resistance to anti-malarial drugs

Resistance can be defined as either the ability of a parasite strain to survive and/or multiply despite the administration and absorption of a drug given in doses equal to or higher than those usually recommended, but within the limits of tolerance of the patient.

Drug resistance is a complex phenomenon, where, by genetic mutation, a parasite acquires the ability to resist, partly or fully, the effects of one or more anti-malarial drugs. When the resistant parasites are exposed to the drug, they multiply selectively. If parasites are resistant to the drug being used, the patient may not respond to treatment. One of the commonest reasons for the development of drug resistance is that the parasites are exposed to insufficient amount of the drug due to low prescription dosage, lesser amount of drug dispensed, incomplete treatment taken by the patient, drug vomited out or low absorption of drug due to any other reason e.g., diarrhoea, poorly stored drug, poor quality drug when supplied or expiry date medicine. In such cases, most of the sensitive parasites are killed by even these small doses, but resistant parasites survive, multiply and spread to other people by mosquitoes. The new patient then gets infection from the resistant malaria parasites and does not respond to the drug at all, or responds only partly. Meanwhile, the earlier patient may appear cured because most of the parasites were killed by the drug, and the symptoms abated.

It should be kept in mind that the patient might have had a fresh reinfection, or in the case of *vivax* malaria, there might have been a relapse of malaria *(23)*.

Treatment failure *(24)*

After treatment patient is considered cured if he/she does not have fever or parasitaemia till day 28th. Some patients may not respond to treatment which may be due to drug resistance or treatment failure, specially in falciparum malaria. If patient does not respond and presents with following, he/she should be given alternative treatment.

Early treatment failure (ETF) : Development of danger signs or severe malaria on Day 1, 2 or 3, in the presence of parasitaemia; parasitaemia on Day 2 higher than on Day 0, irrespective of axillary temperature; parasitaemia on Day 3 with axillary temperature >37.5°C; and parasitaemia on Day 3, > 25% of count on Day 0.

Late clinical failure (LCF) : Development of danger signs or severe malaria in the presence of parasitaemia on any day between Day 4 and Day 28 in patients who did not previously meet any of the criteria of early treatment failure; and presence of parasitaemia on any day between Day 4 and Day 28 with axillary temperature >37.5°C in patients who did not previously meet any of the criteria of early treatment failure.

Late parasitological failure (LPF) : Presence of parasitaemia on any day between Day 7 and Day 28 with axillary temperature <37.5°C in patients who did not previously meet any of the criteria of early treatment failure or late clinical failure.

Such cases of falciparum malaria should be given alternative ACT or quinine with Doxycycline. Doxycycline is contraindicated in pregnancy, lactation and in children upto 8 years. Treatment failure with chloroquine in *P. vivax* malaria is rare in India.

Treatment of severe malaria

CLINICAL FEATURES *(23)*

Severe manifestations can develop in *P. falciparum* infection over a span of time as short as 12–24 hours and may lead to death, if not treated promptly and adequately. Severe malaria is characterized by one or more of the following features:

(1) Impaired consciousness/coma
(2) Repeatd generalized convulsions
(3) Renal failure (Serum Creatinine >3 mg/dl)
(4) Jaundice (Serum Bilirubin >3 mg/dl)
(5) Severe anaemia (Hb <5 g/dl)
(6) Pulmonary oedema/acute respiratory distress syndrome
(7) Hypoglycaemia (Plasma glucose <40 mg/dl)
(8) Metabolic acidosis
(9) Circulatory collapse/shock (Systolic BP<80 mm Hg, < 50 mm Hg in children)
(10) Abnormal bleeding and disseminated intravascular coagulation.
(11) Haemoglobinuria
(12) Hyperthermia (Temperature >106°F or 42°C)
(13) Hyperparasitaemia (<5% parasitized RBCs in low endemic and >10% in hyperendemic areas)

Foetal and maternal complications are more common in pregnancy with severe malaria; therefore, they need prompt attention.

Microscopic evidence may be negative for asexual parasites in patients with severe infections due to sequestration and partial treatment. Efforts should be made to confirm these cases by RDT or repeat microscopy. However, if the symptoms clearly point to severe malaria and there is no alternative explanation, such a case should be treated accordingly.

Criteria for immediate referral are as follows: (a) Persistence of fever after 24 hours of initial treatment; (b) Continuous vomiting and inability to retain oral drug; (c) Headache continues to increase; (d) Severe dehydration (dry, parched skin, sunken eyes etc.); (e) Too weak to walk in the abscence of any other obvious reason; (f) Change in sensorium e.g. confusion, drowsiness, blurring of vision, photophobia, disorientation; (g) Convulsion or muscle twitchings; (h) Bleeding and clotting disorder; (i) Suspicion of severe anaemia; (j) Jaundice; and (k) Hypothermia *(23)*.

Treatment of severe malaria cases *(23)*

Severe malaria is an emergency and treatment should be given as per severity and associated complications which can be best decided by the treating physicians. Before admitting or referring patients, the attending doctor or health worker, whoever is able to do it, should do RDT and take blood smear, give a parenteral dose of artemisinin derivative or quinine in suspected cerebral malaria cases and send case sheet, details of treatment history and blood slide with patient. Parenteral artemisinin derivatives or quinine should be used irrespective of chloroquine resistance status of the area with one of the following options:

Chemotherapy of severe and complicated malaria

Initial parenteral treatment for at least 48 hours: *Choose one of following four options*	Follow-up treatment, when patient can take oral medication following parenteral treatment
Quinine : 20 mg quinine salt/kg body weight on admission (IV infusion or divided IM injection) followed by maintenance dose of 10 mg/kg 8 hourly; infusion rate should not exceed 5 mg/kg per hour. Loading dose of 20 mg/kg should not be given, if the patient has already received quinine.	*Quinine* 10 mg/kg three times a day with: doxycycline 100 mg once a day OR clindamycin in pregnant women and children under 8 years of age. – to complete 7 days of treatment.
Artesunate: 2.4 mg/kg IV or IM given on admission (time=0), then at 12 h and 24 h, then once a day. OR *Artemether:* 3.2 mg/kg bw IM given on admission then 1.6 mg/kg per day. OR *Arteether:* 150 mg daily IM for 3 days in adults only (not recommended for children).	Full oral course of area-specific ACT: *In North-Eastern states:* Age-specific ACT-AL for 3 days + PQ single dose on second day *In other states:* Treat with: ACT-SP for 3 days + PQ single dose on second day

Note : The parenteral treatment in severe malaria cases should be given for minimum of 24 hours once started (irrespective of the patient's ability to tolerate oral medication earlier than 24 hours).

After parenteral artemisinin therapy, patients will receive a full course of area-specific oral ACT for 3 days. Those patients who received parenteral Quinine therapy should receive oral Quinine 10 mg/kg body weight three times a day for 7 days (including the days when parenteral Quinine was administered) plus Doxycycline 3 mg/kg body weight once a day, or Clindamycin 10 mg/kg body weight 12-hourly for 7 days (Doxycycline is contraindicated in pregnant women and children under 8 years of age) or area-specific ACT as described.

Note :

- Pregnant women with severe malaria in any trimester can be treated with artemisinin derivatives, which, in contrast to quinine, do not risk aggravating hypoglycaemia.
- The parenteral treatment should be given for minimum of 24 hours.
- Once the patient can take oral therapy; give:
- Quinine 10 mg/kg three times a day with doxycycline 100 mg once a day or clindamycin in pregnant women and children under 8 years of age, to complete 7 days of treatment, in patients started on parenteral quinine.
- Full course of ACT to patients started on artemisinin derivatives.
- Use of mefloquine should be avoided in cerebral malaria due to neuropsychiatric complications associated with it.

Some don'ts in severe malaria case management

Do not use corticosteroids, do not give intravenous mannitol, do not use heparin as anticoagulant, do not administer adrenaline or do not overhydrate.

Toxic hazards of drugs

Chloroquine has few side-effects. Nausea, vomiting, blurring of vision and headaches may occur, but they are mild and transient. Cases of retinal damage have been reported but only in persons exposed to large cumulative doses over many years. It is important to remember that chloroquine should not be given on empty stomach. Despite reports of teratogenicity in experimental animals, most authorities accept that pyrimethamine can safely be taken alone during pregnancy *(25)*. The teratogenic effect of pyrimethamine in man is not proved. In regard to primaquine, although in recommended doses, no serious toxic manifestations have been encountered so far in India. It is useful to bear in mind the likely toxic symptoms, which may be of three types : *(a) Plasmocid types :* this is a rare toxic manifestation involving the CNS, *(b) Gastrointestinal :* cramps, nausea and vomiting, *(c) Cardiovascular :* This is probably the most serious toxic manifestation which is to be carefully observed during the administration of the drug. Even the first dose may bring about the warning sign of cyanosis. The surveillance worker/MPW must carefully check for all possible toxic symptoms before he administers the daily dose of primaquine. In the case of appearance of any of the toxic symptoms discussed above, primaquine treatment should be stopped immediately *(26)*.

Chemoprophylaxis

Chemoprophylaxis against malaria has, with the development of drug resistance, become unreliable. Experts disagree on whether well–conducted prophylaxis gives an additional benefit if effective treatment is readily available. However, experts feel that it can play a useful role in reducing the risk of fatal disease *(27)*.

Chemoprophylaxis is recommended for travellers from non–endemic areas and, as a short term measure for soldiers, police and labour forces serving in highly endemic areas. Chemoprophylaxis should be complemented by personal protection where feasible and by other methods of vector control *(27)*.

The recommendations for short-term chemoprophylaxis (less than 6 weeks) are as follows *(27)* :

(1) Dosing schedules for the children should be based on body weight.

(2) Antimalarials that have to be taken daily (e.g. Doxycycline) should be started the day before arrival in the risk area.

(3) Weekly chloroquine should be started 1 week before arrival.

(4) Weekly mefloquine should preferably be started 2–3 weeks before departure, to achieve higher pre–travel blood level and to allow side-effects to be detected before travel so that possible alternative can be considered.

(5) All prophylactic drugs should be taken with unfailing regularity for the duration of the stay in the malaria risk area, and should be continued for 4 weeks after the last possible exposure to infection, since parasites may still emerge from the liver during this period.

The recommendations for the long-term chemoprophylaxis (more than 6 weeks) are as follows:

(1) The risk of serious side-effects associated with long-term prohylactic use of chloroquine and proguanil is low. However, anyone who has taken 300 mg of chloroquine weekly for over five years and requires further prophylaxis should be screened twice-yearly for early retinal changes. If daily dose of 100 mg chloroquine have been taken, screening should start after three years *(27)*.

(2) Data indicate no increased risk of serious side-effects with long-term use of mefloquine if the drug is tolerated in the short-term, as mefloquine does not accumulate during long-term intake.

(3) Available data on long-term chemoprophylaxis with doxycycline is limited.

Mefloquine is contraindicated in cases with history of convulsions, neuropsychiatric problems and cardiac conditions.

Chemoprophylaxis is still desirable for pregnant women living in areas where transmission is very intense and leads to parasitaemias, causing low birth weight and anaemia, or to a high risk of life–threatening malaria attacks. However, the choice of safe drugs is becoming increasingly narrow, and it may be necessary to replace chemoprophylaxis by prompt treatment of clinical episodes or periodic treatments during pregnancy. While the choice of strategy should be guided by the national malaria control policy, its implementation should normally be part of antenatal care *(28)*.

The recommended regimens for chemoprophylaxis are as given in Table 2.

ACTIVE INTERVENTION MEASURES

Neither chemotherapy nor chemoprophylaxis will be able to reduce significantly the malaria prevalence or transmission. It can be obtained only when proper anti–mosquito measures are introduced.

TABLE 2

Drug regimens for prophylaxis of malaria

Drugs		Usual amount	Adult dose
Generic name	Common trade names	per tablet or capsule	For prophylaxis
Chloroquine[a]	Aralen Avlochlor Nivaquine Resochin	100 or 150 mg (base)	300 mg (base) = 3 tablets of 100 mg or 2 tablets of 150 mg once a week, on the same day each week OR 100 mg (base) = 1 tablet of 100 mg daily for six days per week
Proguanil[b]	Paludrine	100 mg	200 mg = 2 tablets once a day
Mefloquine[c]	Lariam Eloquin Mephaquin	250 mg	250 mg = 1 tablet once a week, on the same day each week
Doxycycline[d]	Vibramycin	100 mg	100 mg=1 capsule once a day

a. Also available as suspension.
b. Recommended only in association with chloroquine.
c. The use of the higher treatment dose regimen is recommended for infections acquired in areas on the Thailand/Cambodia and Thailand / Myanmar borders only.
d. There is relatively little experience with this drug, and knowledge of its efficacy and toxicity is limited.

1. STRATIFICATION OF THE PROBLEM

Malaria is a complex disease, and its distribution and intensity vary from place to place. Stratification of the problem has become an essential feature for the planning and development of a sound control strategy to maximize the utilization of available resources. It can also provide guidelines as to which strategy could be most suited and economical under the existing conditions. For details please refer to page 416 chapter 7.

2. VECTOR CONTROL STRATEGIES

Vector control is still one of the primary weapons to control malaria in endemic areas. The methods used are as shown in Table 3.

TABLE 3

Malaria vector control measures

Action	For individual and family protection	For community protection
Reduction of human-mosquito contact	Insecticide-treated nets, repellents, protective clothing, screening of houses	Insecticide-treated nets zooprophylaxis
Destruction of adult mosquitoes		Insecticide-treated nets, indoor residual spraying, space spraying, ultra low-volume sprays
Destruction of mosquito larvae	Peri-domestic sanitation	Larviciding of water surfaces, intermittent irrigation, sluicing, biological control
Source reduction	Small-scale drainage	Environmental sanitation, water management, drainage
Social participation	Motivation for personal and family protection	Health education, community participation

Source : *(29)*

(a) Anti–adult measures

(i) Residual spraying : The discovery of DDT in 1940s and followed by other insecticides revolutionized malaria control. The spraying of the indoor surfaces of houses with residual insecticides (e.g., DDT, malathion, fenitrothion) is still the most effective measure to kill the adult mosquito. It has been observed that discontinuation of spraying has very often led to the resurgence of malaria. This implies that spraying once applied may need to be continued for an indefinite period. If indoor spraying is to have any effect, then exhaustive coverage is needed. Indoor house spraying reduces the longevity of the vector.

Malathion and fenitrothion are organophosphate insecticides which are being used with increasing frequency for malaria control following the development of vector resistance to DDT *(30)*.

(ii) Space application : This is a major anti–epidemic measure in mosquito–borne diseases. It involves the application of pesticides in the form of fog or mist using special equipment. The ultra–low–volume method of pesticide dispersion by air or by ground equipment has proved to be effective and economical. Outdoor space sprays reduce vector population quickly.

(iii) Individual protection : Man–vector contact can be reduced by other preventive measures such as the use of repellents, protective clothing, bed-nets (preferably impregnated with safe, long–acting repellent insecticides), mosquito coils, screening of houses etc. The methods of personal protection are of great value when properly employed. However, they have rarely been used on a large scale because of cost.

(b) Anti-larval measures

(i) Larvicides : During the first half of the 20th century, anti-larval measures such as oiling the collections of standing water or dusting them with paris green effectively controlled malaria (but the measures were eclipsed at the end of World War II). With the increase in insecticide resistance, the older methods of mosquito control have now become promising. Some modern larvicides such as temephos which confer long effect with low toxicity are more widely used. However larviciding must be repeated at frequent intervals and for this reason it is a comparatively costly operation.

(ii) Source reduction : Techniques to reduce mosquito breeding sites (often called source reduction) which include drainage or filling, deepening or flushing, management of water level, changing the salt content of water and intermittent irrigation are among the classical methods of malaria control to which attention is being paid again *(31)*. Whenever practicable, measures for the improvement of the environment by the permanent reduction of sources should be instituted.

(iii) Integrated control : In order to reduce too much dependance on residual insecticides, increasing emphasis is being put on "integrated" vector control methodology which includes bioenvironmental and personal protection measure *(32)*. This approach is important because there is no single and simple method that would ensure control of transmission.

By mid 1995 all malaria endemic countries in the region had adopted the revised malaria control strategy to reduce morbidity and mortality and to reduce its area of distribution, particularly of multidrug resistant malaria. The use of stratification approach by the majority of anti-malaria programmes in the Region has led to more cost-effective interventions. Vector resistance to insecticides has necessitated the use of more expensive pyrethroid, thereby limiting the coverage. Malaria control added impetus as **Roll Back Malaria** initiative was launched by WHO, UNICEF, UNDP and the World Bank in 1998.

THE GLOBAL POLICY FOR DIAGNOSIS AND TREATMENT OF MALARIA, INCLUDING PREVENTIVE TREATMENT *(33)*

The government of every country affected by malaria has a national malaria control policy covering prevention and case-management.

The objectives of an antimalarial treatment policy are to : ensure rapid cure of the infection; reduce morbidity and mortality, including malaria-related anaemia; prevent the progression of uncomplicated malaria into severe and potentially fatal disease; reduce the impact of malaria infection on the fetus during pregnancy; reduce the reservoir of infection; prevent the emergence and spread of drug resistance; and prevent malaria in travellers.

The launch of Roll Back Back Malaria (RBM) in 1998, the United Nations Millenium Declaration in 2000, the Abuja Declaration by African Heads of State in 2000 (part of the African Summit on Roll Back Malaria), the World Health Assembly in 2005, and the RBM global strategic plan 2005–2015 have all contributed to the establishment of goals, indicators and targets for malaria control.

With the publication in 2005 of the **Roll Back Malaria global strategic plan** for 2005–2015, WHO and RBM set targets to be achieved by the year 2010 and 2015. The goals established by World Health Assembly and the Roll Back Malaria partnership is to reduce the number of malaria cases and deaths recorded in 2000 by 50 per cent or more by the end of 2010 and by 75 per cent or more by 2015. In September 2008, RBM launched the Global Malaria Action Plan that defines the steps required to accelerate achievement of the partnership's 2010 and 2015 targets for malaria control and elimination *(34)*.

Malaria vaccines

Vaccination against malaria is a burning issue today. Over the past decades, there has been significant progress in malaria vaccine development, yet many valid candidate vaccines have been slow to enter clinical trial and an effective vaccine is thought to be still 10 years away. Several vaccine candidates are now being tested in Africa, Asia and the United States.

LYMPHATIC FILARIASIS

The term "lymphatic filariasis" covers infection with three closely related nematode worms – *W. bancrofti, B. malayi and B. timori.* All three infections are transmitted to man by the bites of infective mosquitoes. All three parasites have basically similar life cycles in man–adult worms living in lymphatic vessels whilst their offspring, the microfilariae circulate in peripheral blood and are available to infect mosquito vectors when they come to feed *(1).* The disease manifestations range from none to both acute and chronic manifestations such as lymphangitis, lymphadenitis, elephantiasis of genitals, legs and arms or as a hypersensitivity state such as tropical pulmonary eosinophilia or as an atypical form such as filarial arthritis. Though not fatal, the disease is responsible for considerable suffering, deformity and disability.

Problem statement

Filariasis is a global problem. It is a major social and economic scourage in the tropics and subtropics of Africa, Asia, Western Pacific and parts of the Americas, affecting over 73 countries. More than 1.4 billion people live in areas where there is a risk of infection, of whom 120 million are infected and in need of treatment, including 40 million people with overt disease. This includes 15 million people with lymphoedema and 25 million men with urogenital swelling principally scrotal hydrocele *(2).*

About 95 per cent of cases of lymphatic filariasis are caused by infection with *W. bancrofti*; other related parasites that infect humans are *Brugia malayi* in South-East Asia and *B. timori* in Indonesia.

The formal goal of the global lymphatic filariasis programme is to eliminate the disease "as a public health problem" and 2020 is the informal target date for interrupting transmission. The strategy to interrupt transmission of the disease calls for mass administration of a 2-drug regimen (ivermectin or DEC plus albendazole) administration as a single dose annually for 4–6 years.

Between 2000–2011, the global programme provided a cumulative total of nearly 4.4 billion treatments to at least 984 million people. It represents about 73.2 per cent of the 1.4 billion people at risk *(2).*

The current hypothesis is that reducing the prevalence of microfilaraemia in humans to <1 per cent will stop transmission. One provisional set of guidelines for stopping treatment would require ≥ 5 annual rounds of MDA with coverage of ≥ 65 per cent of the total population *(3).*

Lymphatic filariasis is a public health problem in India. The disease is endemic all over India, except in Jammu and Kashmir, Himachal Pradesh, Punjab, Haryana, Delhi, Chandigarh, Rajasthan, Nagaland, Manipur, Tripura, Meghalaya, Sikkim, Arunachal Pradesh, Mizoram, and Dadra and Nagar Haveli. However, surveys carried out during the past two decades indicate that areas previously known to be free from filariasis are showing evidence of low degrees of transmission. Heavily infected areas are found in Uttar Pradesh, Bihar, Jharkhand, Andhra Pradesh, Orissa, Tamil Nadu, Kerala and Gujarat .

An estimated 600 million people are at risk of lymphatic filariasis infection in 250 endemic districts in 20 states/UTs in India. Mapping was carried out using epidemiological data supplemented by data from filaria control units, filaria clinics, and survey units under the national filaria control programme. Morbidity surveys (upto 2012) of filaria cases in the states/UTs revealed 8 lacs cases of lymphoedema and 4 lacs cases of hydrocele *(4).* The microfilaria survey reports received from 205 districts revealed microfilaria rate of about 0.45 per cent *(4).*

Mass drug administration (MDA) is being implemented in India since year 2004. In 2007 India changed its strategy from delivery of DEC alone to delivery of DEC plus albendazole; since that time, the number of people treated with combination therapy has increased steadily. In 2012, about 87 per cent people at risk were treated with combination drug *(4).* India has reduced the prevalence of microfilaria to less than 1 per cent in 192 out of 250 implementation units. In implementation units in Nalganda in Andhra Pradesh, the prevalence of microfilaria was reduced from 17 per cent in 2004 to 0.8 per cent in 2009 *(5).*

Epidemiological determinants

Agent factors

There are at least 8 species of filarial parasites that are specific to man *(6).* These are shown in Table 1. The first three worms are responsible for lymphatic filariasis; and the rest for "non–lymphatic filariasis". The parasites causing non–lymphatic filariasis will not be described as they are not found in India. Table 2 shows the differences between the microfilariae *(Mf)* of *W. bancrofti* and *B. malayi.*

TABLE 1
Human filarial infections

Organism	Vectors	Disease produced
1. *Wuchereria bancrofti*	Culex Mosquitoes	Lymphatic filariasis
2. *Brugia malayi*	Mansonia —"—	—"— —"—

4. *Onchocerca volvulus*	Simulum flies	Subcutaneous; nodules; River blindness
5. *Loa loa*	Chrysops flies	Recurrent, transient subcutaneous swellings
6. *T. perstans*	Culicoides	Probably rarely any clinical illness
7. *T. streptocerca*	—"—	—"—
8. *Mansonella ozzardi*	—"—	—"—

TABLE 2
Differences between *Mf* of *W. bancrofti* and *B. malayi*

	Mf. W. bancrofti	*Mf. B. malayi*
1. General appearance	Graceful, sweeping curves	Crinkled, secondary curves
2. Length	244 to 296 μ	177 to 230 μ
3. Fee cephalic space	As long as broad	Nearly twice as long as broad
4. Excretory pore	Not prominent	Prominent
5. Caudal end	Uniformly tapering to a delicate point, No terminal nuclei present	Kinkled and two terminal nuclei present
6. Nuclear column	Nuclei discrete	Smudged

PERIODICITY

The *Mf* of *W. bancrofti* and *B.malayi* occurring in India display a nocturnal periodicity, i.e., they appear in large numbers at night and retreat from the blood stream during the day. This is a biological adaptation to the nocturnal biting habits of the vector mosquitoes. The maximum density of *Mf* in blood is reported between 10 pm and 2 am. When the sleeping habits of the host are altered, a reversal in periodicity has been observed.

In most parts of the world, *Mf* are nocturnally periodic but in the South Pacific islands and in limited foci in the Nicobar islands, Thailand and Vietnam, *W. bancrofti Mf* are non–periodic (sub-periodic), being detectable throughout the 24 hours with a slight peak during day or night. Sub-periodic *B.malayi* is found in parts of Malaysia and Indonesia.

LIFE CYCLE

Man is the definitive host and mosquito the intermediate host of Bancroftian and Brugian filariasis. The adult worms are usually found in the lymphatic system of man. The males are about 40 mm long and the females 50 to 100 mm long. The females are viviparous. They give birth to as many as 50,000 *Mf* per day *(7)* which find their way into blood circulation *via* the lymphatics. The life span of the *Mf* is not exactly known, probably up to a year or more. The adult worms may survive for 15 years or more *(7)*. There is a case on record of a woman, in whom live *Mf* were present 40 years after she left an endemic area *(8)*.

The mosquito cycle begins when the *Mf* are picked up by the vector mosquito during feeding. The following stages of development take place in the vector : *(a) Exsheathing :* The larva comes out of the sheath in which it is enclosed, within 1 to 2 hours of ingestion. This is known as exsheathing which takes place in the stomach of the mosquito. *(b) First stage larva :* After exsheathing, the larva is able to penetrate the stomach wall of the mosquito which it does in 6 to 12 hours and migrate to the thoracic muscles where it grows and develops into a sausage–shaped (short, thick) form. *(c) Second stage larva :* The larva moults and increases in length (long, thick form) with the development of an alimentary canal, but is relatively inactive. *(d) Third stage larva :* There is a final moult to the third stage or infective larva (long, thin form) which may be found in any part of the insect. It is highly active or motile. When it migrates to the proboscis of the mosquito, it is ready to be transmitted to a new host, and the mosquito is said to be infective. Under optimum conditions of temperature and humidity, the duration of mosquito cycle (extrinsic incubation period) is between 10 and 14 days. In the human host, the infective larvae develop into adult male and female worms.

RESERVOIR OF INFECTION

Although filarial infections occur in animals, human filariasis is not usually a zoonosis (sub-periodic *B. malayi* and *T. perstans* are exceptions). Animal reservoirs of Brugia are present in monkeys, cats and dogs *(7);* these animals are believed to acquire their infections from man, and they are not regarded as important sources of infection to man *(1)*. There is no evidence that *W. bancrofti* has animal reservoirs in India.

In humans the source of infection is a person with circulating *Mf* in peripheral blood. In filarial disease (late obstructive stages) *Mf* are not found in the blood.

The minimum level of *Mf* which will permit infection of mosquitoes is not known. It was reported that a man with one *Mf* per 40 cu. mm of blood was infective to 2.6 per cent of the mosquitoes which fed on him *(9)*. On the other hand, when mosquitoes were fed on carriers having as many as 80 or more *Mf* per 20 cu. mm of blood, the heavily infected mosquitoes did not survive when a number of *Mf* began to reach maturity *(10)*.

Host factors

Man is a natural host. (a) AGE: All ages are susceptible to infection. In endemic areas, filarial infection has been found even in infants aged less than 6 months. Infection rates rise with age up to the age of 20–30 years and then level off. After a few years at this plateau level, *Mf* rates may decline in middle and old age. Filarial disease appears only in a small percentage of infected individuals, commonly in the age group over 10 years *(11)*, although there may be exceptions. (b) SEX : In most endemic areas the *Mf* rate is higher in men. (c) MIGRATION : The movement of people from one place to another has led to the extension of filariasis into areas previously non–endemic. (d) IMMUNITY : Man may develop resistance to infection only after many years of exposure *(7)*. The immunological basis of this resistance is not known *(12)*. (e) SOCIAL FACTORS : Lymphatic filariasis is often associated with urbanization, industrialization, migration of people, illiteracy, poverty and poor sanitation.

Environmental factors

(a) CLIMATE : Climate is an important factor in the epidemiology of filariasis. It influences the breeding of

mosquitoes, their longevity and also determines the development of the parasite in the insect vector. The maximum prevalence of *Culex quinquefasciatus* (previously known as *C. fatigans*) was observed when the temperature was between 22 to 38 deg. C and optimum longevity when the relative humidity was 70 per cent. (b) DRAINAGE: Lymphatic filariasis is associated with bad drainage. The vectors breed profusely in polluted water. (c) TOWN PLANNING : Inadequate sewage disposal and lack of town planning have aggravated the problem of filariasis in India by increasing the facilities for the breeding of *C. quinquefasciatus (C. fatigans)*. The common breeding places are cesspools, soakage pits, ill–maintained drains, septic tanks, open ditches, burrow pits, etc.

Vectors of lymphatic filariasis

All three infections *(W. bancrofti, B. malayi and B. timori)* are transmitted to man by the bites of infective mosquitoes. No less than 5 genera are involved in different areas of the world – *Culex, Anopheles* and Aedes serve as vectors for *W. bancrofti;* and *Mansonia, Anopheles* and *Coquillettidia* serve as the vectors of the Brugia species.

The main vectors in India are : *C. quinquefasciatus (C. fatigans)* for Bancroftian filariasis, and *Mansonia (Mansonoides)* mosquitoes *(e.g., M. annulifers and M. uniformis)* for Brugian filariasis. The breeding of *Mansonia* mosquitoes is associated with certain aquatic plants such as *Pistia stratiotes.* In the absence of these plants, these mosquitoes cannot breed.

Mode of transmission

Filariasis is transmitted by the bite of infected vector mosquitoes. The parasite is deposited near the site of puncture. It passes through the punctured skin or may penetrate the skin on its own and finally reach the lymphatic system. The dynamics of transmission depends upon the man–mosquito contact (e.g., infective biting rate).

Incubation period

The time interval between inoculation of infective larvae and the first appearance of detectable *Mf* is known as "pre–patent period". Direct information on the duration of the prepatent period is lacking *(13)*.

The time interval from invasion of infective larvae to the development of clinical manifestations is known as the "clinical incubation period". This period, most commonly, is 8 to 16 months. This period may, however, be longer *(13)*.

Clinical manifestations

Only a small proportion of infected individuals exhibit clinical signs. The disease manifestations can be divided into two distinct clinical types : (a) *lymphatic filariasis* caused by the parasite in the lymphatic system, and (b) *occult filariasis* caused by an immune hyper-responsiveness of the human host (e.g., tropical pulmonary eosinophilia).

1. LYMPHATIC FILARIASIS

The following stages have been described *(13)*:

(i) Asymptomatic amicrofilaraemia : In all endemic areas a proportion of population does not show *Mf* or clinical manifestations of the disease although they have the same degree of exposure to infective larvae as those who become infected. With presently available diagnostic procedures it is not possible to determine whether persons in this group have detectable infections or whether they are free from infection.

(ii) Asymptomatic microfilaraemia : A considerable proportion of people are asymptomatic, although their blood is positive for *Mf.* They may remain without any symptoms for months – in some instances for years. They are an important source of infection in the community. These carriers are usually detected by night blood examination.

(iii) Stage of acute manifestations : In the first months and years there are recurrent episodes of acute inflammation in lymph glands and vessels. The clinical manifestations comprise filarial fever, lymphangitis, lymphadenitis, lymphoedema of the various parts of the body and of epididymo-orchitis in the male.

(iv) Stage of chronic obstructive lesions : The chronic stage usually develops 10–15 years from the onset of the first acute attack. This phase is due to fibrosis and obstruction of lymphatic vessels causing permanent structural changes.

In chronic Bancroftian filariasis, the main clinical features are hydrocele, elephantiasis and chyluria. Elephantiasis may affect the legs, scrotum, arms, penis, vulva and breasts, usually in that order of decreasing frequency. The prevalence of chyluria is usually very low.

The Brugian filariasis is generally similar to Bancroftian filariasis, but strangely the genitalia are rarely involved, except in areas where Brugian filariasis occurs together with Bancroftian filariasis.

Not all elephantiasis is caused by lymphatic filarial infection. Even in endemic areas, a small proportion of cases may be due to other causes – i.e., due to obstructions following infections (such as tuberculosis), tumours, surgery or irradiation *(13)*. In Ethiopia, endemic leg elephantiasis is caused by silica in the iliac lymph glands *(14)*.

2. OCCULT FILARIASIS

The term occult or cryptic filariasis refers to filarial infections in which the classical clinical manifestations are not present and *Mf* are not found in the blood. Occult filariasis is believed to result from a hypersensitivity reaction to filarial antigens derived from *Mf.* The best known example is tropical pulmonary eosinophilia.

Lymphoedema management *(15)*

The recommended management of lymphoedema in areas where lymphatic filariasis is endemic involves simple activities that have demonstrated their effectiveness in significantly improving the quality of life of patients. These activities include providing early detection of lymphoedema, caring for the skin by washing and drying the affected limb or area, preventing and treating entry lesions and providing lymph drainage by elevating the limb and exercising. These are the minimum activities that need to be undertaken, and there is a standard care beyond this that can be accessed where available.

Since the prevention and management of disability caused by lymphatic filariasis is now viewed as public health issue, the guidelines for the first level care worker developed by WHO to manage acute dermato-lymphangioadenitis (ADLA) are as follows:

1. TREATMENT FOR UNCOMPLICATED ADLA

a. Give analgesic such as paracetamol (1g given 3–4 times a day);

b. Give oral antibiotic such as amoxicillin (1.5g in 3 divided doses or oral penicillin) for at least 8 days. In case of allergy to penicillin, oral erythromycin (1g, given 3 times a day) can be used;
c. Clean the limb with antiseptic;
d. Check for any wounds, cuts, abscesses and interdigital infection (especially between the toes). Clean with antiseptic, if any present. If local superficial skin infection is found give antibiotic cream, apply antifungal cream if interdigital infection is present;
e. Give advice about prevention of chronic lymphoedema caused by lymphatic filariasis;
f. Do not give antifilarial medicine.
g. Home management includes drinking plenty of water, rest, elevation of the limb, wriggling the toes, cooling the limb with cold water and washing the limb if the patient can do it; and
h. Follow-up after 2 days at home. If situation does not improve, then refer the patient to physician.

2. MANAGEMENT OF SEVERE ADLA

a. Refer the patient to physician immediately to receive recommended antibiotic treatment
   - Intravenous benzylpenicillin (Penicillin G) 5 million units given 3 times a day or intramuscular procain benzylpenicillin 5 million units given 2 times/day until fever subsides, then give oral phenoxymethylpenicillin (penicillin V) 750 mg (1.2 million units) to 1g. (1.6 million units) given 3 times/day. The minimum total treatment is atleast for 8 days.
   - In case of allergy to penicillin give IV erythromycin 1g 3 times/day until fever subsides, then give oral erythromycin 1g given 3 times/day or give other antibiotic according to local situation.
b. Give analgesic / antipyretic such as paracetamol;
c. Do not give any antifilarial medicine.

Hydrocele management

In the management of hydrocele, the objective of any lymphatic filariasis disability prevention programme should be to increase access to hydrocelectomy. One of the first activities of the programme should be to detect scrotal swelling using an existing community survey (such as enumeration of mass drug administration or other health initiatives). Individuals with scrotal swelling should be referred to a facililty for diagnosis, and if necessary for surgery.

FILARIA SURVEY

The size of the sample to be examined in a filaria survey varies with the type of survey, whether it is a routine survey or survey for evaluation. The NICD (National Institute of Communicable Diseases, Delhi) standard is to examine 5–7 per cent of the population for routine surveys, and at least 20 per cent for evaluation studies. The sample must be random, representative and cover all ages and both sexes. Statistical advice should be obtained when surveys are being planned. A standardized schedule for conducting filaria surveys is given in a WHO Expert Committee Report on Filariasis *(16)*. A filaria survey comprises the following elements :

1. MASS BLOOD SURVEY

The definitive diagnosis of lymphatic filariasis depends upon the demonstration of living parasites in the human body. This calls for a night blood survey.

(i) The thick film : The thick film made from capillary blood is still the most commonly used method for epidemiological assessment. 20 cu. mm of blood is collected by a deep finger prick between 8.30 pm and 12 mid-night. A thick smear is prepared on a glass slide, and the slide is dried and serially numbered. The age, sex and other host factors are recorded on the survey card or register. On the next day or so, the blood films are dehaemoglobanised, stained, dried and examined for *Mf* under low power. The usual technique for enumeration of *Mf* on slides is to start at one end of the smear and work across to the other end, moving the slide field by field till the smear is covered.

(ii) Membrane filter concentration (MFC) methods : The most sensitive method currently available for detecting low-density microfilaraemia in the blood is by concentration techniques. It requires collection of blood by venepuncture and filtering large volumes of blood. Although MFC is the most sensitive method available, some very-low-density carriers will still not be detected *(13)*.

(iii) DEC provocation test : Mf can be induced to appear in blood in the daytime by administering diethylcarbamazine (DEC) 100 mg orally. *Mf* begin to reach their peak within 15 minutes and begin to decrease 2 hours later. The blood may be examined one hour after administration of DEC.

2. CLINICAL SURVEY

At the same time when blood is collected, the people are examined for clinical manifestations of filariasis which should be recorded in the suggested schedule.

3. SEROLOGICAL TESTS

Serological tests to detect antibodies to *Mf* and adults using immunofluorescent and complement–fixing techniques cannot distinguish between past and present infection, and heavy and light parasite loads in the human hosts *(17)*. Recent interest has focussed on the direct detection of parasite antigens in patient's blood or urine *(13)*.

4. XENODIAGNOSIS

The mosquitoes are allowed to feed on the patient, and then dissected 2 weeks later *(8)*. Where other techniques may fail, this may succeed in detecting low–density microfilaraemia.

5. ENTOMOLOGICAL SURVEY

This comprises of general mosquito collection from houses, dissection of female vector species for detection of developmental forms of the parasite, a study of the extent and type of breeding places and other bionomics of mosquitoes.

The data are assembled, analyzed and the results are expressed in terms of certain parameters (clinical, parasitological and entomological) as described below.

ASSESSMENT OF FILARIA CONTROL PROGRAMMES

The effect of filariasis control can be assessed using clinical, parasitological and entomological methods. These are :

1. CLINICAL PARAMETERS

The clinical parameters measured are the incidence of acute manifestations (adeno-lymphangitis, epididymo-orchitis, etc), and the prevalence of chronic manifestations (lymphoedema, elephantiasis, hydrocele, chyluria, etc).

2. PARASITOLOGICAL PARAMETERS

These are : (a) MICROFILARIA RATE : It is the percentage of persons showing *Mf* in their peripheral blood (20 cu. mm) in the sample population, one slide being taken from each person. Specify the species of the parasite. (b) FILARIAL ENDEMICITY RATE : It is the percentage of persons examined showing microfilariae in their blood, or disease manifestation or both. (c) MICROFILARIAL DENSITY : It is the number of *Mf* per unit volume (20 cu. mm) of blood in samples from individual persons. It indicates the intensity of infection. (d) AVERAGE INFESTATION RATE : It is the average number of *Mf* per positive slide, each slide being made from 20 cu.mm of blood. It indicates the prevalence of microfilaraemia in the population.

3. ENTOMOLOGICAL PARAMETERS

These comprise : (a) vector density per 10 man–hour catch (b) percentage of mosquitoes positive for all stages of development (c) percentage of mosquitoes positive for infective (stage III) larvae (d) the annual biting rate – for assessment of transmission (e) types of larval breeding places, etc.

The above parameters help to measure the conditions existing before and after control procedures began, and also to measure the progress of the control campaign against vectors from time to time.

CONTROL MEASURES

The current strategy of filariasis control is based on :

1. Chemotherapy
2. Vector control

Many years of experience with DEC chemotherapy has shown that, even after the full regimen of treatment, some microfilariae still persist in the body. Due to this and other reasons (e.g., toxic effects), it has not been possible to prevent the spread of filariasis by the administration of DEC alone. Chemotherapy must, therefore, be supplemented by an effective vector control programme, if the disease transmission has to be effectively prevented.

1. Chemotherapy

a. Diethylcarbamazine

Diethylcarbamazine (DEC) is both safe and effective. The dose of DEC that is most generally accepted for the treatment of Bancroftian filariasis is 6 mg/kg body weight per day orally for 12 days, given preferably in divided doses after meals. This amounts to a total of 72 mg of DEC per kg of body weight as a full treatment. For Brugian filariasis, recommended doses range from 3 to 6 mg of DEC/kg body weight per day, up to a total dose of 36–72 mg DEC/kg body weight as a full treatment *(13)*.

DEC is rapidly absorbed after oral administration, reaching peak blood levels in 1–2 hours. It is also rapidly excreted – the blood half-life is only 2–3 hours in alkaline urine and about 10–20 hours in acid urine.

DEC causes rapid disappearance of *Mf* from the circulation. It is effective in killing *Mf*. The effect of the drug on the adult worm is uncertain. It has probably no effect on the infective stage larvae.

Toxic reactions : DEC may produce severe side reactions. The reactions may be of two kinds : (a) those due to the drug itself, e.g., headache, nausea, vomiting, dizziness, etc, These reactions are observed a few hours after the first dose of DEC and generally do not last for more than 3 days, and (b) those which are allergic reactions due to destruction of microfilariae and adult worms, e.g., fever, local inflammations around dead worms, orchitis, lymphadenitis, transient lymphoedema and hydrocele. The local reactions tend to occur later in the course of treatment and to last longer. If the drug is given in spaced doses, systemic reactions are much less frequent and less intense after the second dose and are rare after subsequent doses. These reactions disappear spontaneously and interruption of treatment is not necessary.

b. Filaria control in the community

There are three reasons why filariasis never causes explosive epidemics : (a) the parasite does not multiply in the insect vector, (b) the infective larvae do not multiply in the human host, and (c) the life cycle of the parasite is relatively long, 15 years or more. These factors favour the success of control programme *(13)*.

The administration of DEC can be carried out in various ways :

(i) Mass therapy

In this approach, DEC is given to almost everyone in the community irrespective of whether they have microfilaraemia, disease manifestations or no signs of infection except children under 2 years, pregnant women and seriously ill patients. The dose recommended is 6 mg/kg body weight. In some countries it is used alone and some countries with albendazole or ivermectin. Mass therapy is indicated in highly endemic areas *(13)*. For mass chemotherapy to be accepted, a good rapport must be established with the community before the treatment begins. This requires intensive health education of the general public.

(ii) Selective treatment

DEC is given only to those who are *Mf* positive. It is generally accepted that selective treatment may be more suitable in areas of low endemicity than in highly endemic areas.

In India the current strategy is based on detection and treatment of human carriers and filaria cases. The recommended dose in the Indian programme is 6 mg DEC per kg of body weight daily for 12 doses, to be completed in 2 weeks (i.e., 6 days in a week). In endemic areas, treatment must be repeated at specified intervals, usually every 2 years. This is partly because, despite remarkable antimicrofilarial properties, expected microfilaria clearance with DEC is incomplete at times even after adequate treatment *(18)*. The other reason is that people living in endemic areas are exposed to reinfection.

(iii) DEC–medicated salt

The use of DEC–medicated salt is a special form of mass treatment using very low doses of the drug over a long period of time. Common salt medicated with 1–4 g of DEC per kg has been used for filariasis control in some endemic

areas of *W. bancrofti* and *B. malayi*, particularly after an initial reduction in prevalence has been achieved by mass or selective treatment of *Mf* carriers. Treatment should be continued for at least 6 to 9 months. In the Lakshadweep islands, this regimen has been shown to be safe, cheap and effective *(13)*.

The combination of the long life of the adult parasite for several years and infectiousness of a patient with low parasitaemia represents a serious obstacle to control programmes based on chemotherapy alone *(19)*.

c. Ivermectin

Ivermectin is a semisynthetic macrolide antibiotic with a broad spectrum of activity against a variety of nematodes and ectoparasites. The dose is 150–200 μg/kg of body weight

Ivermectin is not used in India. It is used in the region of Africa.

There is no drug toxicity in normal persons. However, in microfilaraemic patients there may be a variety of reactions as a result of inflammatory response triggered by the cleared and dying microfilariae.

2. Vector control

Where mass treatment with DEC is impracticable, the control of filariasis must depend upon vector control. Vector control may also be beneficial when used in conjunction with mass treatment. The most important element in vector control is the reduction of the target mosquito population in order to stop or reduce transmission quickly. The techniques for controlling mosquitoes are given in chapter 12. Briefly they are :

I. Antilarval measures

The ideal method of vector control would be elimination of breeding places by providing adequate sanitation and underground waste-water disposal system. This involves considerable expenditure amounting to several crores of rupees. Because of financial constraints, this may not be feasible in developing countries such as India in the near future. For the time being, therefore, vector control must be based on temporary or recurrent methods.

The current approach in India is to restrict the antilarval measures to urban areas, because it is operationally difficult and very costly to cover the vast rural areas of the country. The urban areas include an extra 3–km peripheral belt because the flight range of *Culex quinquefasciatus (C. fatigans)* is about 3 km.

The anti-larval activities comprise the following *(20)*.

(1) CHEMICAL CONTROL : *(a) Mosquito larvicidal oil :* Mosquito larvicidal oil (MLO) is active against all preadult stages. It has been the main chemical used to control *C. quinquefasciatus* for some time. Since it has proved to be less efficient under field conditions and more expensive than other chemical preparations, it is being replaced by pyrethrum oil, temephos and fenthion. *(b) Pyrosene oil–E :* This is a pyrethrum–based emulsifiable larvicide. The emulsion concentrate contains 0.1 to 0.2 per cent pyrethrins by weight and is required to be diluted with water before use. The emulsion is diluted in the ratio of 1:4, *(c) Organophosphorus larvicides :* During the past 10 years, organophosphorus larvicides (e.g., temephos, fenthion) have been widely used with successful results. However, the vector mosquito has developed resistance to many of these chemicals. The frequency of application is once weekly on all breeding places.

(2) REMOVAL OF PISTIA PLANT : In the case of Mansonia mosquitoes, breeding is best controlled by removing the supporting aquatic vegetation such as the pistia plant from all water collections and converting the ponds to fish or lotus culture. Alternatively, certain herbicides such as phenoxylene 30 or Shell Weed Killer D may be used for destroying the aquatic vegetation.

(3) MINOR ENVIRONMENTAL MEASURES : Larvicidal operations are complemented by minor engineering operations such as filling up of ditches and cesspools, drainage of stagnant water, adequate maintenance of septic tanks and soakage pits, etc. Environmental management is the most efficient approach to the problem of controlling mosquito breeding.

II. Anti-adult measures

The vector mosquitoes of filariasis have become resistant to DDT, HCH and dieldrin. The use of these compounds for indoor residual spraying, tried earlier, has been discontinued. Pyrethrum, as a space spray, still holds promise. It is useful as a temporary means of personal protection, but has no practical value in present–day vector control programmes.

III. Personal prophylaxis

The most effective preventive measure is avoidance of mosquito bites (reduction of man–mosquito contact) by using mosquito nets. Screening of houses can substantially reduce transmission, but it is expensive.

Integrated vector control

None of the above vector control measures applied alone is likely to bring about sustained control of filariasis vectors. An integrated or combined approach is needed to control filariasis using all the above strategies and approaches in optimum combination.

In filariasis four major breakthroughs have occurred. The first of these is the development of safe, single dose, annual drug treatment. Trials have proved that a single dose of DEC is very effective even two years after treatment. A single dose of ivermectin has proved to be equally effective. A combination of single dose of both drugs reduced microfilaraemia more than 95 per cent, 2 years after treatment. Secondly, intensive local hygiene on the affected limb, with or without the use of antibiotic and antifungal creams, has shown to have dramatic effects by halting the progression of, or even reversing elephantiasis and lymphoedema. Thirdly, DEC–medicated tablet or cooking salt has been introduced in India. The carefully controlled addition of very low concentration of DEC has long been recognized as an effective means of eliminating lymphatic filariasis infections in communities. However, the addition increases the price of the salt. During 1994, the first commercially prepared DEC salt went on sale in India, at about twice the price of ordinary salt. Finally, there has been the development of insecticide sprays and polystyrene beads to seal latrines and roof-top water-storage tanks, to eliminate or reduce populations of urban Culex mosquitoes *(21)*.

National Filaria Control Programme

IV. ZOONOSES

Zoonotic diseases have been known since antiquity. Bubonic plague and rabies were known since biblical times. The discovery of causative agents during the "golden era" of microbiology called attention principally to diseases exclusively pathogenic to man. Zoonotic diseases were overshadowed by diseases peculiar to man alone. Only as human infections came under better control was attention drawn to zoonotic diseases.

More than 150 zoonoses have been recognized. In recent years, several new zoonotic diseases have emerged e.g. KFD, Monkey Pox etc., Quite apart from the morbidity and mortality they cause, zoonoses are responsible for great economic losses, particularly in animals, meat, milk and other foods and products of animal origin. The developing countries suffer much more severe losses than do the industrialized countries, partly because they have less well–developed public health and veterinary services and partly because of their unfavourable climatic and environmental conditions.

Zoonoses and human health are matters of particular concern in India – because nearly 80% of India's population is rural and live in close contact with domestic animals, and often not far from wild ones.

Zoonoses have been defined as "Those diseases and infections [the agents of] which are naturally transmitted between [other] vertebrate animals and man." G.S. Nelson has pointed out that it is essential to discuss the direction of transmission, as it is of little value to know that a particular organism is found in both man and animals. What one is really concerned about is its relative significance of man and animals, as maintenance hosts of the particular infection.

The zoonoses have been classified in terms of their reservoir hosts, whether these are men or lower vertebrate animals. Thus, the term anthropo-zoonoses has been applied to infections transmitted to man from lower vertebrate animals. The term zooanthroponoses is applied to infections transmitted from man to lower vertebrate animals; however, these terms have also been used interchangeably for all diseases found in both animals and man. A third term, amphixenoses, has been used for infections maintained in both man and lower vertebrate animals that may be transmitted in either direction.

A classification that is based upon the type of life cycle of the infecting organism and that divides the zoonoses into four categories, each with important shared epidemiologic features, has considerable teaching value.

The four categories are :

(1) Direct zoonoses are transmitted from an infected vertebrate host to a susceptible vertebrate host by direct contact, by contact with a fomite, or by a mechanical vector. The agent itself undergoes little or no propagative changes and no essential developmental change during transmission. Examples are rabies, trichinosis, and brucellosis.

(2) Cyclo–zoonoses require more than one vertebrate host species, but no invertebrate host, in order to complete the developmental cycle of the agent. Examples are the human taeniases, echinococcosis, and pentastomid infections.

(3) Meta-zoonoses are transmitted biologically by invertebrate vectors. In the invertebrate, the agent multiplies or develops, or both, and there is always an extrinsic incubation (prepatent) period before transmission to another vertebrate host is possible. Examples are numerous and include arbovirus infections, plague, and schistosomiasis.

(4) Sapro–zoonoses have both a vertebrate host and a non–animal developmental site or reservoir. Organic matter (including food), soil, and plants are considered to be non–animal. Examples include the various forms of larva migrants and some of the mycoses.

RABIES

Definition

Rabies, also known as *hydrophobia* is an acute, highly fatal viral disease of the central nervous system, caused by *Lyssavirus* type 1. It is primarily a zoonotic disease of warm–blooded animals, particularly carnivorous such as dogs, cats, jackals and wolves. It is transmitted to man usually by bites or licks of rabid animals. Classical hydrophobia is clinically characterized by a long and variable incubation period, a short period of illness due to encephalomyelitis ending in death, despite intensive care. It is the only communicable disease of man that is always fatal.

Problem statement

(i) GEOGRAPHIC DISTRIBUTION

Rabies is an enzootic and epizootic disease of worldwide importance. Some countries have achieved "rabies free" status by vigorous campaigns of elimination, while in others the disease has never been introduced. Geographic boundaries seem to play an important role here. Water appears to be the most effective natural barrier to rabies. Australia, China (Taiwan), Cyprus, Iceland, Ireland, Japan,

Malta, New Zealand, the U.K. and the islands of Western Pacific are all free of the disease. The Liberian peninsula and Finland, Norway and Sweden are also rabies free *(1)*. In India, Union Territory of Lakshadweep and Andman and Nicobar islands are free of the disease *(2)*. A "Rabies-free" area has been defined as one in which no case of indigenously acquired rabies has occurred in man or any animal species for 2 years *(3)*. According to WHO reports, in many countries rabies is spreading inspite of great advances in research and field control methods.

Rabies occurs in more than 150 countries and territories. Although a number of carnivorous and bat species serve as natural reservoir, rabies in dogs is the source of 99 per cent of human infection, and posses a potential threat to more than 3.3 billion people.

In a number of countries, human deaths from rabies are likely to be grossly underreported, particularly in the youngest are groups. Vast majority of the estimated 55,000 deaths caused by rabies each year occur in rural areas of Africa and Asia. In India alone, 20,000 deaths (that is, about 2 per lac population at risk) are estimated to occur annually; in Africa, the corresponding figure is 24,000 (about 4 per lac population at risk) *(4)*.

Although all age groups are susceptible, rabies is most common in children aged less than 15 years; on an average, 40 per cent of post–exposure immunization are given to children aged 5–14 years, and the majority of those immunized are male. In the north–western part of the United Republic of Tanzania, the incidence of rabies was upto 5 times higher in children aged less than 15 years than in adults *(4)*. At the global level, more than 15 million people receive rabies prophylaxis annually, the majority of whom live in China and India. It is estimated that in the absence of post–exposure prophylaxis, about 327,000 persons would die from rabies in Africa and Asia each year *(4)*.

Epidemiological determinants

Agent factors

AGENT : The causative agent (*Lyssavirus* type 1) is a bullet shaped neurotropic RNA containing virus. It belongs to the family rhabdoviridae – serotype 1 (*Lyssavirus*, type 1) and is the causative agent of rabies. Serotype 2, 3 and 4 are *rabies–related* but antigenically distinct viruses; they cause rabies like disease in man and animals *(5)*. Available anti-rabies vaccines may not be effective against the rabies–related viruses *(6)*.

Rabies virus particles contain two distinct, major antigens : a glycoprotein (G protein) antigen from the virus membrane and an internal nucleoprotein antigen. The glycoprotein seems to be the only antigen capable of inducing the formation of virus–neutralizing antibodies *(7)*. The presence of neutralizing antibodies in the blood of man and animals is considered an index of protection against infection with rabies virus *(8)*. Recently, surface glycoprotein of rabies virus has been cloned and expressed in *E. coli* in a bid to develop genetically engineered rabies vaccine.

The virus is excreted in the saliva of the affected animals. The virus recovered from naturally occurring cases of rabies is called *"street virus"*. It is pathogenic for all mammals and shows a long variable incubation period (20–60 days in dogs). Serial brain–to–brain passage of the street virus in rabbits modifies the virus such that its incubation period is progressively reduced until it becomes constant between 4–6 days. Virus isolated at this stage is called a *fixed virus*. A "fixed" strain of virus may be defined as one that has a short, fixed and reproducible incubation period (4–6 days) when injected intracerebrally into suitable animals. It does not form Negri bodies. It no longer multiplies in extra–neural tissues. The *fixed virus* is used in the preparation of antirabies vaccine. There is evidence that *fixed virus* can be pathogenic for humans and mammals under certain conditions, as for example parenteral injection of antirabies vaccine inadequately inactivated *(7)*.

SOURCE OF INFECTION : The source of infection to man is the saliva of rabid animals. In dogs and cats, the virus may be present in the saliva for 3–4 days (occasionally 5–6 days) before the onset of clinical symptoms and during the course of illness till death *(9, 10)*.

Host factors

All warm blooded animals including man are susceptible to rabies. Rabies in man is a dead-end infection, and has no survival value for the virus. The overwhelming number of victims in India belong to the age group 1–24 years *(2)*. Laboratory staff working with rabies virus, veterinarians, dog handlers, hunters and field naturalists face bigger risks of rabies than do general public.

Mode of transmission *(11)*

People are infected following a deep bite or scratch by an infected animal. Dogs are the main host and transmitter of rabies. They are the source of infection in almost all the rabies deaths annually in Asia and Africa.

Bats are the source of most human rabies deaths in the United States of America and Canada. Bat rabies has also recently emerged as a public health threat in Australia, Latin America and western Europe. However in these regions the number of human deaths due to bat rabies remains small compared to deaths following dog bites. Human deaths following exposure to foxes, raccoons, skunks, jackals, mongooses and other wild carnivore host species are very rare.

Transmission can also occur when infectious material – usually saliva – comes into direct contact with human mucosa or fresh skin wounds. Human-to-human transmission by bite is theoretically possible but has never been confirmed.

Rarely, rabies may be contracted by inhalation of virus-containing aerosol or *via* transplantation of an infected organ. Ingestion of raw meat or other tissues from animals infected with rabies is not a source of human infection.

Incubation period

The incubation period in man is highly variable, commonly 1–3 months following exposure but may vary from 7 days to many years *(4)*. The incubation period depends on the site of the bite, severity of the bite, number of wounds, amount of virus injected, species of the biting animal, protection provided by the clothing and treatment undertaken, if any. In general, incubation period tends to be shorter in severe exposures and bites on face, head, neck and upper extremities and bites by wild animals. In no other specific communicable disease is the incubation period so variable and dependant on so many factors as in rabies.

Pathogenesis

Rabies virus replicates in muscle or connective tissue cells at or near the site of introduction before it attaches to nerve endings and enters peripheral nerves. It spreads from the

site of infection centripetally *via* the peripheral nerves towards the central nervous system; most likely it "ascends" passively through the nerve associated tissue space *(7)*. Following infection of the central nervous system, the virus spreads centrifugally in peripheral nerves to many tissues, including skeletal and myocardial muscle, adrenal glands and skin. The salivary glands invasion is crucial for the transmission of the virus to another animal or human *(5)*.

RABIES IN MAN

Clinical picture

Rabies in man is called hydrophobia. The disease begins with *prodromal symptoms* such as headache, malaise, sore throat and slight fever lasting for 3–4 days. About 80% of patients complain of pain or tingling at the site of the bite. This is the only prodromal symptom which is considered reasonably specific *(12)*.

The prodromal stage is followed by widespread excitation and stimulation of all parts of nervous system usually involving, in order, the sensory system, the motor system, the sympathetic and mental system. The patient is intolerant to noise, bright light or a cold draught of air (sensory). Aerophobia (fear of air) may be present and is considered by some to be pathognomonic of rabies *(13)*. It can be elicited by fanning a current of air across the face which causes violent spasms of the pharyngeal and neck muscles. Examination may show increased reflexes and muscle spasms (motor) along with dilatation of the pupils and increased perspiration, salivation and lachrimation (sympathetic). Mental changes include fear of death, anger, irritability and depression.

The symptoms are progressively aggravated and all attempts at swallowing liquid become unsuccessful. At later stage the mere sight or sound of water may provoke spasm of the muscles of deglutition. This characteristic symptom of hydrophobia (fear of water) is pathognomonic of rabies and is absent in animals. The duration of illness is 2 to 3 days, but may be prolonged to 5–6 days in exceptional cases. The patient may die abruptly during one of the convulsions or may pass on to the stage of paralysis and coma. Intensive care may allow an occasional patient to survive *(10)*. To-date, only three people are on record who have been stricken with rabies and have survived *(1)*.

Diagnosis

A clinical diagnosis of hydrophobia can be made on the basis of history of bite by a rabid animal and characteristic signs and symptoms.

Rabies can be confirmed in patients early in the illness by antigen detection using immunofluorescence of skin biopsy, and by virus isolation from saliva and other secretions. Immunofluorescence of corneal impression smears has proved unreliable. Neutralizing antibodies are not usually detectable in serum or CSF before the eighth day *(5)*.

Treatment

There is no specific treatment for rabies. Case management includes the following procedure :

(a) The patient should be isolated in a quiet room protected as far as possible from external stimuli such as bright light, noise or cold draughts which may precipitate spasms or convulsions. (b) Relieve anxiety and pain by liberal use of sedatives. Morphia in doses of 30–45 mg may be given repeatedly. The drug is well tolerated and once the diagnosis is established there appears to be no reason to restrict the administration of a drug which does so much to allay acute suffering. (c) If spastic muscular contractions are present use drugs with curare–like action. (d) Ensure hydration and diuresis. (e) Intensive therapy in the form of respiratory and cardiac support may be given.

Patients with rabies are potentially infectious because the virus may be present in the saliva, vomits, tears, urine or other body fluids. Nursing personnel attending rabid patients should be warned against possible risk of contamination and should wear face masks, gloves, goggles and aprons to protect themselves. Persons having bruises, cuts or open wounds should not be entrusted to look after the patient. Where human cases of rabies are encountered frequently pre-exposure prophylaxis is recommended.

PREVENTION OF HUMAN RABIES

This may be considered under 3 heads.

a. Post-exposure prophylaxis.
b. Pre-exposure prophylaxis.
c. Post-exposure treatment of persons who have been vaccinated previously.

POST-EXPOSURE PROPHYLAXIS

1. General consideration

The vast majority of persons requiring anti-rabies treatment are those who were bitten by a suspected rabid animal. The aim of post-exposure prophylaxis is to neutralize the inoculated virus before it can enter the nervous system. Every instance of human exposure should be treated as a medical emergency. It is now well established that irrespective of the class of wound, the combined administration of a single dose of rabies immunoglobulin if indicated with a course of vaccine, together with local treatment of the wound is the best specific prophylactic treatment after exposure of man to rabies.

2. Local treatment of wound

Prompt and adequate local treatment of all bite wounds and scratches is the first requisite and is of utmost importance. The purpose of local treatment is to remove as much virus as possible from the site of inoculation before it can be absorbed on nerve endings. Local treatment of wounds is of maximal value when applied immediately after exposure (within minutes if possible) but it should not be neglected if several hours or days have elapsed *(3)*. Animal experiments have shown that local wound treatment can reduce the chances of developing rabies by upto 80% *(6)*. The local treatment comprises the following measures :

(a) Cleansing : Immediate flushing and washing the wound(s), scratches and the adjoining areas with plenty of soap and water, preferably under a running tap, for at least 15 minutes is of paramount importance in the prevention of human rabies. If soap is not available, simple flushing of the wounds with plenty of water should be done as first-aid. In case of punctured wounds, catheters, should be used to irrigate the wounds. This procedure is now standard worldwide. It does minimize the risk of contracting rabies. Unfortunately, very few patients get it in right time.

(b) Chemical treatment : Whatever residual virus remains in the wound(s), after cleansing, should be inactivated by irrigation with *virucidal* agents – either alcohol (400–700 ml/litre), tincture or 0.01% aqueous solution of iodine or povidone iodine.

(c) Suturing : Bite wounds should not be immediately sutured to prevent additional trauma which may help spread the virus into deeper tissues. If suturing is necessary, it should be done 24–48 hours later, applying minimum possible stitches, under the cover of rabies immunoglobulin locally.

(d) Antibiotics and anti-tetanus measure : The application of antibiotics and antitetanus procedures when indicated should follow the local treatment recommended above.

3. Immunization

Since their development more than four decades ago, concentrated and purified cell-culture vaccine (CCV) and embryonated egg-based vaccine (EEV) have proved to be safe and effective in preventing rabies. These vaccines are intended for pre-exposure as well as post-exposure prophylaxis.

The internationally available cell-culture and embryonated egg-based vaccines (CCEEVs) consist of rabies virus that has been propagated in cell substrates such as human diploid cells (embryonic fibroblast cells), fetal rhesus diploid cells, Vero cells (kidney cells from the African green monkey), primary Syrian hamster kidney cells, primary chick embryo cells or in embryonated duck eggs. The more recently developed vaccines based on chick embryo cells and Vero cells have safety and efficacy records comparable to those of the human diploid cell vaccines and are less expensive *(4)*.

Rabies vaccines prequalified by WHO do not contain preservatives such as thimerosal. The shelf-life of these vaccines is ≥ 3 years, provided they are stored at +2°C to +8°C and protected from sunlight. Following reconstitution with the accompanying sterile diluent, the vaccines should be used immediately, or within 6–8 hours if kept at the correct temperature.

All CCEEVs should comply with the WHO recommended potency of ≥ 2.5 IU per single intramuscular dose (0.5 ml or 1.0 ml volume after reconstitution, depending on the type of vaccine).

The guidelines for the post–exposure treatment by the WHO are given in Table 1.

TABLE 1

Categories of contact and recommended post-exposure prophylaxis (PEP)

Categories of contact with suspect rabid animal	Post–exposure prophylaxis measures
Category I – touching or feeding animals, licks on intact skin	None
Category II – nibbling of uncovered skin, minor scratches or abrasions without bleeding	Immediate vaccination and local treatment of the wound
Category III – single or multiple transdermal bites or scratches, licks on broken skin; contamination of mucous membrane with saliva from licks, contacts with bats.	Immediate vaccination and administration of rabies immunoglobulin; local treatment of the wound

Source: *(11)*

All category II and III exposures assessed as carrying a risk of developing rabies require PEP. This risk is increased if *(11)*:

- the biting mammal is a known rabies reservoir or vector species;
- the animal looks sick or has an abnormal behaviour;
- a wound or mucous membrane was contaminated by the animal's saliva;
- the bite was unprovoked;
- the animal has not been vaccinated; and
- if biting animal cannot be traced or identified.

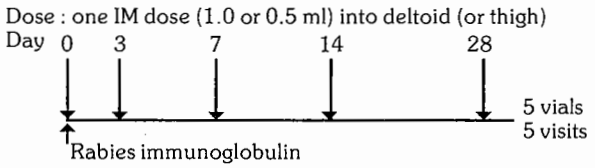
In developing countries, the vaccination status of the suspected animal alone should not be considered when deciding whether to initiate prophylaxis or not.

Post-exposure prophylaxis may be discontinued if the suspected animal is proved by appropriate laboratory examination to be free of rabies or, in the case of domestic dogs, cats or ferrets, the animal remains healthy throughout a 10 day observation period starting from the date of the bite *(4)*.

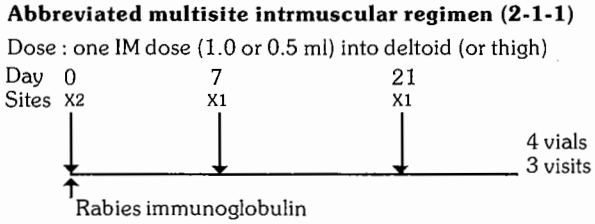
Intramuscular administration of vaccine for post-exposure prophylaxis

The post-exposure vaccination schedule is based on injecting 1 ml or 0.5 ml (the volume depends on the type of vaccine) into the deltoid muscle (or anterolateral thigh in children aged <2 years) of patients with category II and III exposures. The recommended regimen consists of either a 5-dose or a 4-dose schedule:

(i) *Essen regimen:* the 5-dose regimen prescribes 1 dose on each of days 0, 3, 7, 14, and 28; as shown below



(ii) *Zareb regimen:* the 4-dose abbreviated multisite regimen prescribes 2 doses on day 0 (1 in each of the 2 deltoid or thigh sites) followed by 1 dose on each of days 7 and 21, as shown below.



An alternative for healthy, fully immunocompetent, exposed people who receive wound care plus high quality rabies immunoglobulin plus WHO prequalified rabies vaccines, is a post-exposure regimen consisting of 4 doses administered intramuscularly on days 0, 3, 7 and 14.

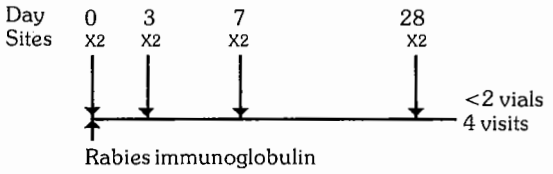
Intradermal administration for post-exposure prophylaxis

The 2-site regimen prescribes injection of 0.1 ml at 2 sites (deltoid or thigh) on days 0, 3, 7 and 28. The day 14 dose is missed. This regimen may be used for people with category II and III exposures in countries where the intradermal route

has been endorsed by national health authorities. The regimen is as shown below:

2-site intradermal regimen (2+2+2+0+2)

Dose : one ID dose = one fifth of IM dose (0.1 ml) ID per site



Post-exposure prophylaxis for previously vaccinated individuals

For rabies-exposed patients who can document previous complete pre-exposure vaccination or complete post-exposure prophylaxis with a CCEEV, 1 dose delivered intramuscularly or a CVV delivered intradermally on days 0 and 3 is sufficient. Rabies immunoglobulin is not indicated in such cases. This 1-site 2-day intradermal or intramuscular regimen also applies to people vaccinated against rabies who have demonstrated rabies-virus neutralizing antibody titres of ≥0.5 IU/ml . As an alternative to this regimen, the patient may be offered a single-visit 4-site intradermal regimen consisting of 4 injections of 0.1 ml equally distributed over left and right deltoids or thighs. Vaccination cards recording previous immunizations are invaluable for making correct decisions.

Immunization of immunocompromised individuals

In immunocompromised individuals including patients with HIV/AIDS, a complete series of 5 doses of intramuscular CCEEV in combination with comprehensive wound management and local infiltration with human rabies immunoglobulin is required for patients with category II and III exposures. When feasible, the rabies-virus neutralizing antibody response should be determined 2–4 weeks following vaccination to assess the possible need for an additional dose of the vaccine.

Rabies immunoglobulin for passive immunization

Rabies immunoglobulin for passive immunization is administered only once, preferably at, or as soon as possible after, the initiation of post-exposure vaccination. Beyond the seventh day after the first dose, rabies immunoglobulin is not indicated because an active antibody response to the CCEEV is presumed to have occurred. The dose of human rabies immunoglobulin is 20 IU/kg body weight; for equine immunoglobulin and F (ab')2 products, it is 40 IU/kg body weight. All of the rabies immunoglobulin, or as much as anatomically possible (but avoiding possible compartment syndrome), should be administered into or around the wound site or sites. The remaining immunoglobulin, if any, should be injected intramuscularly at a site distant from the site of vaccine administration. Rabies immunoglobulin may be diluted to a volume sufficient for all wounds to be effectively and safely infiltrated.

Most of the new equine immunoglobulin preparations are potent, highly purified, safe and considerably less expensive than human rabies immunoglobulin. However they are of heterologous origin and carry a small risk of anaphylactic reaction (1/45,000 cases). There are no scientific grounds for performing a skin test prior to administering equine immunoglobulin because testing does not predict reactions, and it should be given whatever the result of the test. The treating physician should be prepared to manage anaphylaxis which, although rare, could occur during any stage of administration *(14)*.

Guide for pre-exposure prophylaxis (PrEP) *(14)*

PrEP may be performed with any of the modern cell-derived vaccines and is recommended for anyone at increased risk of exposure to rabies virus. Traditionally, PrEP is recommended for anyone who is at continual, frequent or increased risk of exposure to the rabies virus either as a result of their residence or occupation (for example laboratory workers dealing with rabies virus and other lyssaviruses, veterinarians and animal handlers). Travellers with extensive outdoor exposure and children living in rural high-risk areas are at particular risk.

PrEP schedule requires intramuscular doses of 1ml or 0.5 ml, depending on the vaccine type, or intradermal administration of 0.1 ml volume per site (one site each day) given on days 0, 7 and 21 or 28. To lead to significant savings, intradermal PrEP sessions should involve enough individuals to utilize all opened vials within 6–8 hours.

Booster doses of rabies vaccines are not required for individuals living in or travelling to high-risk areas who have received a complete primary series of pre-exposure or post–exposure prophylaxis with a CCV. Periodic booster injections are recommended as an extra precaution only for people whose occupation puts them at continual or frequent risk of exposure. If available, antibody monitoring of personnel at risk is preferred to the administration of routine boosters. For people who are potentially at risk of laboratory exposure to high concentrations of live rabies virus, antibody testing should be done every 6 months. Those professionals who are not at continual risk of exposure through their activities, such as certain categories of veterinarians and animal health officers, should have serological monitoring every 2 years. Because vaccine-induced immunity persists in most cases for years, a booster would be recommended only if rabies virus neutralizing antibody titres fall to <0.5 IU/ml.

Adverse events following immunization *(4)*

In general, CCEEVs have been shown to be safe and well tolerated. However, in 35–45% of vaccinees, minor and transient erythema, pain and/or swelling may occur at the site of injection, particularly following intradermal administration of a booster. Mild systemic adverse events following immunization (AEFI), such as transient fever, headache, dizziness and gastrointestinal symptoms, have been observed in 5–15% of vaccinees.

Contraindications and precautions *(4)*

For pre-exposure prophylaxis, previous severe reaction to any components of the vaccine is a contraindication to further use of the same vaccine. Because rabies is a lethal disease, no contraindications exist to post-exposure prophylaxis following high-risk exposure. This is also the case for post-exposure prophylaxis during infancy or pregnancy, and for immunocompromised individuals, including children with HIV/AIDS. People taking chloroquine for malaria treatment or prophylaxis may have a reduced response to intradermal rabies vaccination. These patients should receive the vaccine intramuscularly.

NERVOUS TISSUE VACCINES

Nervous tissue vaccines are crude products capable of causing severe and even fatal reactions. Although apparently

effective, they are generally of low or variable potency and are usually administered to exposed subjects in a large number of doses. The current trend is to limit or abandon completely the production of nervous tissue vaccines and replace them by safer and more effective inactivated cell-culture vaccines in both developed and developing countries. Government of India has stopped producing nervous tissue vaccine since 2004.

RABIES IN DOGS

In developing countries over 90% of human deaths from rabies are caused by dog bites and dog rabies control is the key that can lock the door against human rabies.

INCUBATION PERIOD

The incubation period in dogs ranges from 3–8 weeks, but it may be as short as 10 days or as long as a year or more *(15)*.

CLINICAL PICTURE

Rabies in dogs may manifest itself in two forms – Furious rabies and Dumb rabies.

(a) Furious rabies : This is the typical "mad-dog syndrome", characterized by *(i) a change in behaviour :* In animals, the cardinal sign is a change in behaviour. The animal loses its fear of people, becomes very aggressive, bites without provocation and bites unusual objects like sticks, straw and mud *(ii) running amuck:* i.e., tendency to run away from home and wander aimlessly and biting humans and animals who may come in its way *(iii) change in voice :* i.e., the dog barks or growls in a hoarse voice or often unable to bark because of paralysis of laryngeal muscles *(iv) excessive salivation* and foaming at the angle of the mouth, and *(v) Paralytic stage :* The animal enters into a paralytic stage, towards the later stages of illness. There is paralysis of the whole body leading to coma and death.

(b) Dumb rabies : In this type, the excitative or irritative stage is lacking. The disease is predominantly paralytic. The dog withdraws itself from being seen or disturbed. It lapses in to a stage of sleepiness and dies in about 3 days.

Once the symptoms of rabies develop in an animal, it rarely survives more than a week *(16)*.

LABORATORY DIAGNOSIS

The head of the animal is cut off and sent to the nearest testing laboratory, duly packed in ice in an airtight container. Alternatively, the brain may be removed with anti-septic precautions and sent in 50% glycerol–saline for examination *(17)*. This should be done by a qualified or trained person soon after the death of the animal.

Laboratory examination is made by : (a) FLUORESCENT ANTIBODY TEST : This is a highly reliable and the best single test currently available for the rapid diagnosis of rabies viral antigen in infected specimens. This test can establish a highly specific diagnosis within a few hours *(3)*. The accuracy of the test is considered equal to that of isolation of the virus by animal inoculation. If the brain is negative by FRA test, one can assume that the saliva contains no virus, and the bitten person need not be treated. Further, fluorescent antibody titres in clinical rabies have been well in excess of 1:10,000 a feature which helps to distinguish between rabies and vaccine reaction *(18)*. (b) MICROSCOPIC EXAMINATION : Although FRA test has largely supplanted other methods of diagnosis, the microscopic examination of brain tissue for Negri bodies is still a useful method for rapid diagnosis of rabies. The microscopic examination for Negri bodies identifies 75–90% of cases of rabies in dogs. (c) MOUSE INOCULATION TEST : Intracerebral mouse inoculation is still one of the most useful tests in the laboratory diagnosis of rabies. Suckling mice are generally more sensitive for virus isolation. A 10% emulsion of suspected brain tissue is prepared in normal saline and centrifuged at 2000 r.p.m. for 5–10 minutes. 0.03 ml of the supernatant fluid is injected intracerebrally using a tuberculin syringe into at least 4 mice. If infected they show signs of rabies between 6–8 days. The virus can be identified by the FRA test or by the presence of Negri bodies. (d) CORNEAL TEST : Rabies virus antigen can be detected in live animals in corneal impressions or in frozen sections of skin biopsies by the FRA test. A positive result is indicative of rabies, but a negative result does not rule out the possibility of infection *(3)*.

Immunization of dogs

Prophylactic vaccination of dogs against rabies is one of the most important weapons in rabies control *(7)*. Studies have shown that, in general, 80–90% of the dog population is accessible for vaccination, thus confirming that the concept of controlling rabies through mass vaccination is a sound one *(19)*. All dogs should receive primary immunization at the age of 3–4 months and booster doses should be given at regular intervals, according to the type of vaccine used.

(1) *BPL inactivated nervous tissue vaccine (Single dose) :* This is based on 20% suspension of infected sheep brain. The dose is 5 ml for dogs and 3 ml for cats. Revaccination is advised after 6 months, and subsequently every year.

(2) *Modified live virus vaccine :* This is based on 33% chick embryo suspension infected with modified virus. The dose is 3 ml by single injection, and boosters every 3 years. As with the vaccines for human use, the adult-brain vaccines for use in animals should be replaced as soon as possible by cell-culture vaccines *(20)*.

Control of urban rabies

Since dog is the major source of infection, the most logical and cost-effective approach is elimination of stray and ownerless dogs combined with a programme of swift mass immunization, in the shortest possible time, of at least 80% of the entire dog population of the area.

Other methods include (i) registration and licensing of all domestic dogs (ii) restraint of dogs in public places (iii) immediate destruction of dogs and cats bitten by rabid animals (iv) quarantine for about 6 months of imported dogs and (v) health education of people regarding the care of dogs and prevention of rabies.

The discovery that foxes could be immunized against rabies by placing modified live virus vaccine directly into the mouths has generated a new control technique. So far no suitable oral bait is developed for use in dogs *(1)*.

Oral vaccines

The successful introduction of oral vaccines for the immunization of foxes is a great advancement in the rabies prophylaxis of wild life. An attempted live rabies vaccine harmless but immunizing to foxes, is placed in baits and distributed over the foxes habitat. Successful control of wild animal's rabies particularly foxes has been achieved in Canada, Germany and Switzerland by the use of "oral

vaccine baits." The technique holds much promise for the future control of rabies not only in foxes but also in other wild life species.

YELLOW FEVER

Yellow fever is a zoonotic disease caused by an arbovirus. It affects principally monkeys and other vertebrates in tropical America and Africa and is transmitted to man by certain culicine mosquitoes. It shares clinical features with other viral haemorrhagic fevers (e.g., dengue HF, Lassa fever) but is characterized by more severe hepatic and renal involvement. The spectrum of disease varies from clinically indeterminate to severe cases. Severe cases develop jaundice with haemorrhagic manifestations (black vomit, epistaxis, melena) and albuminuria or anuria, shock, agitation, stupor and coma *(1)*. In general death occurs between the fifth and tenth day of illness. The case fatality rate may reach 80 per cent in severe cases. Survivors exhibit long–lasting immunity.

Problem statement

45 countries in Africa and Latin America, with a combined population of more than 900 million, are at risk of yellow fever. In Africa, an estimated 508 million people live in 32 countries at risk. The remaining are in 13 countries of Latin America, with Bolivia, Brazil, Colombia, Ecuador and Peru at greatest risk *(2)*.

There are an estimated 200,000 cases and 30,000 deaths worldwide each year. Small number of imported cases occur in countries free of yellow fever. Although disease has never been reported in Asia, the region is at risk because the conditions required for transmission are present there *(2)*.

Epidemiological determinants

Agent factors

(a) AGENT : The causative agent, *Flavivirus fibricus* formerly classified as a group B arbovirus, is a member of the togavirus family. It shares group–specific antigens with other members of the genus (e.g., West Nile, dengue). Under natural conditions, the virus is pantropic but after continued culture in tissues, as in chick embryo, it loses all its pathogenic properties but retains its antigenicity. (b) RESERVOIR OF INFECTION : In forest areas, the reservoir of infection is mainly monkeys and forest mosquitoes. In urban areas, the reservoir is man (subclinical and clinical cases) besides *Aedes aegypti* mosquitoes. (c) PERIOD OF COMMUNICABILITY : (i) MAN : Blood of patients is infective during the first 3 to 4 days of illness. (ii) MOSQUITOES : After an "extrinsic incubation period" of 8 to 12 days, the mosquito becomes infective. The virus multiplies in the insect vector. After becoming infective, the mosquito remains so for life. Transovarian transmission of the virus in mosquitoes has been shown to occur in adverse conditions (e.g., during extended dry seasons), in the absence of susceptible hosts *(1)*.

Host factors

(a) AGE AND SEX : All ages and both sexes are susceptible to yellow fever in the absence of immunity (b) OCCUPATION : Persons whose occupation brings them in contact with forests (wood cutters, hunters) where yellow fever is endemic are exposed to the risk of infection (c) IMMUNITY : One attack of yellow fever gives lifelong immunity; second attacks are unknown. Infants born of immune mothers have antibodies up to 6 months of life.

Environmental factors

(a) CLIMATE : A temperature of 24 deg.C or over is required for the multiplication of the virus in the mosquito. It should be accompanied by a relative humidity of over 60 per cent for the mosquitoes to live long enough to convey the disease. (b) SOCIAL FACTORS : In Africa, urbanization is leading to the extension of yellow fever. In addition, the expanding population is encroaching on areas that were previously sparsely populated, thereby bringing man closer to the jungle cycles of yellow fever. The increasing number of people who travel and the greater speed with which they are transported from endemic areas to receptive areas, also gives a cause for concern *(3)*.

Modes of transmission

There are three known cycles of transmission, the jungle, intermediate and the urban cycles *(2)*.

- *Sylvatic (or jungle) yellow fever.* In tropical rainforests, yellow fever occurs in monkeys that are infected by wild mosquitoes. The infected monkeys then pass the virus to other mosquitoes that feed on them. The infected mosquitoes bite humans entering the forest, resulting in occasional cases of yellow fever. The majority of infections occur in young men working in the forest (e.g. for logging).
- *Intermediate yellow fever.* In humid or semi-humid parts of Africa, small-scale epidemics occur, Semi-domestic mosquitoes (that breed in the wild and around households) infect both monkeys and humans. Increased contact between people and infected mosquitoes leads to transmission. Many separate villages in an area can suffer cases simultaneously. This is the most common type of outbreak in Africa. An outbreak can become a more severe epidemic if the infection is carried into an area populated with both domestic mosquitoes and unvaccinated people.

- *Urban yellow fever.* Large epidemics occur when infected people introduce the virus into densely populated areas with a high number of non-immune people and Aedes mosquitoes. Infected mosquitoes transmit the virus from person to person.

Treatment

There is no specific treatment for yellow fever, only supportive care to treat dehydration and fever. Associated bacterial infections can be treated with antibiotics. Supportive care may improve outcomes for seriously ill patients, but it is rarely available in poorer areas.

Incubation period

3 to 6 days (6 days recognized under International Health Regulations).

CONTROL OF YELLOW FEVER

Jungle yellow fever

Jungle yellow fever continues to be an uncontrollable disease. The virus maintains itself in the animal kingdom. Mosquito control is difficult and can be considered only in restricted areas. Vaccination of humans with 17D vaccine is the only control measure.

Urban yellow fever

(1) VACCINATION : Rapid immunization of the population at risk is the most effective control strategy for yellow fever. For international use, the approved vaccine is the ***17D vaccine.*** It is a live attenuated vaccine prepared from a non-virulent strain (17D strain), which is grown in chick embryo and subsequently freeze-dried.

The sensitivity of the lyophilized 17D vaccine to heat is a major drawback to the use of this vaccine, in mass campaigns in tropical countries. It has to be stored between +5 and -30 deg.C, preferably below zero deg. C until reconstituted with the sterile, cold physiological saline diluent provided. Reconstituted vaccine should be kept on ice, away from sunlight, and discarded if not used within half an hour.

The vaccine is administered subcutaneously at the insertion of deltoid in a single dose of 0.5 ml irrespective of age. Immunity begins to appear on the 7th day and lasts for more than 35 years, and possibly for life *(2)*. However, WHO recommends revaccination after 10 years for international travel.

The risk of death from yellow fever is much higher than the risks related to the vaccine. People who should not be vaccinated include *(2)* :

(a) children aged under 9 months for routine immunization (or under 6 months during an epidemic);
(b) pregnant women – except during a yellow fever outbreak when the risk of infection is high;
(c) people with severe allergies to egg protein; and
(d) people with severe immunodeficiency caused by symptomatic HIV/AIDS or other causes, or in the presence of thymus disorder.

Mild post-vaccinial reactions (e.g., myalgia, headache, low-grade fever) may occur in 2–5 per cent of vaccinees, 5 to 10 days after vaccination. Anaphylaxis is very rare, occurring mainly in those allergic to eggs *(4)*.

Cholera and yellow fever vaccines together or within 3 weeks interfere with each other, so whenever possible, they should be given 3 weeks or more apart *(5)*.

(2) VECTOR CONTROL : The other principal method of preventing yellow fever is through intensive vector control. The objective of vector control is to reduce rapidly the vector population to the lowest possible level and thereby stop or reduce transmission quickly. This approach has proved successful in the Americas to prevent urban epidemics.

The vector, *Aedes* mosquito is peri-domestic in habits. It can be controlled by vigorous anti-adult and anti-larval measures. The long-term policy should be based on organized "source reduction" methods (e.g., elimination of breeding places) supported by health education aimed at securing community participation.

Personal protection against contact with insects is of major importance in integrated vector control. Such protection may include the use of repellents, mosquito nets, mosquito coils and fumigation mats *(6)*.

(3) SURVEILLANCE : A programme of surveillance (clinical, serological, histopathological and entomological) should be instituted in countries where the disease is endemic, for the early detection of the presence of the virus in human populations or in animals that may contribute to its dissemination.

For the surveillance of Aedes mosquitoes, the WHO uses an index known as ***Aedes aegypti index.*** This is a house index and is defined as "the percentage of houses and their premises, in a limited well-defined area, showing actual breeding of *Aedes aegypti larvae" (7)*. This index should not be more than 1 per cent in towns and seaports in endemic areas to ensure freedom from yellow fever *(8)*.

International measures

India is a yellow fever "receptive" area, that is, "an area in which yellow fever does not exist, but where conditions would permit its development if introduced". The population of India is unvaccinated and susceptible to yellow fever. The vector, *Aedes aegypti* is found in abundance. The climatic conditions are favourable in most parts of India for its transmission. The common monkey of India *(Macacus spp)* is susceptible to yellow fever. The missing link in the chain of transmission is the virus of yellow fever which does not seem to occur in India.

The virus of yellow fever could get imported into India in two ways: (i) through infected travellers (clinical and subclinical cases), and (ii) through infected mosquitoes. Measures designed to restrict the spread of yellow fever are specified in the "International Health Regulations" of WHO *(7)*. These are implemented by the Government of India through stringent aerial and maritime traffic regulations. Broadly these comprise :

(i) TRAVELLERS : All travellers (including infants) exposed to the risk of yellow fever or passing through endemic zones of yellow fever must possess a valid international certificate of vaccination against yellow fever before they are allowed to enter yellow fever "receptive" areas. If no such certificate is available, the traveller is placed on quarantine, in a mosquito-proof ward, for 6 days from the date of leaving an infected area. If the traveller arrives before the certificate becomes "valid", he is isolated till the certificate becomes valid.

(ii) MOSQUITOES : The aircraft and ships arriving from endemic areas are subjected to aerosol spraying with prescribed insecticides on arrival for destruction of insect vectors. Further, airports and seaports are kept free from the

breeding of insect vectors over an area extending at least 400 metres around their perimeters. The *"aedes aegypti index"* is kept below 1.

International certificate of vaccination

India and most other countries require a valid certificate of vaccination against yellow fever from travellers coming from infected areas. A few countries (including India) require this even if the traveller has been in transit. It rests with each country to decide whether a certificate of vaccination against yellow fever shall be required for infants under one year of age, after weighing the risk of importation of yellow fever by unvaccinated infants against the risk to the infant arising from vaccination. In this regard, India requires vaccination of infants too *(9)*. The validity of the certificate begins 10 days after the date of vaccination and extends up to 10 years. Revaccination performed before the end of the validity of the certificate renders the certificate valid for a further period of 10 years starting on the day of revaccination. For the purpose of international travel, the vaccination must be given at an officially designated centre, and the certificate must be validated with the official stamp of the Ministry of Health, Government of India. The certificate is valid only if it conforms with the model prescribed under the International Health Regulations. On the other hand, for their own protection, travellers who enter endemic areas should receive vaccination against yellow fever.

Reference centres

The yellow fever reference centres in India are : (1) National Institute of Virology, Pune, and (2) Central Research Institute, Kasauli.

The international control of yellow fever remains one of the major medical challenges of the century *(10)*.

OTHER ARBOVIRAL DISEASES

During the past few years, a large number of arthropod–borne viruses (arboviruses) have been isolated from sick persons, animals and arthropods throughout the world. Arthropod–borne viruses are defined as viruses "which are maintained in nature principally, or to an important extent through biological transmission between susceptible vertebrate hosts by haematophagous arthropods; they multiply in the tissues of arthropods, and are passed on to new vertebrates by the bites of arthropod after a period of extrinsic incubation" *(1)*.

Yellow fever is historically the most prominent among the diseases in this group. In recent years, a number of other arboviruses have emerged as important public health problems in both tropical and temperate zones. The number of arboviruses known in India had risen from two (dengue and sandfly fever) in 1951 to over 40 in 1975 *(2)*.

CLASSIFICATION

The huge family of heterogeneous arboviruses is divided into no less than 7 major groups, and 18 smaller groups *(3)*. Many remain unclassified. The current trend is to name the viruses after the places where they were discovered. Some of the arboviruses known to be prevalent in India are as shown in Table 1.

TABLE 1

Some Arboviruses known to be prevalent in India

Group A	**OTHERS**
(Alphaviruses)	*Umbre*
Sindbis	Sathuperi
Chikungunya	Chandipura
	Chittor
	Ganjam
Group B	Minnal
(Flaviviruses)	Venkatapuram
Dengue	Dhori
KFD	Kaisodi
JE	Sandfly fever
West Nile	African Horse sickness
	Vellore

CLINICAL SYNDROMES

Although arboviruses are many, only a small number of them are known to be capable of infecting man, and a much smaller number capable of producing disease. A high proportion of the infections is inapparent. For convenience, three clinical syndromes have been described : (a) FEBRILE GROUP : This is the most common group which comprises a large number of relatively undifferentiated fevers, generally benign with or without rashes and joint pains. Viruses responsible for this group of illness in India are the sindbis, chikungunya and dengue viruses. (b) HAEMORRHAGIC FEVERS : The second group is that of haemorrhagic fevers, generally associated with moderate or high mortality. Viruses responsible for haemorrhagic fevers in India are the dengue, chikungunya and KFD viruses. (c) ENCEPHALITIDIS : The third group is that of encephalitidis or meningoencephalitis which is associated with a considerable and sometimes high mortality. The disease reported now frequently in some parts of India is the Japanese encephalitis.

1. The dengue syndrome

This is detailed separately at page 246.

2. Japanese encephalitis

Japanese encephalitis (JE) is a mosquito–borne encephalitis caused by a group B arbovirus (Flavivirus) and transmitted by culicine mosquitoes. It is a zoonotic disease, i.e., infecting mainly animals and incidentally man. The envelope glycoprotein of the JE virus contains specific as well as cross-reactive, neutralizing epitopes. The major genotypes of this virus have different geographical distribution, but all belong to the same serotype and are similar in terms of virulence and host preference. Following an infectious mosquito bite, the initial viral replication occurs in local and regional lymph nodes. Viral invasion of the central nervous system occurs probably *via* blood.

JE is the leading cause of viral encephalitis in Asia and occurs in almost 24 Asian and Western Pacific countries. Largely as a result of immunization, its incidence has been declining in Japan, the Korean peninsula and in some regions of China, but the disease is increasingly reported from Bangladesh, India, Nepal, Pakistan, northern Thailand and Vietnam. Transmission occurs principally in rural agricultural location where flooding irrigation is practised. Transmission is seasonal and mainly related to the rainy season in South-East Asia Region *(2)*.

The annual incidence of clinical disease varies both across and within countries, ranging from < 10 to > 100 per 100,000 population. A recent estimate puts nearly 68,000 clinical cases of JE globally each year, with upto 20,400 deaths due to JE *(3)*. The vast majority of cases occur among children less than 15 years of age. Nearly 10 per cent of cases are among those above 60 years, perhaps reflecting waning protective immunity.

The disease is rare in other parts of the world, and when seen, is generally associated with travellers returning from endemic areas *(3)*.

Major outbreaks of JE occur every 2–15 years. JE transmission intensifies during the rainy season, when vector population increases. However, there has not yet been any evidence of increased JE transmission following major floods. The spread of JE in new areas has been correlated with agricultural development supported by irrigation programmes *(3)*.

PROBLEM IN INDIA

Recognition of JE, based on serological surveys, was first made in 1955 in Tamil Nadu. JE has been reported from different parts of the country. The disease is endemic in 18 states. Assam, Bihar, Haryana, Uttar Pradesh, Karnataka, West Bengal and Tamil Nadu report out-breaks every year and contribute about 80 per cent of cases and deaths. In India about 375 million population is at risk. During 2012, about 8,344 cases with 1,258 deaths, and during 2013, 7,825 cases and 1,273 deaths were reported *(4)*. The state-wise reported cases of acute encephalitis syndrome (AES) are as shown in Table 2. Fig. 1 shows the JE endemic areas in the country.

TABLE 2

State-wise reported cases and deaths due to AES in India 2011–2013

State	2011		2012		2013	
	Cases	Deaths	Cases	Deaths	Cases	Deaths
Assam	1,319	250	1,343	299	1,388	272

Epidemiological features

Unlike the dengue viruses, JE virus infects several extrahuman hosts, e.g., animals and birds. Available evidence indicates that the basic cycles of transmission are :

(a) Pig → Mosquito → Pig

(b) The Ardeid bird → Mosquito → Ardeid bird

The disease is transmitted to man by the bite of infected mosquitoes. Man is an incidental "dead–end" host. Man to man transmission has not so far been recorded.

(a) Animal hosts : Among the animal hosts, pigs have been incriminated as the major vertebrate hosts for JE virus. In some places, upto 100 per cent of pigs may be infected with JE virus. Infected pigs do not manifest any overt symptoms of illness but circulate the virus so that mosquitoes get infected and can transmit the virus to man. The pigs are thus considered as "amplifiers" of the virus *(7)*. Cattle and buffaloes may also be infected with the JE virus; although they may not be natural hosts of JE virus, they act as "mosquito attractants." Horses are the only domestic animals so far known which show signs of encephalitis due to JE virus infection. *(b) Birds :* Some species of birds such as pond herons; cattle egrets and perhaps poultry and ducks appear to be involved in the natural history of JE virus *(7)*.

MOSQUITO VECTORS

Culicine mosquitoes, notably *C.tritaeniorhynchus, C. vishnui* and *C. gelidus* along with some anophelines have been incriminated as the vectors of JE. Among these, *C.tritaeniorhynchus* and *vishnui* has been implicated as the most important vector in South India *(8)*. These mosquitoes generally breed in irrigated rice fields, shallow ditches and pools. The rice fields are probably the most important breeding places. These mosquitoes are zoophilic, feeding primarily on vertebrate hosts. Female mosquitoes get infected after feeding on a viraemic host, and after 9–12 days incubation period, they can transmit the virus to other hosts.

JE IN MAN

The incubation period in man, following mosquito bite is not exactly known. Probably, it varies from 5–15 days. Not all individuals bitten by infected mosquitoes develop disease. The ratio of overt disease to inapparent infection is about 1:250. Thus cases of encephalitis represent only the tip of the iceberg compared to the large number of inapparent infections. Encephalitis cases due to JE may show a scattered distribution.

The course of the disease in man may be divided into three stages : *(a) PRODROMAL STAGE :* The onset of illness is usually acute and is heralded by fever, headache, gastrointestinal disturbances, lethargy and malaise. The duration of this stage is usually 1–6 days. *(b) ACUTE ENCEPHALITIC STAGE :* Fever is usually high, 38 to 40.7 deg. C. The prominent features are fever, nuchal rigidity, focal CNS signs, convulsions signs of raised intra-cranial pressure, difficulty of speech, dystonia, ocular palsies, hemiplegia, quadriplegia, extra-pyramidal signs like coarse tremors and altered sensorium progressing in many cases to coma. *(c) LATE STAGE AND SEQUELAE :* This stage begins when active inflammation is at an end, i.e., the temperature and ESR touch normal. Neurological signs become stationary or tend to improve. Convalescence may be prolonged and residual neurological deficits may not be uncommon *(3)*. The case fatality rate varies between 20–40 per cent. The average period between the onset of illness and death is about 9 days *(3)*.

Confirmation of a suspected case of JE requires laboratory diagnosis. The aetiological diagnosis of JE is mainly based on serology using IgM-capture ELISA which detects specific IgM in the cerebrospinal fluid or in the blood of almost all patients within 7 days of onset of disease. Other methods include conventional antibody assays on paired sera for the demonstration of a significant rise in total JE-specific antibody, as well as a dot-blot IgM assay, suitable for use in the field. The virus is rarely recovered in tissue culture from blood or CSF, but may be found in encephalitic brain at autopsy. JE-viral RNA is rarely demonstrated in the CSF *(9)*.

Control of JE

(a) VACCINATION : Vaccination of population at risk has been recommended. Currently, the three types of JE vaccines in large-scale use are : (i) the mouse brain-derived, purified and inactivated vaccine, which is based on either the Nakayama or Beijing strains of the JE virus and produced in several Asian countries; (ii) the cell culture-derived, inactivated JE vaccine based on the Beijing P-3 strain, and (iii) the cell culture-derived, live attenuated vaccine based on the SA 14-14-2 strain of the JE virus. The mouse-brain derived, inactivated vaccine has been used successfully to reduce the incidence of JE in a number of countries, and is likely to be used nationally and internationally for some more years. Drawbacks of the mouse-brain vaccine are the limited duration of the induced protection, the need for multiple doses, and, in most countries, the relatively high price per dose. The cell culture-derived vaccines are manufactured and widely used in China, where the inactivatd vaccine is gradually being replaced by the live attenuated vaccine. Several other promising JE vaccine candidates are in advanced stages of development.

The immunization schedules of the 3 licensed JE vaccines that are currenly in large-scale use vary with the profile of the respective vaccines and depend on local epidemiological circumstances and recommended schedules of other childhood vaccines. When immunizing children 1–3 years of age the mouse brain-derived vaccine provides adequate protection throughout childhood following 2 primary doses 4 weeks apart, and boosters after 1 year and subsequently at 3-yearly intervals until the age of 10–15 years. The vaccine is given subcutaneously in doses of 0.5 ml for children under 3 years and one ml for children more than 3 years of age. Protective immunity develops in about one month time after the second dose. The vaccine is best used in the inter-epidemic period. It should be offered to the most vulnerable and high-risk groups *(7, 8)*. Equally good childhood protection is obtained by a single dose of the cell-culture based, live attenuated vaccine (SA-14-14-2) followed by a single booster given at an interval of about 1 year. This vaccine is available in India and is an integral part of Universal Immunization Programme in 83 endemic districts in Uttar Pradesh, Assam, West Bengal and Karnataka targeting children in age group 1–15 years *(5)*. The importance of achieving long-term protection is underlined by the observation that in some areas an increasing proportion of the JE cases occur in individuals older than 10 years of age *(9)*.

Given the most infrequent occurrence of JE in infancy and the likely interference with passively acquired maternal antibodies during the first months of life, vaccination is not recommended for children before the age of 6 months *(9)*.

For travellers aged more than one year, visiting rural areas of endemic countries for at least 2 weeks, the established current practice is to administer 3 primary doses at days 0, 7 and 28; alternatively 2 primary doses preferably 4 weeks apart. When continued protection is required, boosters should be given after one year and then every 3 years *(9, 10)*.

The vaccination of swine is extremely important for both public health and economic reasons. It prevents viraemia in these animals, and hence eliminates their role as amplifiers of the virus. An inactivated vaccine and more recent modified live virus vaccines are all in current use. However, it is difficult to maintain vaccination coverage in the swine of a given region because the population is renewed so rapidly *(11)*.

(b) VECTOR CONTROL : The vector mosquito(es) of JE are widely scattered and not easily amenable to control. An effective way to deal with them is to resort to aerial or ground fogging with ultra–low–volume (ULV) insecticides (e.g., malathion, fenitrothion). All the villages reporting cases should be brought under indoor residual spray. The spraying should cover the vegetation around the houses, breeding sites and animal shelters in the affected villages. Uninfected villages falling within 2 to 3 km radius of the infected villages should also receive spraying as a preventive measure. Villages within the proximity of infected villages should be kept under surveillance. The use of mosquito nets should be advocated.

GUIDELINES FOR MANAGEMENT OF AES INCLUDING JAPANESE ENCEPHALITIS IN INDIA (2009) *(12)*

Following an outbreak of JE in Gorakhpur and Basti divisions in eastern Uttar Pradesh during 2005, Directorate of NVBDCP developed surveillance guidelines for endemic states and advised that all the JE cases be reported under Acute Encephalitis Syndrome (AES) as they have common

similar clinical manifestations. Their case management usually follows a common protocol along with situation specific treatment. Diagnosis of JE will depend on laboratory investigations. The case definitions and case classification in the programme are as follows *(12)* :

Case definition of suspected case

- Acute onset of fever, not more than 5–7 days duration.
- Change in mental status with/without
  - New onset of seizures (excluding febrile seizures)
  - Other early clinical findings – may include irritability, somnolence or abnormal behaviour greater than that seen with usual febrile illness.

Case classification

Laboratory-confirmed case

A suspected case with any one of the following markers:

- Presence of IgM antibody in serum and/or CSF to a specific virus including JE/Enterovirus or others
- Four fold difference in IgG antibody titre in paired sera
- Virus isolation from brain tissue
- Antigen detection by immunofluroscence
- Nucleic acid detection by PCR

In the sentinel surveillance network, AES/JE is to be diagnosed by IgM Capture ELISA, and virus isolation to be done in National Reference Laboratory.

Probable cases

Suspected case in close geographic and temporal relationship to a laboratory-confirmed case of AES/JE in an outbreak.

Acute Encephalitis Syndrome (AES) due to other agent

A suspected case in which diagnostic testing is performed and an aetiological agent other than AES/JE is identified.

Acute Encephalitis Syndrome (AES) due to unknown agent

A suspected case in which no diagnostic testing is performed/no aetiological agent is identified/test results are indeterminate.

While the above classifications are useful for clearer definitions of AES cases, for practical purposes, the two key definitions to be used are "suspected JE cases" for those that meet the criteria for AES, and "confirmed JE cases" for those AES cases which have laboratory confirmation for JE. In an epidemic situation fever with altered sensorium persisting for more than two hours with a focal seizure or paralysis of any part of body, is encephalitis. Presence of rash on body excludes Japanese Encephalitis. AES with symmetrical signs and fever is likely to be cerebral Malaria.

The causes of AES are shown in Fig. 2.

Management of Acute Encephalitis Syndrome, including Japanese Encephalitis, is essentially symptomatic. To reduce severe morbidity and mortality, it is important to identify early warning signs and refer patients to health facility and to educate the health workers about the first line of treatment for management of the case at the grassroot level.

Fig. 3 summarizes the guidelines for management of a case of AES at PHC and FRU level and management of circulation as blood pressure should be maintained at about 95th centile for the age of the patient with the help of dopamine drip. Failure of autoregulation of the brain makes the cerebral circulation depend solely on systemic blood pressure. Avoid fluid overload. The ultimate decision regarding the management depends upon the attending physician.

Treatment of specific cause

If laboratory investigation shows a non–JE cause, like herpes zoster, varicella, malaria, pyogenic meningitis, tubercular meningitis, toxoplasmosis, amoebiasis, fungal infection or neurocysticercosis; the patient should be given specific treatment for that particular disease.

3. Kyasanur forest disease

Kyasanur forest disease (KFD) is a febrile disease associated with haemorrhages caused by an arbovirus flavivirus and transmitted to man by bite of infective ticks.

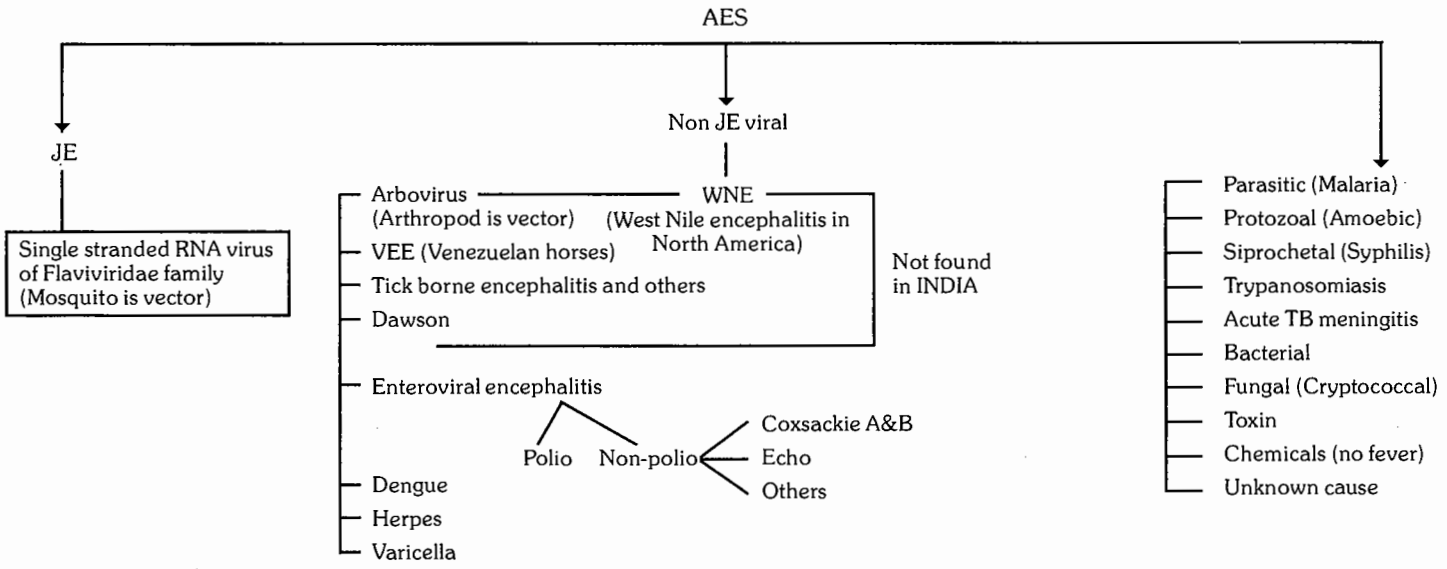

FIG. 2

Causes of Acute Encephalitis Syndrome

Source : *(12)*

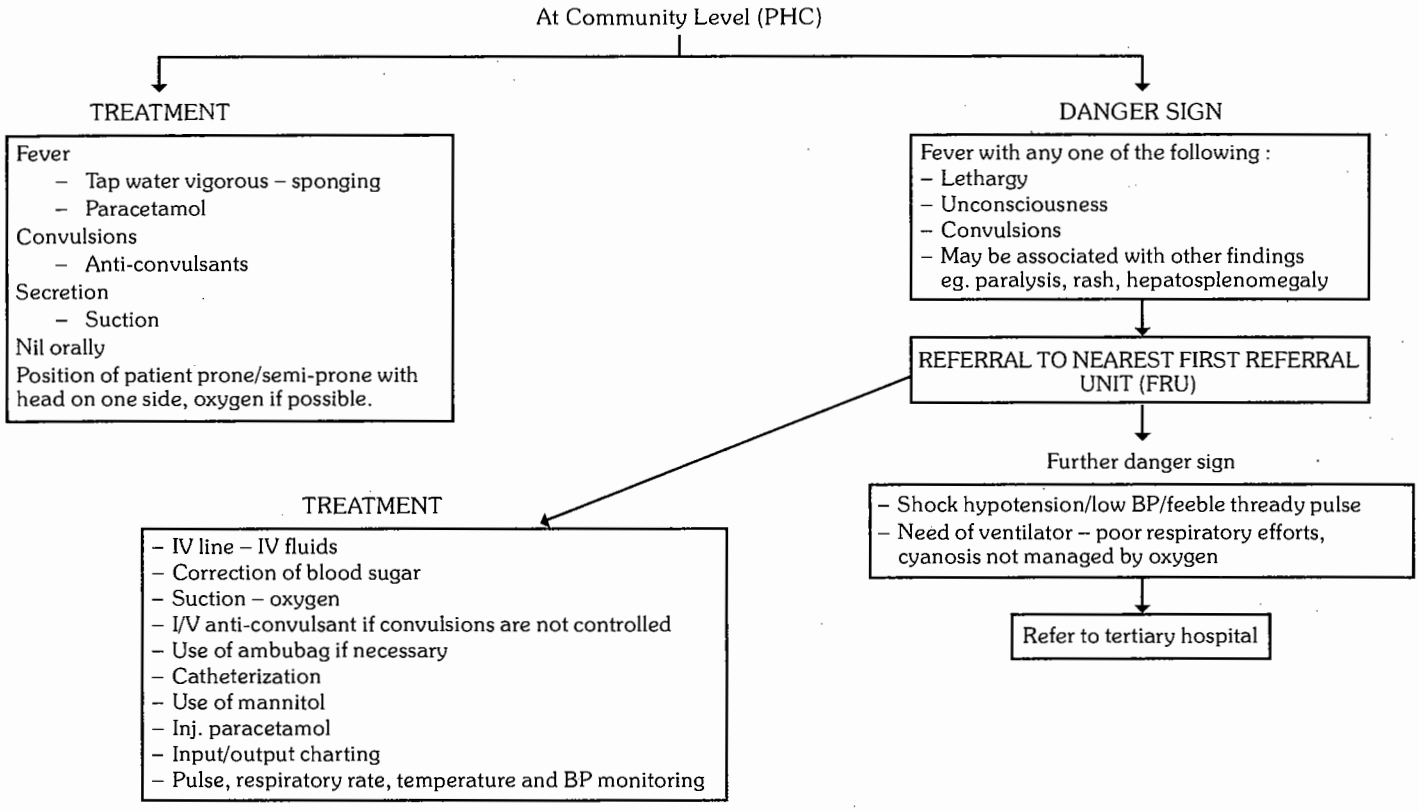

FIG. 3

Management of AES including Japanese Encephalitis

Source : *(12)*

HISTORY

KFD was first recognized in 1957 in Shimoga district of Karnataka State in South India. Local inhabitants called the disease "monkey disease" because of its association with dead monkeys. The disease was later named after the locality – Kyasanur Forest – from where the virus was first isolated.

PROBLEM STATEMENT

Earlier the disease was found to be limited mainly to an area around the original focus (Shimoga district) covering about 800 sq.km. Newer foci have since been recognized. The disease is now restricted to four districts (Shimoga, North Kannada, South Kannada and Chikamagaloor) in Karnataka State in India covering over 6,000 sq.km. *(13)*. Serological surveys in different parts of India revealed antibodies to KFD or a closely related virus in human and animals, particularly in cattle in Kutch and Saurashtra *(14)*.

According to the reports, the disease continues to be active in its endemic foci. The outbreak during 1983–1984 seems to be the largest with 2,167 cases and 69 deaths, as against 571 cases and 15 deaths during 1981. The Karnataka Government has established a surveillance system which monitors the occurrence of KFD in humans and mortality in monkeys in known epidemic areas, as well as neighbouring areas. Deaths of monkeys are considered as heralders of this disease in endemic areas *(15)*.

Epidemiological determinants

(a) AGENT

The agent KFD virus is a member of group B togaviruses (flaviviruses). It is antigenically related to other tick-borne flaviviruses, particularly the Far Eastern tick-borne encephalitis and Omsk haemorrhagic fever. Unlike in many other arbovirus infections, KFD has a prolonged viraemia in man for about 10 days or more.

(b) NATURAL HOSTS AND RESERVOIRS

Small mammals particularly rats and squirrels are the main reservoirs of the virus *(13)*. Birds and bats are less important hosts. The monkeys are recognized as amplifying hosts for the virus. However, they are not effective maintenance hosts because most of them die from KFD infection. Cattle provide *Haemaphysalis* ticks with a plentiful source of blood meals, which in turn leads to a population explosion among the ticks. Thus cattle are very important in maintaining tick populations but play no part in virus maintenance *(13)*. Man is an incidental or dead-end host, and plays no part in virus transmission.

(c) VECTORS

The virus has a complex life cycle involving a wide variety of tick–species. At least 15 species of hard ticks of the genus *Haemaphysalis,* particularly *H. spinigera* and *H. turtura* are known to transmit the disease. KFD has also been isolated from soft ticks *(16)*. The highest number of human and monkey infections occur during drier months, particularly from January to June. This period coincides with the peak nymphal activity of ticks.

(d) HOST FACTORS

(i) Age : Majority of cases affected were between 20 and

40 years. *(ii) Sex :* Attack rate was greater in males than in females. *(iii) Occupation :* The attacked people were mostly cultivators who visited forests accompanying their cattle or cutting woods and *(iv) Human activity :* The epidemic period correlates well with the period of greatest human activity in the forest, i.e., from January until the onset of rains in June.

(e) MODE OF TRANSMISSION

The transmission cycle involves mainly monkeys and ticks. The disease is transmitted by the bite of infective ticks, especially nymphal stages. There is no evidence of man to man transmission.

(f) INCUBATION PERIOD

Estimated to be between 3 and 8 days.

CLINICAL FEATURES

The disease appears with a sudden onset of fever, headache and severe myalgia, with prostration in some patients. The acute phase lasts for about 2 weeks. Gastrointestinal disturbances and haemorrhages from nose, gums, stomach and intestine may occur in severe cases.

In a number of cases, there is a second phase characterized by mild meningoencephalitis after an afebrile period of 7 to 21 days. It is manifested by a return of fever, severe headache followed by neck stiffness, coarse tremors, abnormal reflexes and mental disturbances. The case fatality rate has been estimated to be 5 to 10 per cent *(13)*.

Diagnosis is established only after detecting the presence of the virus in the blood and/or serological evidence.

CONTROL

(a) CONTROL OF TICKS : Since KFD is a tick–borne disease, control of ticks should be undertaken. For control of ticks in forests, application can be made by power equipment or by aircraft–mounted equipment to dispense carbaryl, fenthion, naled or propoxur at 2.24 kg of active ingredient per hectare *(17)*. The spraying must be carried out in "hot spots", i.e., in areas where monkey deaths have been reported, within 50 metres around the spot of the monkey deaths, besides the endemic foci. Since the heavy tick population in the forest areas is attributed partly to the free roaming cattle, restriction of cattle movement is thought to bring about a reduction in vector population. (b) VACCINATION : The population at risk should be immunized with killed KFD vaccine. (c) PERSONAL PROTECTION : Protection of individuals exposed to the risk of infection by adequate clothing and insect repellents such as dimethylphthalate (DMP, DEET) should be encouraged. They should examine their bodies at the end of each day for ticks and remove them promptly. The habit of sitting or lying down on the ground should be discouraged through health education.

4. Chikungunya fever

A dengue-like disease caused by a group A virus, the chikungunya virus and transmitted by *Aedes* mosquitoes. It is manifested by high fever and severe articular pains in the limbs and spinal column. The virus was first isolated from patients and mosquitoes during an epidemic in Tanzania in 1952–53. Chikungunya is a local word meaning "doubling up" owing to excruciating joint pains. The virus occurs widely in sub-Saharan Africa, India and in many areas in Asia.

During 2006, there was a large outbreak of chikungunya in India, with 1.39 million officially reported cases spread over 16 states; attack rates were estimated at 45 per cent in some areas *(21)*. The outbreak was first noticed in Andhra Pradesh and it subsequently spread to Tamil Nadu. Thereafter, Kerala and Karnataka were affected and then northwards as far as Delhi. The other states involved were Maharashtra, Madhya Pradesh, Gujarat, Rajasthan, Pondicherry, Goa, Orissa, West Bengal, Uttar Pradesh, Andaman and Nicobar Islands. During 2013, 18,639 cases were reported by the Government of India *(4)*.

The incubation period of chikungunya fever is 4–7 days, following which the disease has a sudden onset with fever, chills, cephalalgia, anorexia, lumbago and conjunctivitis. Adenopathy is also common. 60 to 80 per cent patients have a morbilliform rash, occasionally with purpura, on the trunk and limbs. The cutaneous eruption may recur every 3 to 7 days. Other symptoms are coffee-coloured vomiting, epistaxis and petechiae. A prominent symptom, seen especially in adult patients is arthropathy, from which the disease gets its name. The arthropathy is manifested by pain, swelling and stiffness, especially of the metacarpophalangeal, wrist, elbow, shoulder, knee, ankle and metatarsal joints. It appears between 3rd and 5th day after the onset of clinical symptoms, and it can persist for many months and even years. No deaths have been attributed to chikungunya fever *(11)*.

There is no specific treatment of chikungunya infection and it is usually self limiting. Analgesics, antipyretics like paracetamol, diclofenac sodium, chloroquine along with fluid supplementation are recommended to manage infection and relieve fever, joint pains and swelling. Drugs like aspirin and steroids should be avoided.

The disease occurs in the rainy season, when the mosquito vector population is at its peak. Research suggests that the virus has a wild cycle, similar to that of yellow fever, operating between jungle primates and mosquitoes, including *Aedes africanus* and members of the *A. furcifer-taylori* group.

DIAGONSIS

The virus can be isolated from the blood of febrile patients by the intracerebral inoculation in suckling mice or on VERO cells.

In serologic diagnosis, which is the approach most commonly used, sero-conversion is demonstrated by comparing acute – and convalescent – phase sera in the haemagglutination inhibition, serum neutralization, or complement fixation test. The enzyme-linked immunosorbent assay (ELISA) is used to detect IgM. A reverse-transcription polymerase chain reaction (RT-PCR) / nested PCR technique has also been shown to be useful in rapidly diagnosing the disease *(11)*.

CONTROL

(a) VECTOR CONTROL : The *Aedes aegypti* mosquito should be the main target of control activities. It requires active community involvement to keep water storage containers free of mosquitoes and to eliminate the other breeding places of mosquitoes in and around houses and dwellings *(4)*. The organophosphorus insecticide, *Abate* is increasingly being used as a larvicide. It can prevent breeding for upto 3 months when applied on sand granules;

does not harm man and does not affect the taste of water. Antilarval measures can prevent an epidemic, but do not give immediate results when an epidemic has already broken out. In such cases, anti-adult measures alone can bring about a rapid interruption of transmission. Another technique consisting of aerosol spray of ultra low–volume (ULV) quantities of malathion or sumithion (250 ml/hectare) has been found to be effective in interrupting transmission and stopping epidemics of DHF. The tiny droplets kill the mosquitoes in the air as well as on water. By making 2 ULV treatments at about 10 days apart, the Aedes Research Unit in Bangkok was able to reduce adult mosquito densities by more than 98 per cent for several weeks *(19, 20).* *(b) VACCINE :* No vaccine has yet been developed that is considered suitable for use.

5. West nile fever

An acute febrile illness caused by a group B arbovirus. The disease is endemic in Africa, the Middle East, South–West Asia and India, and transmitted by certain species of Culex mosquitoes. Clinically, it is manifested by a sudden onset of fever, severe headache and malaise lasting several days. In children, a maculopapular rash of short duration may appear. In the aged, a fatal meningo-encephalitis may be produced.

6. Sandfly fever

Sandfly fever is known to occur in the arid regions of West Pakistan and Middle East. Its occurrence in India was thought to be doubtful. However, in 1967, the sandfly fever virus was isolated in Aurangabad (Maharashtra) from febrile cases. The virus was also isolated from sandflies *(21).* The control of sandfly fever is based on the control of insect vector.

BRUCELLOSIS

Brucellosis is one of the major bacterial zoonoses, and in humans is also known as Undulent fever, Malta fever or Mediterranean fever. It is occasionally transmitted to man by direct or indirect contact with infected animals. It is caused by different species of the brucella group of organisms and characterized by intermittent or irregular febrile attacks, with profuse sweating, arthritis and an enlarged spleen. The disease may last for several days, months or occasionally years. Brucellosis is both a severe human disease and a disease of animals with serious economic consequences.

Problem statement

Brucellosis is a recognized public health problem with worldwide distribution. It is endemic wherever cattle, pigs, goats and sheep are raised in large numbers. Important endemic areas for brucellosis exist in Mediterranean zones, Europe, Central Asia, Mexico and South America. Eastern Mediterranean countries have experienced an increase in the number of cases. The disease is now rare in most European countries, North America and Australia *(1).*

Animal brucellosis is reported from practically every State in India. However, no statistical information is available about extent of infection in man in various parts of the country *(2).*

The prevalence of human brucellosis is difficult to estimate. Many cases remain undiagnosed either because they are inapparent or because physicians in many countries are unfamiliar with the disease.

Epidemiological determinants

Agent factors

(a) AGENT : The agents are small, gram-negative rod-shaped, non-motile, non-sporing and intracellular coccobacilli of the genus *Brucella.* Four species infect man : *B.melitensis, B.abortus, B.suis,* and *B.canis. B.melitensis* is the most virulent and invasive species; it usually infects goats and occasionally sheep. *B.abortus* is less virulent and is primarily a disease of cattle. *B.suis* is of intermediate virulence and chiefly infects pigs. *B.canis* is a parasite of dogs. (b) RESERVOIR OF INFECTION : Main reservoirs of human infection are cattle, sheep, goats, swine, buffaloes, horses and dogs. In animals the disease can cause abortion, premature expulsion of the foetus or death. Cross infections can often occur between animal species. The infected animals excrete Brucella in the urine, milk, placenta, uterine and vaginal discharges particularly during a birth or abortion. The animals may remain infected for life.

Host factors

Human brucellosis is predominantly a disease of adult males. Farmers, shepherds, butchers, and abattoir workers, veterinarians and laboratory workers are particularly at special risk because of occupational exposure. Immunity follows infection.

Environmental factors

Brucellosis is most prevalent under conditions of advanced domestication of animals in the absence of correspondingly advanced standards of hygiene. Overcrowding of herds, high rainfall, lack of exposure to sunlight, unhygienic practices in milk and meat production, all favour the spread of brucellosis. The infection can travel

long distances in milk and dust. The environment of a cowshed may be heavily infected. The organism can survive for weeks, or months in favourable conditions of water, urine, faeces, damp soil and manure.

Mode of transmission

Transmission is usually from infected animals to man. There is no evidence of transmission from man to man *(3)*. The routes of spread are :

(a) Contact infection : Most commonly, infection occurs by direct contact with infected tissues, blood, urine, vaginal discharge, aborted foetuses and especially placenta. Infection takes place through abraded skin, mucosa or conjunctiva (mucocutaneous route). This type of spread is largely occupational and occurs in persons involved in handling livestock and slaughter house workers.

(b) Food-borne infection : Infection may take place indirectly by the ingestion of raw milk or dairy products (cheese) from infected animals. Fresh raw vegetables can also carry infection if grown on soil containing manure from infected farms. Water contaminated with the excreta of infected animals may also serve as a source of infection.

(c) Air-borne infection : The environment of a cowshed may be heavily infected. Few people living in such an environment can escape inhalation of infected dust or aerosols. Brucellae may be inhaled in aerosol form in slaughter houses and laboratories, so these infections are notified as occupational.

Incubation period

Highly variable. Usually 1–3 weeks, but may be as long as 6 months or more.

Pattern of disease

Brucella infection in man can vary from an acute febrile disease to a chronic low–grade ill–defined disease, lasting for several days, months or occasionally years.

The acute phase is characterized by a sudden or insidious onset of illness with (i) swinging pyrexia (upto 40–41 deg C), rigors and sweating. (ii) arthralgia/arthritis (usually monoarticular) involving larger joints such as hip, knee, shoulder and ankle. (iii) low back pain. (iv) headache, insomnia. (v) small firm splenomegaly and hepatomegaly. (vi) leucopenia with relative lymphocytosis *(4)*. The most striking aspect of the clinical picture is the severity of the illness and the absence of clinical signs. The acute phase subsides within 2–3 weeks. If the patient is treated with tetracycline, the symptoms may disappear quickly, but the infection, being intracellular, may persist giving rise to subacute or relapsing disease.

In a few patients (upto 20 per cent), symptoms recur for prolonged periods. Diagnosis is established by isolation of the organism from cultures of blood, bone marrow, exudates and biopsy specimens during the acute phase of the disease; and by serological tests.

Control of brucellosis

(a) IN THE ANIMALS

The most rational approach for preventing human brucellosis is the control and eradication of the infection from animal reservoirs which is based on the combination of the following measures : *(a) Test and slaughter :* Case finding is done by mass surveys. Skin tests are available. The complement fixation test is also recommended. Those animals infected with brucellosis are slaughtered, with full compensation paid to farmers. This is the only satisfactory solution aimed at eradication of the disease. *(b) Vaccination :* Vaccine of *B. abortus* strain 19 is commonly used for young animals. A compulsory vaccination programme for all heifers in a given community on a yearly basis can considerably reduce the rate of infection. Systematic vaccination for a period of 7 to 10 years may result in the elimination of the disease. Control of the infection caused by *B. melitensis* in goats and sheep has to be based mainly on vaccination *(5)*. *(c) Hygienic measures :* These comprise provision of a clean sanitary environment for animals, sanitary disposal of urine and faeces, veterinary care of animals and health education of all those who are occupationally involved.

(b) IN THE HUMANS

(a) Early diagnosis and treatment : In uncomplicated cases the antibiotic of choice is tetracycline. For adults in the acute stage, the dose is 500 mg every 6 hours for about 3 weeks. In patients with skeletal or other complications, intramuscular streptomycin 1 g daily in addition to tetracycline usually achieves a cure. *(b) Pasteurization of milk :* This is a useful preventive measure which will render milk and milk products safe for consumption. Boiling of milk is effective when pasteurization is not possible. *(c) Protective measures :* The aim is to prevent direct contact with infected animals. Persons at risk such as farmers, shepherds, milkmen, abattoir workers should observe high standards of personal hygiene. They should exercise care in handling and disposal of placenta, discharges and foetuses from an aborted animal. They should wear protective clothing when handling carcasses. Exposed areas of the skin should be washed and soiled clothing renewed. *(d) Vaccination :* Human live vaccine of *B. abortus strain* 19–BA is available *(5)*.

Brucellosis would disappear if it were eradicated from animals. The national and international centre for brucellosis is located at FAO/WHO Brucella Reference Centre, Indian Veterinary Research Institute, Izatnagar, (Uttar Pradesh).

LEPTOSPIROSIS

Leptospirosis is essentially animal infection by several serotypes of *Leptospira* (Spirocheates) and transmitted to man under certain environmental conditions. The disease manifestations are many and varied, ranging in severity from a mild febrile illness to severe, and sometimes fatal disease with liver and kidney involvement. Weils disease is one of the many manifestations of human leptospirosis.

Problem statement

Leptospirosis is considered to be the most widespread of the disease transmissible from animal to man *(1)*. It has high prevalence in warm humid tropical countries. Out breaks mostly occur as a result of heavy rainfall and consequent floodings *(3)*. Although the global burden of disease is

unknown, ≥ 500,000 cases of leptospirosis are estimated to occur worldwide each year. The incidence in some areas may be as high as 975 cases per lac population. During the past decade, the occurrence of outbreak has highlighted the strong links between leptospirosis and extreme weather events in Guyana, India, Philippines and Thailand etc *(4)*.

Epidemiological determinants

Agent factors

(a) AGENT : Leptospira are thin and light motile spirocheates 0.1–0.2 μm wide and 5–15 μm long with hooked ends. Only the strains of *L. interrogans* are pathogenic. The organisms are visible by dark–field illumination and silver staining. At present, 23 sero-groups and 200 serovars have been recognized from various parts of the world. They are serologically related with cross reactivity. (b) SOURCE OF INFECTION : Leptospira are excreted in the urine of infected animals for a long time, often for an entire life time in cases of rodents. (c) ANIMAL RESERVOIRS : Leptospirosis affects wild and domestic animals worldwide especially rodents such as rats, mice and voles. Most domestic animals including cattle, sheep, goats, water buffalo, pigs and horses may be infected through grazing in areas contaminated by the urine of the carrier host. Pet animals, particularly dogs may also be infected. Infection may spread from wild animals to domestic livestock, and thence to humans. Rats and small rodents – particularly *R. norvegicus* and *Mus musculus* are the most important reservoirs.

Host factors

(a) AGE : Children acquire the infection from dogs more frequently than do adults. Human infection is only accidental. (b) OCCUPATION : Human infections are usually due to occupational exposure to the urine of infected animals, e.g, agricultural and livestock farmers, workers in rice fields, sugarcane fields, and underground sewers, abattoir workers, meat and animal handlers, veterinarians etc. *(2)*. Leisure time activities such as swimming and fishing may also carry risks. (c) IMMUNITY : A solid serovar specific immunity follows infection.

Environmental factors

Leptospirosis infection is unique in that it is acquired through contact with an environment contaminated by urine and faeces from carrier (reservoir) animal or other infected animals. Leptospira shed in the urine can survive for weeks in soil and water, so environmental contamination may reach high levels in areas where carrier animals frequently urinate *(5)*. The association of poor housing, limited water supply, inadequate method of waste disposal, all combine to make the disease a significant risk for the poor population in both urban and rural areas.

Mode of transmission

(a) DIRECT CONTACT : Leptospira can enter the body through skin abrasions or through intact mucous membrane by direct contact with urine or tissue of infected animal. (b) INDIRECT CONTACT : Through the contact of the broken skin with soil, water or vegetation contaminated by urine of infected animals or through ingestion of food or water contaminated with leptospirae. (c) DROPLET INFECTION : Infection may also occur through inhalation as when milking infected cows or goats by breathing air polluted with droplets of urine *(6)*.

Direct man to man infection is rare.

Incubation period

Usually 10 days with a range of 4 to 20 days.

Diagnosis

It is not possible to diagnose leptospirosis with certainty on clinical grounds alone. Because of the wide spectrum of signs and symptoms, the diagnosis is made by isolation of leptospires from blood during the acute illness and from urine after the first week *(6)*. Early in the disease, the organism may be identified by dark–field examination of the patient's blood or by culture on a semisolid medium. Culture takes 1–6 weeks to become positive. The organism may also be grown from the urine from 10th day to 6 weeks. Diagnosis is usually made by means of serological tests, of which several are available. Agglutination tests (microscopic using live organism, and macroscopic using killed antigen) become positive after 7–10 days of illness and peak at 3–4 weeks and may persist at high level for many years. Indirect haemagglutination, immunoflourescent antibody and ELISA tests are also available. The IgM ELISA is particularly useful in making an early diagnosis, as it is positive as early as 2 days into illness *(7)*. Now Leptodipstick test is also available.

Control

(a) ANTIBIOTICS : Penicillin is the drug of choice but other antibiotics (tetracycline or doxycycline) are also effective. The dosage of penicillin is 6 million units daily intravenously.

(b) ENVIRONMENTAL MEASURES : This includes preventing exposure to potentially contaminated water, reducing contamination by rodent control and protection of workers in hazardous occupation. Measures should be taken to control rodents, proper disposal of wastes and health education etc.

Vaccination

Immunization of farmers and pets prevent disease. In some countries for instance Italy, USSR and China, where certain occupations carry a high risk of infection, vaccines are available. It is important that they should incorporate strains of the serotypes that predominate in the particular area since immunity to one type of *Leptospira* may not protect against infection by another *(6)*.

PLAGUE

Plague is primarily and basically a zoonoses, caused by *Y. pestis*, involving rodents and fleas. It exists in natural foci, and is transmitted by infected flea bites to humans living or intruding into the same ecological environment. Plague occurs in many forms – enzootically, epizootically, sporadically and in epidemics of all types including anthroponotic and primary pneumonic forms. Despite the

enormous body of knowledge regarding plague, this communicable disease continues to pose a threat in many areas.

Problem statement

WORLD

Plague is often seen as a problem of the past or an ancient disease that is unlikely to reappear. But continued outbreaks throughout the world attest to its tenacious presence. Plague continues to be a threat because vast areas exist where wild rodents are infected, particularly in endemic countries in Africa, Asia and the Americas. Although plague is predominantly a rural disease, there have been outbreaks among urban populations in Madagascar and the United Republic of Tanzania. Plague is a major concern in countries where it remains endemic given its inherent communicability, its rapid clinical course and high mortality if left untreated.

The development of rapid diagnostic tests have contributed to better case-management and surveillane in Africa and other continents.

The data shows that from 2004 to 2009, a total of 12,503 cases of human plague, including 843 deaths, were reported by 16 countries in Africa, Asia and the Americas. The global case-fatality rate was 6.7 per cent. Africa reported maximum number of cases (12,209) including 814 deaths, accounting for 97.6 per cent of the total number of cases reported worldwide. Asia reported 149 cases, including 23 deaths (case fatality rate of 15.4 per cent) *(1)*.

In 2004, India reported a localized outbreak of bubonic plague (8 cases and 3 deaths) in the Dangud village, District of Uttarkashi.

Absence of human plague may simply mean that there has been reduced human contact with plague bacteria circulating in nature. Therefore, there is a need to continue to make concerted effort to strengthen surveillance and improve control measures in order to manage human plague in endemic countries.

Epidemiological determinants

Agent factors

(a) AGENT : The causative agent, *Y. pestis* is a gram-negative, non-motile, cocco-bacillus that exhibits bipolar staining with special stains (e.g., Wayson's stain). The bacilli occur in great abundance in the buboes, blood, spleen, liver and other viscera of infected persons, and in the sputum of cases of pneumonic plague. The virulence of the organism is related to its ability to produce exotoxin, endotoxin, fraction 1 and many other antigens and toxins. It has been shown that plague bacilli can survive, and indeed multiply in the soil of rodent burrows where micro-climate and other conditions are favourable *(2)*.

(b) RESERVOIR OF INFECTION : Wild rodents (e.g., field mice, gerbils, skunks and other small animals) are the natural reservoirs of plague. These are found in mountains, deserts, cultivated areas and forests in temperate and tropical regions. Over 200 species of these small animals may carry plague *(3)*. In any given focus, rodent reservoirs may vary.

In India, the wild rodent, *Tatera indica* has been incriminated as the main reservoir, not the domestic rat, *Rattus rattus*, as once thought. Generally the disease is maintained and spread by the resistant species of wild rodents, i.e., rodents which have become immune to plague. The susceptible rodents die of the disease.

(c) SOURCE OF INFECTION : Infected rodents and fleas and case of pneumonic plague.

Host factors

(a) AGE AND SEX : All ages and both sexes are susceptible. (b)HUMAN ACTIVITIES : Man may come into contact with natural foci in the course of hunting, grazing, cultivation, harvesting and construction activities or while engaging in outdoor recreation. These activities offer numerous opportunities to flea–man contact. Social upheavals like war may also account for outbreaks, as had happened in Vietnam. (c) MOVEMENT OF PEOPLE : Plague is associated with movement of people and cargo by sea or land. Rats and rat fleas are transported in this way. Further, in these days of jet travel, it is possible for a person to acquire the disease and become ill thousands of miles away where plague would be least suspected. (d) IMMUNITY : Man has no natural immunity. Immunity after recovery is relative.

Environmental factors

(a) SEASON : Outbreaks of plague are usually seasonal in nature. In northern India, the "plague season" starts from September until May. The disease tends to die out with the onset of hot weather. Researches indicated that the curious phenomenon of "plague season" depended primarily on the field rodent factors; from May onwards all species of rodents in the fields commenced aestivation, closing themselves in their burrows and living on stored food reserves. Then the epizootic ceased to advance and at the same time infection of village rats came to an end. When the field rodents again became active, that is mid-October, when the monsoon floods had dried up, the epizootic revived in the fields followed by human plague *(4)*. On the contrary, in south India, there was no definite plague season. The disease was found to be active all the year round. This is attributed partly to the topographic and climatic conditions in the south, favourable for the breeding of the field rodents. (b) TEMPERATURE AND HUMIDITY : A mean temperature of 20 to 25 deg. C, and a relative humidity of 60 per cent and above are considered favourable for the spread of plague. (c) RAINFALL : Heavy rainfall, especially in the flat fields tend to flood the rat burrows. This factor may be responsible for keeping certain states (e.g., Bengal) free from plague *(5)*. (d) URBAN AND RURAL AREAS: Plague had failed to gain a foothold in many towns of India perhaps due to untoward ecological conditions and lack of efficient flea vectors (as in Chennai and Assam) *(5)*. (e) HUMAN DWELLINGS: Rats, frequent dwelling houses and where housing conditions are poor, there may be an abundance of rats and rat fleas all the year round, and contact with man occurs readily.

Vectors of plague

The commonest and the most efficient vector of plague is the rat flea, *X. cheopis*, but other fleas may also transmit the infection, e.g., *X. astia, X. brasiliensis* and *Pulex irritans* (human flea). Both sexes of the flea bite and transmit the disease.

Blocked flea

A flea may ingest upto 0.5 cu.mm of blood which may contain as many as 5,000 plague bacilli. The bacilli multiply

enormously in the gut of the rat flea and may block the proventriculus so that no food can pass through. Such a flea is called a "blocked flea". A blocked flea eventually faces starvation and death because it is unable to obtain a blood meal. It makes frantic efforts to bite and suck blood over and over again; and in so doing, it inoculates (regurgitates) plague bacilli into the bite wound each time it bites. A blocked flea, therefore, becomes an efficient transmitter of plague. A partially blocked flea is more dangerous than a completely blocked flea because it can live longer. Infected fleas may live upto an year, and certain species survive in the burrow micro-climate for as long as 4 years *(2)*.

Flea indices

Flea indices are useful measurements of the density of fleas. They are also useful in evaluating the effectiveness of a spraying programme. The following flea indices are widely used in rat flea surveys : (a) TOTAL FLEA INDEX : It is the average number of fleas of all species per rat. (b) CHEOPIS INDEX : It is the average number of *X. cheopis* per rat. It is a specific flea index. It is a more significant index than the total flea index. If this index is more than 'one', it is regarded as indicative of potential explosiveness of the situation, should a plague outbreak occur *(6)*. (c) SPECIFIC PERCENTAGE OF FLEAS : It is the percentage of different species of fleas that are found on rats. (d) BURROW INDEX : It is the average number of free–living fleas per species per rodent burrow *(7)*.

Flea indices do not in themselves indicate an imminent plague epidemic. They serve as a warning that more stringent control measures are needed to protect the human population.

PLAGUE IN RODENTS

1. Rodents

Plague is primarily a disease of rodents in which man becomes accidentally involved. Approximately, 1,700 species of rodents are known, of which over 200 species are associated with plague. These are found in mountains, deserts, cultivated areas and forests throughout the world *(8)*.

Rodents may be classified into two distinct groups :

(a) WILD RODENTS : They are the reservoir of plague in nature. The common wild rodents in India are : *Tatera indica, Bandicota bengalensis varius, B. bengalensis kok (Gunomys kok), B. indica, Millardia meltada, M. gleadowi and Mus booduga.* In India, *tatera indica* has been incriminated as the main reservoir of plague, not the domestic rat (*R. rattus*) as once thought.

(b) COMMENSAL RODENTS : These are the rodents which live close to man. They may be further divided into domestic and peridomestic species. The domestic species include *Rattus rattus, Rattus norvegicus and Mus musculus.* The domestic species seldom live in fields. The peridomestic species live in both fields and houses; *R. norvegicus* which frequents sewers, drains as well as houses is a typical example of a peri-domestic species in India. Characteristics which are easily ascertainable of *Rattus rattus and R. norvegicus* are given elsewhere (see chapter 11).

2. Epizootiology

Plague is epizootic and enzootic in wild rodents. ***Two ecological cycles*** have been described :

a. WILD PLAGUE : Wild plague is defined as "plague existing in nature, independent of human populations and their activities" *(2)*. The disease spreads among wild rodents by wild rodent fleas. The epizootic wipes out the susceptible population. Those that survive (i.e., resistant species) maintain the enzootic in natural foci.

b. DOMESTIC PLAGUE : Is defined as "plague that is intimately associated with man and rodents living with him, and has a definite potential for producing epidemics *(2)*.

3. Natural foci

Worldwide, rodent plague is still firmly entrenched in its natural foci. A "natural focus" of plague has been defined as "a strictly delimited area where ecological conditions ensure the persistence of the aetiological agent for considerable periods of time, and where epizootics and periods of quiescence alternate, without introduction of infection from outside" *(2)*.

The long persistence of plague in some natural foci is not achieved through the usual simple chain of "Rat–flea–rat" transmission. Probably several other mechanisms are involved. They include : (a) latent infection in rodents, especially hibernating rodents, has been demonstrated; such animals may relapse and become bacteraemic, so initiating an epizootic. (b) development of resistance to plague infection by some rodents with subsequent localization of plague bacillus in some organ; such an animal may become a source of infection if eaten by another susceptible rodent. (c) survival of rat fleas for as long as 4 years in rat burrows under optimum micro-climatic conditions. This is considered the most likely mechanism of maintaining the natural focus. (d) variations in the pathogenecity of *Y. pestis,* and (e) survival and even multiplication of plague bacilli in the soil of rodent burrows. All these factors may combine to keep the infection alive in natural foci.

4. Epizootic process

The epizootic and enzootic process in each natural plague focus has its specific cyclic and periodical pattern. Researches into the epidemicity of plague indicated that the field rodents spread the infection very slowly from burrow to burrow, and from field to field taking months to cover several miles. In this process they infect the village rats (commensal rodents). The commensal rodents especially the peridomestic species (e.g., *R. norvegicus*) act as "Liaison rodents" between man and field rodents. An outbreak of human plague is always preceded by rodent plague. After the death of house rats, the fleas leave the dead rats and are forced to seek man for food. An unusual mortality among rodents should arouse suspicion of plague and should be investigated immediately.

5. Silent periods

Silences of long duration (10 years or more) followed by sudden explosive outbreaks of rodent or human plague have been repeatedly confirmed in some natural foci *(9)*. A number of explanations for this phenomenon have been put forward. It has been suggested that plague disappears completely for long periods and that it is reintroduced from other areas by infected rodents, fleas or migrating birds. On the other hand, the plague bacillus can survive and indeed multiply in the soil of rodent burrows, where micro-climatic conditions are suitable. It has been demonstrated that healthy rodents re-occupying and excavating such burrows may become infected through contact with contaminated soil *(2, 10)*.

6. Plague in rodents

Animal disease is similar to that in man. The disease is inapparent or mild in resistant species *(11)*.

7. Investigations

(1) COLLECTION AND FORWARDING OF DEAD RATS : Rodents (house or field) found dead regardless of its stage of decomposition should be carefully packed in several layers of packing paper or preferably in plastic bags. Such rodents should not be handled with naked hands. The neck of the bag should be tied to avoid escape of ectoparasites. The bag should then be placed in a wooden box or tin. The empty space left in the box or tin should be filled with absorbent cotton or sawdust to eliminate chances of leakage of effluents outside the box. The box is labelled giving details of collection and sent to the nearest laboratory. (2) AUTOPSY AND COLLECTION OF SMEARS : The rat is held with a pair of tongs, and dipped in a solution of 5 per cent cresol. The animal is laid on its dorsum, stretched and the limbs nailed on a wooden board. The abdomen is swabbed with lysol or spirit. The skin is lifted and cut up to the chest. The instruments used are then put back into boiling water. Using another set of instruments, small portions of the viscera (spleen, liver, lungs, bubo) are cut and the freshly cut surface is first blotted on a blotting paper so as to remove excess of blood or plasma. Then the same surface of the tissue is gently pressed on the glass slides so as to make thin impressions (never rub the tissue on the slides). If the rat is completely decomposed and no tissue is left, smears should be obtained from the bone marrow. The smears are dried, treated with alcohol for three minutes and fixed by exposure to open flame. The fixed smears may be sent for examination. Persons handling infected rats are exposed to the risk of pneumonic plague and this danger should be borne in mind. (3) ANIMAL INOCULATION : It may be difficult to isolate the plague bacilli by cultural methods owing to gross contamination of the carcass. In such cases, small portions of liver or spleen are taken, ground in a mortar with a little saline and inoculated into a guinea pig or a white mouse. If there is plague infection, the guinea pig will die in 7 days and the white mouse in 48 hours. (4) PATHOLOGICAL CHANGES : The pathological changes in an animal infected with plague are as follows: (a) there is oedema and necrosis at the site of injection, (b) the lymph nodes are enlarged, (c) the spleen is enlarged and congested, and shows necrotic patches, (d) liver shows mottling, (e) lungs also show necrotic lesions, and (f) there is subcutaneous congestion and haemorrhages.

HUMAN PLAGUE

Mode of transmission

Human plague is most frequently contracted from : (a) the bite of an infected flea, (b) occasionally by direct contact with the tissues of the infected animal or (c) by droplet infection from cases of pneumonic plague. The dissemination of plague by plague patients (by the bite of the human flea, *Pulex irritans*) is a rare and exceptional occurrence.

There are at least 5 basic types of transmission cycles in plague. These cycles are as follows *(8)* :

1. *Commensal rats → rat fleas →man*
   This is the basic cycle in epidemic bubonic plague.
2. *Wild rodents→wild rodent fleas or direct contact →man*
   The disease is transmitted from rodent to rodent *via* wild rodent fleas or contaminated soil. Man contracts the infection from infectious wild rodent fleas or by direct contact with infected rodents.
3. *Wild rodents, peridomestic rodents, commensal rodents → wild rodent fleas, peridomestic rodent fleas, commensal rodent fleas →man*
   Plague foci impinge upon the habitats of peri-domestic or commensal rodents. Interaction of the rodents and their fleas convey the infection to man.
4. *Man → human flea (Pulex irritans) →man*
   This variety may be encountered in certain areas.
5. *Man → man*
   This results when a primary case of bubonic plague develops secondary pneumonic plague and infects contacts *via* the respiratory route.

Incubation period

(a)	bubonic plague	.....	2 to 7 days
(b)	septicaemic plague	.....	2 to 7 days
(c)	pneumonic plague	.....	1 to 3 days

Disease in man

There are three main clinical forms : ***(a) Bubonic plague :*** This is the most common type of the disease. The infected rat fleas usually bite on the lower extremities and inoculate the bacilli. The bacilli are intercepted by the regional lymphatic glands where they proliferate. Typically the patient develops sudden fever, chills, headache, prostration and painful lymphadenitis. Usually within a few days greatly enlarged tender lymph nodes (buboes) develop in the groin and less often in the axilla or neck, depending upon the site of the bite by the flea. When suppuration takes place it is considered a favourable sign. Bubonic plague cannot spread from person to person as the bacilli are locked up in the buboes and do not find a way or easy exit. ***(b) Pneumonic plague :*** Primary pneumonic plague is rare; it generally follows as a complication of bubonic–septicaemic plague. The incidence of pneumonic plague is usually below 1 per cent *(5)*. Pneumonic plague is highly infectious and spreads from man to man by droplet infection. The plague bacilli are present in the sputum. ***(c) Septicaemic plague :*** Primary septicaemic plague is rare except for accidental laboratory infections. However, bubonic plague may develop into septicaemic plague in the face of an overwhelming infection.

Laboratory investigations

The absolute confirmation of plague infection in human beings, rodents or fleas requires the isolation and identification of the plague bacillus. The important laboratory methods of diagnosis include the following : ***(a) Staining :*** It is important to prepare smears of the clinical material (e.g., bubo fluid, sputum) which should be fixed with alcohol and then stained with Giemsa's or Wayson's stain to demonstrate bipolar bacilli in the specimen. ***(b) Culture :*** Blood for culture should be collected from all patients. Under ideal circumstances, appropriate culture media should be inoculated on the spot with blood, bubo fluid or sputum to ensure speedy isolation of the plague bacilli. When this is not possible, the specimen

must be transported to the laboratory in Cary–Blair transport medium. ***(c) Serology :*** Acute and convalescent specimens of blood sera should be collected for antibody studies. ***(d) Other methods :*** These include inoculation of guinea pigs or mice or immunofluorescent microscopic test.

PREVENTION AND CONTROL

1. Control of cases

(a) EARLY DIAGNOSIS : During epidemic situations, diagnosis of plague can be made readily on clinical grounds, e.g., acute fever and painful lymph node enlargement developing into buboes in the inguinal and other regions of the body. In other situations, "rat falls" (dead rats) provide a useful warning of a possible outbreak. It is essential that plague–suspected humans and rodents be examined bacteriologically to confirm the presence of plague. It is often possible to arrive at a *prima facie* diagnosis by the examination of smears that show the characteristic bipolar stained plague bacilli *(8)*. *(b) NOTIFICATION :* If a human or rodent case is diagnosed, health authorities must be notified promptly. Case notification is required by International Health Regulations *(13)*. *(c) ISOLATION :* Although most bubonic plague patients are non–infectious, isolation is recommended whenever possible. All patients with pneumonic plague including suspected cases should be isolated. *(d) TREATMENT :* Treatment must be started without waiting for confirmation of the diagnosis *(2)*. Unless promptly treated, plague may have a mortality of nearly 50 per cent, and pneumonic plague 100 per cent. The drug of choice is streptomycin (30 mg per kg of body weight daily) administered intramuscularly in two divided doses for 7 to 10 days. Tetracycline orally (30–40 mg per kg of body weight daily) is an alternative drug, and is sometimes given in combination with streptomycin *(12)*. Gentamycin administered as a 2 mg/kg body wt. loading dose, then 1.7 mg/kg body wt. every 8 hours intravenously is effective. Penicillin is rather ineffective. Sulphonamides may be used if other drugs are not available. *(e) DISINFECTION :* Disinfection of sputum, discharges and articles soiled by the patient should be carried out. Dead bodies should be handled with aseptic precautions.

2. Control of fleas

The most effective method to break the chain of transmission (rodent → flea → man) is the destruction of rat fleas by the proper application of an effective insecticide. Flea control must precede or coincide anti-rodent measures. The choice of insecticide is dictated by the results of prior susceptibility tests. In general DDT and BHC should be used as dusts containing 10 per cent and 3 per cent of the active ingredient respectively. In areas where resistance to one or both of these insecticides occurs, dusts of carbaryl (2%) or malathion (5%) should prove effective. About 2 to 3 g of insecticide formulation will be needed for each sq. metre of surface requiring treatment *(8)*. Generally the organochlorine insecticides remain effective for 2 to 4 months.

Before spraying is to be done, the inhabitants of premises should be asked to remove all foodstuffs and eating and cooking vessels from their houses. Spraying is done inside the houses covering the entire floor area, bottoms of all walls up to 3 feet above floor level, back of the doors, roofing of thatched houses, crevices of walls, rat runs, clothing, bedding, cats, dogs and other pets. Rat burrows should be insufflated with the insecticidal dust with the help of a dust blower. Insecticidal spraying up to a radius of 5 miles around each infected locality is considered adequate *(8)*. Within 48 hours of application, the "flea index" should drop down to zero *(8)*.

3. Control of rodents

Continuous mass destruction of rodents is an important plague–preventive measure. The long-term policy for the control of rodents should be based on improvement of general sanitation, improvement of housing and quality of life. The various antirodent measures are given elsewhere.

4. Vaccination

Immunization with plague vaccine is a valuable preventive measure. The WHO recommends that under all circumstances, vaccination should be only for the prevention, not the control of human plague *(2)*. To be effective, vaccination should be carried out at least a week before an anticipated outbreak, and the vaccine should be given in 2 doses.

In 1897, Haffkine developed a killed plague vaccine while working in India and inoculated himself with his experimental vaccine *(14)*. The vaccine used currently is that of Haffkine, modified by Sokhey. It is a formalin–killed vaccine. Virulent strains of *Y. pestis* are grown in casein hydrolysate broth for 2 weeks at 27 deg. C and killed by treatment with 0.1 per cent formalin for 3 days at 37 deg. C. The final vaccine is a suspension of 2000 million killed organisms per ml *(15)*.

The vaccine is given subcutaneously in two doses of 0.5 and 1.0 ml at an interval of 7 to 14 days. A single dose will not result in dependable protection. However, in an emergency, when it is desired to carry out primary immunization by means of a single injection, the dose should be double the second dose, that is, 3 ml for adult males *(15)*. Immunity starts 5 to 7 days after inoculation, and lasts for about 6 months. Booster doses are recommended six–monthly for persons at continuing risk of infection (e.g., geologists, biologists and anthropologists). The recommended doses of the vaccine are given in Table 3. The reactions after inoculation (pain, tenderness, headache, etc) appear in a few hours and subside in 1 to 2 days. The vaccine is indicated for travellers to hyperendemic areas besides persons at special risk.

TABLE 3
Dosage of plague vaccine

Age and Sex	Primary inoculation		Booster dose six–monthly
	1st dose	2nd dose	
Adult males	1.0 ml	1.5 ml	1.0 ml
Adult females	0.75 ml	1.0 ml	0.75ml
Children			
1 – 4 years	0.2 ml		
5 – 10 years	0.3 ml	Double the first dose	Same as the first dose
11 – 16 years	0.4 ml		
Infants under 6 months are not immunized.			

Source : *(15)*

5. Chemoprophylaxis

Chemoprophylaxis is a valuable preventive measure, highly recommended. It should be offered to all plague contacts, medical, nursing and public health personnel exposed to the risk of infection. The drug of choice is

tetracycline. For adults, the dose is 500 mg 6–hourly for 5 days *(16)*. A cheaper alternative is sulfonamide, 2 to 3 gram daily for 5 to 7 days.

6. Surveillance

Plague has a potential for spread into susceptible areas. Therefore, in areas where natural plague foci exist or where there is a history of past infection, surveillance is essential. Surveillance should cover all aspects of rodent and human plague, e.g., microbiology, serology, entomology, mammalogy, epidemiology and ecology. On the basis of information provided by surveillance, effective control measures must be established *(14)*. Surveillance of plague in its natural foci should, therefore, replace quarantine measures which have been shown to be ineffective *(2)*.

7. Health education

Health education is an essential part of any plague control programme. Education should aim at providing the public with the facts about plague and at enlisting their cooperation. Emphasis must be placed on the need for the prompt reporting of dead rats and suspected human cases so that preventive measures can be taken. Medical practitioners should keep plague in mind in differential diagnosis of any cases of fever with lymphadeno-pathy, or when multiple cases of pneumonia occur *(2)*.

Epidemiological investigations *(17)*

The determination of the source of infection and the distribution, prevalence, and potential spread of plague in human population is the main objective of epidemiological surveillance. This means that those engaged in surveillance must evaluate human plague in its relationship with epizootic factors and that the investigations must be based on direct contact with villages and other communities affected by plague. While the collection of demographic data and information on such subjects as population movements and local occupations, customs, and habits is important, special attention must be given to the factors bringing man into contact with the vertebrate reservoirs and vectors of *y. pestis*.

Some of the responsibilities of the surveillance team are as follows :

(1) to make a detailed study of all cases of human plague, giving special attention to dwellings where cases have occurred, in order to establish the rodent/vector source of the infection or the occurrence of man-to-man transmission;

(2) to keep complete and uniform records of each case of plague, using standardized forms, and to issue questionnaires to the population at risk;

(3) to isolate strains of *Y. pestis* and subject them to detailed biochemical analysis, samples being lyophilized for later study;

(4) to make a serological survey of the target population; such surveys are of value in investigation of possible cases of subclinical plague, of recovered untreated infections, and of asymptomatic pharyngeal infection in "carriers";

(5) to investigate changes in the human population, social or economic activities, and other features of natural foci where there is close contact between human populations and commensal rodents;

(6) to keep a watch on containerized cargoes of grain and other food crops originating in areas with natural plague foci and destined for national or international trade;

(7) to undertake surveillance in cooperation with adjacent countries when natural foci are common to two or more countries;

(8) to give special attention, in the case of seaports or airports, to the proximity of natural foci where there is contact between wild and commensal rodents, the proximity of epidemics, and the transport of cargo from enzootic areas.

The surveillance team should also be prepared to assist the national or community health service in organizing and carrying out the treatment of human cases and measures for the control and prevention of plague. An organizational basis should be established for rapid emergency services in the event of an epidemic.

Reporting of cases and outbreaks of plague *(17)*

The WHO should be informed promptly of the occurrence of any epidemic or isolated case of plague. The report should include details about the administrative area and exact locality involved. This preliminary notification should be followed up as soon as possible by a more detailed report containing the following information :

(a) The locality and administrative area, shown on a map if possible

(b) The date, the first case was noticed

(c) The period during which field investigations were made

(d) The number and types of cases of plague detected :
- clinical diagnosis only (presumptive)
- laboratory diagnosis (confirmed)
- recovered and confirmed serologically
- types of cases – bubonic, pneumonic, etc.
- age of patient with a confirmed diagnosis of plague
- number of deaths

(e) The contacts of known cases
- serological test results
- throat swab results

(f) Chemotherapy applied
- number of frank cases
- number of contacts

(g) Vertebrate host population
- identification of domestic rodents
- identification of wild rodents
- results of laboratory test for plague

(h) Vector population
- identification of *X. cheopis*
- identification of other species of flea
- results of laboratory tests for infection
- results of insecticide resistance tests
- control measures applied.

HUMAN SALMONELLOSIS

The term "salmonellosis" covers a complex group of foodborne infections affecting both man and animals *(1)*. The disease causes illness and even death in humans, as well as economic losses in the animal and food industries. The term "food poisoning" is also commonly applied to salmonellosis.

Problem statement

Salmonellosis is a global problem *(2)*. Human salmonellosis represents 60 to 80 per cent of all reported cases of foodborne diseases *(3)*.

While the incidence of typhoid fever has declined, the incidence of other *Salmonella* infections has increased in the developed countries. The problem is aggravated by the widespread use of animal feeds containing antimicrobial drugs that favour drug–resistant salmonellae and their potential transmission to humans. The disease can occur sporadically or in small outbreaks in the general population and usually from food contaminated at its source. The extent of the problem is not clear in developing countries where diarrhoeal diseases are widespread *(2)*.

Epidemiological determinants

Agent factors

AGENT : Salmonellae comprise a large and important group of bacteria. This group is now known to comprise more than 2,500 serotypes capable of infecting humans *(4)*, but in most countries only a small number of them (usually about 10) are endemic at any one time *(5)*.

Compared with other gram-negative rods, salmonellae are relatively resistant to various environmental factors. They have been shown to be resistant to drying, salting, smoking and freezing even for years. This explains why these organisms survive in many kinds of food. As a result, salmonellae have been isolated from divergent foods such as chocolates, biscuits, coconuts and spices. The bacterium is sensitive to heat and will not survive temperatures above 70 deg C.

From an epidemiological point of view, salmonellae can be classified into three main groups *(2)*.

(i) those which infect only man – e.g., *S. typhi, S. paratyphi A* and *C.*

(ii) those that are host–adapted for particular species of animals, e.g., *S. cholera–suis* in swine, *S. dublin* in cattle, *S. abortus equi* in horses, *S. gallinarum* in poultry, etc. Some of these are also pathogenic for man, e.g., *S. cholera–suis, S. dublin.*

(iii) those with no particular host preference and can infect both man and animals – e.g., *S. typhimurium, S.enteritidis.* In this group (approximately 2,200 serovars) are the principal agents of salmonellosis that occurs today *(2)*. They can be transmitted from animals to man and vice versa. *S. typhimurium* is responsible for upto 50 per cent or more of all human salmonella infections all over the world. *S. enteritidis* has also emerged as an important pathogen.

RESERVOIR AND SOURCES OF INFECTION : The main reservoir of Salmonella is the intestinal tract of man and animals. The source of the infecting agent could be contaminated food, animals, man or the environment.

(a) Foods

Foods of animal origin, particularly commercially prepared foods such as meat, poultry and egg products are considered to be the primary sources of salmonellosis. Most of these foods, e.g., meat and poultry become contaminated during slaughter. Every food that is produced or processed (including chocolates, spices, coconut) in a contaminated environment may become contaminated. Cross-contamination of cooked foods from raw ingredients, kitchen utensils or surfaces has been described frequently as a cause of salmonellosis *(5)*. Eggs may be infected directly through shell–cracks. Recent investigations suggest that salmonellae may penetrate the ovaries of egg–laying chickens. What food will ultimately become the vehicle varies from country to country *(6)*. For example, in the USA, beef is the main source of salmonella infection, while in England and Wales poultry accounts for more than 50 per cent of Salmonellosis outbreaks *(2)*.

(b) Animals

Animals are the hosts and the principal vectors of zoonotic salmonellosis. Many animals including cattle, swine, rodents and fowl are naturally infected with a variety of salmonellae and have the bacilli in their tissues (meat), eggs or excreta. Carriers occur among both man and animals.

(c) Environment

Salmonellae are widely distributed in the environment – in dust, water, manure, sewage, sludge, vegetables, insects, birds, fish, rodents and other mammals. They can survive in soil for months *(6)*. They may even multiply in the warm environment provided by the high ambient temperatures of many countries. Man may be infected from these sources.

Multidrug resistant strains of *salmonella* are now encountered frequently. Resistance to fluoroquinolones and third generation cephalosporins is a serious development, which results in severe limitation of the possibilities for effective treatment of human infections *(4)*.

Mode of transmission

By ingestion of contaminated food or drink. In addition, man can contract infection following direct contact with domestic animals especially such as dogs, pigeons, rats, mice and insects. Once man is infected, he becomes a source (case or carrier) and the infection may spread to others by the faecal–oral route.

Transmission is facilitated by food handling methods, local customs, cooking and food habits, food processing, storage and distribution methods, and prevailing sanitary conditions.

Incubation period

6 to 72 hours (usually).

Clinical features

The disease arises from the ingestion of the living organisms. Recent studies indicate that *Salmonella spp.* possess both invasive and cholera–like enterotoxic properties *(6)*. Clinically, the disease may be manifest by one of three syndromes :

(i) Enteric fever : S. typhi, S. paratyphi A and *C* are human pathogens, and are not considered zoonotic agents *(2)*. *S. paratyphi B,* while predominantly found in man has also been isolated from turkeys, chickens, cattle, sheep, swine, mice and monkeys. This syndrome (enteric fever) is dealt with separately (see page 234).

(ii) Salmonella enterocolitis (gastroenteritis) : This is the most common manifestation of *Salmonella* infection. 6 to 48 hours after ingestion of *Salmonellae* there is nausea, headache, vomiting and diarrhoea. Low grade fever is common. Most infections are mild with diarrhoea as the only symptom. In severe cases there may be dehydration requiring replacement of fluids and electrolytes. The episode usually resolves in 2 to 3 days, but the stools often remain loose for several weeks. The excretion of salmonella may be prolonged by antimicrobial therapy. Blood cultures are usually negative but stool cultures are positive for salmonella and may remain positive for several weeks after clinical recovery. Death is rare and occurs primarily in neonates, infants and elderly.

(iii) Septicaemia with focal lesions : Non–typhoid salmonellae (e.g., *S. cholera–suis*) may occasionally invade the blood stream leading to generalized or localized infection presenting itself as pyrexia of unknown origin. Focal infection may result in osteomyelitis, pyelonephritis, arthritis, meningitis, cholecystitis and endocarditis. Stool cultures are negative but blood cultures are positive.

Prevention and control

Since salmonellosis is zoonotic in origin, preventive measures should begin at the farm and embrace all the elements of the food chain through live animals, animal products, processing, final food preparation to consumption. Approaches indicated at the farm level are : (i) disease control, e.g., immunization of farm animals against salmonellosis. (ii) the use of hygienic animal feed, and (iii) ensuring a sanitary environment for the animals. The aim is to raise "salmonella–free" animals.

The other approaches include : hygienic slaughtering and milking, pasteurization of milk and eggs; proper disposal of liquid and solid wastes, cold storage facilities, and health education and training.

Since the health sector alone cannot solve the problem of salmonellosis, responsibility for prevention and control measures may fall to agriculture, veterinary and other ministries, outside the health sector *(1, 7)*.

RICKETTSIAL ZOONOSES
(Rickettsial diseases)

Rickettsial zoonoses are a group of specific communicable diseases caused by rickettsial organisms and transmitted to man by arthropod vectors, (Q fever excepted). Increasingly, it is realized that rickettsial diseases are under-diagnosed and that they contribute substantially to the acute febrile burden and preventive illness in many populations *(1)*.

Classification

Rickettsial diseases may be grouped on the basis of clinical features and epidemiological aspects as follows (Table 1).

TABLE 1
Rickettsial diseases

Diseases	Rickettsial agent	Insect vectors	Mammalian reservoirs
1. Typhus group			
a. Epidemic typhus	*R. prowazekii*	Louse	Humans
b. Murine typhus	*R. typhi*	Flea	Rodents
c. Scrub typhus	*R. tsutsugamushi*	Mite*	Rodents
2. Spotted fever group			
a. Indian tick typhus	*R. conorii*	Tick*	Rodents, dogs
b. Rocky mountain spotted fever	*R. rickettsii*	Tick*	Rodents, dogs
c. Rickettsial pox	*R. akari*	Mite*	Mice
3. Others			
a. Q fever	*C. burnetii*	Nil	Cattle, sheep, goats
b. Trench fever	*Rochalimaea quintana*	Louse	Humans

*Also serve as arthropod reservoir, by maintaining the rickettsiae through ovarian transmission.

Causal agents

Rickettsiae are small bacteria that are obligate intracellular parasites. They are pleomorphic, appearing either as short rods, or as cocci and they occur singly, in pairs, in short chains, or in filaments. With Giemsa's stain they stain blue and are readily visible under microscope. They grow readily in the yolk sac of the embryonated egg. Rickettsial growth is enhanced by the presence of sulfonamides.

Clinical features

Excepting for Q fever, in which there is no skin lesion, rickettsial infections are characterized by fever, headache, malaise, prostration, skin rash and enlargement of the spleen and liver. Tetracycline is the drug of choice for specific treatment of all rickettsial diseases. Long–acting antibiotics (doxycycline, minocycline) now make single dose treatment possible *(3)*.

Diagnostic procedures

These include : (a) isolation of rickettsiae. (b) established serological tests such as indirect fluorescent antibody (IFA) test, the complement fixation test, and the Weil Felix reaction. The newer techniques include ELISA and the fluorescent antibody staining of frozen tissue sections from rickettsial lesions.

Among the major groups of rickettioses, the commonly reported diseases in India are scrub typhus, murine flea–born typhus, Indian tick typhus and Q fever. These are considered in more detail :

SCRUB TYPHUS

Distribution

Of the diseases caused by rickettsiae in man, the most widespread is scrub typhus. It exists as a zoonoses in nature between certain species of trombiculid mites and their small mammals (e.g., field mice, rats, shrews). Scrub typhus is endemic in Northern Japan, South East Asia, the Western Pacific Islands, Eastern Australia, China, Maritime areas and several parts of South-Central Russia, India and Sri Lanka. More than 1 million cases occur annually. Most travel-acquired cases of scrub typhus occur during visits to rural areas in endemic countries for activities such as camping, hiking or rafting, but urban cases have also been described *(4)*.

Epidemiological determinants

Agent factors

(a) AGENT : The causative agent of scrub typhus is *Rickettsia tsutsugamushi*. There are several serologically distinct strains. (b) RESERVOIR : The true reservoir of infection is the trombiculid mite *(Leptotrombidium delinese* and *L.akamushi)*. The infection is maintained in nature transovarially from one generation of mite to the next. The nymphal and adult stages of the mite are free–living in the soil; they do not feed on vertebrate hosts. It is the larva (chigger) that feed on vertebrate hosts and picks up the rickettsiae. The larval stage serves both as a reservoir, through ovarian transmission, and as a vector for infecting humans and rodents.

Mode of transmission

By the bite of infected larval mites. The transmission cycle may be depicted as below :

Mite → Rats and mice → Mite → Rats and mice
↓
Man

The disease is not directly transmitted from person to person.

Incubation period

Usually 10 to 12 days; varies from 6 to 21 days.

Clinical features

Scrub typhus resembles epidemic typhus clinically. The onset is acute with chills and fever (104°–105°F), headache, malaise, prostration and a macular rash appearing around the 5th day of illness. Generalized lymphadenopathy and lymphocytosis are common. One typical feature is the punched–out ulcer covered with a blackened scab (eschar) which indicates the location of the mite bite. The pyrexia falls by lysis in the 3rd week in untreated cases. The Weil Felix reaction is strongly positive with the *Proteus* strain OXK.

Control measures

(a) TREATMENT : Tetracycline is the drug of choice. With proper therapy the mortality is nil. (b) VECTOR CONTROL : Clearing the vegetation where rats and mice live; application of insecticides such as lindane or chlordane to ground and vegetation. (c) PERSONAL PROPHYLAXIS : Impregnating clothes and blankets with miticial chemicals (benzyl benzoate) and application of mite repellents (diethyltoluamide) to exposed skin surfaces *(5)*. No vaccine exists at present.

MURINE TYPHUS
(Endemic or flea–borne typhus)

Distribution

Murine typhus (MT) is a zoonoses. It is worldwide in distribution especially in areas of high rat infestation. It appears to be more prevalent in South-East Asian and Western Pacific countries than previously recognized. In USA, cases tend to be scattered. Successful isolation of the causative agent from rats, fleas and bandicoots was made at many places in India. Focal infections are often associated with docks and shipping places where rats abound.

Agent factors

(a) AGENT : *Rickettsia typhi* (*R. mooseri*). (b) RESERVOIR OF INFECTION : Rats are the reservoir *(Rattus rattus and R.norvegicus)*. Infection in rats is inapparent, long–lasting and non–fatal.

Mode of transmission

The infection spreads from rat to rat *(X. cheopis)* and possibly by the rat louse *(6)*. The actual mode of transmission is not by the bite of the rat flea, but by (i) inoculation into skin of faeces of infected fleas, and (ii) possibly by inhalation of dried infective faeces. There is no direct man to man transmission. Once infected the flea remains so for life. The flea cannot transmit the rickettsiae transovarially. The transmission cycle may be shown as below :

Rat → Rat flea → Rat → Rat flea → Rat
↓
Man

Incubation period

1 to 2 weeks, commonly 12 days.

Clinical features

The clinical features resemble that of louse–borne typhus, but milder and rarely fatal. The Weil Felix reaction with Proteus OX–19 becomes positive in the 2nd week.

Control measures

(a) TREATMENT : Tetracycline is the only drug of choice. Since rickettsial growth is enhanced in the presence of sulfonamides, these drugs should not be given. *(b) CONTROL OF FLEAS :* Residual insecticides (e.g., BHC, malathion) are effective against rat fleas. Rodent control measures should be implemented in the affected areas. No murine typhus vaccine is currently available.

INDIAN TICK TYPHUS

Epidemiological determinants

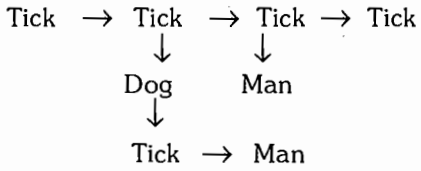
Agent factors

(a) AGENT : The causative agent is *Rickettsia conorii*, a member of the spotted fever group of rickettsiae, the best

known member of which is *R. rickettsii* the causative agent of Rocky Mountain spotted fever. (b) RESERVOIR OF INFECTION : The tick is the reservoir of infection. It is infective at all stages of its life cycle and remains infective for life (commonly 18 months). Various tick genera *(e.g., Rhipicephalus, Ixodes, Boophilus, Haemaphysalis)* have been incriminated as vectors. Infection in nature is maintained by transovarian and trans-stadial passage. The rickettsiae can be transmitted to dogs, various rodents and other animals, which assist in maintaining the disease cycle.

Mode of transmission

Man is only an accidental host. He acquires infection by the bite of an infected tick. Contamination of skin with crushed tissues or faeces of an infected tick may also cause infection. The cycle of transmission is as follows :



Incubation period

Usually 3 to 7 days.

Clinical features

The patient usually gives history of a recent tick–bite and a careful examination will reveal a lesion or eschar at the site of the bite. After an interval of 3 to 7 days, there is an acute onset of fever, which may persist for 2 to 3 weeks, malaise and headache. A maculopapular rash appears on the third day. Unlike the rash in other rickettsial diseases, the rash appears first on the extremities (ankles and wrist), moves centripetally and involves the rest of the body. The clinical syndrome may be confused with atypical measles.

Control measures

(a) TREATMENT : Broad spectrum antibiotics have proved to be effective. (b) PERSONAL PROPHYLAXIS : Known tick–infested areas should be avoided. Daily inspection of the body for ticks is particularly important for those who are exposed to the risk of infection. Disinfection of dogs will minimize the tick population. Health education of the people in the mode of transmission by ticks, and the means of personal protection is equally important.

Q FEVER

Distribution

Q fever is a highly infectious zoonotic disease with world–wide distribution. It occurs mainly in persons associated with sheep, goats, cattle or other domestic animals.

Agent factors

(a) AGENT : The causative agent is *Coxiella burnetii*. It is found in ticks which act as vectors as well as reservoir. (b) ANIMAL HOSTS : Cattle, sheep, goats, ticks and some wild animals are natural reservoirs. Infected animals shed the disease agent in the faeces and urine and heavily contaminate the soil. The placenta of infected cows and sheep contains the infectious agent which may create infectious aerosols during parturition. Camels, horses, dogs and many other domestic animals have been shown to be capable of acting as maintenance hosts *(7)*.

Mode of transmission

Q fever differs from other rickettsial infections in that there is no arthropod involved in its transmission to man. Transmission results from : (i) inhalation of infected dust from soil previously contaminated by urine or faeces of diseased animals. The organism can also be transmitted through aerosols. (ii) the organism can also gain entry into the body through abrasions, conjunctivae or ingestion of contaminated foods such as meat, milk and milk products. In most countries, the respiratory route is regarded as most important.

Incubation period

Usually 2 to 3 weeks.

Clinical features

The disease has an acute onset with fever, chills, general malaise and headache. The clinical picture is one of influenza or non–bacterial pneumonia rather than a typhus fever. There is no rash or local lesion. The infection can cause pneumonia, hepatitis, encephalitis and rarely endocarditis. Inapparent infections also occur.

Control measures

(a) TREATMENT : Chronic Q fever requires prolonged treatment for 18 months or longer. Doxycycline is the drug of choice. *(b) PREVENTIVE MEASURES :* Pasteurization or boiling of milk to inactivate the causative agent; providing sanitary cattle sheds; adequate disinfection and disposal of products. An inactivated *Coxiella* vaccine has also been prepared to protect occupationally exposed workers. Several purified vaccines are under development *(8)*.

OTHER RICKETTSIAL INFECTIONS

1. Epidemic typhus

Epidemic or louse borne typhus was in the past the most formidable disease caused by rickettsiae. It was the cause of devastating epidemics among military and refugee populations and in areas affected by famine. The advent of modern insecticides has considerably reduced the prevalence of epidemic typhus today.

No cases of this disease have been reported from South East Asia since 1978 or from the Western Pacific since 1969 *(1)*. It is still endemic in Africa (notably Burundi, Rwanda and Ethiopia) and South America (notably Peru, Bolivia, and Ecuador). All of them are known endemic areas of the disease.

The infection is transmitted from man to man by the infected louse *(P. corporis and P. capitis)*. The louse gets infected by feeding on an infectious patient during the febrile stage. The organisms multiply in the cells lining the intestinal tract of the louse and begin to appear in 3 to 5 days in the louse faeces. Man acquires the disease not by the bite of the louse, but : (i) by scratching and inoculating himself with the infected louse faeces (ii) by crushing an infected louse on his person, and (iii) possibly by inhalation of infected louse faeces or dust. The infected louse after 10–14 days of existence dies of the infection. In humans, the organisms can persist for many years as latent infection without any symptoms, and the disease may appear later as ***Brill–Zinsser disease,*** and can be transmitted to other humans by the louse.

The control measures comprise anti-louse measures and improvements in personal hygiene and living conditions. Under the International Health Regulations, louse-borne typhus is subject to international surveillance.

2. Rickettsialpox

Man gets the infection through the bite of certain infected mites, which are found on mice *(Mus musculus)*. Transovarial transmission occurs in the mite. The mouse acts as true reservoir as well as vector. Rickettsialpox may be confused with atypical cases of chickenpox.

3. Trench fever

This disease is limited to central Europe. The vector is louse and the disease is transmitted by louse faeces. Man is the only known reservoir.

TAENIASIS

A group of cestode infections which are important zoonotic diseases. Two parasites of importance in taeniasis are *Taenia saginata* and *T. solium*. These are classified as "cyclo-zoonoses" because they require more than one vertebrate host species (but no invertebrate host) to complete their developmental cycles.

Problem statement

(a) T. SAGINATA : This parasite is virtually global in distribution, wherever beef is eaten. Highly endemic regions (prevalence rates exceeding 10 per cent) exist in some African countries south of the Sahara, in Eastern Mediterranean countries and in parts of USSR. There is a moderate prevalence in Europe, in most of the Indian subcontinent, Southern Asia, and in Japan. Australia, Canada and USA are generally regarded as low endemic areas, with prevalence rate below 0.1 per cent *(1)*.

The larval stage of *T. saginata* (Cysticercus bovis) occurs almost all over the world. In some East African countries rates 30 to 80 per cent have been noted. In European countries, it is found in 0.3 to 4.0 per cent of slaughtered animals *(1)*.

(b) T. SOLIUM : T. solium infection is endemic in many countries of Latin America, Africa and Asia as well as in some parts of Europe and the USSR *(2)*. It is endemic in India, and has been widely reported *(3)*. Human cysticercosis caused by *T. solium* is a far more important public health problem than human taeniasis *(4)*.

Hosts of infection

T. saginata and *T. solium* pass their life cycles in two hosts. In man, the adult parasites live in the small intestine. The adult *T. saginata* measures 5 to 12 metres in length, and may be up to 24 metres; *T. solium* measures 2 to 6 metres.

TABLE 1

Hosts of infection

	Parasite	Definitive	Intermediate host
1.	*T. saginata*	Man	Cattle *(C. bovis)*
2.	*T. solium*	Man	Pig *(C. cellulosae)*

The larval stage of *T. saginata (C. bovis)* mainly occurs in cattle. The pig is the main host for the larval stage of *T. solium (C. cellulosae)* but man may also be infected. This may lead to muscular, ocular and cerebral cysticercosis.

The adult stages of *T. saginata* and *T. solium* may persist for several years in infected humans. Mixed infections of both the parasites can occur. Although the life span of *C. cellulosae* in man is not known, it is suspected to be some years.

Mode of transmission

These infections are acquired : (a) through the ingestion of infective cysticerci in undercooked beef *(T. saginata)* or pork *(T. solium)*; (b) through ingestion of food, water or vegetables contaminated with eggs; and (c) reinfection by the transport of eggs from the bowel to the stomach by retroperistalsis is considered to be rare.

Incubation period

For the adult tapeworm, from 8 to 14 weeks.

Clinical illness

The impact of tapeworm infection in man is difficult to quantify because in the vast majority of cases, they do not lead to clinical illhealth, except occasional abdominal discomfort, anorexia and chronic indigestion.

Straying of proglottids may sporadically cause appendicitis or cholangitis. The most serious risk of *T. solium* infection is cysticercosis.

Human cysticercosis

Human infection is caused by the ingestion of eggs of *T. solium* in contaminated water or food (hetero-infection) or regurgitated eggs from the small intestine (auto-infection). The eggs disintegrate and the infective stages leave the intestine via the hepatic portal system, and are dispersed throughout the body where they develop to form cysticerci. Cysticerci that develop in the central nervous system (neuro-cysticercosis), represent a serious threat to the individual and even to the community, if this condition is prevalent. As a result of mechanical pressure, obstruction or inflammation, a variety of pathological changes are produced, leading to epilepsy, intracranial hypertensive syndromes, hydrocephalus, psychiatric diseases or death *(4)*.

Control measures

The methods usually employed for control are : (a) treatment of infected persons, (b) meat inspection, (c) health education, and (d) adequate sewage treatment and disposal *(1, 4)*. Early detection and early treatment of *T. solium* cases is essential to prevent human cysticercosis. Effective drugs (e.g., praziquantel and niclosamide) are available for the treatment of these infections. Surgical removal of symptom-producing cysts is indicated although

cure can seldom, if ever, be complete. In many countries, *T. solium* has been controlled by meat inspection and by the proper housing and feeding of pigs. Thorough cooking of beef and pork is the most effective method to prevent food–borne infections. Education of the public to prevent pollution of soil, water and food with human faeces, and washing of hands before eating and after defecation, are important health educational messages. Improvement of living conditions, especially safe treatment of sewage used for farming, should be aimed at.

Treatment

Praziquantel and niclosamide have replaced former taenicides (i.e., mepacrin). They are safe and effective in more than 90 per cent of patients. Praziquantel is given in a single dose of 10 mg/kg. body wt. It achieves cure rates of about 99 per cent. At this dose, side effects are minimal. With a single dose of 4 tablets (2 grams) of niclosamide, cure rates are over 90 per cent. This drug is given in the morning–empty stomach. The tablets must be chewed thoroughly and swallowed with water. Eating may be resumed after 2 hours. It usually produces no side effects. Pre and post-treatment purges are not used for either drug to treat *T. saginata*. For the treatment of *T. solium*, give moderate purgative 2–3 hours after the drug to rapidly eliminate segments and eggs from the bowels to avoid–theoretical possibility of cysticercosis *(5)*.

TREATMENT FOR CYSTICERCOSIS *(5)* : The treatment should be individualized, based on the number and location of cysts and their viability. Medical treatment is more effective for parenchymal cysts and less effective for intraventricular, subarachnoid, or recemose cysts. Albendazole and praziquantel are both effective in the treatment. 10–15 mg/kg body wt/day of albendazole is given twice daily with a fatty meal. The duration of treatment is unsettled. Seven to 14 days may be sufficient for some patients, but a longer course (up to 28 days) is advisable at present. It can be repeated as necessary. Up to 3 months of treatment may be needed for ventricular and subarachnoid cysts. Praziquantel is given in 50 mg/kg/day in three divided doses for 15 days.

Albendazole is the drug of choice because co-administration of albendazole and a steroid (to treat inflammation) results in increased albendazole absorption, whereas combined use of praziquantel and steroid greatly decreases plasma level of praziquantel. Both the drugs are given with fatty meals as this increases absorption four-fold to five-fold.

HYDATID DISEASE

Hydatid disease is a zoonoses – a group of cestode infections which are important zoonotic diseases of man. The disease in man is caused by the metacystode stage (infective larva) of the canine intestinal tapeworm *Echinococcus;* the adult worms are found in dogs and other carnivores.

Geographic distribution

In recent years, hydatidosis has been recognized as a public health problem of nearly global dimensions *(1)*. It is found in all sheep–raising countries, e.g., Australia, New Zealand, Tasmania, Middle East countries, Turkey, Greece, USSR, Cyprus, Latin America and the Far East etc. It is believed that there are relatively few countries in which cestodes of the genus *Echinococcus* are entirely absent *(2)*. Foci are also known to exist in India where the highest prevalence is reported in Andhra Pradesh and Tamil Nadu than in other parts of the country *(3)*. The prevalence of the disease is reported to be high in food animals in India.

Epidemiological determinants

Agent factors

Echinococcus species are small tapeworms, rarely more than 7 mm in length. The scolex bears four suckers, and there are two rows of hooks, one small and one large on the rostellum. The number of proglottids varies from 2 to 6. At present four species are regarded as valid *(2)*.

(a) E. granulosus : of worldwide distribution, is for the most part, maintained in the domestic transmission cycle involving the dog as final host. In man the infective larva causes hydatidosis, the "unilocular" type of echinococcosis. *(b) E. multilocularis :* is restricted to the northern hemisphere. It has been detected increasingly in various countries (e.g. Iran, Turkey). In man, the metacystode causes the "alveolar" type of the disease. *(c) E. oligarthus :* a species occurring in Central and South America is suspected to cause disease in man, and *(d) E. Vogeli :* a species occurring in Central and South America, has been shown to cause polycystic hydatidosis.

Life cycle

Basically it is a "dog–sheep" cycle with man as an accidental, intermediate host. The adult tapeworm lives in the small intestine of dogs (definitive host) for 2 to 4 years. The eggs are voided in the faeces and contaminate the soil, vegetation and drinking water. They are highly resistant and can survive for several months in pastures, gardens and around households. Sheep, cattle and other intermediate hosts become infected when they ingest vegetation which has become contaminated with faeces from infected dogs. Ingested eggs hatch in the intestine and the larvae penetrate the intestinal lining and migrate to various organs of the body. Most frequently, they lodge in such organs as liver, lungs and brain and develop into hydatid cysts. The life cycle is completed when sheep (cattle) viscera containing hydatid cysts are eaten by dogs. Infected dogs begin to pass eggs of the parasite approximately 7 weeks after infection. Man does not harbour the adult worm.

Host factors

It is becoming increasingly evident that human behaviour, especially in relation to dogs and cats, uncontrolled slaughter of food animals, indiscriminate disposal of offal and carcasses, and eating habits of the people play an important part in the epidemiology of the disease. Human infection is acquired usually in childhood through contact with infected dogs. The impact of hydatidosis can be described only in terms of human suffering, cost of medical diagnosis, hospitalization and surgery, man–hours lost, as well as in terms of temporary or permanent incapacity. The retarded growth of animals, and

reduction in the quality and yield of meat, milk and wool and condemnation of offal are also very great *(4)*. Hydatid disease is an occupational disease of certain groups, e.g., shepherds and their families in endemic areas and shoe-makers.

Mode of transmission

Human infection occurs by ingestion of the eggs of *Echinococcus* inadvertently with food, unwashed vegetables or water contaminated with faeces from infected dogs. Infection can also take place while handling or playing with infected dogs, e.g., hand to mouth transfer of eggs, or by inhalation of dust contaminated with infected eggs. The disease is not directly transmissible from person to person.

The disease is maintained in the "dog–sheep" cycle. Other animal combinations may also be involved, e.g., dog–goat, dog–cattle, and dog–camel. Carnivores get infected by eating viscera containing hydatid cysts. The disease is not directly transmissible from one intermediate host to another.

Incubation period

Variable, from months to years depending upon the number and location of cysts and how rapidly they grow.

Clinical features

In man, symptoms of hydatid disease are usually manifested several years after exposure. The cysts grow slowly from 5 to 20 years before they are diagnosed. The size of the cyst may vary from a pinhead to that of a small football. It has been estimated that more than 70 per cent of the cysts become located in the right lobe of the liver, and the rest in lungs, brain, peritoneum, long bones and kidney. The cysts are filled with watery fluid and contain a large number of tapeworm heads. If the cyst ruptures, the brood capsules can spill out of the cyst, metastasize to other sites and develops into a hydatid, thus ingestion of a single egg can give rise to several hydatid cysts, each containing several brood capsules *(7)*.

Cysts of small size are generally asymptomatic. Large cysts, however, cause pressure symptoms (e.g., jaundice in liver cysts). In vital organs they may cause severe symptoms and death.

Diagnosis

(a) Clinical : Based on the history of residence in an endemic area, close association with dogs and the presence of a slowly growing cystic tumour. *(b) X-ray :* A plain X-ray permits the location of the cyst. Modern techniques of diagnosis include ultrasonography and CAT scan. *(c) Serological :* Serological tests with a high degree of sensitivity and specificity have been introduced such as the indirect immunofluorescent test. ELISA is regarded as a relatively simple method with a high sensitivity superior to that of some other serological procedures *(2)*. The intradermal (Casoni) test is still in wide use, since it is simple to perform. This test often lacks specificity *(2)*.

Treatment

There is no specific treatment excepting surgical removal of cysts which is not without considerable risk in as much as the accidental penetration of one of the cysts can lead to anaphylactic shock which may prove fatal.

Mebendazole (Vermox) has been tried and found very effective in mice. It may well become the drug of choice.

Prevention and control

(a) Preventing dogs from gaining access to raw offal at slaughter houses and on farms, and to dead animals : this involves control of slaughter houses, proper meat inspection and destruction of infected viscera.

(b) Control of dogs : This involves elimination of stray dogs, drastic reduction of dog population, an effective dog–registration system; surveillance of dogs based on periodic stool examinations after administration of a teanifuge such as arecoline hydrobromide, followed by the isolation and treatment of infected animals with praziquantel *(6)*. A single oral dose of 5 mg/kg of body weight will remove all adult worms from the dogs.

(c) Health education of the public particularly butchers, dog owners, animal breeders and shepherds is the basis of effective prevention *(2)*.

LEISHMANIASIS

Leishmaniasis are a group of protozoal diseases caused by parasites of the genus *Leishmania,* and transmitted to man by the bite of female phlebotomine sandfly. They are responsible for various syndromes in humans – kala-azar or visceral leishmaniasis (VL), cutaneous leishmaniasis (CL), muco–cutaneous leishmaniasis (MCL), anthroponotic cutaneous leishmaniasis (ACL), zoonotic cutaneous leishmaniasis (ZCL), post–kala-azar dermal leishmaniasis (PKDL), etc *(1)*. The visceral type of disease, kala-azar, is still an important disease in India. The majority of the leishmaniasis are zoonoses involving wild or domestic mammals (rodents, canines). Some forms (e.g., Indian kala-azar) are considered to be nonzoonotic infections *(2)*.

Problem statement

WORLD

Leishmaniasis is endemic in many countries in tropical and subtropical regions, including Africa, Central and South Americas, Asia and the Mediterranean region.

More than 90 per cent of all cases of cutaneous leishmaniasis occur in Afghanistan, Algeria, Brazil, Colombia, the Islamic Republic of Iran, Peru, Saudi Arabia and the Syrian Arab Republic. More than 90 per cent of all cases of mucosal leishmaniasis occur in Brazil, Ethiopia, Peru and Bolivia *(3)*.

About 200,000–400,000 cases of kala-azar (visceral leishmaniasis) are reported annually worldwide. Six countries, namely India, Bangladesh, Brazil, Nepal, Ethiopia, South Sudan and Sudan account for 90 per cent of the global incidence. Within countries, kala-azar occurs among poorest communities. In SEAR, an estimated 147 million people in Bangladesh, India and Nepal are at risk of kala-azar, largely in rural communities. The disease is endemic in 52 districts in India, 12 districts in Nepal and 45 districts in Bangladesh *(3)*.

Kala-azar situation is worsening due to the occurrence of asymptomatic cases, post-kala-azar dermal leishmaniasis (PKDL), undernutrition, and kala-azar/HIV coinfection. Case fatality rate has decreased perhaps due to improved case management in endemic countries.

INDIA

Kala-azar is endemic in 52 districts in Bihar (31), Jharkhand (4), West Bengal (11) and Uttar Pradesh (4). About 130 million population is at risk of the disease. The present situation is shown in Table 1. While both cutaneous (ZCL and ACL) and visceral (VL) disease occur in India, kala-azar is by far the most important leishmaniasis in India *(4)*.

TABLE 1

State-wise Kala-azar cases and deaths in India

State	2011		2012		2013	
	Cases	Deaths	Cases	Deaths	Cases	Deaths
Bihar	25,222	76	16,036	27	10,730	17
West Bengal	1,962	0	995	0	595	0
Uttar Pradesh	11	1	5	0	11	1
Jharkhand	5,960	3	3,535	1	2,515	0
Delhi	19	0	11	0	6	0
Assam	5	0	6	0	4	0
India	33,187	80	20,600	29	3,869	20

Source : *(4)*

Epidemiological determinants

Agent factors

(a) AGENTS : The leishmania are intracellular parasites. They infect and divide within macrophages. At least nineteen different leishmania parasites have been associated with human infection. Further, the majority of these offer no cross immunity of one against the other *(5)*. *Leishmania donovani* is the causative agent of kala-azar (VL); *L. tropica* is the causative agent of cutaneous leishmaniasis (oriental sore); and, *L. braziliensis* is the causative agent of muco-cutaneous leishmaniasis. But this distinction is not absolute; visceral forms may produce cutaneous lesions, and cutaneous forms may visceralize *(6)*. The life cycle is completed in two different hosts – a vertebrate and an insect; in the former, it occurs in an amastigote form (called "leishmania bodies") and in the latter as a flagellated promastigote. *(b) RESERVOIRS OF INFECTION :* There is a variety of animal reservoirs, e.g., dogs, jackals, foxes, rodents and other mammals. Indian kala-azar is considered to be a non–zoonotic infection with man as the sole reservoir. This assumption is based largely on the absence of evidence *(7)*.

Host factors

(a) AGE : Kala-azar can occur in all age groups including infants below the age of one year. In India, the peak age is 5 to 9 years *(1)*. *(b) SEX :* Males are affected twice as often as females. *(c) POPULATION MOVEMENT :* Movement of population (migrants, labourers, tourists) between endemic and non–endemic areas can result in the spread of infection. *(d) SOCIO-ECONOMIC STATUS :* Kala-azar usually strikes the poorest of the poor. Poverty increases the risk for kala-azar. Poor housing and domestic sanitary conditions (e.g. lack of waste management, open sewerage) may increase sandfly breeding and resting sites, as well as their access to humans. Sandflies are attracted to crowded housing as these provide a good source of blood-meal. Human behaviour, such as sleeping outside or on the ground, may increase risk. As a disease it more often debilitate than kills, and makes people become dependants on others; *(e) MALNUTRITION :* Diets lacking protein-energy; iron, vitamin A and zinc increases the risk that an infection will progress to kala-azar *(3)*. *(f) OCCUPATION :* The disease strongly associates with occupation. People who work in various farming practices, forestry, mining and fishing have a great risk of being bitten by sandflies. *(g) IMMUNITY :* Recovery from kala-azar and oriental sore gives a lasting immunity. During the active phase of kala-azar, there is impairment of cell mediated immunity, this is reflected in the negative skin reaction to leishmanin test.

Environmental factors

(a) ALTITUDE : Kala-azar is mostly confined to the plains; it does not occur in altitudes over 2000 feet (600 metres). (b) SEASON : In the past epidemics, two peaks, one in November and another in March–April were reported. Generally there is high prevalence during and after rains. (c) CLIMATE CHANGES : Kala-azar is climate sensitive, and is strongly affected by changes in rainfall, temperature and humidity. Global warming and land degradation together affect the epidemiology of kala-azar in many ways. It can have strong effects on vector and reservoir hosts by altering their distribution and influence their survival. Drought famine and flood resulting from climate changes can lead to massive displacement and migration of people to areas with transmission of kala-azar, and poor nutrition could compromise their immunity *(3)*. (d) RURAL AREAS : The disease is generally confined to rural areas, where conditions for the breeding of sandflies readily exist compared to urban areas. (e) VECTORS : In India, *P. argentipes* is a proven vector of kala-azar. Cutaneous leishmaniasis is transmitted by *P. papatasi* and *P. sergenti*. Sandflies breed in cracks and crevices in the soil and buildings, tree holes, caves etc. Overcrowding, ill-ventilation and accumulation of organic matter in the environment facilitate transmission. Their habits are primarily nocturnal. Only the females bite. (f) DEVELOPMENT PROJECTS : Ironically many development projects are exposing more people to leishmaniasis. Forest clearing, and cultivation projects, large water resource schemes, and colonization and resettlement programmes are bringing human beings into areas of high vector and reservoir concentration *(3)*.

Mode of transmission

In India, Kala-azar is transmitted from person to person by the bite of the female phlebotomine sandfly, *P. argentipes* which is a highly anthrophilic species. Transmission may also take place by contamination of the bite wound or by contact when the insect is crushed during the act of feeding. Cutaneous leishmaniasis is transmitted by *P. papatasi* and *P. sergenti*.

After an infective blood meal, the sandfly becomes infective in 6 to 9 days (extrinsic incubation period). This is the time required for the development of the parasite in the insect vector. Transmission of kala-azar has also been recorded by blood transfusion *(6)*, and is also possible by contaminated syringes and needles *(8)*.

Incubation period

The incubation period in man is quite variable, generally 1 to 4 months; range is 10 days to 2 years.

Clinical features

1. Kala-azar (VL)

The classical features of kala-azar are fever, splenomegaly and hepatomegaly accompanied by anaemia and weight–loss. A family history of the disease is also common. Darkening of the skin of the face, hands, feet and abdomen is common in India (kala-azar = black sickness). Atypical features of the disease (e.g., lymphadenopathy) may also occur. Kala-azar, if left untreated, has a high mortality.

PKDL : Post-kala-azar dermal leishmaniasis, caused by *L. donovani,* is common in India. It appears one to several years after apparent cure of kala-azar. The lesions consist of multiple nodular infiltrations of the skin, usually without ulceration. Parasites are numerous in the lesion.

2. Cutaneous leishmaniasis

Several forms of cutaneous leishmaniasis have been described – Anthroponotic or urban cutaneous leishmaniasis (ACL), Zoonotic or rural cutaneous leishmaniasis (ZCL), Diffuse cutaneous leishmaniasis (DCL), etc *(1)*. The disease may be mistaken for leprosy. The agent is restricted to skin. The disease is characterized by painful ulcers in the parts of the body exposed to sandfly bites (e.g., legs, arms or face) reducing the victim's ability to work.

3. Muco-cutaneous leishmaniasis

Ulcers similar to the oriental sore (CL) appear around the margins of mouth and nose. It can mutilate the face so badly that victims may become social outcasts.

Laboratory diagnosis

1. Parasitological diagnosis

The demonstration of the parasite LD bodies in the aspirates of the spleen, liver, bone marrow, lymph nodes or in the skin (in the case of CL) is the only way to confirm VL or CL conclusively. The parasite must be isolated in culture to confirm the identity of the parasite.

2. Aldehyde test

The aldehyde test of Napier is a simple test widely used in India for the diagnosis of kala-azar. 1 to 2 ml of serum from a case of kala-azar is taken and a drop or two of 40 per cent formalin is added. A positive test is indicated by jellification to milk–white opacity like the white of a hard–boiled egg so that in ordinary light newsprint is invisible through it. If it occurs within 2 to 20 minutes, it is said to be strongly positive. Reaction after 30 minutes is not significant. The test usually becomes positive 2 to 3 months after onset of the disease, and reverts to negative 6 months after cure. Therefore, this test is good for surveillance but not for diagnosis. The test is non–specific and demands the use of venous blood. Further, the test is positive in many other chronic infections in which albumin to globulin ratio is reversed.

3. Serological tests

Of the numerous serological tests available, Direct Aggutination test (DAT), rk39 dipstick test, ELISA and the indirect fluorescent antibody test (IFAT) are considered most suitable *(9)*. Being a simple test where blood samples can be collected on a filter paper strip and examined at leisure in laboratory, the ELISA test has a wide potential both for diagnosis as well as for epidemiological field surveys.

The rk39 – rapid diagnostic test is based on the recombinant k 39 protein. It is an epitope apparently conserved on amastigotes of *Leishmania* species that cause visceral infection. The test is simple to perform and yields result within five minutes. However, the test should not be used in Kala-azar relapse cases, Kala-azar reinfection cases and Kala-azar and HIV co-infection cases.

Kala-azar dipstick test strip is a membrane, pre-coated with a recombinant VL antigen on the test line region and chicken anti-protein A on the control line region. It is a immunochromatographic assay for qualitative detection of antibodies to *L. donovani* in human serum. During testing the serum sample reacts with the dye conjugate. The mixture then migrates upwards on the membrane chromatographically by capillary action to react with rk39 antigen on the membrane and generates a red line. Presence of this red line indicates a positive result while its absence indicates a negative result.

Regardless of the presence of antibody to VL antigen, as the mixture continues to migrate across the membrane to the immobilized chicken antiprotien A region, a red line at the control line will always appear. The presence of this red line serves as a verification for sufficient sample volume and proper flow, and is a control for the reagent. If no lines appear at control and test line areas, the test is invalid. The test is also invalid if no control line appears, even though a test line is seen *(9)*.

4. Leishmanin (Montenegro) test

This test is based on skin reaction. Leishmanin is a preparation of 10^6 per ml washed promastigotes of leishmania, suspended in 0.5 per cent phenol saline or merthiolate. Sterile and standardized preparations are available commercially. An intradermal injection of 0.1 ml on the flexor surface of the forearm is given and examined after 48 to 72 hours. Induration is measured and recorded. An induration of 5 mm or more is considered positive. The test is usually positive 4 to 6 weeks after onset in the case of CL and MCL. It is usually negative in the active phase of kala-azar and becomes positive in 75 per cent patients within one year of recovery. The test is not species–specific. The test remains a valuable tool for distinguishing immune from non–immune subjects. From this information, it may be possible to infer the endemicity or epidemicity of the infection and to identify groups at risk of infection *(9)*.

5. Haematological findings

These include progressive leucopenia, anaemia and reversed albumin–globulin ratio, with greatly increased IgG. The WBC:RBC ratio is 1:1500 or even 1:2000 (normal 1:750). ESR is increased.

ICMR has developed a new kit to diagnose Kala-azar, which was launched on 3rd Sept. 2014. The test needs the sample of urine or oral fluid of the subject in question. It is mixed with the given solution in the 'tube' - part of the kit. Dip the stipulated strip in the solution thus created. Those infected would get two or one red bond on the strip once it comes out. Absence of the red bond means negative result.

Some definitions *(10)*

1. *Case definition of kala-azar :* A case of kala-azar is defined as a person from an endemic area with fever of more than 2 weeks duration and with splenomegaly, who is confirmed by an RDT or a biopsy.
2. *Treatment outcome definitions of kala-azar*
   a. *Cure :* a patient is considered clinically cured if he/she has completed full treatment and there are no signs and symptoms of kala-azar.
   b. *Non-response :* Signs and symptoms persist or recur despite satisfactory treatment for more than two weeks.
   c. *Relapse :* any reappearance of kala-azar signs and symptoms within a period of six months after the end of treatment.
   d. *Treatment failure :* non-response or relapse.
   e. *Final cure :* an initially cured patient who is symptom-free at six months after the end of treatment.
3. *Case definition of PKDL*
   a. *Probable PKDL :* a patient from kala-azar endemic area with multiple hypopigmented macules, papules or nodules, who is RDT positive.
   b. *Confirmed PKDL :* a patient from kala-azar endemic area with multiple hypopigmented macules, papules, plaques or nodules, who is parasite positive in slit-skin smear (SSS) or biopsy.

Treatment outcome in PKDL

a. *Initial cure :* Clinical improvement at the end of treatment–defined as a considerable reduction in the number and size of skin lesions.
b. *Final cure :* Clinical cure 12 months after the end of treatment–defined as a complete resolution of macules, papules, plaques and nodules.

Key indicators in the kala-azar elimination initiative *(10)*

1. *Detection rate (%)*

$$= \frac{\text{Numer of new cases of KA detected per year in the district, UHC or subdistrict}}{\text{Total population in the same area}} \times 100$$

2. *Treatment completion rate (%)*

$$= \frac{\text{Number of patients that took a full course of first-line drugs}}{\text{All new KA cases that started treatment in a given period}} \times 100$$

3. *Coverage rate of vector control (%)*

$$= \frac{\text{Number of households protected}}{\text{All households at risk}} \times 100$$

Monitoring clinical outcomes *(10)*

1. *Final cure rate (%)*

$$= \frac{\text{Number of patients with final cure}}{\text{Total number who started treatment}} \times 100$$

2. *Treatment failure rate (%)*

$$= \frac{\text{Total number of non-response + relapse + KA - related deaths}}{\text{Total number who started treatment}} \times 100$$

3. *Loss to follow-up rate (%)*

$$= \frac{\text{Number of defaulters + Number of loss to follow-up}}{\text{Total number who started treatment}} \times 100$$

4. *Mortality (%)*

$$= \frac{\text{Number of deaths}}{\text{Total number who started treatment}} \times 100$$

CONTROL MEASURES

In the absence of an effective vaccine, the control measures comprise the following :

1. Control of reservoir

Since man is the only reservoir of kala-azar in India, active and passive case detection and treatment of those found to be infected (including PKDL) may be sufficient to abolish the human reservoir and control the disease. House-to-house visits and mass surveys may be undertaken in endemic areas for early detection of cases.

TREATMENT *(11)*

The drug policy under Kala-azar elimination programme as per recommendation of Expert Committee (2000) is as follows :

A. *1. First line drugs– short-term*
   a. In areas with sodium stibogluconate (SSG) sensitivity more than 90 per cent.
      – SSG 20 mg/kg body wt/day (maximum 850 mg/day) intramuscular or intravenous for 20 days, if partial response to 20 days treatment then continue for 30 days.
   b. In areas with SSG sensitivity less than 90 per cent
      – Amphotericin B 1mg/kg body wt intravenous infusion daily or alternate day for 15–20 infusions, dose can be increased in patients with incomplete response with 30 injections.

2. First line drugs– long-term
   a. In areas with high level of SSG resistance (> 20%)
      – Miltefosine 100 mg daily in two divided doses for 4 weeks. (2.5 mg/kg body wt/day in two divided doses)
   b. In areas with SSG sensitivity > 80 per cent
      – SSG IM or IV 20 mg/kg/day for 30 days.
      – Miltefosine 100 mg daily for 4 weeks (after phase III studies completed with proven safety and efficacy).

B. *Second line drugs*
   1. SSG failures
      – Amphotericin B 1mg/kg body wt, IV infusion daily or alternate day for 15–20 infusions. Dose can be increased in patients with incomplete response with 30 injections.

2. *SSG and Miltefosine failure*
   - Liposomal Amphotericin B (when final results are available with proven efficacy and safety)

   Treatment of PKDL : SSG in usual dosage for kala-azar could be given for 120 days.
   - Repeated 3–4 courses of Amphotericin B can be given in patients failing SSG treatment.

The patient, in either case should be examined 3 and 12 months after the treatment course to detect any relapse.

A new drug namely "Liposomal Amphotericin B" in dose of 10 mg, administered intravenously as a single dose therapy has been introduced in the Kala-azar therapy. It will help reduce human reservior as it cures the patient with a single shot. WHO has agreed to supply the drug free of cost.

Animal reservoirs

If animal reservoirs (e.g., dogs) are involved, appropriate control measures against them should be undertaken. In many endemic countries, extensive dog and rodent control programmes have contributed greatly to the reduction in the number of human cases.

2. Sandfly control

The application of residual insecticides has proved effective in the control of sandflies. DDT is the first choice since the vector of kala-azar, *P. argentipes* is susceptible to DDT. (*P. papatasi* in north Bihar has been shown to be resistant to DDT, but fortunately, it is not the vector of kala-azar in India). Insecticide spraying should be undertaken in human dwellings, animal shelters and all other resting places upto a height of 6 feet (2 metres) from floor level. DDT (two rounds per year) at the rate of 1–2 g per sq. metre is considered sufficient to control transmission. Spraying should be preceded and followed by an assessment of susceptibility. Any sign of resistance in vector should lead to an immediate change in insecticide. BHC should be kept as a second line of defence.

Spraying should be repeated at regular intervals to keep down the density of sandflies. For long-lasting results, insecticidal spraying should be combined with **sanitation measures,** viz elimination of breeding places (e.g., cracks in mud or stone walls, rodent burrows, removal of firewood, bricks or rubbish around houses), location of cattle sheds and poultry at a fair distance from human dwellings, and improvement of housing and general sanitation.

3. Personal prophylaxis

The risk of infection can be reduced through health education and by the use of individual protective measures such as avoiding sleeping on floor, using fine–mesh nets around the bed. Insect repellents (in the form of lotions, creams, or sticks) for temporary protection and keeping the environment clean. There are no drugs for personal prophylaxis.

V. SURFACE INFECTIONS

TRACHOMA

Trachoma is a chronic infectious disease of the conjunctiva and cornea, caused by *Chlamydia trachomatis,* but other pathogenic microorganisms often contribute to the disease. Trachoma inflammation may undergo spontaneous resolution or may progress to conjunctival scarring which can cause inward deviation of eyelashes (trichiasis) or of the lid margin (entropion). The abrasion of the cornea by eyelashes frequently result in corneal ulceration, followed by scarring and visual loss.

From the public health point of view, trachoma is classified as blinding and non-blinding *(1).* A community with blinding trachoma can be recognized by the presence of persons with lesions such as entropion, trichiasis and corneal ulcers. It is the blinding trachoma that requires urgent control measures. Non-blinding trachoma often becomes blinding trachoma when other ocular pathogens interact synergistically and enhance the risk of damage to eye sight *(2).*

Diagnosis

In epidemiological studies, more stress is now put on the upper tarsal conjunctiva as a convenient index of trachomatous inflammation in the eye as a whole *(2).* For the purpose of diagnosis in the field, cases must have at least 2 of the following diagnostic criteria *(3).*

a. follicles on the upper tarsal conjunctiva
b. limbal follicles or their sequelae, Herbert's pits
c. typical conjunctival scarring (trichiasis, entropion)
d. vascular pannus, most marked at the superior limbus

Problem statement

Trachoma is a major preventable cause of blindness in developing countries. According to recent estimates, about 2.2 million people currently suffer from visual impairment due to trachoma, of these 1.2 million are irreversibly blind, and about 324.85 million are at risk of infection *(4).*

The incidence and prevalence of trachoma has shown a significant decrease in many endemic countries of SEAR during the past few decades. This decrease has been mainly due to improved sanitation, water and housing, and implementation of control measures. However, trachoma, particularly in its active form, still remains a public health concern in some parts of Myanmar, in the western region of Nepal and in a few rural areas in India *(5).* It is estimated to be responsible for 0.2 per cent of visual impairment and blindness in India *(6).*

Epidemiological determinants

Agent factors

(a) AGENT : The classical endemic trachoma of developing countries is caused by *C. trachomatis* of immune types A, B, or C. The sexually-transmitted *C. trachomatis* (serotypes D,E,F,G,H,I,J or K) may also infect, causing an eye disease difficult to differentiate from endemic trachoma. Milder cases of this are usually called "inclusion conjunctivitis". These strains rarely produce permanent visual loss – but they cause respiratory infections (pneumonia) in infants and genital tract infections in adults *(2)*. Other pathogenic organisms (e.g., Morax–Axenfeld diplobacillus, the Koch–Weeks bacillus, the gonococcus) often contribute to the disease process. The Morax–Axenfeld diplobacillus is the most innocuos; the Koch–Weeks bacillus is the most widespread, and the gonococcus the most dangerous *(7)*. *C. trachomatis,* originally believed to be a virus, is an obligatory intracellular bacteria, now classified as Chlamydia. (b) RESERVOIR : Children with active disease, chronically infected older children and adults. (c) SOURCE OF INFECTION : Ocular discharges of infected persons and fomites, and (d) COMMUNICABILITY: Trachoma is a disease of low infectivity. It is infective as long as active lesions are present in the conjunctiva, but not after complete cicatrization.

Host factors

(a) AGE : In endemic areas, children may show signs of the disease at the age of only a few months. But typically, children from the age of two to five years are the most infected, and this contributes not only to the high rate of blindness but also to the rate of occurrence among children. (b) SEX : Prevalence equal in younger age groups. In older age groups, females have been found to be affected more than males. The explanation for this may be that women remain more in contact with children who infect them. Further, females are more exposed to irritating factors such as smoke than males. (c) PRE-DISPOSING FACTORS : Direct sunlight, dust, smoke and irritants such as *kajal* or *surma* may predispose to infection.

Environmental factors

(a) SEASON : Seasonal epidemics are associated with vastly increased number of eye–seeking flies. The incidence of active trachoma is found generally high in India during April–May and again during July–September. The higher temperature and rainfall favours the increase in fly population. (b) QUALITY OF LIFE : Trachoma is associated with poor quality of life. The disease thrives in conditions of poverty, crowding, ignorance, poor personal hygiene, squalor, illiteracy and poor housing. As living conditions improve the disease tends to regress. (c) CUSTOMS : The custom of applying *kajal* or *surma* to the eyes is a positive risk factor.

Mode of transmission

In communities where trachoma is endemic, eye-to-eye transmission can be considered as a rule *(8)*. This may occur by direct or indirect contact with ocular discharges of infected persons or fomites, e.g., infected fingers, towels, *kajal* or *surma*. Eye-seeking flies (e.g., *Musca* spp., *Hippelatus* spp.) play some role in spreading the infection by mechanical transmission. In countries where only sporadic cases of trachoma occur, genital localization of *C. trachomatis* (urethral, cervical) may lead to venereal transmission *(7)*.

It has been shown that trachoma is a familial disease. When one case is detected, others will almost certainly be found in the family group. There is a continuous feedback of infection, partly as a result of grandfathers or sisters and brothers tending small children *(8)*.

Incubation period

5 to 12 days.

CONTROL OF TRACHOMA

Trachoma control still requires long-term efforts. It requires proper planning and organization, which should include the following elements :

1. Assessment of the problem

The primary objective of a programme for the control of trachoma is the prevention of blindness. Control programmes should be focussed on communities with a substantial prevalence of "blinding trachoma" – as indicated by the presence of : (a) corneal blindness (b) trachomatous trichiasis and entropion, and (c) moderate and severe trachomatous inflammation. Such communities are likely to be found in countries with blindness rates that are above 0.5 per cent. The first task, therefore, is to undertake an epidemiological survey to identify and delimit communities with blinding trachoma; assess the magnitude of the problem, local conditions and other causes of blindness and to obtain information on existing facilities. The basic principles of these surveys are set out in the WHO publication : "Methods of Assessment of Avoidable Blindness" *(9)*.

2. Chemotherapy

In trachoma control, the main activity is chemotherapeutic intervention. The objective of chemotherapy is to reduce severity, lower the incidence and in the long run decrease the prevalence of trachoma. The antibiotic of choice is 1 per cent ophthalmic ointment or oily suspension of tetracyclines. Erythromycin and rifampicin have also been used in the treatment of trachoma. Treatment may be given to the entire community – this is known as **mass treatment** (or blanket treatment). In some programmes, **selective treatment** is chosen, in which case, the whole population at risk is screened, and treatment is applied only to persons with active trachoma *(10)*.

(a) Mass treatment

A prevalence of more than 5 per cent severe and moderate trachoma in children under 10 years is an indication for mass or blanket treatment. The treatment consists of the application twice daily of tetracycline 1 per cent ointment to all children, for 5 consecutive days each month or once daily for 10 days each month for 6 consecutive months, or for 60 consecutive days *(2)*. An alternative antibiotic is erythromycin.

From the practical point of view, one of the main difficulties is the need for repeated applications of the antibiotic over long periods of time. Emphasis is now being placed on the active participation of the community itself in trachoma control activities and on the utilization of village health guides (primary health care workers). This makes possible a wider coverage and a greater efficacy of the programme *(10)*.

(b) Selective treatment

In communities with a low to medium prevalence, treatment should be applied to individuals by *case finding* rather than by community–wide coverage, the principals of treatment remaining the same. For the selective treatment to be effective, the whole population at risk must be screened for case finding.

3. Surgical correction

Antibiotic ointment is just one component of a trachoma control programme. Individuals with lid deformities (trichiasis, entropion) should be actively sought out, so that necessary surgical procedures can be performed and followed-up. It has an immediate impact on preventing blindness.

4. Surveillance

Once control of blinding trachoma has been achieved, provision must be made to maintain surveillance, which may be necessary for several years after active inflammatory trachoma has been controlled. Since trachoma is a familial disease, the whole family group should be under surveillance.

5. Health education

In the long run, most of the antibiotic treatment must be carried out by the affected population itself. To do this, the population needs to be educated. The mothers of young children should be the target for health education. Measures of personal and community hygiene should also be incorporated in programmes of health education. Thus real primary prevention could only come through health education for the total elimination of transmission. This would require a permanent change in the behaviour patterns and in environmental factors. The final solution would be the improvement of living conditions and quality of life of the people *(10)*.

6. Evaluation

Lastly evaluation. Trachoma control programme must be evaluated at frequent intervals. The effect of intervention can be judged by the changes in the age-specific rates of active trachoma and in the prevention of trichiasis and entropion.

The 28th World Health Assembly in 1975, in a resolution requested the Director General of WHO "to encourage Member countries to develop national programmes for the prevention of blindness especially aimed at the control of trachoma, xerophthalmia, onchocerciasis and other causes". With this came the re-orientation of strategies away from single cause prevention, to the adoption of the concept of integrated delivery of eye care as part of primary health care. In this context, many countries have now integrated their trachoma control programmes into National Programmes for the Prevention of Blindness, to give simultaneous introduction of other specific measures for dealing with all causes of avoidable blindness.

The trachoma control programme in India which was launched in 1963 has now been integrated with the National Programme for Control of Blindness (see chapter 7, page 439). The "Health for All by 2000" had set a target of reducing the prevalence of blindness to 0.3 per cent *(11)*.

TETANUS

An acute disease induced by the exotoxin of *Clostridium tetani* and clinically characterized by muscular rigidity which persists throughout illness punctuated by painful paroxysmal spasms of the voluntary muscles, especially the masseters (trismus or "lock–jaw"), the facial muscles (risus sardonicus), the muscles of the back and neck (opisthotonos), and those of the lower limbs and abdomen *(1)*. The mortality tends to be very high, varying from 40 to 80 per cent.

Problem statement

WORLD

Tetanus is now comparatively rare disease in the developed countries. Neonatal tetanus (NT) is a killer disease, second only to measles among the six target diseases of the EPI. Even with treatment, the case–fatality rate can be as high as 80–90 per cent. It tends to occur in areas with poor access to health care, hence it often remains hidden within the community.

Community surveys have consistently shown that only a small proportion of NT cases are routinely reported to notifiable disease reporting system in most developing countries; and under-reporting is often highest in areas at highest risk for NT. Because of this low notification efficiency, WHO makes estimates of annual neonatal tetanus morbidity and mortality. Estimation methods previously used the number of live births, the estimated number of infants protected at birth by routine vaccination strategies and prevaccination mortality rates based on community surveys. Estimation methods were updated to account also for the number of infants protected through supplementary vaccination and as a result of skilled deliveries.

During 2012, a total of 10,392 cases of tetanus and 4,650 cases of neonatal tetanus were reported to WHO worldwide *(3)*.

INDIA

Tetanus is an important endemic infection in India. Behaviours such as hand-washing, delivery practices, traditional birth customs and interest in immunization, are all important factors affecting the disease incidence. Medically under-served areas and livestock raising regions are two environments particularly associated with behaviour conducive to neonatal tetanus.

Since 1983 in India, the nationwide EPI has recommended the provision of 2 doses of tetanus toxoid to all pregnant women during each pregnancy (or one booster dose if <3 years have passed since the previous pregnancy) to prevent neonatal and maternal tetanus. In addition to immunization, hospital and primary health centres where clean deliveries can be performed have been established and a cadre of trained ANM and other trained birth attendants have been developed and deployed to ensure clean delivery and cord care practices. More recently, under the National Rural Health Mission launched in 2005, the Government of India has provided training to health workers. The mission also actively encourages institutional deliveries through interventions such as the "Janani Suraksha Yojana".

These measures have contributed to reducing the burden of neonatal tetanus (NT) in India considerably. In 2013, about 528 cases of neonatal tetanus were reported in India compared to 11,000 in 1989. However, as the disease is typically and vastly underreported, the true NT burden in India is likely to be substantially higher than reported numbers indicate *(4)*.

By the end of 2008, India had validated NT elimination in 15 states/UTs. They are Andhra Pradesh, Chandigarh, Goa, Haryana, Karnataka, Kerala, Laskhadweep, Maharashtra, Puducherry, Punjab, Sikkim, Tamil Nadu and West Bengal. In June 2008, community-based surveys were carried out to assess whether NT had also been eliminated in the states of Gujarat and Himachal Pradesh *(4)*.

The preventive measures in the areas of high risk are being accelerated to reduce the number of cases. In areas considered at low risk, the surveillance system is being sensitized to ensure that no case is missed. A district classification has, therefore, been suggested, so that area-specific action oriented measures, could be taken and the progress monitored.

Districts are being classified into three categories depending on NT incidence rates, immunization coverage levels in pregnant women with two doses or a booster dose of tetanus toxoid vaccine, and proportion of clean deliveries by trained personnel *(6)*.

Neonatal tetanus elimination (Classification of districts)

NT high risk :		–	Rate > 1/1000 live births
	or	–	TT_2 coverage < 70%
	or	–	Attended deliveries < 50%
NT control :		–	Rate < 1/1000 live births
	and	–	TT_2 coverage > 70%
	and	–	Attended deliveries > 50%
NT elimination :		–	Rate < 0.1/1000 live births
	and	–	TT_2 coverage > 90%
	and	–	attended deliveries > 75%

Hospital records show a major male preponderance of cases. Since there is no biological reason why male infants should be more susceptible, it is in all likelihood, due to the male children being brought to the health facilities more frequently. For purpose of classification of districts with NT risk, the male bias is taken into account. The total number of cases of NT for a district is considered to be two times the number of reported male cases *(6)*.

NT has a marked seasonal incidence in India. More than 50 per cent of the total annual cases of NT occur in the month of July, August and September.

Reporting of NT cases by hospitals and other treatment facilities has been made mandatory. A monthly "nil" report is required to be submitted by all hospitals, if no NT case is seen. The cases are reported to the chief medical officer of the concerned district. Line lists of the cases are submitted to enable identification of high risk pockets of areas for specific interventions.

Epidemiological determinants

Agent factors

(a) AGENT : *Cl. tetani* is a gram–positive, anaerobic, spore–bearing organism. The spores are terminal and give the organism a drum-stick appearance. The spores are highly resistant to a number of injurious agents, including boiling, phenol, cresol and autoclaving for 15 minutes at 120 deg. Centigrade *(7)*. They germinate under anaerobic conditions and produce a potent exotoxin ("tetanospasmin"). The spores are best destroyed by steam under pressure at 120 deg. C for 20 minutes or by gamma irradiation. (b) RESERVOIR OF INFECTION : The natural habitat of the organism is soil and dust. The bacilli are found in the intestine of many herbivorous animals, e.g., cattle, horses, goats and sheep and are excreted in their faeces. The spores survive for years in nature. The bacilli may be found frequently in the intestine of man without causing ill-effects. The spores are blown about in dust and may occur in a wide variety of situations, including operation theatres. (c) EXOTOXIN : Tetanus bacilli produce a soluble exotoxin. It has an astounding lethal toxicity, exceeded only by botulinum toxin. The lethal dose for a 70 kg man is about 0.1 mg *(8)*. The toxin acts on 4 areas of the nervous system : (a) the motor end plates in skeletal system (b) the spinal cord (c) the brain, and (d) the sympathetic system *(7)*. Its principal action is to block inhibition of spinal reflexes *(8)*. (d) PERIOD OF COMMUNICABILITY : None. Not transmitted from person to person.

Host factors

(a) AGE : Commonly, tetanus is a disease of the active age (5 to 40 years). This period predisposes to all kinds of trauma and therefore, the risk of acquiring the disease is pretty high. Tetanus occurring in the new-born is known as "neonatal tetanus". Infants typically contact the disease at birth, when delivered in non–aseptic conditions – especially when the umbilical cord is cut with unclean instruments or when the umbilical stump is dressed with ashes, soil or cowdung. (b) SEX : Although a higher incidence is found in males, females are more exposed to the risk of tetanus, especially during delivery or abortion leading to "puerperal tetanus". Males appear to be more sensitive to tetanus toxin than females *(9)*. (c) OCCUPATION : Agricultural workers are at special risk because of their contact with soil. (d) RURAL–URBAN DIFFERENCES : The incidence of tetanus is much lower in urban than in rural areas. Within the urban areas, there may be vast differences in the incidence of tetanus. For example, it was observed in one town that tetanus was more frequent on the outskirts where floors were earthen and animals lived close to human beings, than in the centre of the town where there were paved and mosaic floors *(10)*. (e) IMMUNITY : No age is immune unless protected by previous immunization. The immunity resulting from 2 injections of tetanus toxoid is highly effective and lasts for several years. As a general rule, patients who have recovered from tetanus must be actively immunized, because the amounts of toxin responsible for the disease in man do not stimulate protective immunity *(8)*.

Immunity lasting for a few weeks (less than 6 months) can be transferred to the baby, if the mother is immunized during pregnancy or if she already has a high level of immunity at the time she becomes pregnant. Tetanus is one disease in which herd immunity does not protect the individual.

Environmental and social factors

Tetanus is a positive environmental hazard *(11)*. Its occurrence depends upon man's physical and ecological surroundings – the soil, agriculture, animal husbandry – and not on the presence or absence of infection in the population. The environmental factors are compounded by social factors such as unhygienic customs and habits (e.g., application of dust or animal dung to wounds); unhygienic delivery practices (e.g., using unsterilized instruments for cutting the umbilical cord); ignorance of infection and lack of primary health care services. In the developed countries, urbanization, industrialization and mechanization of agriculture have interfered with the normal process of distribution of *Cl. tetani* and have reduced the morbidity rate, as has occurred, for example in UK, USA and Germany during the last 40 years *(9)*.

Mode of transmission

Infection is acquired by contamination of wounds with tetanus spores. The range of injuries and accidents which may lead to tetanus – comprise a trivial pin prick, skin abrasion, puncture wounds, burns, human bites, animal bites and stings, unsterile surgery, intra-uterine death, bowel surgery, dental extractions, injections, unsterile division of umbilical cord, compound fractures, otitis media, chronic skin ulcers, eye infections, and gangrenous limbs *(8)*.

The sequence of events are : introduction of spores, germination and elaboration of the exotoxin and binding to the receptor.

Incubation period

The incubation period is usually 6 to 10 days. However, it may be as short as one day or as long as several months *(8)*. Long incubation is probably explained by the spores lying dormant in the wounds. Incubation is also prolonged by prophylaxis *(8)*.

Types of tetanus

(a) TRAUMATIC : Trauma is a major and important cause of tetanus. Sometimes tetanus may result from most trivial or even unnoticed wounds. (b) PUERPERAL : Tetanus follows abortion more frequently than a normal labour. A post–abortal uterus is a favourable site for the germination of tetanus spores. (c) OTOGENIC : Ear may be a rare portal of entry. Foreign bodies such as infected pencils, matches, and beads may introduce the infection. Otogenic tetanus is a paediatric problem, but cases, may occur in adults also. (d) IDIOPATHIC : In these cases there is no definite history of sustaining an injury. Some consider it to be the result of microscopic trauma. Others hold the view that it is due to the absorption of tetanus toxin from the intestinal tract. A third view is that the tetanus spores may be inhaled and may start the infection. (e) TETANUS NEONATORUM : In many countries, neonatal tetanus kills about 85 per cent of those afflicted *(12)*. The common cause is infection of the umbilical stump after birth, the first symptom being seen about the 7th day. Therefore tetanus is known as "8th day disease" in Punjab *(10)*. In any country where hygiene is poor, neonatal tetanus may be common.

PREVENTION

1. Active immunization (13, 14, 15)

Tetanus is best prevented by active immunization with tetanus toxoid. It stimulates the production of the protective antitoxin. The aim should be to vaccinate the entire community and ensure a protective level of antitoxin approximately 0.01 IU/ml serum throughout life. All persons should be immunized regardless of age.

Two preparations are available for active immunization

a. *Combined vaccine – DPT*
b. *Monovalent vaccines*
   i) Plain or fluid (formal) toxoid
   ii) Tetanus vaccine, adsorbed (PTAP, APT)

a. COMBINED VACCINE

Tetanus vaccine is offered routinely to infants (Expanded Immunization Programme) in combination with diphtheria vaccine and killed *B. pertussis* organisms as DPT vaccine. According to the National Immunization Schedule (see page 123), the primary course of immunization consists of 3 doses of DPT, at intervals of 4–8 weeks, starting at 6 weeks of age, followed by a booster at 18 months of age, and a second booster (Only DT) at 5–6 years of age and a third booster (Only TT) after 10 years of age.

b. MONOVALENT VACCINES

Purified tetanus toxoid (adsorbed) has largely supplanted plain toxoid because it stimulates a higher and longer–lasting immunity response than plain toxoid *(16)*. However, the latter may be employed for purposes of booster injection when rapid protection is indicated.

A primary course of immunization consists of two doses of tetanus toxoid adsorbed (each dose 0.5 ml, injected into the arm) given at intervals of 1–2 months. The longer the intervals between the two doses, the better is the immune response. The first booster dose (the third in order) should be given a year after the initial two doses. The opinion was expressed that no more than one additional booster dose (a total of 4 doses altogether) given 5 years after the third dose is required in adults (including pregnant women) in developing countries *(17)*. Frequent boosters must be avoided.

Reactions following the injections of tetanus toxoid are uncommon. They are less likely to occur with a refined and adsorbed toxoid such as Purified Tetanus Toxoid (Aluminium Phosphate Adsorbed). However, in persons giving history of allergy usual precautions should be observed. Purified tetanus toxoid should be stored between 4 and 10 deg. C. It must not be allowed to freeze at any time.

2. Passive immunization (13, 14)

Temporary protection against tetanus can be provided by an injection of human tetanus hyperimmunoglobulin (TIG) or ATS. (i) HUMAN TETANUS HYPERIMMUNOGLOBULIN : It is the best prophylactic to use. The dose for all ages is 250 IU. It does not cause serum reactions. It gives a longer passive protection upto 30 days or more compared with 7–10 days for horse ATS. Human tetanus Ig is now available in India – it is produced by the Serum Institute of India, Pune. (ii) ATS (EQUINE) : If human antitoxin is not available, equine antitoxin (anti-tetanus serum or ATS) should be used. The

standard dose is 1500 IU, injected subcutaneously after sensitivity testing. ATS gives passive protection for about 7–10 days. Being a foreign protein, ATS is rapidly excreted from the body and there may be very little antibody at the end of 2 weeks. Because of this drawback, ATS may not cover the tetanus incubation period in all cases. Horse ATS has other disadvantages too – (i) It causes sensitivity reaction in many people because it contains foreign proteins. A person receiving ATS for the first time may tolerate it well, but there is a possibility that subsequent injections of horse serum may lead to allergic reactions varying in severity from rash to anaphylactic shock. It is estimated that the incidence of serious systemic reactions to ATS is 5 to 10 per cent of the persons who receive it. It is well to remember that local tests for sensitivity are unreliable as to general sensitivity to horse serum. (ii) Another drawback of ATS is that it stimulates the formation of antibodies to it and hence a person who has once received ATS tends to rapidly eliminate subsequent doses. As such the value of second and subsequent doses of ATS becomes questionable. In practice, therefore, ATS becomes less and less reliable as a prophylactic. These drawbacks have been responsible for the growing unpopularity of ATS as an agent for immediate protection against tetanus.

3. Active and passive immunization

Simultaneous active and passive immunization is widely carried out in non-immune persons. The patient is given 1500 units of ATS or 250 units of Human Ig in one arm, and 0.5 ml of adsorbed tetanus toxoid (PTAP or APT) into the other arm or gluteal region. This should be followed 6 weeks later by another dose of 0.5 ml of tetanus toxoid, and a third dose one year later. The purpose of antitoxin is for immediate temporary protection, and the purpose of toxoid is for long–lasting protection.

4. Antibiotics

Active immunization with tetanus toxoid is the ideal method of tetanus prophylaxis, but it is of no immediate avail to a person who is non-immune and has sustained injury. ATS as an agent for immediate protection against tetanus has its drawbacks. For these reasons, antibiotics are indicated in the prophylaxis against tetanus. A single intramuscular injection of 1.2 mega units of a long–acting penicillin (e.g., benzathine penicillin) will provide a sustained concentration of the drug for 3 to 4 weeks, which is sufficient to kill any vegetative forms of tetanus bacilli that may emerge from the sporulating stage. Penicillin has no effect on tetanus spores. For patients who are sensitive to penicillin, a 7–day course of erythromycin estolate 500 mg 6–hourly by mouth will kill vegetative forms of *Cl. tetani* but not spores. Antibiotics should be given as soon as possible after an injury, before a lethal dose of toxin is produced in the wound, which may be as soon as 6 hours after injury. Antibiotic prophylaxis should not be relied upon for patients seen later than 6 hours after injury. Moreover, it is not certain whether the antibiotic can reach the bacilli, if there is dead tissue present in the wound. Therefore, antibiotic alone is ineffective in the prevention of tetanus; it is not a substitute to immunization.

Prevention of neonatal tetanus *(18, 19)*

Neonatal tetanus is well controlled in some industrialized countries through clean delivery practices alone. Over the last decade, most programmes in developing countries have concentrated on training the traditional birth attendants, providing home delivery kits and educating pregnant women about the "three cleans" – clean hands, clean delivery surface and clean cord care i.e., clean blade for cutting the cord, clean tie for the cord and no application on the cord stump. Operational research has shown that training of birth attendants alone can reduce death due to neonatal tetanus by 90 per cent *(20)*.

Tetanus toxoid will protect both the mother and her child. In **unimmunized** pregnant women, two doses of tetanus toxoid should be given, the first as early as possible during pregnancy and the second at least a month later and at least 3 weeks before delivery. According to the National Immunization Schedule (see page 123), these doses may be given between 16–36 weeks of pregnancy, allowing an interval of 1–2 months between the 2 doses. In previously **immunized** pregnant women, a booster dose is considered sufficient. There is no need for a booster at every consecutive pregnancy, because of the risk of hyper-immunization and side-effects.

In areas where the incidence of neonatal tetanus is high, the primary 2–dose course can be extended to all women of child-bearing age, particularly if the present coverage of antenatal care is low.

In developing countries, the majority of pregnant women are not seen antenatally. Since a pregnant woman coming for an antenatal visit may in fact never return again, immunization should be given regardless of the month of pregnancy as there is no evidence to suggest that tetanus toxoids are dangerous or harmful to the foetus. The golden rule is that no pregnant mother should be denied even one dose of tetanus toxoid if she is seen late in pregnancy.

The infants born to the mothers who have not previously received 2–doses of tetanus toxoid are exposed to the risk of neonatal tetanus. They can be protected by injection of antitoxin (heterologous serum, 750 IU), if it is administered within 6 hours of birth.

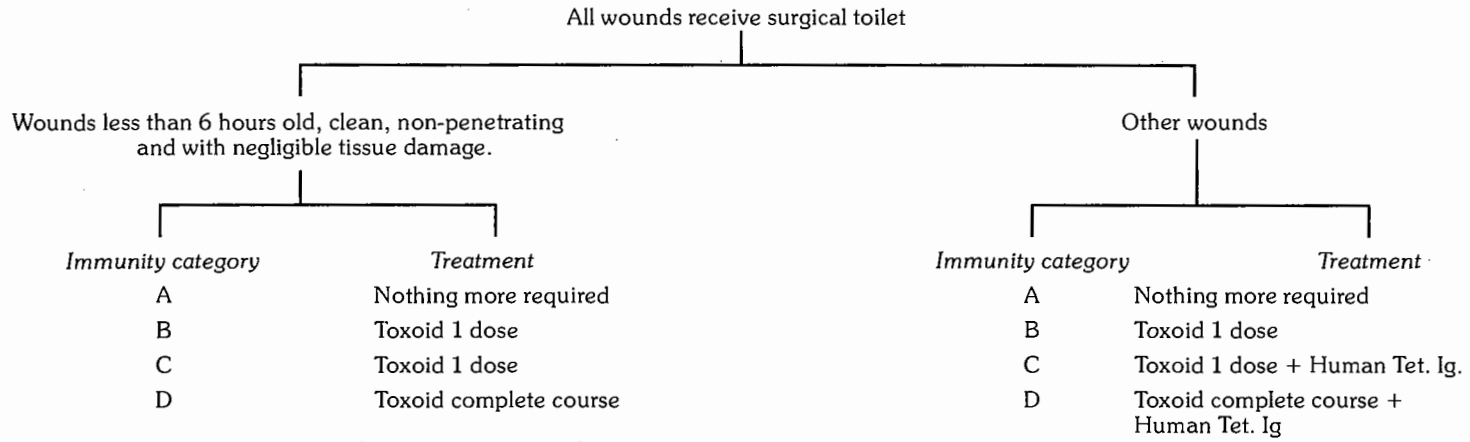
Prevention of tetanus after injury *(15)*

All wounds must be thoroughly cleaned soon after injury – removal of foreign bodies, soil, dust, necrotic tissue. This procedure will abolish anaerobic conditions which favour germination of tetanus spores.

A useful scheme for the prevention of tetanus in the wounded is given in Fig. 1.

When ATS is given, adrenaline solution 1 in 1000 for intramuscular injection in the dosage of 0.5 to 1 ml and hydrocortisone 100 mg for intravenous injection must be kept available in case of a generalized anaphylactoid reaction *(14)*. A test dose of ATS (0.1 ml in a tuberculin syringe) should be given subcutaneously (not intradermally) and the patient observed carefully (not casually) at least for half an hour for any evidence of general reaction (not only local reaction), e.g., alteration in pulse, fall in blood pressure, dyspnoea and distress. If there is reaction, the rest of the antitoxin should be given in gradually increasing fractions after treatment with adrenaline. In patients with history of allergy, e.g., asthma, eczema, food or drug idiosyncracy, the above test should be preceded by a dose of 0.05 ml of 1 in 10 dilution of the ATS. If there is reaction, ATS should be withheld.

Lastly, it should be pointed out that tetanus may occasionally occur inspite of active or passive immunization



A = Has had a complete course of toxoid or a booster dose within the past 5 years.
B = Has had a complete course of toxoid or a booster dose more than 5 years ago and less than 10 years ago.
C = Has had a complete course of toxoid or a booster dose more than 10 years ago.
D = Has not had a complete course of toxoid or immunity status is unknown.

FIG. 1

Recommendations for prevention of tetanus in the wounded

or both. Nevertheless, the aim is to provide as much protection as possible in the light of our present scientific knowledge.

LEPROSY

Leprosy (Hansen's disease) is a chronic infectious disease caused by *M. leprae.* It affects mainly the peripheral nerves. It also affects the skin, muscles, eyes, bones, testes and internal organs. The disease manifests itself in two polar forms, namely the lepromatous leprosy and tuberculoid leprosy, lying at the two ends of a long spectrum of the disease. Between these two polar types occur the borderline and indeterminate forms depending upon the host response to infection.

Leprosy is clinically characterized by one or more of the following cardinal features :

a. hypopigmented patches
b. partial or total loss of cutaneous sensation in the affected areas (the earliest sensation to be affected is usually light touch)
c. presence of thickened nerves, and
d. presence of acid–fast bacilli in the skin or nasal smears.

The signs of advanced disease are striking : presence of nodules or lumps especially in the skin of the face and ears; plantar ulcers; loss of fingers or toes, nasal depression, foot-drop, claw toes and other deformities.

Problem statement

WORLD

In 1991, WHO member states resolved to decrease the level of leprosy in the world by over 90 per cent. This has now been accomplished, and the overall target for the global elimination of leprosy as a public health problem has been attained *(1).* The fall in prevalence rate is largely explained by an improvement in the management of cases, very low rates of relapse, high cure rates, absence of drug resistance and shorter duration of treatment with MDT *(2).*

The achievement can be summarized as follows *(3)* :

(1) Over the past 20 years, more than 16 million leprosy patients have been cured.

(2) The prevalence rate of the disease has dropped from 21.1 cases per 10,000 population in 1985 to 0.32 per 10,000 at the beginning of 2014.

(3) The global burden of leprosy has declined dramatically, from 5.2 million cases in 1985 to 180,618 cases at the beginning of 2014.

(4) Leprosy has been eliminated from 119 of 122 countries where the disease was considered as a public health problem in 1985.

(5) To date, there has been no resistance to antileprosy medicines when used as MDT.

(6) Efforts currently focus on eliminating leprosy at a national level in remaining endemic countries and at a sub-national level from the others.

Although significant progress has been made in controlling the disease and reducing the disease burden, much remains to be done in order to sustain the gains and further reduce the impact of the disease, especially the burden due to the physical, mental and socio-economic consequences of leprosy on persons affected and their families. There is a growing need to develop more effective tools and procedures for early recognition and management of leprosy reactions and nerve damage. Most programmes need to initiate activities to improve the quality of life of persons affected by leprosy through prevention of disability and community-based rehabilitation measures. One of the long-term needs is to develop reliable diagnostic tests for early diagnosis and an effective vaccine for the prevention of leprosy.

WHO has been regularly collecting data on several indicators from various WHO regions and member states. The indicators and reported data is as follows *(3)* :

(1) 215,656 new cases of leprosy were detected during 2013, and the registered prevalence at the beginning of 2014 was 180,618 cases; The number of new cases detected during 2013 in the 14 countries that reported ≥1000 new cases accounted for 95 per cent of all new cases;

(2) Among new cases detected in 2013, the proportion of multibacillary cases of leprosy was about 71.68 per cent; in South East Asia Region (SEAR) it ranged from 43.9 per cent in Bangladesh to 83.4 per cent in Indonesia.

(3) The proportion of females among newly detected cases in 2013 was 44.26 per cent. In SEAR it ranged from 40.8 per cent in Sri Lanka to 16.7 per cent in Timor Leste;

(4) The proportion of children below 15 years was 10.96 per cent. In SEAR it ranged from 4.1 per cent in Nepal to 11.9 per cent in Indonesia;

(5) The proportion of new cases with grade-2 disability was 7.36 per cent. In SEAR it ranged from 2.7 per cent in Nepal to 14.3 per cent in Myanmar. Annually, around 13,289 new cases with grade-2 disability are detected globally.

(6) The number of relapses remained low at about 0.88 per cent.

The South East Asia Region accounts for about 64.44 per cent of the global prevalence at the beginning of 2014, and 72.05 per cent of all new detected cases during 2013. The scenario in detail is as shown in Table 1.

In view of the changing trends in leprosy, the Director General of WHO placed the management of the Global Leprosy Programme under the Regional Director, SEAR, considering that this region has the highest burden of disease globally. The office and staff of the Global Leprosy Programme moved from Geneva to New Delhi on July 1st 2005. The WHO has evolved the Global Strategy for further reducing the leprosy burden and sustaining leprosy control activities 2010–2015.

The WHO enhanced global strategy for further reducing the disease burden due to leprosy (Plan Period : 2011–2015) (4) :

The main principles of leprosy control, based on timely detection of new cases and their treatment with effective chemotherapy in the form of multidrug therapy, will not change over the coming years. The emphasis will remain on sustaining the provisions for quality patient care that are equitably distributed, affordable and easily accessible. Currently, there is no new technological breakthrough or development that warrant any drastic changes to the strategy for leprosy control that is in place. However, there is an urgent need to make decisive changes in the organization of leprosy control, in the attitude of health care providers and beneficiaries, and in the working arrangements between all partners.

It is proposed to introduce the global target of reducing the rate of new cases with grade-2 disabilities per 100,000 population by at least 35 per cent by the end of 2015, compared to the baseline at the end of 2010 *(5)*.

INDIA

Leprosy is widely prevalent in India. Although the disease is present throughout the country, the distribution is uneven. After introduction of MDT in the country, the recorded leprosy case load has come down from 57.6 cases per 10,000 population in 1981 to less than one case per 10,000 population at national level in December 2005, and the country achieved the goal of leprosy elimination at national level.

Based on the reports received from the states/UTs for the year 2013–2014, the current leprosy situation in the country is as follows *(6)* :

TABLE 1

Leprosy situation in SEAR countries at the beginning of 2014

Country	Registered prevalence (beginning of 2014)	During 2013						Cure rate (%)	
		No. of new cases detected	No. of new cases of multibacillary leprosy	No. of new female cases	No. of new cases among children	No. of new cases with grade-2 disabilities	No. of relapses	Pb	MB
Bangladesh	3,087	3,141	1,380	1,237	166	341	11	95.0	94
India	86,147	126,913	63,337	46,845	12,043	5,256	919	95.6	92.9
Indonesia	19,730	16,856	14,062	6,021	2,002	1,694	187	90.0	82.2
Myanmar	2,721	2,950	2,155	997	134	423	11	96.3	95.2
Nepal	2,425	3,225	1,698	1,043	131	88	14	96.0	95.0
Sri Lanka	1,608	1,990	947	812	182	133	59	78.6	72.3
Thailand	560	188	125	72	8	18	10	73.0	82.0
Bhutan	21	17	17	7	0	4	4	100	100
Total	116,396	155,385	85,788	57,052	14,674	7,964	1,218	-	-

Source : *(3)*

A total of 1.27 lac new cases were detected during the year 2013–14, which gives annual new case detection rate (ANCDR) of 9.98 per lac population, a decrease of 4.7 per cent from 2012–13. A total of 0.86 lac cases were on record as on 1st April 2014, giving a prevalence rate (PR) of 0.68 per 10,000 population. The detailed information on new leprosy cases detected during 2013–14 indicates the proportion of multibacillary cases was 51.48 per cent, proportion of female cases was 36.91 per cent, child case proportion was 9.49 per cent (which gives the child case rate of 0.95 per lac population), 4.14 per cent patients were with grade-II deformity, giving deformity rate of 0.413 per lac population).

33 states/UTs had already achieved the level of leprosy elimination i.e. PR of less than 1 case per 10,000 population. Chhattisgarh and Dadra & Nagar Haveli has PR of 2–4 per 10,000 population.

As on 31st March 2014, 459 districts out of 657 have ANCDR less than 10 per lac population, 83 districts more than 20 per lac population, and only 18 districts are with more than 50 per lac population (of which 2 are in Chhattisgarh, 5 in Gujarat, 2 in Maharashtra, 1 in Dadra & Nagar Haveli, 6 in Odisha and 2 in Bihar.

Out of the total 1.31 lac new cases deleted from record, a total of 1.25 lac (94.6 per cent) completed their treatment within specified time period and were released from treatment as cured during 2013–14. Poor performing states are Tripura (74.6%), Meghalaya (67.7%), Rajasthan (81.2%) and Delhi (76.8%).

The trend of leprosy prevalence and annual new case detection rate (ANCDR) in the country is as shown in Fig. 1.

Epidemiological determinants

Agent factors

(a) AGENT : Leprosy is caused by *M. leprae*. They are acid–fast and occur in the human host both intracellularly and extracellularly. They occur characteristically in clumps or bundles (called globi). They have an affinity for Schwann cells and cells of the reticulo–endothelial system. They remain dormant in various sites and cause relapse. The bacterial load is the highest in the lepromatous cases. As many as 2 to 7 billion were estimated in one gram of leproma *(7)*. Numerous antigens (more than 20) have been detected in *M. leprae* by electrophoretic techniques. Some of these are shared by those of pathogenic and non–pathogenic mycobacteria, e.g., BCG, *M. smegmatis, M. vaccae, M. tuberculosis,* etc. Most interesting of these antigens is the phenolic glycolipid (PGL) which may be the specific *M. leprae* antigen. Recent years have witnessed the successful transmission of *M. leprae* to some experimental animals. Currently large quantities of *M. leprae* are being produced by multiplication in the 9–banded armadillo and nude mouse. Despite repeated claims, *M. leprae* has not yet been conclusively shown to grow in artificial medium *(8)*. It is perhaps mainly for this reason that progress in research has lagged behind than that of many other diseases.

(b) SOURCE OF INFECTION : It is generally agreed that multibacillary cases (lepromatous and borderline lepromatous cases) are the most important source of infection in the community. The inapparent infections are also source of infection. The role of individuals with tuberculoid forms of the disease as sources of infection is not clear. The current view is that all patients with "active leprosy" must be considered infectious *(9)*. Until recently man was considered to be the only host and source of infection. There is now evidence that natural infections with *M. leprae* are present in wild animals, e.g., armadillos, mangabey monkeys and chimpanzees. It is not yet known if leprosy in wild animals is a threat to public health.

(c) PORTAL OF EXIT : It is widely accepted that the nose is a major portal of exit. Lepromatous cases harbour millions of *M. leprae* in their nasal mucosa which are discharged when they sneeze or blow the nose. The bacilli can also exit through ulcerated or broken skin of bacteriologically positive cases of leprosy *(10)*.

(d) INFECTIVITY : Leprosy is a highly infectious disease but of low pathogenicity *(11)*. It is claimed that an infectious patient can be rendered non-infectious by treatment with dapsone for about 90 days *(12)* or with rifampicin for 3 weeks *(14)*. Local application of rifampicin (drops or spray) might destroy all the bacilli within 8 days *(13)*.

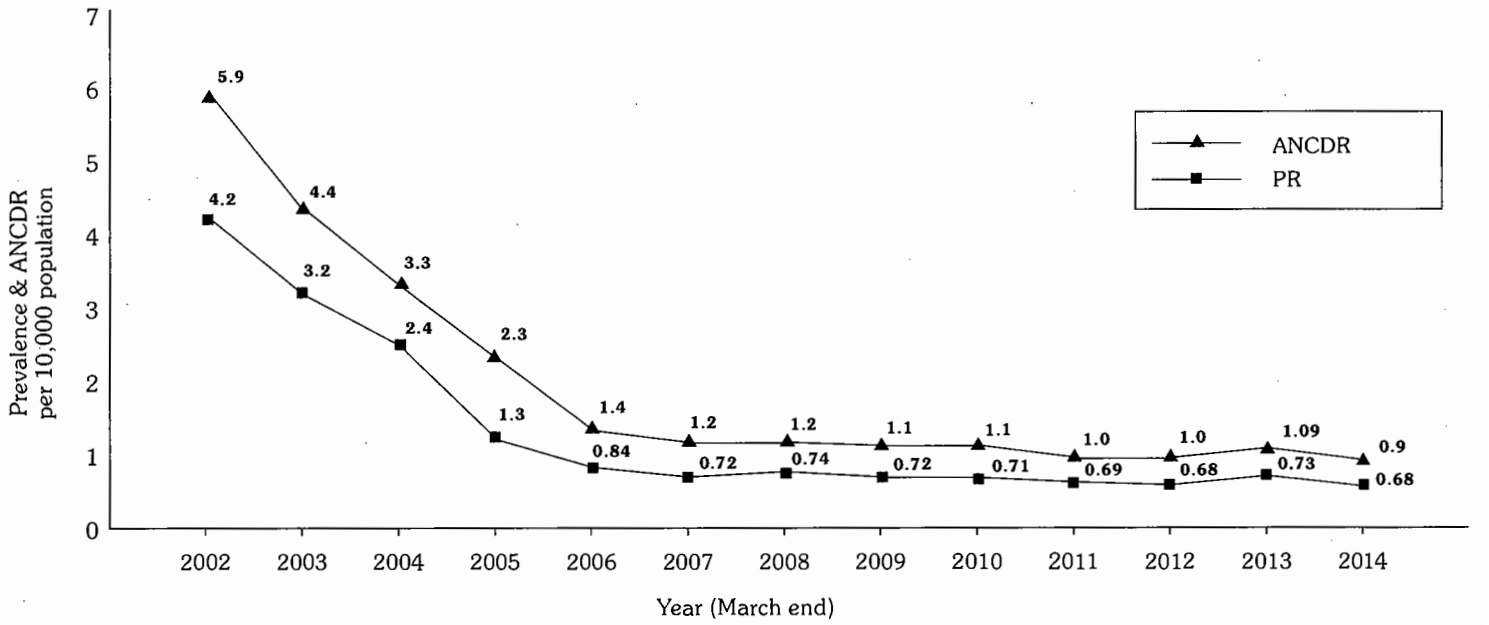

FIG. 1
Trend of leprosy prevalence and annual new case detection rate per 10,000 population in India

Source : *(6)*

(e) ATTACK RATES : Among household contacts of lepromatous cases, a varying proportion – 4.4 per cent to 12 per cent – is expected to show signs of leprosy within 5 years *(13)*. This occurs despite treatment of the index case, most, if not all, cases having been infectious for long periods, before treatment is sought.

Host factors

(a) AGE : Leprosy is not particularly a disease of children as was once believed *(14)*. Infection can take place at any time depending upon the opportunities for exposure. In endemic areas, the disease is acquired commonly during childhood. The youngest case seen in South India was an infant $2^1/_2$ months old *(15)*. Incidence rates generally rise to a peak between 10 and 20 years of age and then fall *(8)*. In areas where leprosy is rare, the first contact may not take place early in life and consequently, the disease may appear late. However, the presence of leprosy in child population is of considerable epidemiological importance. A high prevalence of infection among children means that the disease is active and spreading.

(b) SEX : Both the incidence and prevalence of leprosy appear to be higher in males than in females in most regions of the world. Sex difference is found least in children below 15 years, and more marked among adults; more marked among lepromatous cases than among non-lepromatous cases. The excess of cases in males has sometimes been attributed to their greater mobility and increased opportunities for contact in many populations.

(c) MIGRATION : In India leprosy was considered to be mostly a rural problem. However, because of the movement of population from rural to urban areas, leprosy is creating a problem in the urban areas also *(15)*.

(d) THE PREVALENCE POOL *(16)*: The prevalence pool of leprosy in a population in general is in a constant flux resulting from inflow and outflow. The inflow is contributed by the occurrence of new cases, relapse of cured cases, and immigration of cases. The outflow is mainly through cure or inactivation of cases, death of cases, and emigration of cases. Of the various factors that influence the prevalence pool, the importance of inactivation of disease and mortality are less well recognized.

(e) INACTIVATION OF DISEASE *(16)* : Where leprosy treatment facilities exist, inactivation or cure due to specific treatment is an important mode of elimination of cases from the prevalence pool. Even in the absence of specific treatment, a majority of patients, particularly of the tuberculoid and indeterminate types, tend to get cured spontaneously. An earlier study in India had shown that over a period of 20 years, the extent of spontaneous regression among children with tuberculoid leprosy was about 90%. A study in Culion Island in the Philippines showed that among children self-healing occurred in 77.7% of cases (Lara & Nolasco, 1956). A later study in South India involving long-term follow-up of a high endemic population showed that among newly detected tuberculoid cases of all ages and both sexes, the rate of inactivation was 10.9% per year, the bulk of inactivation in the study being spontaneous (Noordeen, 1975).

(f) IMMUNITY : It is a well-established fact that only a few persons exposed to infection develop the disease. A large proportion of early lesions that occur in leprosy heal spontaneously. Such abortive and self-healing lesions suggest immunity acquired through such lesions. Subclinical infections are far more common than was thought earlier; they are also believed to contribute to active immunity. A certain degree of immunity is also probable through infections with other related mycobacteria *(17)*.

It is now recognized that cell-mediated immunity (CMI) is responsible for resistance to infection with *M. leprae*. In lepromatous leprosy, there is a complete breakdown of CMI; in these cases the lepromin test is negative. CMI does not however, exclude the participation of humoral response. Antibodies have been demonstrated throughout the spectrum of leprosy; they are more pronounced at the lepromatous end. Similarly an increase of immunoglobulins of IgG and IgM classes is noted towards the lepromatous end *(18)*. Leprosy workers have found that the anergy of lepromatous leprosy is due to suppression of T cell production of interleukin–2 (T–cell growth factor). This is normally secreted by activated T cells to make other T cells proliferate. If exogenous interleukin–2 is added, the process may be reversed. However, further studies are needed to find out whether administration of IL–2 would benefit the lepromatous patient *(18)*.

(g) GENETIC FACTORS : There is now evidence that human lymphocyte antigen (HLA) linked genes influence the type of immune response that develops *(8)*.

Environmental factors

The risk of transmission is predominantly controlled by environmental factors *(12)* : (a) the presence of infectious cases in that environment. There is evidence that humidity favours the survival of *M. leprae* in the environment. *M. leprae* can remain viable in dried nasal secretions for at least 9 days and in moist soil at room temperature for 46 days *(8)*, (b) overcrowding and lack of ventilation within households.

Mode of transmission

The mode of transmission of leprosy has not been established with certainty. The following theories are frequently debated :

(A) DROPLET INFECTION : There is more and more evidence that leprosy may be transmitted *via* aerosols containing *M. leprae* (droplet infection). With the realization of the importance of the nose as a portal of exit, there has been increased emphasis on the respiratory tract as the portal of entry. The possibility of this route of transmission is based on (a) the inability of the organisms to be found on the surface of the skin; (b) the demonstration of a large number of organisms in the nasal discharge; (c) the high proportion of morphologically intact bacilli in the nasal secretions; and (d) the evidence that *M. leprae* could survive outside the human host for several hours or days *(16)*.

(B) CONTACT TRANSMISSION : Numerous studies indicate that leprosy is transmitted from person–to–person by close contact between an infectious patient and a healthy but susceptible person. This contact may be direct or indirect (e.g., contact with soil, and fomites such as contaminated clothes and linen).

Now that it is known that leprosy bacilli can survive for long periods of time in the soil under favourable environmental conditions, the hypothesis that leprosy can be transmitted by indirect contact has been strengthened *(19)*. In epidemiological studies, the first lesions were found in feet and legs of patients from hilly areas in India, where injury to the skin is common. In the Philippines 91 per cent of the first lesions were seen in extremities open to injury *(15)*. These observations lend support to indirect transmission. Although

contact transmission has been a long-favoured hypothesis, leprologists opine that skin–to–skin contact is really not necessary to acquire infection, and that the disease is transmissible with far less than intimate contact *(9, 11)*.

(C) OTHER ROUTES : Bacilli may also be transmitted by insect vectors, or by tattooing needles. These transmission channels cannot be ruled out *(19)*. However, there is no evidence that any of these transmission routes is important in nature *(8)*.

Incubation period

Leprosy has a long incubation period, an average of 3 to 5 years or more for lepromatous cases. The tuberculoid leprosy is thought to have a shorter incubation period *(8)*. Symptoms can take as long as 20 years to appear. Failure to recognize early symptoms or signs may contribute to an assumed prolonged incubation period in some patients. Some leprologists prefer the term "latent period" to incubation period because of the long duration of the incubation period.

Knowledge of incubation period of relapses is also essential, as this will define the duration of surveillance after treatment has been stopped.

Classification

Leprosy is a disease bedevilled by classifications, e.g., the Madrid classification *(20)*, Ridley–Jopling classification *(21)*, the Indian classification *(22)*, etc. These classifications are based on clinical, bacteriological, immunological and histological status of patients.

The Indian and Madrid classification systems are the most widely used in field leprosy programmes; they are not essentially different, as the following comparison shows :

Indian classification	*Madrid classification*
indeterminate type	indeterminate
tuberculoid type	tuberculoid; flat; raised
borderline type	borderline
lepromatous type	lepromatous
pure neuritic type	

The Indian classification has an additional form, the pure neuritic in which no skin lesions exist.

The classification system of Ridley and Jopling *(23)* divides leprosy cases into five groups according to their position on an immuno-histological scale : tuberculoid (TT), borderline tuberculoid (BL), borderline (BB), borderline lepromatous (BL) and lepromatous (LL). The neuritic type of leprosy does not find a place in the Ridley and Jopling classification. This classification can be used only when full research facilities are available.

Indian classification

The Indian classification (1981) is the official classification of the Indian Leprosy Association (Hind Kusht Nivaran Sangh). It is a clinico–bacterial classification. The clinical characteristics of the various types are as below :

(a) Indeterminate type : This denotes those early cases with one or two vague hypopigmented macules and definite sensory impairment. The lesions are bacteriologically negative.

(b) Tuberculoid type : This type denotes those cases with one or two well–defined lesions, which may be flat or raised, hypopigmented or erythematous and are anaesthetic. The lesions are bacteriologically negative.

(c) Borderline type : This type denotes those cases with four or more lesions which may be flat or raised, well or ill–defined, hypopigmented or erythematous and show sensory impairment or loss. The bacteriological positivity of these lesions is variable. Without treatment, it usually progresses to lepromatous type.

(d) Lepromatous type : This type denotes those cases with diffuse infiltration or numerous flat or raised, poorly defined, shiny, smooth, symmetrically distributed lesions. These lesions are bacteriologically positive, and

(e) Pure neuritic type : This type denotes those cases of leprosy which show nerve involvement but do not have any lesion in the skin. These cases are bacteriologically negative.

Clinical classification for control programme *(24)*

In 1981, the WHO Study Group on Chemotherapy of Leprosy for Control Programmes classified patients as having multibacillary or paucibacillary leprosy according to the degree of skin-smear positivity *(25)*. It was essentially an operational classification to serve as a basis for chemotherapy. Multibacillary leprosy included polar lepromatous (LL), border line lepromatous (BL) and mid-borderline (BB) cases in the Ridley–Jopling classification with bacteriological index (BI) of ≥ 2 at any site in the initial skin smears. Paucibacillary leprosy included indeterminate (I), Polar tuberculoid (TT) and borderline tuberculoid (BT) in the Ridley–Jopling classification, with a bacteriological index of < 2 at all sites in the initial skin smears. At its sixth meeting in 1987, the Committee endorsed the principles upon which this classification is based, with the modification that all the patients showing smears positivity should be classified as having multibacillary leprosy for the purpose of MDT treatment *(8)*. In 1993, a WHO Study Group on Chemotherapy of Leprosy concluded that approaches based on clinical classification may be required where reliable facilities for the bacteriological examination of skin smears are not available, and recommended that when classification is in doubt, the patient should be treated as having multibacillary leprosy *(24)*.

Because services for processing skin smears are not always available, and also because their reliability is often doubtful, patients are being classified on clinical grounds. The criteria differs from programme to programme, but are essentially based on the number of lesions, especially skin lesions *(26)*, or on the number of body areas affected *(27)*. The assumption is that the protective immunity is inversely correlated with the number of lesions or the number of body areas affected and, therefore, the multibacillary patients have a significantly greater number of lesions or number of body areas affected than the paucibacillary patients. On the basis of the information available, patients could be classified into two groups :

(1) Paucibacillary leprosy (1–5 skin lesions); and

(2) Multibacillary leprosy (more than six skin lesions).

Diagnosis

1. CLINICAL EXAMINATION

Leprosy, in the majority of instances, is diagnosable on the basis of a proper clinical examination alone. Therefore, a set pattern must be followed in the examination of a patient for the presence of leprosy. This procedure is called "case taking" in leprosy, which comprises of *(28)* :

a. Interrogation

(i) collection of biodata of the patient such as name, age, sex, occupation and place of residence
(ii) family history of leprosy
(iii) history of contact with leprosy cases
(iv) details of previous history of treatment for leprosy, if any, and
(v) presenting complaint or symptom.

b. Physical examination

(i) A thorough inspection of the body surface (skin) to the extent permissible, in good natural light for the presence of suggestive, or tell tale evidence of leprosy
(ii) Palpation of the commonly involved peripheral and cutaneous nerves for the presence of thickening and/or tenderness. They are the ulnar nerve near the median epicondyle, greater auricular as it turns over the sternomastoid muscle, lateral popliteal and the dorsal branch of the radial, and
(iii) Testing for (a) loss of sensation for heat, cold, pain and light touch in the skin patches. It cannot be emphasized that not all the hypopigmented patches show sensory impairment; (b) paresis or paralysis of the muscles of the hands and feet, leading to the disabilities or deformities.

However, the disease should not be diagnosed if only nerve thickening is present, without any other accompanying symptoms or signs.

Before the introduction of MDT, most leprosy cases were diagnosed by medical officer or specialized leprosy workers, and it often led to delay in diagnosis and initiation of treatment. Since the introduction of MDT, many procedures have been simplified, so that leprosy patients can be detected by health workers in the field.

2. BACTERIOLOGICAL EXAMINATION

Skin smears are useful for diagnosing multibacillary leprosy and were originally used for distinguishing between paucibacillary and multibacillary leprosy. However, the quality of skin smears and of microscopy is probably the weakest link in most leprosy elimination programmes. In view of this situation, and since it is possible to classify leprosy without skin smear results, it should not be a pre-requisite for implementing the MDT *(24)*.

A brief account of method of skin smear and nasal smear examination is as follows :

(i) Skin smears : Material from the skin is obtained from an active lesion, and also from one of the ear lobe by the "slit and scrape" method. Conventionally, two sites are examined. The skin is cleaned with ether or spirit and allowed to dry. A fold of the skin is nipped between the thumb and forefinger (of left hand in an operator). Enough pressure should be applied to stop or minimize bleeding. Holding the point of knife vertical to the apex of the skin fold, it is pushed into the skin to a depth of about 2 mm or so, to reach the dermis. A tiny incision is made 5 mm or so in length. If blood exudes, it should be wiped off with a small dry cotton–wool swab. The knife blade is rotated transversely to the line of the cut 90° and the knife point is used to scrape first on one side and then on the other side of the incision 2 or 3 times to obtain a tissue pulp from below the epidermis. This material is transferred on to a glass slide and spread over an area of about 8 mm diameter. Six smears can conveniently be made on one microscopic slide. The sites of the smear should be accurately recorded so that the same sites can be used for successive sets of smears made for assesing the effect of treatment. The wound is dressed and closed with a piece of sticking tape applied over the site.

(ii) Nasal smears or blows : Nasal smears can be best prepared from early morning mucus material. The patient blows his nose into a clean dry sheet of cellophane or plastic. The smear should be made straightaway and fixed. This should be done in the early morning from the first blowing of the nose. Nose-blowing smears are used for assessing the patient's infectivity. In patients with untreated lepromatous leprosy, nose-blow smears may show a higher percentage of solid-staining bacilli than skin smears.

(iii) Nasal scrapings : An alternative is to use a nasal mucosal scrapper. After going in 4.5 cm, the blade is rotated towards the septum and scraped a few times and withdrawn. A small ball of cotton is introduced into the nostril to absorb any blood that may ooze out. Nasal scrapings are not recommended as a routine, because they are painful, and non-pathogenic atypical mycobacteria may be present in the nose of healthy persons. Leprosy bacilli are not found in nasal mucosa if they are absent in skin lesions. During treatment, *M. leprae* may disappear from the nasal mucosa before they disappear from the skin lesions *(29)*.

The skin or nasal smear is immediately fixed by lightly passing the underside of the slide over the spirit lamp flame and transported to the laboratory for staining with Ziehl–Neelsen method.

The glass slides used should be absolutely clean. They should not be reused for making smears a second time as organisms from a previous examination may give a false positive result *(22)*. Before a smear is declared negative, at least 200 fields should be examined *(9)*.

Bacterial index *(29)*

Bacterial index (BI) is the only objective way of monitoring the benefit of treatment. The Bacteriological (or Bacterial) Index indicates the density of leprosy bacilli in smears and includes both living (solid-staining) and dead (fragmented or granular) bacilli. According to **Ridley's logarithmic scale,** it ranges from zero to 6+ and is based on the number of bacilli seen in an average microscopic field of the smear using an oil-immersion objective.

0 No bacilli in any of the 100 oil-immersion fields
1+ 1–10 bacilli, on average, in 100 oil-immersion fields
2+ 1–10 bacilli on average, in 10 oil-immersion fields
3+ 1–10 bacilli, on average, in each oil-immersion field
4+ 10–100 bacilli, on average, in each oil-immersion field
5+ 100–1000 bacilli, on average, in each oil-immersion field
6+ More than 1000 bacilli, on average, in each oil–immersion field

The BI of the patient is calculated by adding up the index from each site examined and dividing the total by the number of sites examined.

(e.g. Right ear 5+ Left ear 5+
Back 4+ Chin 4+

$$\text{Bacteriological Index} = \frac{5+5+4+4}{4} = \frac{18}{4} = 4.5+$$

When the bacteriological Index is BI 1+ and BI 2+, at least 100 oil immersion fields should be examined. When the index is BI 3+, BI 4+, BI 5+ and BI 6+, at least 25 oil immersion fields should be examined *(29)*.

Morphological index

During the course of microscopic examination of smears, it is possible to distinguish and count the number of solid staining organisms (organisms that stain completely) and irregularly staining bacilli. The MI is calculated after examining 200 pink-stained free standing (i.e. not in clumps) bacilli. The percentage of solid staining bacilli in a stained smear is referred to as morphological index (MI). The total of the MIs for all sites divided by the number of sites gives the average MI for the body. The criteria for calling the bacilli solid rods are *(22)* :

a. uniform staining of the entire organism
b. parallel sides
c. rounded ends, and
d. length 5 times that of the width.

It has been widely believed that only solid-staining organisms are viable. Accurate evaluation of the MI requires much skill and experience. It is a valuable indicator of the patient's response to treatment with drugs, during the first few months and helps to signal drug resistance.

Solid-fragmented-granular (SFG) percentage (29)

The procedure for recording the percentages of solid, fragmented and granular bacilli is basically the same as that used for determining the MI. Since percentages of solid, fragmented and granular bacilli are mentioned separately. SFG percentages give a better picture of the bacterial morphology than the MI, and are a more sensitive indicator of the patient's response to treatment.

3. FOOT-PAD CULTURE

The only certain way to identify *M. leprae* is to inoculate the material into the foot-pads of mice and demonstrate its multiplication. Mouse foot-pad inoculation is 10 times more sensitive at detecting *M. leprae* than are slit-skin smears *(30)*.

The drawback of this technique is that it is time consuming and requires 6 to 9 months before the results are obtained. Newer *in vitro* methods such as macrophage culture have been evolved, which take only 3 to 4 weeks to obtain results.

Mouse foot-pad technique has been successfully used for (i) detecting drug resistance (ii) evaluating the potency of anti-leprosy drugs, and (iii) detecting the viability of the bacilli during treatment.

4. HISTAMINE TEST

The histamine test is a very reliable method for detecting at an early stage peripheral nerve damage due to leprosy. The test is carried out by injecting intradermally 0.1 ml of a 1:1000 solution of histamine phosphate or chlorohydrate into hypopigmented patches or in areas of anaesthesia. In normal persons, it gives rise to a wheal surrounded by an erythematous flare within a few minutes (Lewis triple response). In cases of leprosy where the nerve supply is destroyed, flare response is lost. Histamine test is recommended when difficulty is experienced in the diagnosis, as for example, indeterminate leprosy *(27)*.

5. BIOPSY

When the examinations detailed above do not yield diagnosis, histopathological examination may be necessary. It allows a more accurate classification of the disease. It also gives information about the bacterial content of the skin.

6. IMMUNOLOGICAL TESTS

There are now available different kinds of immunological tests. These may be classified as *(31)* :

a. tests for detecting cell mediated immunity (CMI)
b. tests for humoral antibodies (serological tests).

a. TESTS FOR DETECTING CMI

(i) LEPROMIN TEST

The test is performed by injecting intradermally 0.1 ml of lepromin into the inner aspect of the forearm of the individual. As a routine, the reaction is read at 48 hours and 21 days *(9)*. Two types of positive reactions have been described :

(a) EARLY REACTION : The early reaction is also known as Fernandez reaction. An inflammatory response develops within 24 to 48 hours and this tends to disappear after 3 to 4 days. It is evidenced by redness and induration at the site of inoculation. If the diameter of the *red area* is more than 10 mm at the end of 48 hours, the test is considered positive.

The early positive reaction indicates whether or not a person has been previously sensitized by exposure to and infection by the leprosy bacilli. In this sense, the early reaction is much superior to the late reaction. The early reaction has been described as delayed hypersensitivity reaction to "soluble" constituents of the leprosy bacilli. The reaction corresponds to the Mantoux reaction in tuberculosis, caused by the soluble antigens (PPD) of the tubercle bacilli.

(b) LATE REACTION : This is the classical Mitsuda reaction. The reaction develops late, becomes apparent in 7–10 days following the injection and reaching its maximum in 3 or 4 weeks. The test is read at 21 days. At the end of 21 days, if there is a *nodule* more than 5 mm in diameter at the site of inoculation, the reaction is said to be positive. The nodule may even ulcerate and heal with scarring if the antigen is crude.

It may be noted that the diameter of the *red area* in the early reaction, and the diameter of the *nodule* in the late reaction are measured. The early reaction is induced by the soluble constituents of the leprosy bacilli; and the late reaction by the bacillary component of the antigen. It indicates cell-mediated immunity.

In the first 6 months of life, most children are lepromin negative; some may become positive by the end of first year. Data obtained from different parts of the world indicate that in endemic areas, lepromin reaction is already positive in 20 per cent of children under 5 years of age, and this proportion increases to around 60 per cent or more in the 10–14 years age group, and to 80 per cent or more in persons over 19 years of age *(14)*. BCG vaccination is capable of converting the lepra reaction from negative to positive in a large proportion of individuals.

Value of the lepromin test

Lepromin test is not a diagnostic test. The two drawbacks that stand in the way of this test being used for diagnosis are : (i) positive results in non-cases, and (ii) negative results in lepromatous and near-lepromatous cases *(15)*.

The test has been generally accepted as a useful tool in evaluating the immune status (CMI) of leprosy patients. It is of considerable value in confirming the results of

classification of cases of leprosy on clinical and bacteriological grounds. In other words, the test is widely used as an aid to classify the type of disease.

The test is also of great value in estimating the *prognosis* in cases of leprosy of all types. The test is usually strongly positive in the typical tuberculoid cases, and the positivity getting weaker as one passes through the spectrum to the lepromatous end, the typical lepromatous cases being lepromin negative indicating a failure of CMI. It is known that lepromin negative individuals are at a higher risk of developing progressive multibacillary leprosy, but those who are lepromin positive either escape the clinical disease (the majority) or develop paucibacillary disease (the minority).

(ii) LTT and LMIT

In recent years, newer *in vitro* tests such as lymphocyte transformation test (LTT) and leucocyte migration inhibition test (LMIT) have been developed. They give a measure of the cell mediated immunity. These tests have been used to detect subclinical infection. A disadvantage of these highly sophisticated tests is that they cannot be applied on a mass scale under field conditions *(32)*.

b. TESTS FOR HUMORAL RESPONSES TO M. LEPRAE

Probably the most important recent advance in the study of the epidemiology of leprosy is the development of serological tests. These tests are expected to have value in detecting subclinical infections, preclinical manifestations and follow-up efficacy of drug treatment. These tests include :

(i) FLA–ABS test

The Fluorescent Leprosy Antibody Absorption Test is now widely used for identification of subclinical infection. Studies revealed that FLA–ABS test is 92.3 per cent sensitive and 100 per cent specific in detecting *M. leprae* specific antibodies in all types of leprosy irrespective of the type and duration of the disease *(33)*.

(ii) Monoclonal antibodies

Monoclonal antibodies against *M. leprae* antigens have been produced. It has been shown that these antibodies recognize specific and non-specific epitopes of *M. leprae* antigens. If antibodies against specific antigens are found, they will become reagents of choice for identifying *M. leprae*. An antibody competition test (SACT) based on this approach has been found to be quite sensitive for detection of *M.leprae* antibody *(34)*.

(iii) Others

There are numerous other sensitive tests which include the radio-immune assay and ELISA tests. The ELISA test is based on a phenolic glycolipid (PGL) antigen.

For the present, the only practical approach is to use FLA–ABS test till some other more sensitive and specific tests are available for use on a large scale *(35)*.

LEPROSY CONTROL

The introduction of multidrug therapy has infused a new hope that the disease could be brought under effective control in the not too distant future. A revised strategy of leprosy control has emerged based on multidrug therapy. The following elements are considered as a minimum requirement for all leprosy control programmes :

1. *Medical measures*
   - I. estimation of the problem
   - II. early case detection
   - III. multidrug therapy
   - IV. surveillance
   - V. immunoprophylaxis
   - VI. chemoprophylaxis
   - VII. deformities
   - VIII. rehabilitation
   - IX. health education
2. *Social support*
3. *Programme management*
4. *Evaluation*

The three main goals of leprosy control are *(9)* : (a) to interrupt transmission of the infection, thereby reduce the incidence of the disease so that it no longer constitutes a public health problem; (b) to treat patients in order to achieve their cure and where possible, complete rehabilitation; and (c) to prevent the development of associated deformities. Ultimate prevention is achieved by breaking the chain of transmission.

1. MEDICAL MEASURES

I. Estimation of the problem

The first step in a leprosy control programme is to define the size of the problem or disease load in the community by means of epidemiological surveys. Random sample surveys are good enough to collect baseline data. The survey should bring out not merely the prevalence of leprosy, but also the age and sex distribution of cases, the various forms of leprosy and the facilities available for providing the needed health care. A rough estimate of the prevalence can be determined by examining all school-age children; the total prevalence will be about 4 times the number of cases found *(31)*. Estimates of the prevalence of leprosy are essential for planning and implementing an anti-leprosy programme and also for evaluating the results of the programme.

II. Early case detection

The aim of case detection is to identify and to register all cases of leprosy as soon as possible after they become evident *(8)*. Ideally, patients should seek medical care voluntarily. However, because leprosy is frequently symptomless in the early stages, patients do not know they have the disease. By the time patient becomes aware of the disease and reports voluntarily, there is usually a lag period of 2 to 3 years *(36)*. Because of the social stigma, some patients are afraid to disclose themselves. It is, therefore, necessary to devise active methods of case detection *(9)*. Even in countries, with a satisfactory case-finding programme, new cases could still be found *(11)*. The current trend is to involve the primary health care workers (village health guides, multipurpose workers) in case detection with the active participation of the community *(11)*. These workers need to be adequately trained to make a tentative diagnosis of leprosy. The desirability of confirming the diagnosis by laboratory methods is not mandatory. It is important that criteria for identifying cases are valid, unambiguous and reproducible as far as possible. If data are to be compared between different areas and different times, it is important that diagnostic criteria used for leprosy around the world is standardized.

Case-finding methods : The choice of case-finding methods should be related to the prevalence rate of leprosy

in the region : (a) CONTACT SURVEY : In areas where the prevalence of leprosy is generally low, (less than 1 case per 1000 population), the technique of choice is examination of all contacts (e.g., household contacts, especially children and persons reported to be suspected cases). These examinations will have to be arranged with discretion so as not to cause alarm. (b) GROUP SURVEYS : When the prevalence is about 1 per 1000 or higher, additional case finding methods should be employed such as screening of preschool and school children, people living in slums, military recruits, industrial labour and other selected groups for all types of skin diseases; this technique ("skin camps") may bring out additional cases of leprosy. It should be noted that the value of school surveys as a case finding method will be considerably diminished if the school enrolment is less than 70 per cent of all children in the 6–14 years age group *(13)*. (c) MASS SURVEYS : Total population surveys for examination of each and every individual, family by family by house–to–house visits are recommended only in hyperendemic areas, i.e., areas where the prevalence of leprosy is about 10 or more per 1000 population. In mass surveys, a coverage of not less than 95 per cent of the population should be obtained *(11)*. Mass surveys require high quality team work. They should be multipurpose covering not only leprosy but also possibly other diseases. They should have the full backing of the administration and whole-hearted participation of the local community.

Records : The case information should be collected for all patients in a standardized manner. The WHO has already a standard computer–based proforma for data collection from individual patients (see Annex 3 of WHO Expert Committee Report No. 716, page 58) which should be followed or suitably adapted. The Government of India had also approved a set of forms for keeping records and submitting reports.

Leprosy is an "iceberg" disease. The problem is one of discovering the subclinical cases, as considerable proportion of these cases lie outside the scope of existing case detection technology.

III. Multidrug therapy

In the absence of primary prevention by a leprosy vaccine, the strategy of leprosy control is based on effective chemotherapy (secondary prevention). Till recently, chemotherapy of leprosy has relied almost entirely on dapsone (DDS). Due to dependence on dapsone monotherapy for many years, drug-resistant leprosy bacilli (both primary and secondary resistance) have emerged in all parts of the world. This has led to relapse of the disease even in those in whom the disease had been arrested and the spread of dapsone–resistant strains to susceptibles jeopardizing the whole strategy of leprosy control *(25)*. In order to cope with this problem, a WHO Study Group on Chemotherapy of Leprosy, has recommended multiple drug therapy for both multibacillary and paucibacillary leprosy *(25)*.

OBJECTIVES

The main objectives of multidrug chemotherapy of leprosy are *(25)*

a. to interrupt transmission of the infection in the community by sterilizing infectious patients as rapidly as possible with bactericidal drugs;
b. to ensure early detection and treatment of cases to prevent deformities, and
c. to prevent drug resistance.

The multidrug treatment has the additional advantage of curtailing the duration of treatment of leprosy considerably. Shorter therapy has the added advantages of patient compliance, cost-effectiveness and decreased work load.

DEFINITIONS

Following the introduction of multidrug therapy, some changes in terminology have taken place. The following working definitions have been proposed by WHO *(8)*.

(i) Case of leprosy : A "case" of leprosy is a person showing clinical signs of leprosy with or without bacteriological confirmation of the diagnosis, and who has not yet completed a full course of treatment with MDT. This definition is for estimating the prevalence of leprosy.

(ii) Paucibacillary leprosy : A person having 1–5 skin lesions and/or only one nerve involvement *(37)*.

(iii) Multibacillary leprosy : A person having 6 or more skin lesions and/or more than one nerve involvement *(37)*.

(iv) Adequate treatment : Adequate treatment implies the completion of a regimen of multidrug therapy within a reasonably short period of time : (a) for paucibacillary cases, adequate treatment implies that the patient has received 6 monthly doses of combined therapy within 9 months. (b) for multibacillary cases, adequate treatment implies that the patient has received 12 monthly doses of combined therapy within 18 months.

(v) Regular treatment : A patient may be considered to have had regular treatment if he or she has received MDT for at least two-thirds of the months in any interval of time. For example, regular treatment for 12 months, implies that the patient has had at least 8 full months of combined therapy during that 12–month period.

(vi) Newly diagnosed case : A person who has been diagnosed as a leprosy case, and who has not taken MDT in the past.

(vii) Defaulter case : A defaulter is a leprosy patient on MDT, who has not collected treatment for 12 consecutive months.

Any patient who has been categorized as a defaulter should be removed from the register *(39)*.

(viii) Relapsed case : A patient whose therapy was terminated, having successfully completed an adequate course of multidrug therapy, but who subsequently develops new signs and symptoms of the disease, either during the surveillance period or thereafter, is considered to have "relapsed" *(8)*.

Drugs

In multidrug regimens, only bactericidal drugs are used. At present, only a small number of such drugs are available : these are rifampicin, dapsone, clofazimine, ethionamide and protionamide. A brief account of these drugs is given below :

(a) Rifampicin

Rifampicin (RMP) is the only drug that is highly bactericidal against *M. leprae*. A single dose of 1500 mg or 3–4 consecutive daily doses of 600 mg appear to kill 99 per cent of viable organisms *(38)*. Further the drug is effective when given at monthly intervals, which is a big advantage. The drug is expensive but safe.

The toxic effects of RMP are anorexia, nausea, abdominal pain and occasionally vomiting. It is hepatotoxic. The patient should be kept under supervision for 1 hour, after

the administration of the drug since shock and collapse are known to occur.

RMP is now an essential drug in the chemotherapy of leprosy. Given alone, resistance to the drug develops. Hence it is given in combination with other anti-leprosy drugs.

(b) Dapsone

Dapsone (DDS) has been in use all over the world for the control of leprosy for more than 30 years. It continues to be an important drug in the multidrug chemotherapy of leprosy. It is cheap and effective in the dosage employed (1–2 mg/kg of body weight). When given orally, it is completely absorbed from the gut and fairly well tolerated. It has shown to be weak bactericidal against *M. leprae (40)*.

The common adverse effects following DDS administration are haemolytic anaemia, methaemoglobinaemia, agranulocytosis, hepatitis, peripheral neuropathy, psychosis and lepra reaction. A rare syndrome, known as *DDS–syndrome* consisting of fever, enlarged lymph glands, exfoliative dermatitis, hepatitis and maculopapular rash has also been reported. Since dapsone is a haemolytic drug, care should be taken that the haemoglobin level is not less than 60 per cent, and the dosage of DDS is strictly weight-based. Iron tablets are prescribed routinely to correct anaemia.

(c) Clofazimine

Clofazimine (CLF) was originally synthesized for the treatment of tuberculosis, but was subsequently found to have far greater value in leprosy. It has both anti–leprosy and anti–inflammatory properties. CLF though less effective than dapsone has the added advantage in suppressing and preventing reactions. CLF is relatively expensive and is reasonably free from toxic effects in the usual dosage. It is used as the third drug, whenever possible in leprosy chemotherapy.

Clofazimine may be unacceptable to some patients because it may give rise to darkish red coloration to skin, mucous membranes, urine and sweat. These symptoms are not serious. They would disappear after the drug is stopped. If totally unacceptable, it may be replaced by ethionamide or protionamide.

(d) Ethionamide and protionamide

These are bactericidal drugs killing 98 per cent of viable bacilli in 4 to 5 days. They are virtually interchangeable and gives rise to cross-resistance with each other. They are both more expensive and more toxic than dapsone. The WHO *(34)* has recommended that ethionamide or protionamide should be used as the third drug in the treatment of multibacillary leprosy in those patients, who find clofazimine unacceptable.

(e) Quinolones

These drugs work by inhibiting DNA synthesis during bacterial replication. Ofloxacin, a fluorinated quinolone is the most preferred drug in this group. Oral ofloxacin is 98 per cent bioavailable with elimination half-life of about 5 to 8 hours. 22 doses of ofloxacin kill about 99.9 per cent of viable *M. leprae (41)*. This is the basis of very short term clinical trials of a combination of 400 mg ofloxacin and 600 mg rifampicin daily for 28 days.

Side-effects include nausea, diarrhoea and other gastrointestinal complaints and a variety of central nervous system complaints.

(f) Minocycline

This is the most lipid–soluble of the tetracyclines and inhibits bacterial protein synthesis. In clinical trials, the clearance of viable *M. leprae* from the skin by minocycline was faster than that reported from dapsone or clofazimine and similar to that for ofloxacin. Minocycline may strengthen MDT, for multibacillary patients and thereby shorten the duration of treatment needed to treat leprosy effectively *(25)*. The standard dose is 100 mg daily. The side-effects include discoloration of teeth in infants and children, occasional pigmentation of the skin and mucous membrane, various gastrointestinal symptoms and central nervous system complaints. It should not be given to infants, children and during pregnancy *(24)*.

(g) Clarithromycin

Clarithromycin is a member of the macrolid group of antibiotics and displays a significant bactericidal activity against *M. leprae*. In patients with lepromatous leprosy, daily administration of 500 mg of clarithromycin killed 99 per cent of viable *M. leprae* within 28 days, and 99.9 per cent by 56 days. Side-effects include nausea, vomiting and diarrhoea.

RECOMMENDED REGIMENS OF CHEMOTHERAPY

(1) WHO RECOMMENDATIONS

The proper application of multidrug therapy is crucial to the success of leprosy control. The regimens recommended by WHO have been widely accepted in many countries. They are as below *(25)*.

a. Multibacillary leprosy

The WHO has recommended the following combination of drugs for treatment of adult multibacillary cases of leprosy :

- Rifampicin ..... 600 mg, once monthly, given under supervision
- Dapsone ..... 100 mg daily, self–administered
- Clofazimine ..... 300 mg once monthly supervised; and 50 mg daily, self–administered.

Where clofazimine is totally unacceptable owing to the colouration of skin, its replacement by 250 to 375 mg self–administered daily doses of ethionamide or protionamide has been suggested.

b. Paucibacillary leprosy

Paucibacillary cases should also receive combined therapy in view of primary dapsone resistance which is becoming widespread. The recommended standard regimen for adults is :

- Rifampicin ..... 600 mg once a month, supervised
- Dapsone ..... 100 mg (1–2 mg/kg of body weight) daily, self–administered

The standard treatment regimen for children aged 10–14 years is as follows :

a. Multibacillary leprosy

- Rifampicin ..... 450 mg once a month, given under supervision
- Dapsone ..... 50 mg daily, self administered
- Clofazimine ..... 150 mg once a month supervised; and 50 mg every other day.

b. Paucibacillary leprosy

- Rifampicin ..... 450 mg once a month, supervised

- Dapsone ..... 50 mg daily, self administered

Children under the age of 10 years should receive appropriately reduced doses of the above drugs.

Duration of treatment

The treatment duration varies according to the type of disease. The recommendations are as follows :

Multibacillary leprosy – MB blisterpacks for 12 months, within 18 months

Paucibacillary leprosy – PB blisterpacks for 6 months, within 9 months

A defaulter who returns to the health centre for treatment should be given a new course of MDT when he or she shows one or more of the following signs *(39)*:

- reddish and/or raised skin lesions;
- appearance of new skin lesions (since the previous examination);
- new nerve involvement (e.g. changes in skin sensation) since the previous examination;
- lepromatous nodules;
- signs of reversal reaction or ENL.

For registration purposes, returning defaulters are not considered as newly detected cases.

MDT is not contraindicated in patients with HIV infection. Management of leprosy and of lepra reactions is same as that of any other leprosy patient. The response of such patients to MDT is also similar *(39)*.

Since leprosy is exacerbated during pregnancy, it is important that MDT be continued. The evidence so far indicates that MDT is safe during pregnancy. Small quantities of anti-leprosy drugs are excreted through breast milk, but there is no report of adverse reaction as a result of this, except for mild discolouration of the infant's skin caused by clofazimine *(42)*.

Lepra reaction *(43)*

During the course of leprosy, immunologically mediated episodes of acute or subacute inflammation known as reactions may occur. Because peripheral nerve trunks are often involved, unless reactions are promptly and adequately treated, such episodes can result in permanent deformities.

Lepra reactions are usually diagnosed by clinical examination only. Inflammatory changes in skin lesions or appearance of new lesions, patches or nodules with acute onset, draw the attention of patient to report. Some cases develop signs of nerve damage without changes in skin lesions.

There are two types of reaction : Reversal reaction (or Type 1) and Erythema Nodosum Leprosum (ENL or Type 2). Both types can occur before the start of multi-drug treatment, during treatment, or after treatment has been completed. Both types can be mild or severe. Only severe reactions are treated with corticosteroids.

Distinguishing between the two types of reactions is usually not difficult. In a reversal reaction, the leprosy skin lesions themselves become inflamed, red and swollen. In an ENL reaction, new inflamed, red nodules (about 1–2 cm across) appear under the skin of the limbs or trunk, while the original leprosy skin patches remain as they were. In addition, ENL reactions cause a general feeling of fever and malaise, while reversal reactions cause less systemic upset. Common differentiating features are as shown in Table 2.

Because of the high risk of permanent damage to the peripheral nerve trunks, reversal reaction needs to be diagnosed as soon as possible, and treated adequately. The drug of choice is prednisolone, the cheapest and most widely available corticosteroid.

Most reversal reactions and neuritis can be treated successfully under field conditions, with a standard 12–week course of prednisolone. The potential risk of serious adverse effects caused by long-term corticosteroid therapy must not be ignored, particularly under field conditions. The more common problems of prolonged steroid therapy include weight gain, peptic ulcer, diabetes, hypertension, reactivation of tuberculosis, osteoporosis and psychiatric disorders.

ENL varies in severity, duration and organ involvement. Acute or subacute neuritis, with or without loss of nerve function, is one of the major criteria in distinguishing mild and severe ENL. Mild ENL can be treated with analgesic or antipyretic drugs such as aspirin, while severe ENL can be treated with prednisolone, as for reversal reaction.

Clofazimine is also effective for ENL, but is less potent than cortico-steroids and often takes 4–6 weeks to develop its full effects, so it should never be started as the sole agent for the treatment of severe ENL.

Signs of a severe reversal reaction

If any of the following signs are found, the reaction should be treated as severe :

TABLE 2

Difference between reversal reaction and ENL

Type I (Reversal Reaction)	Type II (ENL)
1. Delayed hypersensitivity.	1. Antigen antibody reaction.
2. Occurs in both PB and MB cases in unstable types like BT.BB.BL.	2. Seen in MB cases only (BL and LL type).
3. Skin lesions suddenly become reddish, swollen, warm, painful, and tender. New lesions may appear.	3. Red, painful, tender, sub-cutaneous nodules – ENL may appear, commonly on face, arms, legs, bilaterally symmetrical. They appear in crops and subside within few days even without treatment (Evanescent skin nodules). Nodules are better felt than seen and these are recurrent (episodic).
4. Nerves close to skin may be enlarged, tender and painful (neuritis) with loss of its functions (loss of sensation and muscle weakness) which may appear suddenly.	4. Nerves may be affected but not as common or severe and acute as in Type I.
5. Other organs – not affected.	5. Other organs like eyes, testis, and kidney may be affected.
6. General symptoms – not common.	6. Fever, joints pain, red eyes with watering may be associated.

Source : *(43)*

- Loss of nerve function – that is, loss of sensation or muscle weakness in the area supplied by nerve.
- Pain or tenderness in one or more nerves.
- Silent neuritis/quiet nerve paralysis i.e. signs of nerve damage without symptoms.
- A red, swollen skin patch on the face, or overlying another major nerve trunk.
- A skin lesion anywhere that becomes ulcerated.
- Marked oedema of the hands, feet or face.

Signs of a severe ENL reaction

If any of the following signs is found, the reaction should be treated as severe :

- Pain or tenderness in one or more nerves, with or without loss of nerve function.
- Ulceration of ENL nodules.
- Pain of eyes with or without redness and loss of visual acuity.
- Painful swelling of the testes (orchitis) or of the fingers (dactylitis).
- Marked arthritis or lymphadenitis.

Treatment of Lepra reactions (moderate to severe cases)

It includes bed rest, rest to affected nerves by splint, analgesics, prednisolone. Each case of reaction should be assessed for his/her fitness to put on prednisolone as per check list given above *(43)*.

Prednisolone regimen	Add Clofazimine in ENL
40 mg daily for first 2 weeks 30 mg daily for weeks 3 and 4	One capsule (100 mg) 3 times a day × 4 weeks
20 mg daily for weeks 5 and 6 15 mg daily for weeks 7 and 8	One capsule (100 mg) 2 times a day × next 4 weeks
10 mg daily for weeks 9 and 10 5 mg daily for weeks 11 and 12	One capsule (100 mg) once a day × third month
For neuritis, treatment with Prednisolone should be prolonged to four weeks from 20 mg onwards	

Prednisolone tablets issued must be entered in 'Prednisolone card'. Tapering of prednisolone may be done according to its response. Patient must be instructed on salt restriction, no prednisolone intake on empty stomach and reporting adverse effects/symptoms immediately.

Adding Clofazimine for Type II reaction may be extremely useful for reducing or withdrawing corticosteroids in patients who have become dependent on them. Total duration of Clofazimine therapy should not exceed 12 months.

If a patient develops lepra reaction during the treatment, do not stop MDT (rather complete the course of MDT). Lepra reactions, which occur after completion of treatment, should also be managed as mentioned earlier. MDT should not be restarted for such cases. Response to treatment should be monitored and assessed, including check on adverse effects of prednisolone.

Before starting the steroid treatment, the patient should be asked questions about epigestric pain and diarrhoea, with or without blood and or mucous; and examined for fungal infection, scabies, and worm infestations, as all these conditions may be made worse by steroids. Treatment of all these conditions can be started at the same time as steroids are started *(43)*.

Before starting the steroid treatment the patient should be explained the reason for treatment; the duration of the treatment; importance of taking daily dose and that the treatment should not be stopped suddenly (the dosage is decreased gradually) and importance of completing the full course of treatment; and possible side-effects.

Follow-up after treatment with steroids

People who have been given a course of steroids for reaction or nerve damage should be followed up closely because of the risk of recurrence. Each person must understand that a reaction or new nerve damage may recur. They must know how to recognize the early signs of nerve damage and be aware of how important it is to return promptly to the clinic for treatment. These signs include pain or tingling sensations, further loss of feeling or loss of muscle strength and inability to close the eye.

Patients still on MDT should have their nerve function checked monthly by the health worker when they come to collect their treatment. Any deterioration should be noted and the person referred. Patients who have already completed MDT, by the time they come to the end of a course of steroids, should be asked to come back three months and six months after the end of the course for review and nerve function assessment. Patients who still have lagophthalmos (weakness of eyelids) after completion of treatment with steroids should be referred to ophthalmic surgeon.

Groups requiring special precautions when prescribing steroids

The following groups of people require special precautions when steroids are prescribed. One must not give steroids to people with tuberculosis, diabetes, deep ulcers, osteomyelitis, corneal ulcers or other serious conditions without starting treatment for the underlying condition.

Pregnant women

All pregnant women should be treated at referral level, so as to minimize the steroid dose they are given and thus avoid harmful effects, such as growth retardation on the foetus. If steroids are given in the third trimester, this may cause adrenal suppression in the newborn infant. Ideally, such infants should be monitored in a referral centre for a few days after birth. The dose of prednisolone to be given during pregnancy are as follows :

- PB cases : start at 30 mg daily instead of 40 mg and limit the course to ten weeks rather than the usual twelve weeks regime.
- MB cases : starting at 30 mg daily but lasting for twenty weeks.

Children

All children under the age of twelve should be treated at referral level, so as to minimize the effects of steroids on their growth. Children can be given a course similar to that for pregnant women, but the starting dose of prednisolone should not exceed 1 mg per kilogram of body weight per day. Giving children steroids on alternate days may reduce the effect on their growth. A suitable regimen for PB cases would be 30 mg of prednisolone daily for two weeks, then 30 mg on alternate days for two weeks with a gradually reducing dose over the total course of ten weeks. For MB cases, one should double the duration of each stage of the course.

Diabetes

Patients who show symptoms that suggest diabetes or whose urine tests positive for glucose should be referred to

confirm whether the diagnosis is correct and, if it is confirmed, for management of the diabetes condition. Steroids may increase the diabetic's requirement for insulin.

A person taking steroids may also develop diabetes for the first time. This possibility must be considered when patient develops typical symptoms of diabetes during the treatment with steroids. The condition usually resolves itself when steroids are stopped.

Ulcers or osteomyelitis

Patients with deep or dirty ulcers or osteomyelitis should be referred for surgical treatment and antibiotics. Starting steroids before such treatment may lead to a worsening of the sepsis and more permanent damage, including the need for amputation. One should suspect osteomyelitis if the person's hand or foot is warmer than normal, with or without swelling. Any person with a wound discharging pus should be referred for surgical advice and debridement (removal of dead and infected tissue) before taking steroids, or osteomyelitis may develop.

Eye involvement

Patients who have corneal damage or iritis should be referred for specialist diagnosis and management at a centre properly equipped for eye care. Corneal ulcers and keratitis are inflammatory conditions of the cornea. They are often caused by exposure, as a result of the person being unable to close the eye properly. Steroids, whether taken by mouth or locally applied, may make these conditions worse. Iritis, uveitis, iridocyclitis and scleritis are all types of inflammation inside the eye and they can all occur as part of a Type-2 reaction. These conditions cause pain, redness, photophobia and loss of vision, although the symptoms are not always severe. The treatment includes atropine eye ointment to prevent adhesion.

Tuberculosis

If tuberculosis is suspected, the diagnosis must be confirmed and treatment started before giving steroids.

The crucial elements in the management of leprosy reactions and thereby, the prevention of disabilities are early diagnosis of reactions together with prompt and adequate treatment. Usually the diagnosis of leprosy reactions is relatively straightforward, but occasionally, in paucibacillary patients who have completed treatment, differentiation of a reversal reaction from relapse may be difficult. Nevertheless, it is essential that this distinction must be made correctly. The differences are as summarized in Table 3.

As a consequence of all these factors, the diagnosis and treatment of leprosy reactions may often be delayed and, by the time the patients arrive at the referral centres, they may have already developed permanent deformities. In order to avoid these problems, national leprosy programmes should try to ensure that patients are taught to recognize the early signs of reactions, and to report promptly for treatment; health workers are able to diagnose and treat reactions and to refer patients when necessary; and adequate stocks of prednisolone are maintained at the peripheral level *(24)*.

IV. Surveillance

Clinical surveillance of cases after completion of treatment is an important part of the current recommendations for multidrug therapy; it is essential for the assurance of long-term success of treatment and for the early detection of any relapses.

(a) Paucibacillary leprosy : It is recommended that paucibacillary cases be examined clinically at least once a year for a minimum of 2 years after completion of treatment *(8)*.

(b) Multibacillary leprosy : It is recommended that multibacillary cases be examined clinically at least once a year for a minimum period of 5 years after completion of therapy *(8)*.

A patient who has completed the required period of surveillance following the course of multidrug therapy and shows no evidence of relapse is considered to have completed surveillance. The phrase "release from control" should not be applied in the context of multidrug therapy *(8)*.

V. Immunoprophylaxis

The fact that a scientifically valid tool for the detection of infection is not yet available which could deepen the understanding of how leprosy is transmitted, and could lead to the development of an effective vaccine and other interventions. Trials in different population groups with BCG vaccine either alone or in combination with other vaccine (from killed *Mycobacterium leprae* or atypical *Mycobacteria*), have shown protective efficacy ranging between 28 per cent and 60 per cent. High BCG coverage remains an important contribution to reducing the disease burden due to leprosy *(5)*.

VI. Chemoprophylaxis

Chemoprophylaxis in chronic infectious diseases has an established benefit, particularly when given to persons who are known to be at higher risk of developing the disease. The

TABLE 3
Differences between reversal reaction and relapse

	Reversal reaction	Relapse
Time interval	Generally occurs during chemotherapy or within 3 years of stopping treatment	Usually occurs only when chemotherapy has been discontinued, after an interval of usually more than 3 years
Onset	Abrupt and sudden	Slow and insidious
Old lesions	Existing lesions become oedematous, erythematous or tender	Lesion may show erythema and infiltration, but no tenderness
New lesions	Several new lesions appear	New lesions are minimal
Ulceration	Lesions may ulcerate	Ulceration does not occur
Nerve involvement	Multiple nerve involvement common, painful and tender	Nerve involvement may occur only in a single nerve; usually no pain or tenderness
General condition	May have fever, joint pains, malaise	Not usually affected
Response to steroid treatment	Rapid	Nil

Source : *(26, 43)*

immediate contacts of a case of leprosy, especially multibacillary, are known to have a higher risk of developing the disease than compared to the general population. It is important, therefore, to consider possible interventions to prevent the occurrence of leprosy among household contacts. However, there must be robust trial evidence to demonstrate that the drug/s used for chemoprophylaxis are safe, effective and cost-efficient in terms of the number of new cases prevented.

On account of lack of consistent results from various studies using various drugs (dapsone, acedapsone, rifampicin) it is too premature to advise chemoprophylaxis as a public health measure. Further research is needed to use this as a routine tool to prevent the occurrence of disease among contacts *(5)*.

VII. Deformities

It is estimated that approximately 25 per cent of the patients who are not treated at an early stage of disease develop anaesthesia and/or deformities of the hands and feet. As a single disease entity, leprosy is one of the foremost causes of deformities and crippling.

The deformities may result due to the disease process (e.g. loss of eye brows, other facial deformities), or those resulting from paralysis of some muslces due to damage to peripheral nerve trunk (e.g. claw-hand, foot-drop, lagophthalmos), or those resulting from injuries or infections to hands and feet (e.g. scar contractures of fingers, mutilation of hands and feet, corneal ulceration).

The findings of the examination are first noted in the Disability Assessment Form separately for right and left eyes, hands and feet. Thereafter each eye, each hand and each foot is given its own grade. Deformities are classified into three grades. The criterias are as follows *(44)* :

Examination of parts	WHO Disability Grades	Sensory testing	Voluntary muscle testing	
	0	Sensation present	Muscle power normal	
Hands	1	Sensation absent	Muscle power normal	
	2	Sensation absent	Muscle power weak or paralyzed	
	0	Sensation present	Muscle power normal	
Feet	1	Sensation absent	Muscle power normal	
	2	Sensation absent	Muscle power weak or paralyzed	
		Vision	Lid Gap	Blinking
	0	Normal	No lid gap	Present
Eye	2	Cannot count fingers at 6 metres	Gap present/ red eye/ corneal ulcer or opacity	Absent

The highest grade given in any of the part is used as the Disability Grade for that patient. Eye, hand and feet score i.e. sum of all the individual disability grades for two eyes, two hands and two feet 0–12, should be recorded at each examination.

Table 4 shows deformities occurring in patients with leprosy.

TABLE 4
Deformities occurring in leprosy

Face	Mask face, facies leonina, sagging face, lagophthalmos, loss of eyebrows (superciliary madarosis) and eyelashes (ciliary madarosis), corneal ulcers and opacities, perforated nose, depressed nose, ear deformities, e.g. nodules on the ear and elongated lobules.
Hands	Claw hand, wrist–drop, ulcers, absorption of digits, thumb–web contracture, hollowing of the interosseous spaces and swollen hand.
Feet	Plantar ulcers, foot–drop, inversion of the foot, clawing of the toes, absorption of the toes, collapsed foot, swollen foot and callosities.
Other deformities	Gynaecomastia and perforation of the palate.

Source : *(29)*

The measures to prevent disabilities include actions to take care of the dry, denervated skin of palms and soles, heal the wounds, ulcers and skin cracks in palms and soles, prevent injuries to hands and feet by using protective gloves and footwear, prevent joint stiffness in cases of paralytic deformities, protect the eyes, and assess periodically the commonly damaged nerves for loss of nerve function and its progression, using simple tests that can be carried out in the field.

Improvement of disabilities is achieved through the use of prostheses and orthopaedic devices, including corrective splints, as well as by corrective surgery. All these measures, however, require special expertise and facilities.

VIII. Rehabilitation

The WHO Expert Committee on Leprosy in its Second Report *(45)* defined rehabilitation as :

> *"the physical and mental restoration, as far as possible, of all treated patients to normal activity, so that they may be able to resume their place in the home, society and industry".*

Rehabilitation is, therefore, an integral part of leprosy control. It must begin as soon as the disease is diagnosed. The cheapest and surest rehabilitation is to prevent physical deformities and social and vocational disruption by early diagnosis and adequate treatment. The measures that are taken in this direction are known as "preventive rehabilitation". The approach to rehabilitation should, therefore, begin with preventing dehabilitation. We should never allow dehabilitation to take place and afterwards take up the uphill task of rehabilitation *(46)*.

Community-based rehabilitation defined by WHO and major NGOs is as follows (5) :

"Community-based rehabilitation is a strategy within general community development for the rehabilitation, equalization of opportunities and social inclusion of all people with disabilities. Community-based rehabilitation is implemented through the combined efforts of the people with disabilities themselves, their families, organizations and communities, and the relevant governmental and non-governmental health, education, vocational, social and other services".

Rehabilitation measures may appear to be simple; they require planned and systematic actions – medical, surgical, social, educational and vocational – consistently over years with sustained counselling and health education for training or retraining of the individual to the highest possible level of functional ability. For this purpose, coordinated efforts by the Departments of Health, Education and Social Welfare, as well as voluntary organizations are necessary.

IX. Health education

No anti-leprosy campaign is complete without health education. Health education aims at helping people develop attitudes and behaviour by their own actions and efforts and seeking professional help when needed. Health education should be directed towards the patient and his family and the general public. *(a) Patient and his family :* The main problem in leprosy control is poor patient compliance with the drug regimen and high drop-out rates. The patient and his family should be educated about the need for regular treatment, repeated examination of contacts, self care regarding prevention of disabilities and protection of children. Health education thus minimizes hurdles in implementing the leprosy control programme. *(b) General public :* There is a growing realization that technological advances alone cannot solve the leprosy problem, unless we succeed in involving the people in the control programme. Health education aims at ensuring community participation. The public should be made aware that leprosy is not a hereditary disease; it is a bacterial disease like tuberculosis; it is curable; not all leprosy patients are infectious; regular and adequate treatment is essential to obtain cure and prevent disabilities, and that the patient needs sympathy and social support. A nationwide mass education is needed to educate people on the true facts about leprosy and remove superstitions and wrong beliefs and the social stigma associated with leprosy *(36)*.

2. SOCIAL SUPPORT

Chemotherapy alone is not likely to solve the whole problem of leprosy. The economic and social problems of the patient and his family should be identified and met. This may include social assistance and social support. This may take various forms depending upon the local situation, e.g., assistance to the patient to travel to and from the clinic; help to the needy families in terms of foodgrains, clothes, care of children and their education, and job placement; programmes such as slum improvement, etc. Such care should be provided through voluntary agencies and Departments of Social Welfare.

3. PROGRAMME MANAGEMENT

Leprosy control is a long-term activity. Therefore planning and programme management are essential ingredients. It is generally assumed that with existing tools, we can achieve rapid control of leprosy, provided the "operational performance" is stepped up to the maximum level required. This is the responsibility of programme managers. These issues are discussed under evaluation (see operational indicators and epidemiological indicators below). Among the resources that are needed are adequate infrastructure, trained health personnel, adequate supply of drugs and vehicles, and financial allocation. The National Leprosy Eradication Programme incorporates all these elements (see chapter 7, page 422).

4. EVALUATION

An important aspect of leprosy control is to assess the impact of the control operations on the endemicity of the disease, and to compare results between different times and places. Indicators are required for such an evaluation. It is important that these indicators can be easily used and satisfy the criteria of repeatability and validity. Ideally they should be conceived and treated as signals for action by programme managers *(8)*. There are two main types of indicators in leprosy control.

I. Epidemiological indicators

These are required to evaluate the effectiveness of the programme, that is to assess the impact of the action taken with regard to the problem reduction. These indices are : (a) INCIDENCE : Incidence rates are often calculated separately for different subgroups of population, e.g., age, sex, frequency of household contact. It is the most sensitive index of transmission of the disease. It is the only index for measuring the effectiveness of the measures taken, i.e., reduction of transmission. Thus they are useful in monitoring the success of a control programme. (b) PREVALENCE : This provides a measure of the "case load" and is useful in the planning of the treatment services. The continued reduction in the prevalence could also give information about the downward trend of the disease. It is often useful to calculate prevalence rates for different subgroups, e.g., age sex, geographic area. The fact that leprosy is not uniformly distributed should be borne in mind when these statistics are interpreted *(8)*.

II. Main or core indicators for monitoring progress *(5)*

(1) The number and rate of new cases detected per 100,000 population per year.
(2) Rate of new cases with grade-2 disabilities per 100,000 population per year.
(3) Treatment completion/cure rate.

(1) NUMBER AND RATE OF NEW CASES DETECTED PER YEAR

The nature (e.g. type, grade of disability, etc.) and number of new cases detected in a given area are mainly influenced by four factors :

(a) Effectiveness of IEC activities in promoting awareness and self-reporting.
(b) Health workers' competence in making an accurate and timely diagnosis.
(c) Quality of monitoring and supervision by programme managers.
(d) Completeness of programme coverage, ensuring that all inhabitants are reached.

In order to ensure the quality of new case detection, programmes should ensure that :

(a) Case-finding is mainly focused on promoting self-reporting, with appropriate clinical examination and history-taking to avoid wrong diagnosis and re-registration.
(b) Case definitions are adhered to, as per national guidelines.
(c) Previously fully or partly treated cases are not registered as new cases. Partly treated cases should be given treatment.

All national programmes should collect and report this information, distinguishing paucibacillary and multibacillary leprosy and child/adult patients.

(2) RATE OF NEW CASES WITH GRADE-2 DISABILITIES PER 100,000 POPULATION

It is the percentages of people with grade-2 disability among the new leprosy cases detected during the reporting year and for whom a disability assessment was carried out.

$$\text{Disability grade-2 proportion} = \frac{\text{Number of new cases with disability Gr-2 in a year}}{\text{Total number of new cases detected in that particular year}} \times 100$$

For the first time this indicator has been included in the current list of core indicators to monitor the progress made against leprosy. When reviewed together with other

indicators, these can be used to :

(1) estimate under-detection;
(2) measure the need for physical and social rehabilitation;
(3) advocate activities for the prevention of disabilities; and
(4) promote collaboration with other sectors.

(3) TREATMENT COMPLETION/CURE RATE

The two most important components of the leprosy control programme are :

(1) timely detection of new cases; and
(2) ensuring that all new patients who start multidrug therapy complete the full course of treatment within a reasonable period of time.

A satisfactory treatment completion rate is indicative of efficient case-holding, counselling and the degree of patient satisfaction with the services. Completion of treatment means that a paucibacillary leprosy patient completes six monthly doses of PB-MDT within nine months and a multibacillary leprosy patient completes 12 monthly doses of MB-MDT within 18 months.

All national programmes should undertake cohort analysis of treatment completion rates for both paucibacillary and multibacillary leprosy at least on a sample basis.

III. Main indicators for evaluating case detection

The following indicators should be collected to evaluate the case detection activities and to calculate MDT drug requirements.

(1) PROPORTION OF NEW CASES PRESENTING WITH GRADE-2 DISABILITIES/IMPAIRMENTS.

This indicator has been included in core indicators also and has been discussed in detail there.

(2) PROPORTION OF CHILD CASES AMONG NEW CASES

It denotes the percentage of children among all new cases detected during the reporting year. A high child proportion may be a sign of active and recent transmission of the disease. It is thus an important epidemiological indicator. The child proportion (rather the number of new PB and MB children) is also valuable for calculating drug requirements.

$$\text{Child proportion rate} = \frac{\text{Number of children (<15 years age) among new cases detected in a year}}{\text{Total number of new cases detected in that particular year}} \times 100$$

(3) PROPORTION OF FEMALE PATIENTS AMONG NEW CASES

In most leprosy endemic countries more men than women are diagnosed with leprosy. It is not clear whether the higher leprosy rates in men reflect epidemiological differences or the influence of operational factors *(5)*.

(4) PROPORTION OF MULTIBACILLARY CASES AMONG NEW CASES

It denotes the percentage of MB cases among the total number of new leprosy cases detected during the reporting year. Since 1997, every one who shows more than five anaesthetic hypo-pigmented patches in addition to those who have positive skin smears are considered MB cases. As the people with MB leprosy are considered to be more infectious, and this is more likely to be responsible for leprosy transmission, it is important to know how many of the newly detected cases fall into this category. It is also necessary for calculating drugs requirement. Proportion of multibacillary cases is calculated by the following formula :

$$\text{Percentage of MB cases} = \frac{\text{No. of MB cases among newly detected cases in a given year}}{\text{Total number of new cases detected in that year}} \times 100$$

IV. Main indicators for assessing the quality of services

The programme may collect the following indicators to assess the quality of services on a sample basis as part of an integrated supervision process :

(1) Proportion of new cases verified as correctly diagnosed.
(2) Proportion of treatment defaulters.
(3) Number of relapses.
(4) Proportion of patients who develop new/additional disability during multidrug therapy.

Anti-leprosy activities in India

The history of anti-leprosy work in India goes back to 1874 when the Mission to Lepers (now Leprosy Mission) was founded by Baily at Chamba, in the Himachal Pradesh. The headquarters of this organization later moved to Purulia in West Bengal. Since then, many voluntary organizations (now about 150) have sprung up in the cause of leprosy. Important among these are the Hind Kusht Nivaran Sangh (formerly the British Empire Leprosy Relief Association); Gandhi Memorial Leprosy Foundation, Sevagram, Wardha; the German Leprosy Relief Association; the Damien Foundation; the Danish Save the Child Fund; and the more recent JALMA which was taken over by the ICMR in 1975. A federation body, "National Leprosy Organization" came into being in 1965 to provide a common platform to discuss their problems and share their experiences. The campaign against leprosy in India is accomplished through an official programme, the National Leprosy Control Programme which was initiated in the middle of 1954. In 1983, it was converted into an eradication programme.

An account of the National Leprosy Eradication Programme is given in chapter 7, page 422.

SEXUALLY TRANSMITTED DISEASES

The sexually transmitted diseases (STD) are a group of communicable diseases that are transmitted predominantly by sexual contact and caused by a wide range of bacterial, viral, protozoal and fungal agents and ectoparasites.

During the past few decades, STDs have undergone a dramatic transformation *(1)*. First, the change in name from venereal diseases (V.D.) to sexually transmitted diseases (STD) indicates this transformation. The list of pathogens which are sexually transmissible has expanded from the 5 "classical" venereal diseases (syphilis, gonorrhoea, chancroid, lymphogranuloma venereum and donovanosis) to include more than 20 agents, as shown in Table 1 *(2)*. Secondly, attention is now given not only to specific diseases, but also to clinical syndromes associated with STDs as shown in Table 3 *(1)*. Most of the recently recognized STDs are now referred to as **second generation STDs**. AIDS, the most recently recognized, is a totally new disease.

TABLE 1
Classification of sexually transmitted disease agents

A.	**Bacterial agents**
	Neisseria gonorrhoeae
	Chlamydia trachomatis
	Treponema pallidum
	Haemophilus ducreyi
	Mycoplasma hominis
	Ureaplasma urealyticum
	Calymmatobacterium granulomatis
	Shigella spp.
	Campylobacter spp.
	Group B streptococcus
	Bacterial vaginosis–associated organisms
B.	**Viral agents**
	Human (alpha) herpesvirus 1 or 2 (herpes simplex virus)
	Human (beta) herpesvirus 5 (formerly cytomegalovirus)
	Hepatitis virus B
	Human papilloma viruses
	Molluscum contagiosum virus
	Human immunodeficiency virus
C.	**Protozoal agents**
	Entamoeba histolytica
	Giardia lamblia
	Trichomonas vaginalis
D.	**Fungal agents**
	Candida albicans
E.	**Ectoparasites**
	Phthirus pubis
	Sarcoptes scabiei

Extent of the problem

WORLD

The true incidence of STDs will never be known not only because of inadequate reporting but because of the secrecy that surrounds them. Most of them are not even notifiable. All available data, however, indicate a very high prevalence of STD.

STDs have a profound impact on sexual and reproductive health world-wide, and rank among the top 5 disease categories for which adults seek health care.

More than 1 million people acquire a sexually transmitted disease every day. Each year, an estimated 500 million people acquire one of the four STDs, i.e., chlamydia, gonorrhoea, syphilis and trichomoniasis. More than 530 million people are living with HSV2 that causes genital herpes. More than 290 million women have an human papilloma virus infection, which is one of the most common STD *(3)*.

STDs can have serious consequences beyond the immediate impact of the infection itself. Some STDs can increase the risk of HIV infection three-fold or more. Mother to child transmission of STDs can result in stillbirth, neonatal death, low birth-weight and prematurity, sepsis, pneumonia, neonatal conjunctivitis, and congenital deformities. Syphilis in pregnancy leads to approximately 305,000 foetal and neonatal deaths every year and leaves 215,000 infants at an increased risk of dying from prematurity, low-birth-weight or congenital disease *(3)*.

Human papilloma virus causes 530,000 cases of cervical cancer and 275,000 cervical cancer deaths each year. Gonorrhoea and chlamydia are major causes of pelvic inflammatory disease, adverse pregnancy outcomes and infertility *(3)*.

INDIA

Sexually transmitted diseases are becoming a major public health problem in India.

(a) Syphilis : Serological surveys continue to be the best source of information on the prevalence of syphilis. During 2013, about 33,570 cases of syphilis (18,081 male and 15,489 female) were reported in the country with 1 death *(4)*.

(b) Gonorrhoea : Information on the morbidity of gonorrhoea is notoriously lacking as most cases are not reported. The general impression is that gonorrhoea is more widely prevalent than syphilis. During 2013, about 97,180 gonorrhoea cases (31,564 male and 65,616 female) were reported in the country *(4)*.

(c) Chancroid : Chancroid or soft sore is reported to be fairly widely prevalent in India.

(d) LGV : It is reported to be more prevalent in the southern States of Tamil Nadu, Andhra Pradesh, Maharashtra and Karnataka than in the northern States.

(e) Donovanosis : Donovanosis or granuloma inguinale is endemic in Tamil Nadu, Andhra Pradesh, Orissa, Karnataka and Maharashtra. A greater prevalence along the coastal areas has been reported.

(f) Other STDs : Information on the other STDs is not readily available, as there is no reporting system for these diseases.

Epidemiological determinants

Agent factors

Over 20 pathogens have been found to be spread by sexual contact. A classification of these agents and the diseases caused by them are as shown in Table 2.

TABLE 2
Important sexually transmitted pathogens and the diseases caused by them

Pathogen	Disease or syndrome
Neisseria gonorrhoeae	Gonorrhoea, urethritis, cervicitis, epididymitis, salpingitis, PID, neonatal conjunctivitis
Treponema pallidum	Syphilis
Haemophilus ducreyi	Chancroid
Chlamydia trachomatis	LGV, urethritis, cervicitis, proctitis, epididymitis, infant pneumonia, Reiter's syndrome, PID, neonatal conjunctivitis
Calymmatobacterium granulomatis	Donovanosis (granuloma inguinale)
Herpes simplex virus	Genital herpes
Hepatitis B virus	Acute and chronic hepatitis
Human papillomaviruses	Genital and anal warts
Human immuno–deficiency virus (HIV)	AIDS
Molluscum contagiosum	Genital molluscum contagiosum
Candida albicans	Vaginitis
Trichomonas vaginalis	Vaginitis

Source : *(2, 5)*

Host factors

(a) Age : For most notifiable STDs, the highest rates of incidence are observed in 20–24 year-olds, followed by the 25–29 and 15–19 years age groups. The most serious morbidity is observed during foetal development and in the neonate *(2)*. *(b) Sex :* For most STDs, the overall morbidity rate is higher for men than for women, but the morbidity caused by infection is generally much more severe in women, as for example, pelvic inflammatory disease. *(c) Marital status :* The frequency of STD infection is higher among single, divorced and separated persons than among married couples. *(d) Socio-economic status :* Individuals from the lowest socio–economic groups have the highest morbidity rate.

Demographic factors

Certain demographic factors will undoubtedly contribute to increase in STDs in the developing countries. These include population explosion and marked increase in the number of young people, the group at highest risk for STD in the population; rural to urban migration; increasing educational opportunities for women delaying their marriage and increasing STD risks.

Social factors

Numerous social and behavioural factors are involved in the spread of STDs. These include : *(a) Prostitution :* This is a major factor in the spread of STDs. The prostitute acts as a reservoir of infection. In Asia, most STDs are contracted from prostitutes, whereas in many developed countries, the professional prostitute has largely been replaced by the "good–time girl". The male component of prostitution – the prostituant is equally important. Prostitution supplies a demand; if there were no prostituants, there would be no prostitutes. *(b) Broken homes :* Social studies indicate the promiscuous women are usually drawn from broken homes, e.g., homes which are broken either due to death of one or both parents or their separation. The atmosphere in such homes is unhappy, and children reared in such an atmosphere are likely to go astray in search of other avenues of happiness. *(c) Sexual disharmony :* Married people with strained relations, divorced and separated persons are often victims of STDs. *(d) Easy money :* In most of the developing world, prostitution is simply a reflection of poverty. It provides an occupation for earning easy money. It is fostered by lack of female employment and the prospect of a financial return impossible to achieve by other means *(6)*. *(e) Emotional immaturity :* This has been often stressed as a social factor in acquiring STDs. *(f) Urbanization and industralization :* These are conductive to the type of lifestyle that contributes to high levels of infection, since long working hours, relative isolation from the family and geographical and social mobility foster casual sexual relationships. *(g) Social disruption :* Caused by disasters, wars and civil unrest have always caused an increase in the spread of STDs. *(h) International travel :* Travellers can import as well as export infection and their important role in the transmission of STD is exemplified by the rapid spread throughout the world of resistant strains of *N. gonorrhoea* and AIDS *(2)*. *(i) Changing behavioural patterns* : In modern society, the value traditionally set on chastity is in conflict with the more recent ideas of independence, freedom from supervision, and equal rights for both sexes. There has been a relaxation of moral and cultural values in present–day society. The tendency to break away from traditional ways of life is particularly marked among young people. *(j) Social stigma :* The social stigma attached to STDs accounts for the non–detection of cases, not disclosing the sources of contact, dropping out before treatment is complete, going to quacks for treatment, and self-treatment. *(k) Alcoholism :* The effect of alcohol seems to be more indirect than direct. Alcohol may

encourage prostitution and conversely, prostitution may boost the sale of alcohol.

Clinical spectrum *(7)*

GONOCOCCAL INFECTION : Gonococcal infection causes inflammation of the genital tract involving the urethra in men and women, the cervix and rectum in women, and the rectum in men who have sex with men. Other sites are the throat (pharyngitis) and the eyes. The possible complications in women include pelvic inflammatory disease (PID). Long-term sequelae of PID are increased risk of ectopic pregnancy, infertility and chronic pelvic pain. In men, complications include inflammation of the epididymis. Long term consequences are sub-fertility and possibly urethral strictures. Serious consequences in infants include eye infection which can lead to blindness if not treated promptly. The antibiotics of choice are ciprofloxacin, ceftriaxone, cefixime or spectinomycin.

SYPHILIS : Syphilis causes ulceration of the uro-genital tract, mouth or rectum. Other signs of this infection, occurring in later stages, range from skin eruptions to complications of the cardiovascular and nervous system. Congenital syphilis is an important cause of stillbirth. The antibiotics used to treat syphilis are penicillin, doxycycline and erythromycin.

CHLAMYDIAL INFECTION : A high percentage of individuals have no obvious clinical manifestations of this infection. If symptoms occur they are similar to those caused by gonorrhoea. Complications, which are similar to those of gonorrhoea, can result in steriltiy in women or vertical transmission during childbirth, leading to conjunctivitis or eye inflammation in the newborn. In men it can cause urethritis with possible epididymitis. The antibiotics used are doxycycline or azithromycin. The alternatives are amoxycillin, ofloxacin, erythromycin or tetracycline.

TRICHOMONIASIS : This parasitic infection leads to vaginitis and vaginal discharge in women. Usually, there are no symptoms. In most men there are no symptoms but it may cause urethritis. There is increasing evidence that *T. Vaginalis* may cause adverse outcomes in pregnancy, e.g. low birth weight and premature rupture of the membranes. The treatment option is metronidazole or tinidazole.

CHANCROID : After infection a small papule develops at the site of inoculation, normally within 2–3 days. The lesion then erodes into a deep ulcer that is extremely painful. In about 25 per cent of patients there is a painful swelling of one or the other inguinal lymph nodes (bubo). The antibiotics used are ciprofloxacin, erythromycin, ciftriaxone and azithromycin.

LYMPHOGRANULOMA VENEREUM : It commonly presents with swelling of lymph nodes in the groin. Although initially there is a small, painless ulcer of the genitalia 3–30 days after exposure it may pass unrecognized and resolve spontaneously. Untreated, the disease may cause extensive lymphatic damage resulting in elephantiasis of the genitalia. The antibiotics used are doxycycline, erythromycin and tetracycline. Benefit in late cases, e.g. with rectal stricture is slight. Surgical operation may be of benefit in cases with extensive elephantiasis or deformity.

DONOVANOSIS : Synonyms are granuloma inguinale, granuloma venereum. The first manifestation, appearing after a 3–40 days incubation period, is usually a small papule which ruptures to form a granulomatous lesion that is characteristically pain free and bleeds readily on contact, often elevated above the level of the surrounding skin. Antibiotics used are azithromycin and doxycline, or alterantively erythromycin, tetracycline, trimethoprim–sulfamethoxazole.

GENITAL HERPES : Herpes simplex virus type 2 (HSV-2) is the primary cause of genital herpes. Classical genital herpes can be recognized by the presence of typical papular lesions that progress to multiple blisters and ulcers. However, the features can be variable in many people and the appearance can easily be confused with other genital infections. First episode of disease manifestation are frequently associated with a prolonged course of ulceration, lasting up to three to four weeks. Antiviral treatment of these episodes can be very effective in shortening the duration and alleviating pain. HSV-2 infection is life-long and recurrent ulcerative episodes occur. The median recurrence rate after a symptomatic first episode of genital herpes is four to five episodes per year. Asymptomatic or subclinical infection does occur, as do subclinical recurrences, accompanied by viral shedding without a visible ulcer. These subclinical episodes can be infectious to sexual partners. There is no cure for HSV-2 infection. However, oral antiviral medications such as acyclovir, valaciclovir and famciclovir are all effective in reducing the severity and duration of first-episode genital herpes. Topical creams are less effective. Episodic treatment has a limited role in reducing the duration of lesions as they tend to last less than a week.

HUMAN PAPILLOMA VIRUS : Human papilloma virus (HPV) causes ano-genital warts, which vary from the common soft, flesh-coloured protuberances which may become exuberant (cauliflower like) to papular flat warts on drier areas (eg. shaft of penis), which resemble those seen on other parts of the body. They can be seen anywhere in the genitalia including in the perianal region, even in those denying anal sexual intercourse. The other commonly recognized manifestation of genital HPV infection is cervical cancer, caused by some sub-types of HPV. Treatment is generally reserved for large lesions because sub-clinical infection tend to resolve on their own. For any viral infection the mainstay of control is prevention, especially in young sexually active individuals. Regular examination of the cervix and cervical cytology using Papanicolaou staining method is recommended for female patients and female contacts in order to detect progression of lesions to cervical cancer. Detection programmes based on cervical cytology screening and colposcopy services have been successful in curbing the incidence of, and mortality from cervical cancers in industrialized countries, but are expensive to run in developing countries.

Syndromic approach to STD

Many different agents cause sexually transmitted diseases. However, some of these agents give rise to similar or overlapping clinical manifestations. Common syndromes and sequelae are as shown in Table 3.

TABLE 3

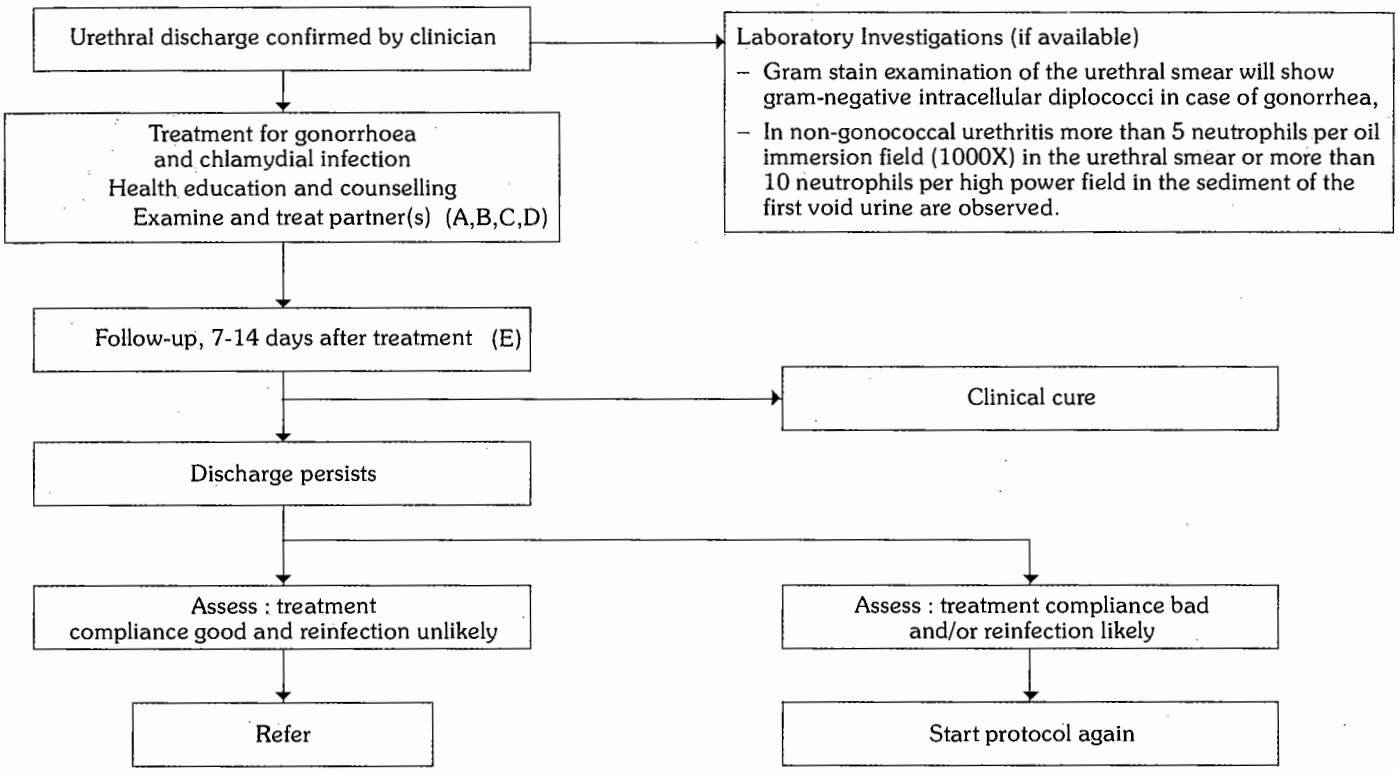
Common syndromes and sequelae for which sexual transmission is of epidemiological importance

Male urethritis
Lower genital syndromes in women : vaginitis/cervicitis/urethritis
Genital ulceration
Proctitis/colitis
Salpingitis
Epididymitis/orchitis
Infertility/ectopic pregnancy
Postnatal and perinatal morbidity
Hepatitis/hepatic carcinoma
Genital carcinoma
Acquired Immuno Deficiency Syndrome (AIDS)

Source : *(1)*

The traditional method of diagnosing STD is by laboratory tests. However, these are often not available or are expensive. Since 1990 WHO has recommended syndromic management of STDs in patients presenting with consistently recognized signs and symptoms of STD. The syndromic approach is a scientifically derived approach and offers accessible and immediate treatment, that is effective and efficient, management of STD using flowcharts (as shown in Fig. 1, 2, 3, 4, 5 and 6) is more cost-effective than diagnosis based on laboratory tests *(8)*.

1. Syndromic management of urethral discharge in males



(A) Notification and treatment of female partners of men with urethritis are of the highest priority as one of the best ways of identifying women at high risk of having asymptomatic gonococcal and chlamydial infections.

(B) Treatment :
As dual infection is common, the treatment for urethral discharge should adequately cover therapy for both, gonorrhea and chlamydial infections.
Recommended regimen for uncomplicated gonorrhea + chlamydia
Uncomplicated infections indicate that the disease is limited to the anogenital region (anterior urethritis and proctitis).
- Tab. Cefixime 400 mg orally, single dose Plus Tab Azithromycin 1 gram orally single dose, under supervision
- Advise the patient to return after 7 days of start of therapy.

When symptoms persist or recur after adequate treatment for gonorrhea and chlamydia in the index patient and partner(s), they should be treated for *Trichomonas vaginalis*.
If discharge or only dysuria persists after 7 days – Tab. Secnidazole 2 gm orally, single dose (to treat for T. vaginalis)
If the symptoms still persists - Refer to higher centre as early as possible.
If individuals are allergic to Azithromycin, give Erythromycin 500 mg four times a day for 7 days.

(C) Syndrome specific guidelines for partner management :
Treat all recent partners; Treat female partners (for gonorrhea and chlamydia) on same lines after ruling out pregnancy and history of allergies; advise sexual abstinence during the course of treatment; provide condoms, educate about correct and consistent use; refer for voluntary counselling and testing for HIV, syphilis and Hepatitis B, and schedule return visit after 7 days.

(D) Management of pregnant partner :
Pregnant partners of male clients with urethral discharge should be examined by doing as per speculum as well as per vaginal examination and should be treated for gonococcal as well as chlamydial infections.
- Cephalosporins to cover gonococcal infection are safe and effective in pregnancy
  - Tab. Cefixime 400 mg orally, single dose OR Ceftriaxone 125 mg by intramuscular injection
    +
  - Tab. Erythromycin 500 mg orally four times a day for seven days OR Cap Amoxicillin 500 mg orally, three times a day for seven days to cover chlamydial infection
- Quinolones (like ofloxacin, ciprofloxacin), doxycycline are contraindicated in pregnant women.

(E) Follow up after seven days to see reports of tests done for HIV, syphilis and Hepatitis B; if symptoms persist, to assess whether it is due to treatment failure or re-infection; and for prompt referral if required.

FIG. 1

Snydromic management of urethral discharge (in the absence of laboratory support)

Source : *(8)*

2. Syndromic management of vaginal discharge

Causative Organisms

Vaginitis : Trichomonas vaginalis (Tv); Candida albicans; and Gardnerella vaginalis, Mycoplasma causing bacterial vaginosis (Bv).

Cervicitis : Neisseria Gonorrheae, Chlamydia trachomatis, Trichomonas vaginalis, and Herpes simplex virus.

History
- Menstrual history to rule out pregnancy
- Nature and type of discharge (amount, smell, color, consistency)
- Genital itching
- Burning while passing urine, increased frequency
- Presence of any ulcer, swelling on the vulval or inguinal region
- Genital complaints in sexual partners
- Low backache.

Examination
- Per speculum examination to differentiate between vaginitis and cervicitis.

(a) Vaginitis:
Trichomoniasis – greenish frothy discharge
Candidiasis – curdy white discharge
Bacterial vaginosis – adherent discharge
Mixed infections may present with atypical discharge.

(b) Cervicitis :
- Cervical erosion / cervical ulcer / mucopurulent cervical discharge
- Bimanual pelvic examination to rule out pelvic inflammatory disease
- If speculum examination is not possible or client is hesitant, treat both for vaginitis and cervicitis.

Laboratory investigations (if available)
- Wet mount microscopy of the discharge for Trichomonas vaginalis and clue cells
- 10% KOH preparation for candida albicans
- Gram's stain of vaginal smear for clue cells seen in bacterial vaginosis
- Gram's stain of endocervical smear to detect gonococci.

Treatment

Vaginitis (TV+BV+Candida)
- Tab. Secnidazole 2 gm orally, single dose OR Tab. Tinidazole 500 mg orally, twice daily for 5 days.
- Tab. Metoclopropramide taken 30 minutes before Tab. Secnidazole, to prevent gastric intolerance.
- Treat for candidiasis with Tab Fluconazole 150 mg orally single dose OR local Clotrimazole 500 mg vaginal pessaries once.

Treatment for cervical infection (chlamydia and gonorrhea)
- Tab cefixime 400 mg orally, single dose.
- Plus – Azithromycin 1 gram, 1 hour before lunch. If vomiting within 1 hour, give anti-emetic and repeat
  - If vaginitis and cervicitis are present treat for both.
  - Instruct client to avoid douching.
  - Pregnancy, diabetes, HIV may also be influencing factors and should be considered in recurrent infections.
  - Follow-up after one week.

Management in pregnant women

Per speculum examination should be done to rule out pregnancy complications like abortion, premature rupture of membranes.

Treatment for vaginitis (TV+BV+Candida)

In first trimester of pregnancy
- Local treatment with Clotrimazole vaginal pessary/cream only for candidiasis. Oral Flucanozole is contraindicated in pregnancy.
- Metronidazole pessaries or cream intravaginally if trichomoniasis or BV is suspected.

In second and third trimester oral metronidazole can be given
- Tab. Secnidazole 2 gm orally, single dose or Tab. Tinidazole 500 mg orally, twice daily for 5 days.
- Tab. Metoclopropramide taken 30 minutes before Tab. Metronidazole, to prevent gastric intolerance.

Specific guidelines for partner management
- Treat current partner only if no improvement after initial treatment.
- If partner is symptomatic, treat client and partner using above protocols.
- Advise sexual abstinence during the course of treatment.
- Provide condoms, educate about correct and consistent use.
- Schedule return visit after 7 days.

FIG. 2

Syndromic management of vaginal discharge

Source : *(8)*

3. Management of lower abdominal pain in females

Causative organisms
Neisseria gonorrheae; Chlamydia trachomatis; and Mycoplasma, Gardnerella, Anaerobic bacteria (Bacteroides specially gram positive cocci).
Differential diagnosis : ectopic pregnancy, twisted ovarian cyst, ovarian tumor, appendicitis, and abdominal tuberculosis.

History
- Lower abdominal pain
- Fever
- Vaginal discharge
- Menstrual irregularities like heavy, irregular vaginal bleeding
- Dysmenorrhoea
- Dyspareunia
- Dysuria, tenesmus
- Low backache
- Contraceptive use like IUD.

Examination
- General examination : temperature, pulse, blood pressure.
- Per speculum examination : vaginal/cervical discharge, congestion or ulcers.
- Per abdominal examination : lower abdominal tenderness or guarding.
- Pelvic examination :
  Uterine/adnexal tenderness, cervical movement tenderness,

Note : A urine pregnancy test should be done in all women suspected of having PID to rule out ectopic pregnancy.

Laboratory investigations (if available)
- Wet smear examination
- Gram stain for gonorrhea
- Complete blood count and ESR
- Urine microscopy for pus cells

Treatment (out patient treatment)
In mild or moderate PID (in the absence of tubo ovarian abscess), out patient treatment can be given. Therapy is required to cover *Neisseria gonorrheae, Chlamydia trachomatis and anaerobes*.
- Tab. Cefixime 400 mg orally twice daily for 7 days + Tab. Metronidazole 400 mg orally, twice daily for 14 days
  +
- Doxycycline, 100 mg orally, twice a day for 2 weeks (to treat chlamydial infection)
- Tab. Ibuprofen 400 mg orally, three times a day for 3-5 days.
- Tab. Ranitidine 150 mg orally, twice daily to prevent gastritis.
- Remove intra uterine device, if present, under antibiotic cover of 24-48 hours.
- Advise abstinence during the course of treatment and educate on correct and consistent use of condoms.
- Observe for 3 days. If no improvement (i.e. absence of fever, reduction in abdominal tenderness, reduction in cervical movement, adnexal and uterine tenderness) or if symptoms worsen, refer for In patient treatment.

Caution : PID can be a serious condition. Refer the patient to the hospital if she does not respond to treatment within 3 days and even earlier if her condition worsens.

Syndrome specific guidelines for partner management
- Treat all partners in past 2 months.
- Treat male partners for urethral discharge (gonorrhea and chlamydia).
- Advise sexual abstinence during the course of treatment.
- Provide condoms, educate on correct and consistent use.
- Refer for voluntary counselling and testing for HIV, syphilis and Hepatitis B.
- Inform about the complications if left untreated and sequelae.
- Schedule return visit after 3 days, 7 days and 14 days to ensure compliance.

Management of pregnant women
Though PID is rare in pregnancy,
- Any pregnant woman suspected to have PID should be referred to district hospital for hospitalization and treated with a parenteral regimen which would be safe in pregnancy.
- Doxycycline is contraindicated in pregnancy.
- Note : Metronidazole is generally not recommended during the first three months of pregnancy. However, it should not be withheld for a severly acute PID, which represents an emergency.

Hospitalization of clients with acute PID should be seriously considered when
- The diagnosis is uncertain.
- Surgical emergencies e.g. appendicitis or ectopic pregnancy cannot be excluded.
- A pelvic abscess is suspected.
- Severe illness precludes management on an out patient basis.
- The woman is pregnant.
- The patient is unable to follow or tolerate an out patient regimen.
- The patient has failed to respond to out patient therapy.

Note : All patients requiring hospitalization should be referred to the district hospital.

FIG. 3

Management of lower abdominal pain in females

Source : *(8)*

4. Management of genital ulcers

Causative organisms :
Treponema pallidum (syphilis),
Haemophilus ducreyi (chancroid),
Klebsiella granulomatis (granuloma inguinale),
Chlamydia trachomatis (lymphogranuloma venerum),
Herpes simplex (genital herpes)

History
- Genital ulcer/vesicles
- Burning sensation in the genital region.
- Sexual exposure of either partner to high risk practices including orogenital sex.

Examination
- Presence of vesicles
- Presence of genital ulcer-single or multiple.
- Associated inguinal lymph node swelling and if present refer to respective flowchart.

Ulcer characteristics
- Painful vesicles/ulcers, single or multiple – herpes simplex.
- Painless ulcer with shotty lymph node – syphilis.
- Painless ulcer with inguinal lymph nodes – granuloma inguinale and LGV.
- Painful ulcer usually single, sometimes – chancroid associated with painful bubo.

Laboratory investigations
- RPR test for syphilis.
- For further investigations refer to higher centre.

Treatment
- If vesicles or multiple painful ulcers are present treat for herpes with Tab. Acyclovir 400mg orally, three times a day for 7 days.
- If vesicles are not seen and only ulcer is seen, treat for syphilis and chancroid and counsel on herpes genitalis.

To cover syphilis give
Inj Benzathine penicillin 2.4 million IU IM after test dose in two divided doses (with emergency tray ready).
(In individuals allergic or intolerant to penicillin, Doxycycline 100 mg orally, twice daily for 14 days)
+
Tab. Azithromycin 1g orally single dose OR
Tab. Ciprofloxacin 500 mg orally, twice a day for three days to cover chancroid.

Treatment should be extended beyond 7 days if ulcers have not epithelialized i.e. formed a new layer of skin over the sore)

Refer to higher centre
- If not responding to treatment.
- Genital ulcers co-existent with HIV.
- Recurrent lesion.

Syndrome specific guidelines for partner management
- Treat all partners who are in contact with patient in last 3 months.
- Partners should be treated for syphilis and chancroid.
- Advise sexual abstinence during the course of treatment.
- Provide condoms, educate about correct and consistent use.
- Refer for voluntary counselling and testing for HIV, Syphilis and Hepatitis B.
- Schedule return visit after 7 days.

Management of pregnant women
- Quinolones (like ofloxacin, ciprofloxacin), doxycycline, sulfonamides are contraindicated in pregnant women.
- Pregnant women who test positive for RPR should be considered infected unless adequate treatment is documented in the medical records and sequential serologic antibody titers have declined.
- Inj Benzathine penicillin 2.4 million IU IM after test dose (with emergency tray ready).
- A second dose of benzathine penicillin 2.4 million units IM should be administered 1 week after the initial dose for women who have primary, secondary, or early latent syphilis.
- Pregnant women who are allergic to penicillin should be treated with erythromycin and the neonate should be treated for syphilis after delivery.
- Tab. Erythromycin 500 mg orally four times a day for 15 days.
- (Note : Erthromycin estolate is contraindicated in pregnancy because of drug related hepatotoxicity. Only Erythromycin base or Erythromycin ethyl succinate should be used in pregnancy).
- All pregnant women should be asked history of genital herpes and examined carefully for herpetic lesions.
- Women without symptoms or signs of genital herpes or its prodrome can deliver vaginally.
- Women with genital herpetic lesions at the onset of labour should be delivered by caesarean section to prevent neonatal herpes.
- Acyclovir may be administered orally to pregnant women with first episode genital herpes or severe recurrent herpes.

FIG. 4

Management of genital ulcers

Source : *(8)*

5. Management of scrotal swelling

Causative Organisms
Neisseria gonorrhoeae
Chlamydia trachomatis.

Differential diagnosis (non RTIs/STIs)
Infections causing scrotal swelling :
tuberculosis, filariasis, coliforms, pseudomonas, mumps virus infection.
Non infectious causes :
trauma, hernia, hydrocele, testicular torsion, and testicular tumors.

History of
- Swelling and pain in scrotal region.
- Pain or burning while passing urine.
- Systemic symptoms like malaise, fever.
- Sexual exposure of either partner to high risk practices including oro-genital sex.

→

Examination
Look for
- Scrotal swelling.
- Redness and edema of the overlying skin.
- Tenderness of the epididymis and vas deferens.
- Associated urethral discharge/genital ulcer/inguinal lymph nodes and if present refer to the respective flowchart.
- A transillumination test to rule out hydrocele should be done.

→

Laboratory Investigations
(If available)
- Gram's stain examination of the urethral smear will show gram-negative intracellular diplococci in case of complicated gonococcal infection.
- In non-gonococcal urethritis more than 5 neutrophils per oil immersion field in the urethral smear or more than 10 neutrophils per high power field in the sediment of the first void urine are observed.

↓

Treatment
- Treat for both gonococcal and chlamydial infections
  Tab Cefixime 400 mg orally twice daily for 7 days, Plus
  Cap. Doxycycline 100 mg orally, twice daily for 14 days and refer to higher centre as early as possible since complicated gonococcal infection needs parenteral and longer duration of treatment.
- Supportive therapy to reduce pain
  (bed rest, scrotal elevation with T-bandage and analgesics)

Note :
If quick and effective therapy is not given, damage and scarring of testicular tissues may result, causing sub-fertility.

↓

Syndrome specific guidelines for partner management.
Partner needs to be treated depending on the clinical findings.

Management protocol in case the partner is pregnant
- Depending on the clinical findings in the pregnant partner (whether vaginal discharge or endocervical discharge or PID is present) the drug regimens should be used.
- Doxycycline is contraindicated in pregnancy.
- Erythromycin base/Amoxicillin can be used in pregnancy.

(Erythromycin estolate is contraindicated in pregnancy due to hepatotoxicity.
Erythromycin base or erythromycin ethyl succinate should be given).

FIG. 5
Syndromic management of scrotal swelling

Source : *(8)*

6. Management of inguinal bubo

Causative organisms
- Chlamydia trachomatis serovars L1, L2, L3, causative agent of lympho granuloma venerum (LGV).
- Haemophilus ducreyi causative agent of chancroid.

Differential diagnosis
- Mycobacterium tuberculosis, filarisis.
- Any acute infection of skin of pubic area, genitals, buttocks, anus and lower limbs can also cause inguinal swelling.

If malignancy or tuberculosis is suspected refer to higher centre for biopsy.

History
- Swelling in inguinal region which may be painful.
- Preceding history of genital ulcer or discharge.
- Sexual exposure of either partner to high risk practices including oro-genital sex.
- Systemic symptoms like malaise, fever.

Examination
Look for
- Localized enlargement of lymph nodes in groin which may be tender and fluctuant.
- Inflammation of skin over the swelling.
- Presence of multiple sinuses.
- Edema of genitals and lower limbs
- Presence of genital ulcer or urethral discharge, and if present refer to respective flowchart.

Laboratory Investigations.
Diagnosis is on clinical grounds.

Treatment
- Start Cap. Doxycycline 100 mg orally twice daily for 21 days (to cover LGV)
  Plus
- Tab Azithromycin 1g orally single dose OR
- Tab. Ciprofloxacin 500 mg orally, twice a day for three days to cover chancroid.
- Refer to higher centre as early as possible.

Note :
- A bubo should never be incised and drained at the primary health centre, even if it is fluctuant, as there is a high risk of a fistula formation and chronicity. If bubo becomes fluctuant always refer for aspiration to higher centre.
- In severe cases with vulval edema in females, surgical intervention may be required for which they should be referred to higher centre.

Syndrome specific guidelines for partner management
- Treat all partners who are in contact with patient in last 3 months.
- Partners should be treated for chancroid and LGV.
- Tab Azithromycin 1 g orally single dose to cover chancroid
  +
  Cap Doxycycline 100 mg orally, twice daily for 21 days to cover LGV
- Advise sexual abstinence during the course of treatment.
- Provide condoms, educate on correct and consistent use.
- Refer for voluntary counselling and testing for HIV, syphilis and Hepatitis B.
- Schedule return visit after 7 days and 21 days.

Management of Pregnant partner
- Quinolones (like ofloxacin, ciprofloxacin), doxycycline, sulfonamides are contraindicated in pregnant women.
- Pregnant and lactating women should be treated with the erythromycin regimen, and consideration should be given to the addition of a parenteral amino glycoside (e.g., gentamicin)

Tab. Erythromycin base, 500 mg orally,
4 times daily for 21 days and refer to higher centre.
(Erythromycin estolate is contraindicated in pregnancy due to hepatotoxicity. Erythromycin base or erythromycin ethyl succinate should be given)

FIG. 6

Syndrome management of inguinal bubo

Control Of STDs

The aim of the control programme for STDs is the prevention of ill-health resulting from the above conditions through various interventions. These interventions may have a primary prevention focus (the prevention of infection), a secondary prevention focus (minimizing the adverse health effects of infection), or usually a combination of the two. The control of STD may be considered under the following heads *(9)*.

1. Initial planning
2. Intervention strategies
3. Support components
4. Monitoring and evaluation

INITIAL PLANNING

Control programmes have to be designed to meet the unique needs of each country and to be in line with that country's health care system, its resources and priorities. This requires initial planning which comprises the following steps : (1) PROBLEM DEFINITION : The disease problem must be defined in terms of prevalence, psychosocial consequences and other health effects – by geographic areas and population groups, with the aid of sero–epidemiological surveys and population surveys. This is an important first step, since such information is usually inadequate or non–existent in most cases. (2) ESTABLISHING PRIORITIES : Rational planning requires establishment of priorities. This will depend upon health problem considerations (e.g., magnitude, consequences) and feasibility of control (e.g., availability of adequate resources, social and political commitment). Priority groups may be categorized on the basis of age, sex, place of residence, occupation, drug addiction, etc. (3) SETTING OBJECTIVES : Priorities must be converted into discrete, achievable and measurable objectives. That is, to reduce the magnitude of the problem, in a given population and a stated time. To be most useful, objectives should be unambiguous and quantifiable. Broad coverage of the population is crucial for effective STD control. (4) CONSIDERING STRATEGIES : A variety of intervention strategies are available. Planners must define the mixture of strategies that appears to be most appropriate to the setting. (The reader is referred to chapter 20 for a broad discussion of the planning cycle).

INTERVENTION STRATEGIES

1. Case detection

Case detection is an essential part of any control programme. The usual methods of early detection in a STD control programme are :

(a) SCREENING : Screening is the testing of apparently healthy volunteers from the general population for the early detection of disease. High priority is given to screening of special groups, viz. pregnant women, blood donors, industrial workers, army, police, refugees, prostitutes, convicts, restaurant and hotel staff etc. The availability of an appropriate test is critical for screening purposes. The sensitivity, specificity, and the predictive value of a test are important considerations (see Chapter 4).

(b) CONTACT TRACING : Contact tracing is the term used for the technique by which the sexual partners of diagnosed patients are identified, located, investigated, and treated *(10)*. This is one of the best methods of controlling the spread of infection. Patients are interviewed for their sexual contacts by specially trained staff. The key to success in contact tracing is the patient himself who must disclose all sex contacts voluntarily. In some parts of USA, contacts are sought as quickly as possible using telephone, telegram and other rapid means of communication. The contacts are then persuaded to attend a STD clinic for examination and treatment. Where prevalence is low, contact tracing is relatively expensive.

(c) CLUSTER TESTING : Here the patients are asked to name other persons of either sex who move in the same socio–sexual environment. These persons are then screened (e.g., blood testing). This technique has been shown almost to double the number of cases found *(11)*.

2. Case holding and treatment

Adequate treatment of patients and their contacts is the mainstay of STD control. There is a tendency on the part of patients suffering from STDs to disappear or drop out before treatment is complete. Therefore every effort should be made to ensure complete and adequate treatment. A recent WHO Expert Committee *(2)* drew up a list of recommended regimens for treating STDs. Not less than the recommended dosages should be used.

3. Epidemiological treatment

What is known as epidemiological treatment or more appropriately **contact treatment** has become a keystone of the control campaigns *(10)*. It consists of the administration of full therapeutic dose of treatment to persons recently exposed to STD while awaiting the results of laboratory tests *(12)*. Epidemiological treatment should not be an end in itself. Its effects are not lasting unless it is combined with a venereological examination and the tracing of contacts revealed by that examination.

4. Personal prophylaxis

(i) Contraceptives : Mechanical barriers (e.g., condoms and the diaphragms) can be recommended for personal prophylaxis against STDs. These barrier methods, especially when used with spermicides, will minimize the risk of acquiring STD infections. However, their use is limited by lack of motivation, acceptability and convenience. The effectiveness of most of the prophylactic techniques available is poorly documented since few controlled studies have been carried out *(2)*. The exposed parts should be washed with soap and water as soon after contact as possible. *(ii) Vaccines :* The development of a vaccine for hepatitis B has raised hopes that vaccines will be found for other STDs.

5. Health education

Health education is an integral part of STD control programmes. The principal aim of educational intervention is to help individuals alter their behaviour in an effort to avoid STDs, that is, to minimize disease acquisition and transmission. The target groups may include the general public, patients, priority groups, community leaders, etc. The primary health care of WHO also underlines the importance of health education.

SUPPORT COMPONENTS

1. STD clinic

The starting point for the control of STDs is the

establishment of STD clinics where all consultation, investigations and treatment, contact tracing and all other relevant services are available. An ideal service is one that is free, easily accessible to patients and available for long hours each day. There should be suitable arrangements for treating female patients separately. Since the patients desire anonymity, the STD clinic should try to maintain it.

Because of the stigma attached to the STD clinics, many patients seek alternative sources of medical care, including self-medication. It is now considered that the key to the success of a STD control programme is the integration of its essential elements into the primary health care services.

However, it is essential to have in each administrative unit one specialized centre, which should provide the necessary clinical, and laboratory expertise and coordinate control activities at all levels of the health care system. The centre should be housed adjacent to other medical facilities and training centres.

2. Laboratory services

Adequate laboratory facilities and trained staff are essential for proper patient management. It provides a basis for correct aetiological diagnosis and treatment decisions; for contact tracing; surveillance of morbidity and detection of antimicrobial resistance. The diagnostic tests that should be available for the important sexually transmitted pathogens are given in a WHO report *(9)*.

3. Primary health care

The current trend is to integrate STD control activities into primary health care system. This will imply inclusion of primary health care workers (e.g., village health guides, multipurpose workers) in the STD "health team". Then only it will be possible to provide effective treatment to the greatest number of cases in the community. Such management limits further disease transmission. Primary health care which is based on the principles of universal coverage, community participation, equity and intersectoral coordination is ideally suited to control STD in the community.

4. Information system

The basis of an effective control programme of any communicable disease is the existence of an information system. It is a prerequisite for effective programme planning, coordination, monitoring and evaluation. Three types of data requirement are relevant in the control of STDs: these are clinical notification, laboratory notification, and sentinel and *adhoc* surveillance.

National notification system, at best, includes only the "classical" venereal diseases, where existing, reporting systems suffer from undernotification, inaccurate diagnosis and concealment of cases owing to social stigma. Without a notification system, it is not possible to assess the magnitude of the problem, to allocate resources and to evaluate the impact of control measures. There is an urgent need to develop an effective and detailed reporting system of STDs in countries where it does not exist. Sentinel surveillance systems and/or *adhoc* surveys can be used to supplement the routine reporting system. Population–based sample surveys may also be used to identify the true distribution of disease in a particular setting. Such surveys are very expensive and are generally of limited use for sexually transmitted disease programmes *(9)*.

The information system should be built around a small number of questions : How many cases were interviewed ? How many villages were visited ? How many cultures were examined? The system should provide information on activities, resource utilization and task accomplishment of programme personnel *(9)*.

5. Legislation

Many countries are still far away in enacting suitable legislation for the control of STDs *(13)*. Although legislations and regulations cannot wipe out STDs, they are nonetheless needed, particularly to establish responsibilities and define standards. The purpose of legislation should be to encourage patients to seek early treatment and name their sexual contacts, to screen high risk groups, to improve notification by general practitioners, health education of the public, etc. The Immoral Traffic (Prevention) Act, 1986 (which replaced the earlier Suppression of the Immoral Traffic Act, 1956) covers all persons, whether male or female, who are exploited sexually for commercial purposes. It makes punishment for the offences under the Act more stringent than the previous Act.

6. Social welfare measures

STDs are social problems with medical aspects. It implies there should be "social therapy" which would prevent or control the conditions leading to promiscuity and STDs. The various social measures include : rehabilitation of prostitutes; provision of recreation facilities in the community; provision of decent living conditions; marriage counselling; prohibiting the sale of sexually stimulating literature, pornographic books and photographs, etc.

MONITORING AND EVALUATION

A critical aspect of effective management is the monitoring of disease trends and evaluating programme activities. Evaluation will show if the activities have been performed in a satisfactory way. Ongoing evaluation of disease trends provides a more direct measure of programme effectiveness and may be used to determine the appropriateness of the selected intervention strategies for a particular setting *(9)*.

National STD Control Programme

See chapter 7, page 437 for details.

ENDEMIC TREPONEMATOSIS

Endemic treponematoses (pinta, endemic syphilis (Bejel, yaws) continue to be public health problems in some tropical countries. Of these, yaws and endemic syphilis still constitute a considerable health hazard to the child population in medically under–served areas, particularly in West and Central Africa and, the Americas *(1)*. These diseases are caused by agents which are microscopically indistinguishable. Typically these diseases have a patchy distribution in population groups away from the network of health centres *(1)*. They are usually contracted in childhood, non–venereally. Intrauterine transmission is absent. The late cardiac and cerebral manifestations of venereal syphilis which are particularly severe in that disease, do not occur in these infections (excepting scanty or mild lesions in endemic syphilis). In most countries, the prevalence of these diseases was reduced to low levels, and in some areas their transmission was interrupted due to mass–treatment campaigns. However, complacency after successful mass campaigns and the premature discontinuation of surveillance activities have led to resurgence of these infections in a number of countries *(1)*.

PINTA

A chronic infectious disease caused by *T. carateum*. Reports suggest that pinta has virtually disappeared from countries of Latin America *(1, 2)*. The disease is now restricted to the Philippines and some areas of the Pacific. The disease is essentially one of childhood, often beginning after the age of 10 to 15 years. Transmission is non-venereal, by direct contact with infectious lesions. After an incubation period of 7 to 21 days, an initial papular lesion appears on the hands and legs, followed by a maculo-papular, erythematous rash (pintides) lasting for years. A late stage is characterized by depigmented, leukodermic patches which may be permanent. Individuals with late pinta are resistant to infection with *T. pallidum*. In the treatment of pinta, the antibiotic of choice is benzathine penicillin G (BPG) which has replaced PAM. The dose for patients under 10 years is 0.6 mega units, and for those 10 years and over 1.2 mega units *(3)*.

ENDEMIC SYPHILIS

Endemic syphilis (Bejel is a local name for this disease in Syria) occurs in the arid areas of Syria, Saudi Arabia, Iraq, Iran, Yugoslavia, northern and southern Africa and Australia. It does not occur in the Americas. The causative agent is difficult to differentiate from *T. pallidum*. The claim that it is the same microorganism has yet to be substantiated *(4)*. It is transmitted non–venereally by direct or indirect contact – among children and adolescents through their play or by drinking vessels and common eating and other household utensils under primitive, crowded and substandard conditions of living. It is thought that poor hygiene rather than climatic conditions is a major factor in the continued transmission of Bejel. It is thought that 25 per cent of children acquire the infection before the age of 10 years. The figure is increased to 60 per cent before the age of 16 years *(4)*. Endemic syphilis produces highly infectious skin lesions. Late manifestations include gumatous lesions of the skin, nasopharynx and bones *(5)*. A single injection of benzathine penicillin G is the treatment of choice. For patients under 10 years the dose is 0.6 mega units, and for patients age 10 years and over, the dose is 1.2 mega units *(3)*.

YAWS

Yaws is a chronic contagious non-venereal disease caused by *T. pertenue*, usually beginning in early childhood. It resembles syphilis in its clinical course and is characterized by a primary skin lesion (mother yaw) followed by a generalized eruption and a late stage of destructive lesions of the skin and bone. Yaws is also known as pian, bubas or framboesia.

Geographic distribution and prevalence

Yaws is exclusively confined to the belt between the Tropic of Capricorn and the Tropic of Cancer. Not long ago, it was a significant public health problem in Africa, South East Asia and Central America. Recent country reports reveal marked variations in prevalence and patchiness in distribution in the former endemic areas *(3)*. In Africa (e.g., Benin, Ghana, Ivory Coast) there has been a great resurgence of yaws. In the Americas, reported yaws incidence is very low with small foci remaining in Brazil, Columbia, Ecuador, Guyana and Surinam *(3)*. In Asia, it occurs in Indonesia, Papua New Guinea and the South Pacific. Persistent low levels of yaws is reported in Sri Lanka and India.

Problem in India

The disease was reported in India from the tribal communities living in hilly forests and difficult to reach areas in 49 districts of 10 states, namely Andhra Pradesh, Assam, Chhattisgarh, Gujarat, Jharkhand, Madhya Pradesh, Maharashtra, Orissa, Tamil Nadu and Uttar Pradesh. Yaws eradication programme was started in 1996–97 in Koraput district of Orissa and then extended to endemic states as centrally sponsored health scheme. The number of reported cases has come down from 3500 during 1996 to zero during 2004. Since then, no new case has been reported *(6)*. Certification for disease free status requires an abscence of disease for at least 5 years. In India, this happened on 19th Sept. 2011.

Epidemiological determinants

Agent factors

(a) AGENT : Yaws is caused by *T. pertenue* which closely resembles *T. pallidum* culturally and morphologically. It measures 20μ in length with 8 to 12 rigid spirals. The agent occurs in the epidermis of the lesions, lymph glands, spleen and bone marrow. The organism rapidly dies outside the tissues. (b) RESERVOIR OF INFECTION : Man is the only known reservoir of yaws. He is an infected person. Clinical lesions may relapse 2 to 3 times or more during the first 5 years of infection, and serve as source for new infections *(1)*. Most latent cases are found in clusters centred around an infectious case. There are frequent relapses in latent cases within the first 3 to 5 years of infection. The source of infection is usually the skin lesions and the exudates from early lesions. (c) COMMUNICABILITY : Variable, and may extend over several years intermittently as moist lesions break out. Treponema are usually not found in late lesions.

Host factors

(a) AGE : Yaws is primarily a disease of childhood and adolescence. Over 75 per cent of cases occur before the age of 15 years, but the disease can occur at any age *(9)*. (b) SEX : Generally, the prevalence among males is greater than among females. (c) IMMUNITY : Man has no natural immunity. Acquired resistance develops slowly and may take

months or years to develop fully unless suppressed by treatment. There is considerable experimental and epidemiological evidence *(3)* that yaws provides partial immunity to venereal syphilis. The near eradication of yaws in Haiti has been followed by a high prevalence of venereal syphilis.

Environmental factors

(a) CLIMATE : Yaws is endemic in warm and humid regions. High humidity for at least 6 months of the year and an average rainfall of at least 40 inches are considered favourable for the transmission of yaws. (b) SOCIAL FACTORS : Social factors are even more important than biological factors in the perpetuation of yaws in the endemic areas. Yaws is mostly endemic among the tribal people, whose ways of living favour its transmission. Scanty clothing, poor personal cleanliness, overcrowding, bad housing, low standard of living and the absence of soap are important socio-economic factors in the epidemiology of yaws. Yaws is a crippling disease; lesions on palms and soles may disable a person for long periods making him dependant on others.

Mode of transmission

Yaws is transmitted non–venereally by : (a) DIRECT CONTACT : That is, by contact with secretions from infectious lesions. (b) FOMITES : Yaws may also be transmitted by indirect contact. The organism may remain alive on fomites or on the earthen floor in hot and humid conditions long enough to cause infection, and (c) VECTOR : There is some evidence that small flies and other insects feeding on the lesion may possibly convey the infection mechanically for brief periods.

Transplacental, congenital transmission does not occur.

Incubation period

9–90 days (average 21 days).

Clinical features

(a) EARLY YAWS : The primary lesion or "mother yaw" appears at the site of inoculation after an incubation period of 3 to 5 weeks. The lesion is extra-genital and is seen on exposed parts of the body such as legs, arms, buttocks or face. The local lymph glands are enlarged and the blood becomes positive for STS. Within the next 3 to 6 weeks, a generalized eruption appears consisting of large, yellow, crusted, granulomatous eruptions often resembling condylomata lata in secondary syphilis. During the next 5 years skin, mucous membrane, periosteal and bone lesions may develop, subside and relapse at irregular intervals. The early lesions are highly infectious.

(b) LATE YAWS : By the end of 5 years, destructive and often deforming lesions of the skin, bone and periosteum appear. The lesions of sole and palms are called "crab yaws". The destructive lesions of soft palate, hard palate, and nose are called "Gangosa". Swelling by the side of the nose due to osteo–periostitis of the superior maxillary bone is called "Goundu".

CONTROL OF YAWS

The control of yaws is based on the following principles :

1. Survey

A clinical survey of all the families in endemic areas is made. The survey should cover not less than 95 per cent of the total population. During the survey, persons suffering from yaws and their contacts are listed.

2. Treatment

Treatment is based on the following observations : (a) treatment with a single dose of Azithromycin oral or a single injection of long-acting penicillin will cure infection. (b) the simultaneous treatment of all clinical cases and their likely contacts in the community will interrupt transmission in the community *(9)*.

Benzathine penicillin G is the penicillin of choice. It has now replaced PAM *(3)*. The dose of BPG is 1.2 million units for all cases and contacts, and half that dose (0.6 million units) for children under 10 years of age. Azithromycin is given as a single oral dose at 30 mg/kg body weight (maximum 2 gm).

The WHO *(3)* has recommended three treatment policies : (a) TOTAL MASS TREATMENT : In areas where yaws is hyperendemic (i.e., more than 10 per cent prevalence of clinically active yaws), a great part of the population is at risk. The entire population including the cases should be given penicillin in the doses mentioned above. (b) JUVENILE MASS TREATMENT : In meso-endemic communities (5 to 10 per cent prevalence), treatment is given to all cases and to all children under 15 years of age and other obvious contacts of infectious cases. (c) SELECTIVE MASS TREATMENT : In hypo-endemic or areas of low prevalence (less than 5 per cent) treatment is confined to cases, their household, and other obvious contacts of infectious cases.

3. Resurvey and treatment

It is unlikely that a single round of survey and treatment will cover the entire population. In order to interrupt transmission, it is necessary to find out and treat the missed cases and new cases. Resurveys should be undertaken every 6 to 12 months. Several such follow-ups may be needed before eradication is achieved.

4. Surveillance

With the decline of yaws to very low levels, emphasis has shifted to "Surveillance and containment" – a technique which has proved highly successful in the eradication of smallpox. The surveillance and containment measures would be concentrated on affected villages, households and other contacts of known yaws cases. The measures comprise epidemiological investigation of cases to identify probable source(s) of infection and contacts of each known case so as to discover previously unknown cases and prevent new cases; treatment of cases; prophylactic treatment of contacts with BPG; and, monthly follow-up of households with confirmed cases for at least 3 to 4 months after treatment of the last active case to assure interruption of transmission.

5. Environmental Improvement

In a disease like yaws, an attack on social and economic conditions of life is as important as an attack on the biological cause. Recrudescence of the disease is apt to occur unless environmental improvement is promoted, e.g., improvement of personal and domestic hygiene, adequate water supply, liberal use of soap, better housing conditions and improvement of the quality of life.

6. Renewed eradication efforts *(7)*

The WHO roadmap for neglected tropical diseases

(NTDs) have set 2020 target for the eradication of yaws from the remaining countries.

Since January 2012, when the WHO roadmap for NTDs were set and an article in the Lancet on the efficacy of a single-dose azithromycin in the treatment of yaws was published, WHO has taken steps to move the renewed eradication efforts by developing a new eradication strategy based on single dose treatment with azithromycin. These are:

a. *Total community treatment (TCT)* – treatment of the endemic community, irrespective of the number of active clinical cases;
b. *Total targeted treatment (TTT)* – treatment of all active clinical cases and their contacts (household, school, playmates).

As a first step in implemeting the new eradication strategy, 7 countries were selected for the initial pilot treatment campaigns. In 2012 it was implemented in Betou and Enyelle districts of Congo. In 2013, implementation was carried out in Ghana, Papua New Guinea and Vanuatu, achieving a coverage of more than 90 per cent. In 2014, Cameroon, Indonesia, and Solomon Islands are to implement mass treatment activities *(7)*.

7. Evaluation

To determine whether or not yaws has really been brought under control, serological studies are needed. Ideally if no yaws antibodies were found among children born since the yaws mass campaign was completed, it would mean that the campaign had been totally successful. The actual sample of the population to be tested may be as low as 1 or 2 per cent.

AIDS

AIDS, the acquired immuno-deficiency syndrome (sometimes called "slim disease") is a fatal illness caused by a retrovirus known as the human immuno-deficiency virus (HIV) which breaks down the body's immune system, leaving the victim vulnerable to a host of life–threatening opportunistic infections, neurological disorders, or unusual malignancies *(1)*. Among the special features of HIV infection are that once infected, it is probable that a person will be infected for life. Strictly speaking, the term AIDS refers only to the last stage of the HIV infection. AIDS can be called our modern pandemic, affecting both industrialized and developing countries.

Problem statement

WORLD

Recognized as an emerging disease only in the early 1980s, AIDS has rapidly established itself throughout the world, and is likely to endure and persist well into the 21st century. AIDS has evolved from a mysterious illness to a global pandemic which has infected tens of millions people.

Promising development have been seen in recent years in global efforts to address the AIDS epidemic, including increased access to effective treatment and prevention programmes. However, the number of people living with HIV continues to grow, as does the number of deaths due to AIDS. Of particular concern are trends affecting Eastern Europe and Central Asia, where the numbers of people acquiring HIV infection and dying from HIV-related causes continue to increase. The key indicators for HIV epidemic are as shown in Table 1.

WHO and UNAIDS define the different types of HIV epidemics as follows *(5)* :

Low-level HIV epidemics

Although HIV may have existed for many years, it has never spread to substantial levels in any sub-population. Recorded infection is largely confined to individuals with higher risk behaviour e.g. sex workers, drug injectors, men having sex with other men. Numerical proxy : HIV prevalence has not consistently exceeded 5% in any defined sub-population.

Concentrated HIV epidemics

HIV has spread rapidly in a defined sub-population, but

TABLE 1
Key Indicators for the HIV epidemic 2009–2012

	2009	2010	2011	2012
Number of people living with HIV (in millions)	32.9 (31.0–34.4)	34.0 (31.6–35.2)	34.2 (31.9–35.9)	35.2 (32.2–38.2)
Number of people newly infected with HIV (in millions)	2.7 (2.5–2.9)	2.7 (2.4–2.9)	2.5 (2.2–2.8)	2.3 (1.9–2.7)
Number of people dying from AIDS–related causes (in millions)	1.9 (1.7–2.1)	1.8 (1.6–1.9)	1.7 (1.5–1.9)	1.6 (1.4–1.9)
% of pregnant women tested for HIV[a]	26%	35%	–	40%
Number of facilities providing antiretrovial therapy [a]	18,600	22,400	–	–
Number of people receiving antiretrovial therapy [a]	5,255,000	6,650,000	8,000,000	9,700,000
Number of children receiving antiretrovial therapy [a]	354,600	456,000	566,000	647,000
Coverage of antiretrovial medicines for preventing mother-to-child transmission (%) [a]	48%[b]	48%[c]	57%	67%[b]

a In low-and middle-income countries.
b The coverage data includes provision of single-dose nevirapine which is no longer recommended by WHO.
c This data does not include single-dose nevirapine regimen which is no longer recommended by WHO. It should not be compared with the previous years. When including single-dose nevirapine, the coverage in 2010 was 59%.

Source : *(2, 3, 4)*

is not well-established in the general population. This epidemic state suggests active networks of risk within the sub-population. The future course of the epidemic is determined by the frequency and nature of links between highly infected sub-populations and the general population. Numerical proxy : HIV prevalence is consistently over 5% in at least one defined sub-population but is below 1% in pregnant women in urban areas.

Generalized HIV epidemics

In generalized epidemics, HIV is firmly established in the general population. Although sub-populations at high risk may contribute disproportionately to the spread of HIV, sexual networking in the general population is sufficient to sustain an epidemic independent of sub–populations at higher risk of infection. Numerical proxy : HIV prevalence consistently over 1% in pregnant women.

On the verge of fourth decade of the AIDS epidemic, the world has turned the corner – it has halted and begun to reverse the spread of HIV. The question remains how quickly the response can chart a new course towards vision zero discrimination, zero new HIV infection and zero AIDs–related deaths through universal access to effective HIV – prevention, treatment, care and support.

HIV incidence (the number of new HIV infections in a population per year) is the key parameter that prevention efforts aim to reduce, since newly infected persons contribute to the total number of persons living with HIV; they will progress to disease and death over time; and are a potential source of further transmission. Since 1997, the year in which annual new infections peaked to 3.2 million cases globally, the number of new infections has fallen to 2.3 million in 2012. This reduction in HIV incidence reflects natural trend of epidemic, as well as the result of prevention programmes resulting in behavioural changes in different contexts *(2)*.

Most new infections are transmitted heterosexually, although risk factors vary. In some countries, men who have sex with men, injecting drug users and sex workers are at significant risk. Although HIV testing capacity has increased over time, enabling more people to learn about their HIV status, the majority of people with HIV are still unaware about their infective status *(4)*.

Women represent about half of all people living with HIV worldwide, and more than half (about 60 per cent) in sub–Saharan Africa. HIV is the leading cause of death among women in reproductive age. Gender inequalities, differential access to services and sexual violence increase women's vulnerability to HIV, and women, especially younger women, are biologically more susceptible to HIV *(4)*.

In 2013, WHO issued revised treatment guidelines recommending earlier initiation of antiretroviral therapy, at a CD4 count of ≤500 cells/mm^3. These new criteria increased the total number of people medically eligible for therapy from 16.7 million to 25.9 million, an increase of 9.2 million in low and middle income countries *(6)*.

The *"Treatment 2.0"* initiative, launched by WHO and UNAIDS in 2010 is continuing the drive for optimizing and innovating treatment in the key areas of drug regimens, point-of-care diagnostics, integrated and decentralized delivery of HIV services, and mobilizing communities *(7)*. In 2011, WHO member states adopted a new *"Global health sector strategy on HIV/AIDS for 2011–2015"*. It outlines four strategic direction for next 5 years : (a) Optimize HIV prevention, diagnosis, treatment and care outcomes; (b) Leverage broader health outcomes through HIV responses; (c) Build strong and sustainable health systems; and (d) Address inequalities and advance human rights *(8)*.

The interaction of HIV/AIDS with other infectious diseases is an increasing public health concern. Tuberculosis, bacterial infection and malaria have been identified as the leading cause of HIV-related morbidity in Sub-Saharan Africa. HIV infection increases the incidence and severity of clinical malaria in adults *(9)*.

The national HIV strategic plans in most SEAR countries accord priority to prevention, care and treatment interventions to high-risk populations; however coverage of a comprehensive package of HIV interventions for sex workers, men having sex with men, transgender persons and injecting drug users remains low in all countries.

INDIA

Now into its fourth decade, India's epidemic is marked by heterogeneity – not a single epidemic but made up of a number of distinct epidemics, in some places within the same state.

India's epidemic seems to be following the pattern first described in Thailand. The epidemic shifts from the highest risk group (commercial sex workers, homosexual men, drug users) to bridge population (clients of sex workers, STD patients, migrant population, population in conflict areas and partners of drug users), and then to general population. The shift usually occurs where the prevalence in the first group reaches 5%. There is a time–lag of 2–3 years between the shift from one group to the next *(10)*. The trends indicate that HIV infection is spreading in two ways; from urban to rural areas and from individuals practising high-risk behaviour to the general population. Data from antenatal clinics indicate rising HIV prevalence among women, which in turn contribute to increasing HIV infection in children.

Available evidence on HIV prevalence and future statistical projections shows signs of stabilization of HIV epidemic in India at national level. Provisional estimates for the year 2012 show that there were 20.89 lakh people living with HIV/AIDS with estimated adult HIV prevalence of 0.27 per cent. Declining trends are noted in high prevalence states indicating possible impact of sustained programme interventions. Even the prevalence among pregnant women in the age group of 15–24 years, which is considered proxy for incidence/new infections in general population, is showing a declining trend.

Information from persons testing positive for HIV at the integrated counselling and testing centres across the country during 2011–2012 shows that 88.2 per cent of HIV infections are still occurring through heterosexual route of transmission. Fig. 1 shows the routes of transmission of HIV and their percentage.
