Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on his or her own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Editors assume any liability for any injury and/or damage to persons or property arising out of or related to any use of the material contained in this book.

Dean, School of Medicine
Health Sciences Center
Texas Tech University
Lubbock, Texas

RAVI S BHAT MBBS DPM MD FRANZCP

Associate Professor of Psychiatry
School of Rural Health
The University of Melbourne;
Consultant Old Age Psychiatrist and
Director of Psychiatry
Goulburn Valley Area Mental Health Service
Goulburn Valley Health
Shepparton, Victoria, Australia

ARNAB BHOWMICK MBChB FRCS (Gen Surg)

Department of Surgery
Lancashire Teaching Hospitals NHS Trust
Lancashire, United Kingdom

ITALO BIAGGIONI MD

Professor of Medicine and Pharmacology
Vanderbilt University
Nashville, Tennessee

SIMON G BIGGS BSc PhD AFBPsS

Professor of Gerontology
Director, Institute of Gerontology
King's College London
London, United Kingdom

DAVID A. BLACK MA MBA FRCP

Dean and Director
Kent, Surrey and Sussex Postgraduate Medical and
Dental Deanery;
Consultant Physician
South London Healthcare Trust
London, United Kingdom

HARRISON G BLOOM MD

Associate Clinical Professor
Brookdale Department of Geriatrics and
Palliative Medicine
Mount Sinai School of Medicine;
Senior Associate and Director, Clinical Education and
Consultation Service
International Longevity Center
New York, New York

CHARLOTTE E BOLTON MD MRCP

Associate Professor in Respiratory Medicine
Nottingham Respiratory Biomedical Research Unit
University of Nottingham;
Honorary Consultant in Respiratory Medicine
Nottingham City Hospital
Nottingham, United Kingdom

JULIE BLASKEWICZ BORON MS PhD

Assistant Professor
Department of Psychology
Youngstown State University
Youngstown, Ohio

CLIVE BOWMAN FRCP FFPH

Medical Director
BUPA Care Services
Leeds, United Kingdom

SIDNEY S BRAMAN MD FCCP

Professor of Medicine
Director, Division of Pulmonary and Critical Care Medicine
Department of Medicine
Rhode Island Hospital, The Alpert Medical School of
Brown University
Providence, Rhode Island

LAWRENCE J BRANDT MD MACG FACP FAAPP

Professor of Medicine and Surgery
Albert Einstein College of Medicine,
Chief of Gastroenterology
Montefiore Medical Center
Bronx, New York

ROBERTA DIAZ BRINTON PhD

Professor
Department of Pharmacology and Pharmaceutical Sciences
School of Pharmacy, Pharmaceutical Sciences Center and
Program in Neuroscience
University of Southern California
Los Angeles, California

SCOTT E BRODIE MD PhD

Associate Professor
Department of Ophthalmology
Mount Sinai Medical Center
New York, New York

GINA BROWNE RN PhD

Professor
School of Nursing, Clinical Epidemiology and Biostatistics
and Ontario Training Centre in Health Services and
Policy Research
McMaster University
Hamilton, Ontario, Canada

PATRICIA BRUCKENTHAL PhD APRN

Clinical Associate Professor
School of Nursing
Stony Brook University
Stony Brook;
Nurse Practitioner
Pain and Headache Treatment Center, Department of
Neurology
North Shore University Hospital
Manhasset, New York

ANDREW K BURROUGHS MBChB (Hons) FEBG FRCP

Professor of Hepatology
Centre for Liver Studies
University College London;
Professor and Consultant Physician
The Royal Free Sheila Sherlock Liver Centre
Royal Free Hospital
Hampstead, London, United Kingdom

ROBERT N BUTLER MD

President and CEO
International Longevity Center—USA
New York, New York

RICHARD CAMICOLI MSc MD FRCP(C)

Professor of Medicine (Neurology)
University of Alberta
Edmonton, Alberta, Canada

IAN A CAMPBELL FRCP

Consultant Physician
Chest Department
Llandough Hospital
Cardiff, Wales, United Kingdom

ROBERT VICTOR CANTU MD

Assistant Professor of Orthopaedic Surgery
Dartmouth-Hitchcock Medical Center
Lebanon, New Hampshire

MARGRED CAPEL

Consultant in Palliative Medicine
George Thomas Hospice Care
Cardiff, Wales, United Kingdom

HARVINDER S CHAHAL BMedSci MBBS MRCP

Specialist Registrar in Endocrinology
Department of Endocrinology
St Bartholomew's Hospital
London, United Kingdom

HERMAN S CHEUNG PhD

James L. Knight Professor
Department of Biomedical Engineering and Medicine
University of Miami;
Senior VA Career Scientist
Geriatric Research, Education, and Clinical Center
Bruce W. Carter VA Medical Center
Miami, Florida

SEAN D CHRISTIE MD FRCS

Associate Professor
Department of Surgery (Neurosurgery)
Dalhousie University
Queen Elizabeth II Health Sciences Centre
Halifax, Nova Scotia, Canada

DUNCAN S COLE BSc FRCPC MD PhD

Senior Scientist
Division of Genomic Medicine
Toronto General Research Institute
Toronto, Ontario, Canada

CLAUDIA COOPER BM MRCPsych MSc PhD

Senior Lecturer
Psychiatry of Older People
Research Department of Mental Health Sciences
University College of London
London, United Kingdom

TARA K COOPER MBBCh MRCOG

Department of Medicine and Veterinary Medicine
University of Edinburgh
Edinburgh;
Department of Obstetrics and Gynaecology
St Johns Hospital
Livingston, United Kingdom

RICHARD A COWIE BSc(Hons) MBChB FRCSE(SN)

Consultant Neurosurgeon
Greater Manchester Neuroscience Centre
Salford Royal Hospital
Salford, United Kingdom

PETER CROME MD PhD DSc FRCP (Lond, Edin and Glasg) FFPM

Professor of Geriatric Medicine
School of Medicine
Keele University
Newcastle-under-Lyme
Staffordshire, United Kingdom

SIMON C M CROXSON MD FRCP

Consultant Physician
Department of the Elderly
Bristol General Hospital
Bristol, United Kingdom

STUTI DANG MD MPH

Assistant Professor of Medicine
Department of Medicine
Geriatrics Institute, University of Miami Miller School of
Medicine;
Researcher, Physician, and Director, T-Care and TLC
Geriatric Research, Education, and Clinical Center
Bruce W. Carter VA Medical Center;
Stein Gerontological Institute
Miami Jewish Home Health Systems
Miami, Florida

GWYNETH A DAVIES MRCP MD

Senior Clinical Lecturer
School of Medicine
Swansea University;
Honorary Consultant
Department of Respiratory Medicine
Singleton Hospital, ABMU Health Board
Swansea, Wales, United Kingdom

TIMOTHY J DOHERTY MD PhD FRCP(C)

Associate Professor
Department of Clinical Neurological Sciences
The University of Western Ontario
London, Ontario, Canada

LIGIA J DOMINGUEZ MD

Assistant Professor of Geriatric Medicine
Department of Internal Medicine and
Emergent Pathologies
University of Palermo
Palermo, Italy

WILLIAM M DRAKE DM FRCP

Consultant Endocrinologist
Department of Endocrinology
St Bartholomew's Hospital
London, United Kingdom

EAMONN EELES MBBS MRCP MSc

Assistant Professor
Department of Geriatrics and Internal Medicine
Dalhousie University
Halifax, Nova Scotia, Canada;
Consultant Physician
Department of Geriatrics and General Medicine
Llandough Hospital
Cardiff, Wales, United Kingdom

WILLIAM B ERSHLER MD

Senior Investigator
Clinical Research Branch
National Institute on Aging
National Institutes of Health
Baltimore, Maryland

WILLIAM J EVANS PhD

Adjunct Professor
Department of Medicine, Division of Geriatrics
Duke University
Durham,
Vice President and Head
Muscle Metabolism Discovery Performance Unit
GlaxoSmithKline
Research Triangle Park, North Carolina

MARTIN R FARLOW MD

Professor and Vice Chair of Neurology
Indiana University School of Medicine;
Neurologist
University Clinical Neurologists
Indianapolis, Indiana

RICHARD C FELDSTEIN MD MSc

Department of Gastroenterology
New York University School of Medicine;
Attending Faculty
Department of Gastroenterology
Woodhull Medical and Mental Health Center
Brooklyn, New York

HOWARD M FILLIT MD

Clinical Professor of Geriatrics and Medicine
The Mount Sinai Medical Center
Executive Director
The Alzheimer's Drug Discovery Foundation and the
Institute for the Study of Aging
New York, New York

ANDREW Y FINLAY MBBS FRCP (Lond and Glas)

Professor of Dermatology
Department of Dermatology
Cardiff University School of Medicine
Cardiff, Wales, United Kingdom

ILORA FINLAY MBBS FRCP FRCGP

Professor of Palliative Medicine
Cardiff University;
Consultant in Palliative Medicine
Velindre Hospital
Cardiff, Wales, United Kingdom

ROGER M FRANCIS MB ChB FRCP

Professor of Geriatric Medicine
University of Newcastle upon Tyne;
Consultant Physician Bone Clinic
Musculoskeletal Unit
Freeman Hospital
Newcastle upon Tyne, United Kingdom

ANTHONY J FREEMONT MD FRCP FRCPath

Professor of Osteoarticular Pathology
School of Clinical and Laboratory Sciences
University of Manchester;
Honorary Consultant in Osteoarticular Pathology
Department of Histopathology
Central Manchester NHS Foundation Trust
Great Manchester, United Kingdom

JAMES E GALVIN MD MPH

Associate Professor
Department of Neurology
Washington University School of Medicine
St Louis, Missouri

NICHOLAS J R GEORGE MD FRCS FEBU

Senior Lecturer and Consultant in Urology
Department of Urology
University Hospital South Manchester
Manchester, United Kingdom

NEIL D GILLESPIE BSc(Hons) MBChB MD
Senior Lecturer in Medicine (Ageing and Health)
Newwells Hospital and Medical School
University of Dundee
Dundee, United Kingdom

ROBERT GLICKMAN DMD

Professor and Chair
Department of Oral and Maxillofacial Surgery
New York University College of Dentistry;
Director
NYU Medical Center/Bellevue Hospital Center
New York, New York

ADAM G GOLDEN MD MBA

Assistant Professor of Medicine
Department of Medicine
Geriatrics Institute, University of Miami Miller School of
Medicine;
Researcher and Physician
Geriatric Research, Education, and Clinical Center
Bruce W. Carter VA Medical Center
Miami, Florida

LESLIE B GORDON MD PhD

Associate Professor of Pediatrics Research
Department of Pediatrics
Warren Alpert Medical School of Brown University
Hasbro Children's Hospital
Providence, Rhode Island;
Medical Director
The Progeria Research Foundation Peabody, Massachusetts

MICHELLE GORENSTEIN PsychD

Psychology Intern
Department of Psychiatry
The Mount Sinai Medical Center
New York, New York

MARGOT A GOSNEY MD FRCP

Director
Department of Clinical Health Sciences
University of Reading;
Professor of Elderly Care Medicine
Department of Elderly Care
Royal Berkshire NHS Foundation Trust
Reading, United Kingdom

JOHN TREVOR GREEN MB Bch MD FRCP

Clinical Senior Lecturer
Department of Medical Education
Cardiff University;
Consultant Physician
Department of Gastroenterology
University Hospital Llandough
Cardiff, Wales, United Kingdom

DAVID A GREENWALD MD FACG FASGE AGA-F

Associate Professor of Clinical Medicine
Albert Einstein College of Medicine;
Gastroenterology Fellowship Director
Montefiore Medical Center
Bronx, New York

**CELIA L GREGSON BMedSci(Hons)
MRCP(UK) MSc**

Wellcome Clinical Research Fellow
Academic Rheumatology
University of Bristol
Bristol, United Kingdom

MICHAEL L GRUBER MD

Clinical Professor of Neurology and Neurosurgery
New York University School of Medicine;
Attending
Department of Neurology and Neurosurgery
NYU Langone Medical Center
New York, New York;
Director, Brain Tumor Center of New Jersey
Department of Neurology
Overlook Hospital
Summit, New Jersey

DAVID R P GUAY PharmD

Professor
College of Pharmacy
University of Minnesota
Department of Geriatrics
HealthPartners Inc.
Minneapolis, Minnesota

RENATO MAIA GUIMARÃES MD MSc

Director
Geriatric Medical Center
Hospital Universitario de Brasilia
Brasilia, Brazil

KHALID HAMANDI MB BS BSC MRCP PhD

Consultant Neurologist
Welsh Epilepsy Unit
Department of Neurology
University Hospital of Wales and University Hospital
Llandough
Cardiff, Wales, United Kingdom

PETER HAMMOND BM BCh MA MD FRCP

Consultant Physician
Department of Diabetes and Endocrinology
Harrogate District Hospital
Harrogate – North Yorkshire, United Kingdom

STEVEN M HANDLER MD MS

Division of Geriatric Medicine
Department of Medicine
Department of Biomedical Informatics
School of Medicine
University of Pittsburgh
Geriatric Research Education and Clinical Center
Veterans Affairs Pittsburgh Healthcare System
Pittsburgh, Pennsylvania

Acknowledgments

Dr. Fillit wishes to thank his wife Janet and children, Marielle and Michael, for their support, patience, and encouragement. He also expresses his appreciation to Leonard Lauder and Ronald Lauder, founders and chairmen of the Institute for the Study of Aging, for their vision and dedication to aging research. He also thanks Filomena Machleder, whose tireless and excellent assistance made this book possible.

Howard M. Fillit

Professor Rockwood would like to thank many organizations that supported research on aging, including the Canadian Institutes of Health Research, the Dalhousie Medical Research Fund, and the Fountain Innovation Fund of the Queen Elizabeth II Health Sciences Foundation. He expresses special thanks for the support from his wife, Susan Howlett, and their sons, Michael and James.

Kenneth Rockwood

Professor Woodhouse would like to thank his wife, Judith, and his children for their unwavering support and encouragement. The support of his colleagues is very much appreciated and acknowledged. He would also like to thank his assistant, Shirley Green, whose knowledge of journal and book production procedures has proved invaluable in assisting him to fulfill his editorial commitment to the book.

Kenneth Woodhouse

All three editors wish to pay special tribute to the outstanding editorial support from Anne Snyder and Druanne Martin at Elsevier.

Introduction: Aging, Frailty, and Geriatric Medicine

Howard M. Fillit
Kenneth Rockwood
Kenneth Woodhouse

There are many landmarks in the history of care for older adults. In ancient times, Hippocrates and Cicero wrote on aging and health. The first medical textbook on aging was published by Charcot in 1881 (*Clinical lecture on senile and chronic diseases*, London, New Sydenham Society). The term *geriatrics* was coined by Ignatz Nascher in 1909:

“Geriatrics, from geras, old age, and iatrikos, relating to the physician, is a term I would suggest as an addition to our vocabulary, to cover the same field that is covered in old age that is covered by the term pediatrics in childhood, to emphasize the necessity of considering senility and its disease apart from maturity and to assign it a separate place in medicine” (New York Medical Journal 1909; 90:358–359).

Nascher, who was later recognized as the father of geriatrics, published the first American textbook of geriatric medicine in 1914 (*Geriatrics: The diseases of old age and their treatment*, Philadelphia, P. Blakiston’s Son & Co). The book had three major sections: physiologic old age, pathologic old age, and hygiene and medicolegal relations. Geriatrics was first embedded as a component of a modern health system and became a specialty in 1948 within the National Health Service in the United Kingdom. As a result, the first “modern” textbook of geriatrics was published in 1973, edited by John Brocklehurst. We are proud, then, to present the heir of this lineage, the Seventh Edition of *Brocklehurst’s Textbook of Geriatric Medicine and Clinical Gerontology*.

The first edition of *Brocklehurst* contained 39 chapters written by 44 authors. The current edition contains 128 chapters and 205 authors. This growth reflects our increasing knowledge, based on research, about gerontology and geriatric medicine. There has also been a significant advance in our understanding, in our perspective, and in our health systems, which also contribute to the evolution of our knowledge. Nevertheless, we have remained true to the original concept.

In the seventh edition, we have attempted to make the book more useful and valuable to the gerontologist, be they a biologic, social, psychological, or medical gerontologist. Indeed, the study of aging as an interdisciplinary field of research has expanded exponentially since the first edition. Consequently, the content on gerontology has been significantly reorganized and expanded. Although the effort to effectively combine gerontology and geriatric medicine

in one comprehensive book is ambitious, we believe it is necessary since the clinician clearly requires knowledge of the gerontologic basis of geriatric practice, whereas the gerontologist needs the clinical perspective for his or her work to be relevant. Whether for the gerontologist, the geriatrician, the primary care physician, the specialist, or the care managers and other providers, we hope the book has value as a resource to improve the care of elderly persons, to create better systems of care, and to advance knowledge and research in gerontology.

Fundamentally, geriatric medicine encompasses three essential “bodies of knowledge.” The first is gerontology, essential to the practice of geriatrics. One cannot effectively practice geriatrics without understanding the basic fundamentals of aging itself, much as a pediatrician cannot practice pediatrics without understanding child development. Indeed, geriatricians often refer to “adult development,” not aging, as key to the practice of geriatric medicine. For example, evaluating the cognition of an aged person requires a working knowledge of the degree and nature of “normal” changes in cognition at that age. Gerontology, the study of aging, is also a fundamentally interesting scientific field relevant to geriatric medicine in that it encompasses the demography of aging, the biology of aging, the neuropsychology of aging, and medical gerontology.

The second component of the body of knowledge in geriatrics is disease specific. That is, geriatrics requires knowledge of the diseases that are more common in the aged than in the middle-aged (such as Alzheimer’s disease), and knowledge of how common diseases such as pneumonia, hypertension, diabetes, or hypothyroidism differ in their presentation in old age.

The third component of geriatric medicine knowledge may be called complexity. Complexity, a focus on function, and an emphasis on multidisciplinary coordinated care management are each critical to geriatric medicine. Complexity refers to the fact that many older patients (in contrast to most middle-aged “internal medicine” patients with single illnesses) often have many comorbid illnesses, are on multiple medications, and suffer problems in the multiple spheres of physical, functional, psychological, and social health.

Complexity is further reflected in the “geriatric syndromes”—falls, polypharmacy, delirium, sleep disorders, and others—that are presented in the section on “geriatric syndromes.” The focus on function is important in the evaluation of complexity in the frail elderly patient and key to the practice of geriatric medicine.

Because of the preponderance of chronic illness, complexity, and the resulting frailty (a state of increased vulnerability that arises from multiple, interacting medical and social problems), geriatric patients require effective health systems

of chronic care, a multidisciplinary team approach, comprehensive yet efficient means of evaluation (such as geriatric assessment), and the increasing use of technology, such as electronic medical records and telemedicine. In particular, physicians and other care providers need to know how to participate in and to lead and manage health systems critical to the provision of quality and efficient geriatric care, which is presented in the section on health systems.

In the twenty-first century, with the emergence of billions of persons into a newly globalized world, we have expanded our international perspective. Aging is clearly now a global challenge, with all societies needing new and effective ways to provide quality, cost-effective care to the elderly with a focus on quality of life and continuing productivity.

This edition also aims for easier ways for readers to provide feedback for future editions, through the "contact us" button on the book's Web site (www.expertconsult.com). The introduction of a Web site for the book also reflects our aim to move from an exhaustive referencing style of textbook. We have given thought to why anyone might read—much less write—a textbook when so much information is readily available, and so quickly, on the web. The immediacy and proliferation of information is both the triumph and the challenge of the Internet, a "place" where the quality of information can be questionable.

Since information is not knowledge, we are persuaded that there remains a role for a textbook that provides practitioners and scientists, in one text, a compendium of useful and validated information. We hope that as you read the chapters, you will get the sense that they were written by experts who care about their field and care about what you should know about it.

With the seventh edition, we aim to build on what has been achieved in geriatric medicine and gerontology, and to renew our commitment to provide gerontologists, geriatricians, and other academics and practitioners with updated, useful information to aid them in their special mission of providing care for older persons. To do this, we have recruited new editors: Professors Kenneth Rockwood (from Canada) and Kenneth Woodhouse (from the United Kingdom). Each has undertaken major research in the field and each brings a wealth of clinical, scholarly, and health systems experience and perspective to this important endeavor.

Thus, when colleagues or patients question "what is geriatrics?" we often reach for our "body of knowledge," here, a textbook weighing several pounds with more than 1350 pages of "small print."

In the twenty-first century, there can be no more important subject in medicine than gerontology and geriatrics. We believe this textbook represents the knowledge base for that effort.

The Epidemiology of Aging

Norman Vetter

It must be obvious that, senescence apart, old animals have the advantage of young. For one thing, they are wiser. The Eldest Oyster, we remember, lived where his juniors perished.

SIR PETER MEDAWAR¹

INTRODUCTION

Epidemiology is about measuring and understanding the distribution of the characteristics of populations. The origin of epidemiologic methods relates to the study of epidemics, initially set up by the rich to know when it was time to leave the area when a new epidemic spread among the poor. Epidemiologists are still concerned about the distribution of disease, but apart from being perhaps less likely to head for the hills when infection is rife, they have also added noninfectious diseases and the determinants of disease to their interests. Some have strayed into areas which are not disease-related, but are characteristics of the population itself; one such area is the epidemiology of aging.

The body of knowledge of the epidemiology of aging has evolved into concentrating on three main areas: the causes and results of the aging of populations, the natural history of diseases of old age, and the evaluation of services set up to assist older people. This chapter will concentrate on the first of these; the other two will be covered elsewhere in the textbook.

The causes and results of the aging of populations

The early twenty-first century is unique in a number of aspects, but in relation to the people of the world it is most remarkable as a time when humans live appreciably longer than ever before. Perhaps even more remarkably this rate of prolongation of average life expectancy shows little sign of abating. This extraordinary piece of good luck for those of us who live at this time is tempered a little by the knowledge that life insurers and those calculating pensions have been betting our money on our not living so long, as a result of which we may be poorer than we had hoped.

Longevity

The increase in human life expectancy over the past 10 years has taken both scientists and the population generally by surprise.² Until recently, demographers were confidently predicting that once the gains made by reducing mortality in early and middle life had reached completion, growth in longevity would stop and we would see the fixed reality of the aging process. This has not happened. Mortality experts who have repeatedly asserted that life expectancy is close to an ultimate ceiling have repeatedly been proven wrong. The apparent leveling off of life expectancy in individual countries has been an artifact of laggards catching up and leaders falling behind. In the developed world, average prolongation of life continues at 4 to 5 hours a day. Late-life mortality,

which people theorized was likely to remain stable, has steadily increased (Figure 2-1).

The probable causes for the linear quality of this increase in life expectancy are twofold. Before 1950, most of the gain in life expectancy was due to reductions in death rates at younger ages. In the second half of the twentieth century, improvements in survival after age 65 caused the increase in the length of people's lives. Most forecasts of the maximum possible life expectancy in recent years have been broken within five years of the forecast.³ World life expectancy has more than doubled over the past 200 years. So where will this lead? Life expectancy has increased by 2.5 years per decade for a century and a half; a reasonable suggestion would be that this trend will continue in coming decades. If so, average life expectancy will reach 100 in about 60 years.

Why do we age?

There now appears to be a reasonably clear consensus that the aging process is caused by an accumulation over time of molecular damage. The rate of aging in an individual is therefore a complex interaction between damage, maintenance, and repair. These interactions are, of course, influenced by both genetic and environmental factors. It has been said that whoever created humans, whether nature or a creator, did a poor job, but being aware of it, put in a lot of back-up systems. On the other hand it may be a universal law that hyperefficiency is less effective in the long run than flexibility. This may be a useful lesson beyond the realms of longevity in a world more fussed about efficiency than effectiveness.

It is assumed that genetic changes are unlikely to alter appreciably, under evolutionary pressure, over the short period, during which longevity has dramatically increased. The reason for the increasing longevity is therefore said to be caused by the interplay of advances in income, nutrition, education, sanitation, and medicine, with the mix varying over age, period, cohort, place, and disease. It seems likely then that these changes are largely a result of a wide range of environmental factors.

That being said, the birth cohorts of people born around the early 1900s experienced huge changes in socioeconomic conditions, hygiene, lifestyle, and medical care, leading to dramatic falls in infant mortality and infectious and respiratory diseases. The main effects were socioeconomic, leading to smaller families, better housing, and nutrition, though later in the century vaccination must have played some part. In later years it seems to have been the survival of older people that has led to the extension of life expectancy. The reason for this survival is not fully understood. The best we can do is to guess that it may be the availability of specific treatments for diseases of old age.⁶

However, it may be that we were working to the wrong theory of maximum human lifespan all along. Studies of large populations of humans, wasps, fruitflies, nematodes, and yeast have revealed a leveling off, and in some species even a decline, in mortality late in life instead of a continuously increasing rate. The possible reason that this has been

Figure 2-1. Life expectancy by time (United Kingdom \pm 95% confidence intervals).

missed until now in humans may be that the deceleration in age-specific death rates does not seem to begin in humans until after 80 years of age, the plateau is not seen until after 110 years of age, and it requires the observation of large populations.⁴

In addition, genetics and environment are known to be intimately entwined. The length of telomeres has been said to be a measure of aging. Telomeres are the ends of chromosomes that help to protect the DNA from wearing down during the replication process that replenishes cells. Telomeres shorten over an individual's lifetime and are thought to be a marker for aging. For instance it is known from matched twin studies that telomeres in a physically active group of people (who performed more than 3 hours and 20 minutes of exercise a week) were 200 nucleotides longer than those in a less active group (who performed less than 16 minutes exercise a week). Smokers and obese people are known to have shorter telomeres than their healthier counterparts.⁵

QUALITY OF LIFE AND DISABILITY

The measurement of quality of life on older people is self-evidently a vital outcome measure for deciding upon, for instance, the comparative effectiveness of different treatments. Many approaches have been made to this. For an overview for large populations, questionnaire methods are most commonly used, including the Bartel index, the SF-12, and more recently the WHOQOL-OLD, a generic health-related

QOL measure developed for the World Health Organization.⁷ A number of good reviews of measuring quality of life have been written by Bowling⁸ and Haywood.⁹

The latter explored 122 articles relating to 15 measuring instruments. The most extensive evidence was found for the SF-36, COOP Charts, EQ-5D, Nottingham Health Profile (NHP), and Sickness Impact Profile (SIP). Four instruments had evidence of both internal consistency and test-retest reliability: the NHP, SF-12, SF-20, and SF-36. Four instruments lacked evidence of reliability: the HSQ-12, IHQL, QWB, and SQL. Most instruments were assessed for validity through comparisons with other instruments, global judgments of health, or clinical and sociodemographic variables. The author concluded that there was good evidence for reliability, validity, and responsiveness for the SF-36, EQ-5D, and NHP. There is more limited evidence for the COOP, SF-12, and SIP. The SF-36 was recommended where a detailed and broad-ranging assessment of health is required, particularly in community-dwelling older people with limited morbidity. The EQ-5D was recommended where a more succinct assessment is required, particularly where a substantial change in health is expected.

Another study of more than 16,000 in the health survey for England provided evidence that the SF-6D is an empirically valid and efficient alternative multiattribute utility measure to the EQ-5D, and is capable of discriminating between external indicators of health status.¹⁰

Figure 2-2 shows data from the above study for EQ-5D data by age. EQ-5D is an especially useful measure, where valid, because it can be used directly to measure utilities in cost-effectiveness studies when using the measure to build up quality-adjusted life-years (QALYs). QALY maximization as a means of, for instance, comparing two treatments, is sometimes criticized for being ageist, because other things being equal, the elderly with a shorter life expectancy will be given lower priority.

It is not the place of this chapter to go into detail on this argument, but some people believe that everyone, when faced with a sudden illness or accident at least, should be regarded as equal no matter what their state of health or likely longevity. This seems untenable at one extreme, say elderly patients with severe dementia. In that case it would seem that "not striving to keep alive" makes sense. However, a fit 90-year-old is usually able to benefit from high

Figure 2-2. EQ-5D utility data by age.

technology solutions to his or her disease process as anyone else.

In contrast some people believe that QALYs are not ageist enough (e.g., the QALY-based view would give the same weight to treating a 10-year-old with a quality-adjusted life-expectancy of 10 years as to an 80-year-old with the same life expectancy). This does not account for the greater benefits that the old person has already received so that some people think that younger people should have priority over older people, regardless of life expectancy.¹¹

Changes with time

It is a truism to say that older people nowadays are fitter than they were in the past. Measuring this between successive generations of the same age has been attempted. At the level of overall quality of life, it has been reported that people in their late 70s in the 1990s were less functionally impaired than was a similar group in the 1980s.¹² Since then various other longitudinal studies conducted in the United States, Europe, and in other developed countries have examined this. Although the findings are not consistent, several consensus publications and a meta-analysis that stratified results based upon the adequacy of measurement concluded that there appeared to have been a significant reduction in the rate of functional decline over the last 3 decades and that this finding was robust with respect to measurement approach, methodology, and to some extent by country.¹³ This was difficult to pinpoint in the face of an approximately 1% reduction in mortality in older people, but most researchers conclude that there has been at least a 2% reduction in disability over the last several decades.

Turning to more specific problems that are common in older people, it is thought that, for example, average blood pressure measurements in successive cohorts of older people appear to be declining. Thus in the Gothenburg study, it was found that successive cohorts of 70-year-olds had lower arterial blood pressure with time.¹⁴ Others have agreed that although the prevalence of disability and need for help increases with advancing age, within an age group these improve over time from one birth cohort to another.^{15,16} The exception to this, until recently, has been fractures in older people where age-adjusted fracture incidence seemed to be rising steadily during the 1990s. However, since then, in Finland where the best data have been collected over time, the rate is changing rapidly, rising for some fractures¹⁷ and falling for others.^{18,19}

The exact reasons for the secular change in the risk of hip fracture are unknown. A cohort effect toward healthier elderly populations in the developed countries cannot be ruled out: in earlier birth cohorts, the early-life risk factors for fracture, such as perinatal nutrition, may have had stronger impact on the late-life fracture risk than in the others. A second reason could be the rising average body weight and body mass index (BMI). In all adult age groups in developed countries, the prevalence of obesity has increased since the 1980s. A low BMI is a strong risk factor for hip fracture, and it has been estimated that a one unit increase in the BMI of a population could result in an 7% decrease in the fracture incidence—the effect being greatest with weight gain among the thinnest older adults.

Measuring differences: predicting future quality of life

Data from the English longitudinal study of aging have been used to investigate whether longstanding illnesses, social context, and current socioeconomic circumstances predict quality of life.²⁰ This was a nationally representative sample of noninstitutionalized adults living in England using a standardized quality of life scale. The quality of life of the group was found, where adversely affected, in rank order to be reduced by depression, a poor financial situation, limitations in mobility, difficulties with everyday activities, and limiting longstanding illness. Quality of life was improved, again in rank order, by trusting relationships with the family, friends, and frequent contacts with friends; living in a good neighborhood; and having two cars. The regression models explained 48% of the variation in quality of life scores.

The authors concluded that efforts to improve quality of life in early old age need to address financial hardships, functionally limiting disease, lack of at least one trusting relationship, and inability to move out of a disfavored neighborhood. They did not mention the possible provision of extra cars.

This importance of the perceptions of older people about their neighborhood was also underlined by a further study of over-65-year-olds in the community.²¹ In this study, perceptions of problems in the area (noise, crime, air quality, rubbish/litter, traffic, and graffiti) were predictive of poorer health. The good news about these findings is that many of these factors are modifiable and could have an important impact on the quality of life of older people.

A 65-year-old person with severe disability will have differences in need for support when compared with an 85-year-old person. The severe disability is likely to be complicated by multiple problems, especially social and mental problems, so that their health needs are likely to be greatly complicated by housing and financial needs and by isolation and loneliness.

Measuring differences: cross-sectional versus longitudinal data

Much of the research done on the aging process has been performed on cross-sectional data. This is not particularly surprising because such studies are easier and much less complicated to perform than longitudinal studies. Generally speaking, cross-sectional data indicate that aging has a more marked deleterious effect on the study group than longitudinal. The process of aging for us all is demonstrably longitudinal, so that wherever possible we should be guided by such data.

A number of examples of the differences between cross-sectional and longitudinal studies exist. A classic longitudinal study showed that cognitive decline appeared to be much more closely related to age in cross-sectional studies than in longitudinal.²² Other cross-sectional studies that originally were thought to show that smoking had a protective effect on Alzheimer's disease were shown by longitudinal studies to be the opposite of the true effect, probably because smokers died before they had a chance to suffer from Alzheimer's.²³ In addition, marked effects have been seen in different cohorts born more recently. Age cohorts born only 5 years apart show notable differences in their

height, weight, and other measures associated with changes in activity level.²⁴ It is therefore important to distinguish between the sorts of data that are available when making judgments about populations of older people. Generally, cross-sectional data paint a bleaker picture of the impact of aging than do longitudinal data.

Measuring differences: age

The age distribution of older men and women is very different, especially in the oldest age groups. For example, 3.8% of older women compared with 1.7% of older men are aged 90 and above. This situation is expected to persist for some time, but gender differences according to age will become less notable in the future.

When describing age groups there is a particular problem for the oldest group and sometimes for those below that. The groups 65 to 69, 70 to 74, 75 to 79, 80 to 84, and 85+ are commonly used in the literature and in research findings. This is a means of summarizing the data when looking at trends and other differences. However, closer examination of these groups compared with single year of age data may show that, although the first four of these represent 5-year age groups, the 85+ group can, depending on the population studied, only go up to 90 years of age or may continue beyond 100. In other words the 85+ group is not strictly comparable with the other two. By grouping the data, one is making the assumption that the group represents a midpoint.

This, together with the likelihood of small numbers in the oldest age group, can account for anomalous findings in that group.

Table 2-1 shows data for a population based in a large general practice in South Wales by year of age and divided into age groups. It can be clearly seen that the 85+ age group is heavily skewed with the frequency midpoint of the group between 86 and 87 years, nowhere near the 5 years which is the midpoint of the others.

Figure 2-3 shows a typical example of how the top age group is out of line with previous groups. It shows the prevalence of breathlessness in the group shown in Table 2-1. The difference in value in the oldest age group may reflect a true difference or it may be due to assuming that the oldest group is at the midpoint, as explained above.

Measuring differences: sex

The average life expectancy at birth of females born in the United Kingdom is 80 years compared with 76 years for males. Women are more likely than men to be living with high blood pressure, arthritis, back pain, mental illness, asthma, and respiratory disease. Men are more likely than women to be living with heart disease. Older men are much more likely than older women to drive. Among people aged 75 and over, 58% of men and 33% of women have access to private transport. Among people aged under 75, women are more likely than men to be providing unpaid

Table 2-1. Year of Age by Age Groups

Figure 2-4. Projected percentage of older women by age in the United Kingdom.

care to relatives, neighbors, or friends; but among people aged 85 and over, men are more likely than women to be providing unpaid care. This is because of different average lifespans—older women are more likely to live alone, whereas older men are more likely to be married. Figure 2-4 shows the projected percentage of older women by age group.

Population aging is particularly rapid among women because of lower mortality rates among women. In older age groups, the proportion of women is therefore higher than men; increasingly so with advancing age. Therefore, when studying older people, it is essential to study gender as a basis of differentiation. For example, it has been suggested that older women's much higher level of functional impairment coexists with a lack of gender differences in self-assessed health. Some studies have reported no gender differences in self-reported health status among elderly people, whereas higher levels of more objectively measured disability existed among women. It has been shown that gender differences in health depend on the indicator and the age stratum analyzed. It could very well be that among older adults the impacts of different measures of socioeconomic position differ by health indicator and that disability-related indicators may be more sensitive to gender inequalities than

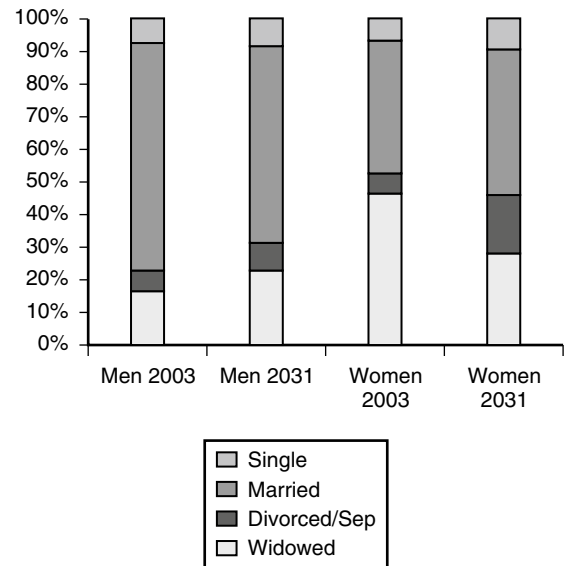

Figure 2-5. Projected percentage of older people by sex and marital status (England and Wales).

broad indicators of general health such as self-perceived health status.²⁵

Among some older married couples, the man controls household finances, meaning that his partner may be left in a difficult position if suddenly she has to take over money management. Women's pension entitlement is often lower than men's and their risk of poverty in later life significantly greater.

Although the gender differences in the structure by age of the older population is expected to persist in the future, things will slowly change. As a result of the faster increase in life expectancy of men, gender differences in the composition of the older age groups will most likely shrink over time. Thus it is estimated that between 2006 and 2031, women will remain in the majority, but their share is due to decrease. For example, the percentage of women aged 80 to 89 is expected to decrease from 63.2% in 2006 to 56.3% in 2031.

Measuring differences: marriage

Older men and women are very different with respect to their marital status: 61% of men are married compared with 36.7% of women, whereas 16.5% of men are widowed compared with 46.1% of women. This gender imbalance varies by age, becoming more marked with time or among older cohorts. In the future these differences are expected to decrease dramatically. Figure 2-5 shows these changes.

There is predicted to be a dramatic increase in the share of divorced and separated individuals in the younger age groups of the older population between 2003 and 2031. Among the 65-74 year olds, one in five women will belong to this group, whereas now the percentage stands at just below 9%. The increase in the proportion of divorced and separated men will not be as great because men have a higher propensity to remarry, but the proportion of single men will reach more than 16%. In short, for both genders, but particularly so for men aged 65-74, the proportion married will

diminish whereas the proportion of those in other groups will increase.

Measuring differences: features of older compared with younger people in the population

Figure 2-6, adapted from work by Professor Grimley Evans,²⁶ shows a general outline of the main differences between young and older people. These are divided into two main groups, differences due to the aging process itself and those not due to that process. Aging may be primary and intrinsic, set by the cellular makeup of the individual or it may be extrinsic and due to environmental challenges—the day-to-day wear and tear of the environment on that person.

Secondary aging is said to be either individual, such as the adaptations in an older person's gait because of poor proprioception or a tendency to write down things to overcome problems with memory. They are not themselves due to aging but are a response to some aspect of the aging process. Some aspects of old age give an advantage to the species. Thus humans with their odd need to stand on their swivel have to go through those pelvises at birth, have as a result very immature offspring who take many years to become independent beings. It appears that, in evolutionary terms, additional help in child care in the shape of grandmothers provided an advantage. Thus the menopause gave a major advantage to humankind and was adopted generally.

Then there are three main categories of difference which are not due to the aging process per se: selective survival, the fact that people who take more risks, whether by smoking or by dangerous sports, are less likely to be found in the older age group so that that group is lacking in such individuals. The second, a cohort effect, which I have mentioned elsewhere in the chapter and the third differential challenges for older people compared with those for the young, which I will now describe more fully. In many countries older people live in low quality housing as a consequence of social policy as well as poverty. More pervasive is the poorer quality of medical care provided for older people, largely as a result of discrimination against those who are older.

Indices of dependency

The ratio of the dependent population to the economically active or working population is sometimes called the dependency ratio. This is used in setting taxation policies, in particular, as the working population pay income tax. In fact the taxman, when extracting taxes, is much cleverer than just taking money from wage packets these days; so that all groups of people who purchase pay value-added and other taxes. There are a number of groups who are not part of the working population: children, students, housewives, husbands, and the unemployed. Being not formally employed does not mean that they are not contributing to the economy. In particular grandparents contribute hugely in terms of child care for working people and retired people, especially women, and are one of the biggest groups caring for elderly disabled relatives, most often a spouse.

Another indicator of the age structure is the aging index, defined as the number of people aged 65 and over divided by the number under age 15. By 2030 it is thought that all developed countries will have more people aged 65 and over than people under 15.

Is aging inevitable?

The old joke says "aging is inevitable, maturing is optional." However, lifestyle factors seem able to have an impact on aging. The best-known and obvious of these is smoking, which is related to a wide range of problems, some well known, as in lung disease, heart disease, and cancers, resulting in its being the most important predictor for mortality in a combination of six large longitudinal studies.²⁷ Others have a particular resonance with older people, notably bone strength and hearing ability.²⁸ These changes are so ubiquitous that there is a suggestion that smoking may accelerate the aging process itself.

On the positive side, there are also a number of studies that show the importance of continuing to perform exercise^{29,30} and others that have shown that muscular strength in old age can, with training, be increased proportionately to a similar extent to that found in younger people³¹ and that training appears to have some effect on the prevention of falls.³²

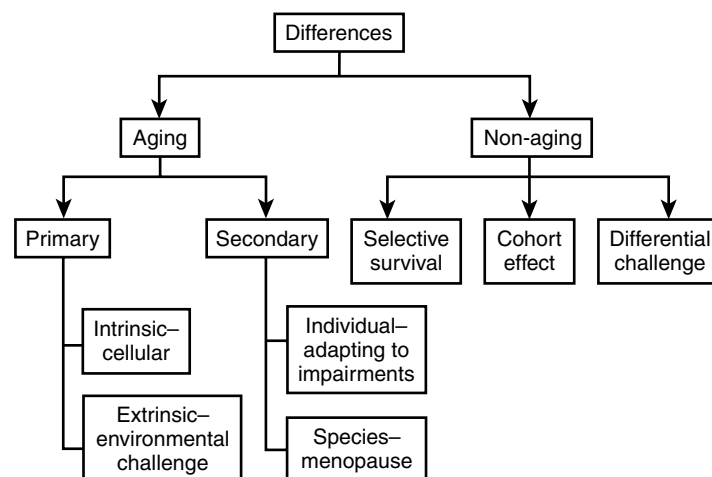

Figure 2-6. Differences between young and older individuals.

Living alone

The vast majority of those who live alone are widowed, although this percentage is much higher for women than men. The distribution of those who live with a partner (the vast bulk of older people) is similar between men and women and consists mainly of married or remarried individuals. By contrast, the category “living with others” is quite heterogeneous. Men are more likely to be married, perhaps living with a younger wife, whereas women in this group are for the most part widowed (Figure 2-7).

Living alone is likely to be increasingly common as the millennium advances. It is likely that a quarter of people born in the 1960s will be lone householders by age 60 and that close to a half of the 1960s Baby Boomers will be living solo by age 75.³³ Living alone is not directly related to loneliness, but the cause of living alone, especially widowhood, is closely related, so they are often associated.

Ethnicity, emigration, and immigration (internal and external)

Because of the youthfulness of immigrants, immigration is often seen as a solution to the “problem” of population aging in countries with low fertility. Presently the lack of people to take jobs in developed countries draws young people from developing countries, lowering the average age of the population. The overall large numbers and proportions emigrating again among the overseas-born population suggest that this U.K. subpopulation ages more slowly than does the U.K.-born subpopulation. This implies that the currently observed processes of immigration and emigration among U.K.'s overseas-born immigrants will lower the U.K.'s old-age dependency ratio in the long run as well as in the short run.

Table 2-2 shows the proportion of older people in the 2001 census by ethnic origin. There are a great preponderance of white people in the United Kingdom, with only very minor differences in the proportion between males and females.

Inequalities

Older people have tended to be neglected in research on health inequalities compared with people in other stages of life. Similarly, there has been a lack of research on how class interacts with gender in later life. One of the central reasons for this has been the difficulty of assigning people to social groupings after retirement because the approach has

Figure 2-7. Marital status of older people living alone. (Data from United Kingdom 2001 census.)

Table 2-2. Older People by Sex and Ethnicity – United Kingdom

Ethnicity	Male	Female	Total
White	96.9	97.7	97.4
Asian	1.8	1.3	1.5
Black	1.0	0.7	0.8
Other	0.3	0.3	0.3
Total	100.0	100.0	100.0

Data from Census (2001) Office of National Statistics, United Kingdom.

traditionally been based on occupational status and this is difficult to attribute when older people are mainly retired.

There is evidence that increasing inequalities will occur between future cohorts of elderly people. Inequalities will persist between those who will have experienced full work histories, have acquired pension rights and housing wealth, and those who have not. The 1960s baby boomers, in particular, faced high unemployment levels when they first entered the labor market. Some of them have never had a full-time job, whereas others benefited from the Thatcher era, giving rise to the 1980s “yuppies.” Inheritance of housing wealth primarily goes to individuals who are already owner-occupiers, further increasing the trend toward increased inequality and Richard Titmuss’ notion of “two nations in old age.”³⁴

Inequalities by socioeconomic group continue even up to the end of life. During the last year of life, older people were still reluctant to take up their entitled benefits.³⁵ Primary health care professionals saw nearly all of the people who died during their last year. They could play an important role in ensuring that the elderly and the less well-off are aware of the services and benefits available to them.

CONCLUSIONS

Epidemiology is about measuring and understanding the distribution of the characteristics of populations. In relation to aging, the early twenty-first century is unique in the span of human existence for the longevity of the race. The aging of the population is a global phenomenon that requires international coordination nationally and locally.

The United Nations and other international organizations have developed a number of recommendations intended to reduce adverse effects of population aging. These include reorganization of social security systems, changes in labor, immigration, and family policies, promoting active and healthy life-styles, and more cooperation between governments in resolving socioeconomic and political problems

KEY POINTS

The Epidemiology of Aging

- The world population is older than it has ever been.
- Measuring the effect of an aging population is not straightforward; longitudinal approaches more accurately describe people's experience than do cross-sectional studies.
- Older people at a given age are fitter than they used to be in nearly all objective parameters measured.
- Inequalities between different social groups of older people, both for health and income, appear to be increasing in the U.K.

related to population aging. A country with an aging population may be helped by immigration of young workers to enlarge the working population, potentially with benefit to both countries as long as it is carefully monitored.

On the positive side, the health status of older people of a given age is improving over time because recent generations are fitter and have had less diseases. As a result, older vigorous and active people live to a much later age than

previously, and given the opportunities, they can contribute economically. We have already extended the healthy and productive period of human life and this shows little sign of abating.

The Future of Old Age

Kenneth G. Manton

The future of old age in the twenty-first century in the United States and other economically developed countries will be dynamic and will generate historically unprecedented demographic, social, economic, and medical conditions. This is due to quantitative and qualitative population, social, economic, and health factors. Some quantitative demographic factors are well known, although details of their operation are still not fully appreciated.

First, in the United States, there were rapid declines in mortality at young ages from at least 1900 because of reductions in infectious disease risks and infant and maternal mortality. Responsible for these declines were improved nutrition, new antibiotic therapies, immunization and vaccination programs for childhood diseases, and improved public hygiene (e.g., improved sanitation, drinking water, and, recently, air quality). The likelihood of surviving to 65 for United States' males in 1900 was 37.3%; for females 41.0%.¹ By 1950, this had increased to 61.8% for males and 74.3% for females. By 2005 this increased to 78.8% for males and 87.0% for females. From 1954 to 1968, United States mortality was viewed as static—male mortality rates increased 0.2% per year; although female mortality rates, in contrast, declined 0.8% per year. Federal agencies began to plan, and operate, as if the upper limit to population life expectancy had been reached.² Projections of the Social Security beneficiary population in the mid-1970s assumed that mortality would decline no further.³ This view was also expressed by many epidemiologists who suggested that the third phase of the epidemiologic transition involved increases in the prevalence of chronic degenerative diseases⁴ caused by adverse social⁵ and public health conditions intrinsic to industrial society.⁶ Additionally, some authors suggested there were few medical innovations successfully reducing chronic disease progression in the elderly.⁷

Second, the size of birth cohorts increased. Post-World War II baby boom cohorts reached a maximum in 1963 in the United States. The first of those cohorts reaches age 65 in 2012, and age 85 in 2032. The largest cohorts reach age 65 in 2029 and 85 in 2049. The larger size of recent cohorts, and improved mortality up to age 65, will produce large future increases in the elderly population in the United States. Similar population dynamics operate in other developed, and some major developing (e.g., China, India) countries. This will produce severe strains on economic and medical programs for elderly populations.

Third, after being static from 1954 to 1968, mortality in the United States above age 65 began to decline, in part because of the start of national research programs on chronic diseases. The National Heart Institute was created in 1949. The Framingham Heart Study began in 1950. Actually, although reductions in chronic disease mortality were identified as starting in 1968, a more comprehensive examination suggests that mortality declines for select chronic diseases began earlier. Declines in stroke mortality can be traced back to at least 1925.⁸ Declines in male heart disease prevalence became evident after examining data on U.S. Civil War veterans age 65 and over who were assessed for

pensions in 1910. A comparison of heart disease prevalence in Civil War veterans in 1910 with World War II veterans aged 65 and over in 1985 showed a decline of 66% in the intervening 75 years.⁹ From 1950 to 1998, age-standardized heart disease mortality rates declined 58.8%, stroke mortality declined 71.7%.

Reductions in chronic disease mortality raised concern about society's "carrying" capacity for a growing elderly population because it suggested that the number of years individuals live after age 65 would be significantly extended. Although Social Security finances benefit from an increasing number of persons living through their labor force years to age 65, living beyond 65 increases the financial burden on Social Security, Medicare, and Medicaid programs. Recognition of the declines after 1968 in chronic disease mortality, and life expectancy increases above age 65, raised concerns about the long-term fiscal stability of the U.S. Social Security system. In 1982, in addition to payroll tax increases, increases in the Social Security normal retirement age from 65 to 67 were scheduled to occur from 2003 to 2017. Increases in the retirement age to age 70, or even 74, are currently being debated in Britain and Japan. A Japanese study suggested that future economic growth could be compromised by population aging. That study anticipated that one quarter of Japan's population will be over 65 by 2025 using estimates of life expectancy limits that were exceeded by 3 years by Japanese females in 1992.^{10,11} Japanese life expectancy continues to be the world's highest, with 85.6 years for females in 2005.

Policy and social responses to population aging depends upon a fourth dynamic—changes in the average health of the elderly. Was the health of a person age 70 in 2005 better on average than the health of a 70-year-old in 1970; will the health of an 80-year-old in 2040 be better than the health of an 80-year-old in 2005? U.S. data suggest that the answers to these questions are yes. Significant declines in the prevalence of chronic disability and morbidity in the elderly population were observed from 1982 to 2004–2005, and appear likely to continue to 2006 and beyond.^{12–17}

Even recent concerns over an obesity epidemic in the United States seem to be overstated. Although obesity (measured by BMI >30.0) prevalence did increase in the United States from 1980 to 2000, its adverse health effects seem to have been muted by improvements from 1960 to 2006 in the ability to manage the circulatory disease risk factors that link obesity to diabetes and circulatory disease and death. Indeed, even the linkage of obesity to chronic disability seems to have been modulated.¹⁸ Thus the obesity epidemic will not aggravate U.S. Medicare spending to the degree suggested by some U.S. economists.¹⁹

Such health changes have profound effects on the social and economic institutions of a country and on its health care delivery and financing system.²⁰ There are already popular responses in the perceived lower limit to "old age" in the United States. A recent survey suggested that persons age 50 thought a person has to reach age 80 before being "elderly." This was due to changing social perceptions and economic

realities due to the growing proportion of the total U.S. population over age 65, and the effects on housing, insurance, and other private markets along with physical changes in younger old persons. Fundamental research issues involve determining parameters of the population health dynamics underlying changing social perceptions and economics. Whether or not improvements in health and functioning continue at late ages, and can be accelerated by judicious public health and medical innovations and investments, will affect how the United States' and other developed countries' social and economic institutions respond in the future to a growing elderly population.

A difficulty in anticipating future improvements in health at, for example, ages 85 and 95, is that changes depend in part upon both historical and future conditions. Historical factors are important because the individuals who will be the elderly and oldest-old cohorts in the next 65 years are already alive and have accumulated significant early exposures that partly determine the age trajectories of health parameters. Historical factors determine both the number of elderly persons (by reducing early mortality), and the mix of health problems they present (i.e., parameters of individual's health change with age and vary due to differences in the prior risk factor experiences of birth cohorts). That is, depending both upon the cohort an elderly person is in and the individual's life experiences, the principal health manifestations of aging may vary considerably. For example, very elderly cohorts may have little early smoking experience, and hence, little chronic pulmonary disease. Recent cohorts of postmenopausal females, because of the early use of exogenous estrogens, may have reduced osteoporosis and coronary heart disease (CHD) risks. An analysis of future conditions is necessary because we are in a historically unique period where many biomedical technologies and their clinical application are maturing so that many conditions once palliatively managed are now subject to disease-modifying treatments (e.g., rheumatoid arthritis²¹ and, recently, osteoarthritis using orthobiologics²²). Next, we briefly review historical and future inputs to the health dynamics of the elderly population, and then forecast what "old age" will signify in the future.

HISTORICAL DETERMINANTS OF THE FUTURE HEALTH OF THE ELDERLY

The realized human life span is increasing. The first well-documented case of a centenarian was reported in 1800.²³ The first well-documented achievement of the age of 110 years was in 1932. The first well-documented achievement of the age of 120 years (Jean Marie Calment; who lived over 122 years) was in 1995. There are partly documented reports of ages of 125 years being achieved for a Brazilian female; and 127 years for a U.S. Hispanic female. Thus the maximum documented human life span increased 10 years from 1800 to 1932, and over 12 years from 1932 to 1997 (i.e., at over twice the earlier rate). The number of centenarians in the United States increased 7% per year from 1960 to 1987. That growth continued with 54,000 centenarians estimated to be alive in 1995 and 82,000 centenarians estimated to be alive in 2007 (a 51% increase).²⁴ Similar annual rates of increase in the number of centenarians are found in other developed countries.²⁵ Thus

centenarians are no longer a rarity, although population studies of their current and past health characteristics are.²⁶ One U.S. population study, the National Long Term Care Survey (NLTC), oversampled persons 95 and above in 1994, 1999, and 2004. The age range of new elderly and extreme elderly cohorts is now broad enough (e.g., 65 to 115 years of age) that the parameters of the health consequences of aging can differ significantly across the cohorts.²⁷

Evidence suggests that the health of the extreme elderly is improving and that interventions can be successful at late ages. Indeed, one recent study showed active life expectancy increased relatively faster at age 85 than at age 65.¹⁷ One factor in health improvements is the effect of early mortality on the health of very elderly populations; "high" early mortality in a cohort "selects out" its genetically less fit members between ages 50 to 85. In a Swedish study, the relative risk of CHD mortality in monozygotic twin pairs was roughly 15 to 1 in middle age. Above age 85, the relative risk was 1.0.²⁸ Selection caused thyroid autoantibodies in Italian centenarians to be only as prevalent as they were at 50, even though their prevalence increased from ages 50 to 85.²⁹ Genetically determined lung cancer (because of defects in the cytochrome P-450 enzyme system) peaks at 70% at age 50; by age 70 the genetic form of the disease is 20% of cases.³⁰ ApoE4 (apolipoprotein E4), associated with heart disease and dementia risk, declines with age from a prevalence of more than 20% at age 80 to about 5% at age 100.³¹ The null allele C4B*Q0 is associated with heart attack risk in middle-aged males, with such risks (and selection against the genotype) occurring at later ages for females.^{32,33}

If mortality selection were the only factor determining the health of extreme elderly cohorts, average health would decline as the proportion surviving from birth to late ages increased. Indeed, in recent analyses, younger cohorts had higher active life expectancies than older cohorts (M837). Thus factors other than selection must affect the health of the extreme elderly including medical innovations.

A study of surgery performed on patients aged 90 to 103 showed that intraoperative mortality declined from 29% in the 1960s to 8% by 1985.³⁴ The study was performed because surgery rates over age 90 increased fivefold from 1979 to 1989. The 5-year survival of this surgical group (mean age 93.5 years) was better than the general population (i.e., a 5-year survival of 21% versus 16% in regional life tables). A factor in the success of surgical interventions was the small number of "ever smokers" in the cohort and the low prevalence of chronic pulmonary disease.

Nutritional factors were thought to cause the reductions in chronic morbidity in Fogel's⁹ study of Civil War veterans. One theory suggests that prenatal nutrition affects the risk of chronic disease at late ages³⁵⁻³⁷ because the prenatal development of major organ systems is affected by maternal nutrition. In U.S. Civil War veterans born 1825 to 1844, the high prevalence of chronic disease was thought to be a result of poor maternal and early nutrition differentially affecting the development of major organ systems. Improvements from 1910 to 1985 in physiologic status at late ages was argued to be a result of improved early nutrition between the experience of the 1825 to 1844 and 1900 to 1920 cohorts. Fogel traced this to temporal increases in stature and body mass

index (BMI) on Waaler surfaces.³⁸ Similar improvements were found in functional and strength measures between Civil War recruits and military personnel post–World War II in the Gould samples.³⁹

Another theory suggests that improved food hygiene reduced exposures to viral and other chronic “slow” infections (e.g., cytomegalovirus [CMV], herpesvirus, and *Chlamydia pneumoniae*^{40,41}) in animal food sources causing later reductions in atherosclerosis in adults.⁴² They suggest that thermal food processing and tighter regulations on livestock production reduced the risk of chronic circulatory diseases and certain cancers⁴³ by reducing the risk of chronic viral and other infections.^{42,44} That is, recent declines in heart disease mortality were traced to the ingestion of atherogenic viruses in pre–World War II and postwar declines in infection rates as food hygiene improved. A number of events shaped these trends; vesicular exanthema, a viral disease of swine, was discovered in 1932. Controls for this and other livestock infections began in California in 1945 to 1949, a state showing early (1950) declines in heart disease. An outbreak of vesicular exanthema in 1952 mandated national regulations requiring thermal processing of livestock feed. Hog cholera eradication programs began in 1962. The Swine Health Protection Act was passed in 1980 to prevent another virus from entering the food chain. Thermal processing of prepared foods, although existing as a technology at the turn of the century, expanded rapidly after World War II. Some early models of atherosclerosis^{45,46} suggested that infectious agents were involved in addition to inflammatory processes, homeostatic factors, and blood lipids.⁴⁷ However, the technical ability (e.g., polymerase chain reaction [PCR] or fluorescence in situ hybridization [FISH]) to detect the presence of agents, their genetic effects, or persistent immunologic responses is relatively recent.⁴⁸

Another model suggests that chronic circulatory disease change was in part due to changes in the dietary levels of micronutrients, such as vitamins A, B, C, E, and D. Vitamins A, C, and E are antioxidants and may reduce the rate of oxidation of low-density lipoprotein (LDL) cholesterol in macrophages (producing “foam cells”)—a factor in atherogenesis.⁴⁷ Vitamins A and E are cellular redifferentiating agents possibly reducing the risk of some cancers.⁴⁹ The dietary levels of vitamins A (and other retinoids) and C depend upon the availability of fresh fruits and vegetables—foodstuffs difficult to preserve before refrigeration and transportation technologies allowed persons in northern temperate climates to continue to consume such foodstuffs through the winter. This also could affect hypertension and stroke risk in that refrigeration reduced the use of salt as a food preservative. Increased consumption of fruits may also have increased potassium intake and lowered hypertension.

Vitamin D has long been a supplement. Moon et al⁵⁰ noted that the curative effects of cod liver oil on rickets were documented in 1917. By 1923, the United States imported half a million gallons of fish liver oil, nearly 3 million gallons in 1930. Ultraviolet radiation of milk began in the United States in 1924. Production of vitamin D rose from 35 lb in 1948 to 14,000 lb in 1972. Supplementation became problematic in that vitamin D is a potent hormonal agent with a narrow therapeutic trough. Reductions in supplementation were mandated by the Food and Drug Administration (FDA) in 1972.

Vitamin D metabolism is complex, including effects on cellular calcium metabolism and parathyroid hormone production, possibly leading to hypertension.⁵¹ Vitamin D interferes with the uptake of magnesium. Concomitant with increased vitamin D supplementation were declines in magnesium in the United States diet because of the use of nitrogen-based fertilizers. Vitamin D also increases the absorption of iron, so oversupplementation could affect heart disease by reducing magnesium (which could increase production of aldosterone⁵²) and by increasing iron absorption—increasing LDL oxidation (also by causing increases in serum calcium and calcification of plaque), stroke (by affecting hypertension), and osteoporosis (by direct effects on osteoclasts and bone resorption). It is relatively recent that the standards for vitamin D supplementation, especially in the elderly, are now argued to be too low with increases of vitamin D intake in the elderly suggested.

A fourth model involves elevated homocysteine because of increased meat consumption and genetic or dietary deficiencies of vitamin B₆ and B₁₂. Decreasing renal function with age may adversely affect physiologic vitamin B levels, as may age changes in liver metabolism through the eighth decade of life. The homocysteine model suggests that atherosclerosis is partially a disease of protein toxicity whereby failure to detoxify certain sulfur-based amino acid products of protein metabolism leads to damage in arterial endothelium.⁵³ The homocysteine model may not only explain initiating events in circulatory disease,⁵⁴ but also possibly osteoarthritic and rheumatoid arthritic changes (by affecting cartilage matrix formation) and increases in dementia.⁵⁵ Vitamin B₆ also has a wide range of physiologic effects (e.g., DNA binding and nuclear localization) on a super family of ligand activated transcription factors that exert biologic effects by regulating target gene expression.^{56,57} Recently, however, folic acid supplementation mandated in Canada and the United States was associated with considerable reduction in stroke risk as compared to Britain, where such supplementation did not occur.⁵⁸

CURRENT AND FUTURE BIOMEDICAL INPUTS TO AGING

The factors described above determined health parameters of persons now entering advanced age ranges. To respond to this heterogeneity of aging parameters, and recent changes in the physiologic manifestation of aging changes, are treatment modalities made possible by recent biomedical research. Research focused on aging began in the United States with the creation of the National Institute on Aging (NIA) in 1974. In the 1960s, biologic senescence was often viewed as a genetically determined cellular process operating universally in all tissue types, with chronic diseases believed to be manifestations of its effects. Hayflick⁵⁹ suggested such a model after observing that human fibroblasts could reproduce only 50 to 60 times. An experiment⁶⁰ challenging this view examined the number of cell replications remaining for fibroblasts drawn from persons aged 30 to 80 years. Cells lost one replication for every 5 years of life. Cristofalo et al⁶¹ found similar results. Thus, if this is the basic mechanism of senescence, it would not limit life spans near current levels. It has been suggested that defects in mitochondrial DNA may be a more likely biologic limitation to the maximum human life span, suggesting a limit of 129 years.

In the 1970s it became clear that many aging studies had design flaws (i.e., the rate of loss of physiologic function was tracked in "representative" elderly populations). This confounded the intrinsic physiologic rate of aging with the age-dependent prevalence of chronic disease determined by the history of environmental exposures. Studies of populations screened for existing chronic diseases lowered estimates of the age rate of loss of physiologic functions (e.g., the age rate of loss of cardiac function in an active elderly population was one half that in earlier studies).⁶² Age-related disease processes were found to be physiologically more complex, with much wider variation in expression than previously thought.^{63,64}

In the 1980s, medical science began to demonstrate significant potential for modifying chronic disease processes. Atherosclerosis was once thought to be a product of an aging circulatory system. Now it appears to be reversible by nutritional modification (e.g., cholesterol reduction) and other interventions,^{65,66} with functional responses evident before anatomic changes^{67,68} and facilitated by antioxidant therapy.⁶⁹ Left ventricular hypertrophy (LVH) was thought to be because of age-related remodeling of cardiomyocytes. However, angiotensin-converting enzyme (ACE)-II inhibitors and controlling hypertension can also cause regression of LVH,⁷⁰ possibly by blocking the effects of aldosterone in remodeling myocytes as fibrotic tissue.⁷¹ Many classic signs of senescence, or old age, are now well-defined pathologic processes (e.g., frailty and osteoporosis, cognitive impairment, and Alzheimer's disease). With the pathologic mechanisms identified, it is possible to develop disease-modifying interventions, especially at the molecular level, and thus to remold the aging process.

Some early chronic disease and aging interventions were initiated serendipitously. Exogenous estrogens were used by 3 million U.S. women in 1985 for post menopausal symptoms. By 1994 this had grown to 10 million women. It appears that exogenous estrogens reduce the risk of osteoporosis and CHD⁷² in postmenopausal women.⁷³ Research⁷⁴ suggested that estrogen supplementation could reduce the risk of dementia by 50%. A recent major clinical trial, however, calls those benefits into question, although reanalysis of those data suggested female Hormone Replacement Therapy has to be initiated shortly after menopause to have positive effects. Negative effects of HRT seemed most manifest in very elderly women where HRT was initiated 15 to 20 years postmenopause. Further analysis is needed to clarify the dynamics of treatment and response. Evidence suggests that testosterone supplementation may have benefits for males in terms of reduced dementia risk. Data from the 1999 NLTCS suggested there have been large declines in dementia risk from 1982 to 1999.¹⁵

Aspirin has long been used as an analgesic and to control fever. Recently, its potential in secondary prevention of stroke and heart attack by affecting platelet adhesion has been realized.⁷⁵ An association of aspirin consumption with reduced risk of colorectal cancer was found, as has a speculative association with reductions in Alzheimer's disease risks.⁷⁶ Nonsteroidal anti-inflammatory drugs (NSAIDs), by blocking inflammatory tissue responses, may affect other cancers by affecting the ability of tumor cells to metastasize and clonally organize.

Modeling senescence as the genetic control of the number of cell replications was given impetus by investigations of

the end-segment of the human chromosome, the telomere, and an enzyme, telomerase, that induces its lengthening.⁷⁷ The evidence for the telomere controlling senescence is mixed. The telomere does decrease in length as the cell replicates but may correlate more strongly with oxidative stress. However, even when a given length is reached, although the cell ceases to divide, it may exhibit stable metabolism and function. Bone marrow and blood cells express low levels of telomerase, with that activity distributed across different cell types. Furthermore, its production may be controlled hormonally and by growth factors in damaged (e.g., the lung) tissues. Thus there may not be an absolute shutoff of telomerase in somatic cells but continuing production at low levels and with continuing genetic potential for production. This is consistent with templates of telomerase ribonucleic acid (RNA) existing in somatic cells and the ability of tumor cells to express telomerase after a crisis phase.⁷⁸

Evidence of the role of telomerase in neoplastic growth is clear. Normally, cells stop replicating while the telomere is still long. It may be that the p53 mediated pathway to apoptosis⁷⁹ is activated when the telomere drops below a functionally suboptimal length. Then the cell enters a crisis phase that leads either to cell death or a reactivation of telomerase, a stabilized telomere length, and an immortal cell line.⁸⁰ Confirmation was found in that telomerase activity was present in 68% of stage I, and 95% of advanced stage breast tumors, but not in normal tissue. Telomerase was expressed in 45% of fibroadenomas, benign breast lesions.⁸¹

The search for mechanisms of senescence is difficult.⁸² Many physiologic mechanisms associated with aging and cell growth have proved to be more mutable by environmental factors, even at the genetic and molecular level, than once thought.^{47,83,84} Some authors⁸⁵ argued that human life expectancy is limited to 85 years unless medical science develops interventions at the molecular level to modify parameters of aging. The problem with these arguments is in defining molecular interventions; many existing interventions operate at a molecular level. Nutritional factors (e.g., vitamins A, B) may affect receptor structure in the cell membrane, the message to DNA, and the transcription of genetic code to specific proteins. Some interventions have been used for a long time, even though their mechanisms were initially not understood. Doxorubicin, an anthracycline, is a potent chemotherapeutic agent that disrupts cell replication by affecting nuclear proteins: Topoisomerase II α and β .⁸³ Early chemotherapeutic techniques were based on relatively simple principles where cell death was a function of drug concentration. The ways (e.g., interactions of *c-myc*, *bcl-2*, and *p53* genes⁴⁸) in which apoptosis is induced, and interventions in ancillary processes such as angiogenesis, growth factor dependency, metastatic invasion, and cellular redifferentiation, are therapeutic avenues being investigated at the molecular level.

To illustrate, an agent in use a long time, for which the mechanisms of molecular action are still being elaborated, is the antiestrogen, tamoxifen. This compound was given to older women with advanced estrogen receptor positive breast cancer to control its growth.⁸⁶ At first, growth inhibition was attributed to competitive binding with estrogen in a tumor cell's estrogen receptors. This initially raised concern that tamoxifen would exacerbate osteoporosis and heart disease. However, tamoxifen's interaction with the receptor was

more complex—sometimes being an agonist (i.e., it was protective against bone loss and circulatory disease). It appears that tamoxifen affects the ability to induce transcriptional activity in the carboxy-terminal ligand binding domain.⁸⁷ Of further interest was that tamoxifen affected estrogen receptor–negative tumor cells, and in interaction with chemotherapeutic agents (e.g., cisplatin),⁸⁸ by synergistically interacting in inducing apoptosis with other agents (e.g., vitamin D)⁸⁹—possibly by increasing the expression of estrogen receptors or by blocking the action of drug-resistant genes by affecting the calcium channel membrane transport of the drug.^{90,91} The effects on estrogen receptor–negative breast cancer cells may be due to the induction of apoptosis by overexpression of *c-myc*, mRNA, and protein.⁹² These effects may be enhanced by retinoic acid and vitamin D₃ analogs.^{93,94} Interventions into the transcriptional expression of genotypes by known agents is interesting, given growing insights into the relation of carcinogenesis and senescence.^{80,95,96}

THE FUTURE OF AGING

The above suggest that (1) the physiologic expression of aging changes will vary in the future because of major changes in nutrition, infectious disease risks, and hygiene, some exposures inducing stable genetic aberrations,^{48,84} and (2) that we already have many agents and therapies affecting the molecular transcriptional expression of genotype, although our knowledge of the details of those mechanisms, and how to intervene, are not complete. It can be argued, however, that we have only recently developed the scientific tools (e.g., PCR, restriction fragment length polymorphism [RFLP]; chromosome painting^{48,84}) to accelerate our understanding of these mechanisms, and the techniques and agents for intervening (e.g., rational drug design; nonimmunosuppressive cyclosporin, PSC833).⁹⁷

Techniques intervening at a molecular level are not restricted to cancer treatments but also apply to many other disorders.⁹⁸ A promising area is the improved regulation of the aging immune system.⁹⁹ A promising recent development was the observation that interleukin-10 (IL-10) suppressed tumor growth and inhibited spontaneous metastasis.^{100,101} This was a surprise because IL-10 suppressed macrophage and helper T-cell function, and delayed hypersensitivity reactions. In suppressing macrophage activity, IL-10 suppressed release of proinflammatory cytokines, nitric oxide, and reactive oxygen intermediaries. It, however, stimulated natural killer (NK) cells and chemoattraction of CD8+ cells and neutrophils. Inhibition of macrophage activity may have a tumor suppressive effect by reducing the local production of multiple growth or angiogenesis factors. Alterations of immune function (e.g., by vitamin A, C, or E supplementation^{102,103}), and inflammatory responses and angiogenesis may be important in autoimmune disorders¹⁰⁴ and in certain stages of atherogenesis.^{105,106} As in other cases, nutritional factors hold promise for modifying abnormal immunoreponse (e.g., the role of fish oil supplementation on MHC-II molecules and the membranes of human white blood cells affecting auto-immune disorders).¹⁰⁷ Omega 3 fatty acids may protect against chronic obstructive lung disease in ever smokers.¹⁰⁸

Thus there is a matrix of interrelations of physiologic processes that underlie the major chronic diseases expressed

in old age. For example, the expression of Lp(a), a factor in circulatory disease risks, also has a strong association with breast cancer risk and its ability to metastasize.¹⁰⁹ The role of inflammatory response, and of the local production of growth factors, is likely crucial to both tumor growth and the development of atherosclerotic plaque.^{101,105,106} There are likely associations of osteoporosis and atherosclerosis due to altered calcium metabolism.¹¹⁰ Osteoporosis may be linked to hypertension and renal function by vitamin D metabolism.^{98,111}

Because of this rapidly increasing understanding of disease process and therapeutic intervention at the molecular level, it is reasonable to anticipate future and accelerating changes in disease, function, and mortality risks at late ages. One of the crucial factors is to develop therapeutics with positive effect profiles. This is possible because of the above-mentioned matrix of physiologic functions that interrelate many age-dependent pathologies at the molecular level. For example, ACE-II inhibitors have positive effects on lipid and glucose metabolism, reduce LVH, possibly increase β -receptor density, and control hypertension.^{112–114} Certain β -blockers may improve β -receptor activity in the myocardium by downregulating both the response to norepinephrine and to activity as an antioxidant.¹¹⁵ The reason that IL-10 is promising is because it does not produce the serious side effects found with many other cytokines.¹¹⁶

An area of molecular medicine that is likely to strongly affect the health and functioning of the U.S. elderly population is in the management of osteoarthritis. Osteoarthritis is currently viewed as a medically untreatable condition in the United States (less so in Europe where glucosamine supplementation is more accepted), with current clinical responses involving surgical joint replacement (especially of the knee and hip). Although reasonably effective, alternative surgeries (e.g., hip resurfacing approved for use in the United States only last year by the FDA) and orthobiologic approaches to cartilage regeneration (using growth factors, stem cells for chondrocytes, and new materials for cartilage growth matrices) are finishing phase II trials and may represent improved approaches to deal with the 50% to 60% of elderly with some degree of osteoarthritis.²² This, combined with new immunomodulatory drugs for rheumatoid arthritis, could greatly enhance the functionality of the U.S. elderly population.

One argument may be that this increased understanding of disease mechanisms may produce medical interventions too expensive to provide en masse to a rapidly growing elderly population (e.g., the prescription of human growth hormone). This may, however, be due to a misunderstanding of the economics of biomedical innovation in that while the initial development of new technologies is expensive the evolution of subsidiary production technologies reduces unit costs and more of the population is treated (i.e., research and development costs are amortized over larger numbers of patients and the full benefits for the population are realized).¹¹⁷ For example, ACE-II inhibitors reduce the number of days of hospitalization required for congestive heart failure (CHF).¹¹⁸ As a result, the cost benefit ratio of ACE-II inhibitors, appropriately applied, can be quite high.⁷⁰ *Helicobacter pylori* was characterized in 1984. The role of *H. pylori* in the mechanism for most ulcers and gastric cancers¹¹⁹ identified new treatment modalities that are very cost-effective.

Antibiotic treatment for *H. pylori* costs about \$200 compared with about \$100 per month for the use of histamine blockers, which do not cure the disease. Given that there may be 4.5 million ulcer cases in the United States, the savings would be significant. Other technologies have proven cost-effective, such as day surgery and plastic lens implants for cataracts¹²⁰; pacemakers more appropriate for cardiac functional decline at late ages with dual chambers which respond to the increasing importance of arterial pulse in regulating cardiac output with age.¹²¹ Thus the correct understanding of a disease mechanism and linkages may produce synergistic interventions that eventually prove economic, especially if disease control is also accompanied by functional increases at late ages.¹²² Estimates of the savings to Medicare of reductions in functional disability prevalence from 1982 to 1995 could be more than 7% of costs, or \$180 billion to \$200 billion (in 1995 dollars¹²).

Even more important is the failure of economic evaluations of medical costs to compare costs to the benefits of improved health (i.e., the return on investment). For example, the U.S. labor force rate of growth is projected to slow from 1.2% in 1996 to 0.8% in 2006, and 0.3% in 2016 with the consequence of slowing economic growth. Improving health at later ages, at the rates achieved from 1982 to 2004, could prove to be a strong stimulus to economic growth by enhancing the size and quality of the human capital pool at later ages.¹²³ In addition, economically, the share of GDP expended on health services could usefully grow as other consumer goods (e.g., electronics) markets saturate and disposable income grows.¹²⁴

If costs are not such an important limiting factor to advancement of health at late ages when improved health is properly economically evaluated, what might aging in the mid-twenty-first century look like? Projections for the United States suggest that control of major circulatory disease risk factors, over a long enough time for their regulation to affect existing disease, could significantly increase the mean age at which CHD and stroke deaths occur.¹²⁵ The predominant forms of CHD would involve interactions of hypertension, atherosclerotic change, and age-related declines in cardiac function (e.g., age-related loss of β -receptor binding efficiency) that would become further dominated by the age-related changes in cardiac function. Cancer mortality has begun to show significant declines (e.g., 16% drop from 1990 to 2006) because of a variety of factors, with many new treatments now in clinical trials. Evidence suggests that significant breast cancer mortality reductions have occurred because of the use of tamoxifen in estrogen receptor-positive disease and adjuvant therapy in early node-negative disease.^{126,127} Greenspan¹²⁸ suggests current chemotherapy, rigorously applied, could reduce the number of U.S. breast cancer deaths by one third. The aging of the population could promote this trend, as recent studies indicate that very young women with breast cancer may respond less favorably than older women to chemotherapy.^{129,130} This is due to the generally less aggressive nature of disease in older women and probably to better management of the adverse effects of more aggressive treatments at later ages (e.g., use of granulocyte-colony stimulating factor [G-CSF]). However, progress is evident even for the more aggressive forms of breast cancer because of the development of monoclonal antibodies against specific growth factors, such as Herceptin.

The mix of cancers affecting an older population will change significantly. This will be related to the nature of the host tissue in which the tumor arises. For example, cancer related to infectious processes (liver cancer, gastric cancer) or food spoilage may decline. Other neoplasia related to biologic aging processes (e.g., prostate cancer, multiple myeloma, certain types of lymphoma, late-onset breast cancer) will increase in importance, although the mean age of death from those cancers will also increase. The effects of viral diseases on cancer risks and possibly on atherogenesis and general immunologic dysfunction (e.g., plasma cell dyscrasias of unknown significance, which often progress to multiple myeloma)⁹⁹ will become more treatable as antiviral agents improve and as our understanding of the chronic effects of viruses on the immune system advances. Thus there are a number of areas where therapeutic advances could occur, affecting multiple stages of very lengthy chronic disease processes. In addition, therapeutic advances could be supported by behavioral and lifestyle changes among middle-aged and elderly persons. This can be anticipated in that (1) the proportion of elderly cohorts who are better educated is increasing (i.e., better educated populations tend to be more amenable to public health messages)¹³¹ and (2) physical activity has been shown to have benefits to extreme ages.^{132–134}

These changes could increase life expectancy in the next 50 to 60 years (i.e., by 2050 to 2060) to 95 to 100 years.^{135,136} This compares with U.S. Census Bureau high life expectancy projections for 2050 of 86.4 years for males and 92.3 years for females.²⁴ Census Bureau life expectancy estimates are based on extrapolations of mortality trends. Our higher estimates are based on using multiple risk factor data, their dynamics, and assumptions about the ability to jointly control those factors.^{135,136} For example, in Kravchanko et al,¹³⁷ comparison of stringent risk factor control versus programs for progenitor cell replacement to reduce the arterial damage caused by atherosclerosis shows the potential benefits of such stem cell therapies.

These projections do not assume that heart disease, stroke, and cancer are eliminated. They do assume that the mean age at death for each is increased because of preventive and disease-modifying interventions on risk factor profiles. Those changes will also affect the proportion of deaths because of specific causes. Male cancer mortality could increase from about 20% to 40% of deaths at all ages. The largest changes would come from increased proportions of cancer deaths above age 85. For females, cancer mortality would increase relatively more (to about 60% of all deaths) because the adverse effects of menopausal changes in multiple cardiovascular disease (CVD) risk factors are assumed controlled in the projections. CVD risks would decline moderately (from 65% to 50%) for males as a proportion of all deaths, but those deaths would occur at later ages. For females, the projected declines in CVD deaths are much larger.

Such projections imply different things for U.S. society's carrying capacity for the elderly. In census projections, the high life expectancy series projects a U.S. population of 416 million by 2050. In this projection, 1% would be over age 100 (4.1 million), 7.2% would be over age 85 (30 million), and 23.3% would be over age 65 (97 million). The proportion of the population above a given age in the census

projections is strongly affected by fertility assumptions. For example, Social Security Administration (SSA) cohort life tables for persons born in 1950 (which use less favorable mortality assumptions) imply that 5.6% of females and 1.5% of males live to age 100. Assuming a 3 to 1 survival advantage for females to age 100, this suggests that 4.6% of the 1950 cohort survives to age 100. For the 1990 cohort, survival to age 100 is 10.2% for females and 3.3% for males, or 8.4% combined. Thus in a stable population, a large proportion of persons reach age 100 even in less optimistic SSA 1990 life tables. In risk factor–based projections, the U.S. population is projected to be 456 million persons in 2050, with 14% over age 85, and 33% over age 65. Although these proportions are larger than in the census projections, they are not grossly different from the 25% of the Japanese population expected to be over age 65 in 2025. If fertility and immigration is lower than assumed in Japanese census projections, then the proportion of the population over age 65 and over 85 would be higher. Even the extreme projections made from risk factor data do not take into account recent studies suggesting that human mortality never exceeds 40% at any age (i.e., 40% is the maximum mortality rate)—an assumption built into the Society of Actuaries 1994 group annuity tables.¹³⁸ Such estimates are consistent with estimates from multiple studies showing that the annual increase in mortality rates slows to very low values (2% to 3%) about age 100.²⁶ These slow increases in mortality are apparently because of the high mortality rates of very elderly persons with high levels of disability. Thus the average level of disability about age 95 tends to stabilize because of the equilibrium with mortality rates at those ages.¹²⁵ Recent analysis even suggests prospects for mortality risk decline at advanced (i.e., 105+) ages.¹³⁹

The question emerges of how a society and economy must change to deal with a population with such a high proportion of elderly, and quite possibly healthy and functional, persons. This is primarily a problem only if the commensurate change in the age-specific health status of the population does not occur. The health-mortality factors discussed above suggest that the natural dynamics of mortality, disability, and mortality (i.e., their dynamic equilibrium¹⁴⁰) enforce this in part. There is also evidence of such changes in current health expenditures. Lubitz et al¹⁴¹ found that the average Medicare expenditure for those who died at age 70 was \$35,511, compared with \$65,633 for those who survived to age 101. Thus the average Medicare expense per year for centenarians from ages 65 to 101 was \$1,823 compared with

\$7,100 per year for those who died at age 70. Thus the pattern of a declining rate of Medicare expenditures with age contrasts to the accumulated liability of increased life expectancy for Social Security.

If disability declines, as observed from 1982 to 2004–2005, health costs may decrease even more rapidly at later ages.^{17,123} This pattern also seems consistent with the different patterns of medical problems that may be faced at late ages in the future. Disability will not only be prevented but, in the future, functional loss will be increasingly reversed by “regenerative medicine” (e.g., orthobiologic management of osteoarthritis). Thus the primary response to the social costs of such large elderly populations might be increases in the normal retirement age for Social Security. Each year of increase in the normal retirement age for Social Security has a large fiscal impact. Thus, if the normal retirement age could be increased to age 70 (or 74), because the average physiologic status at those ages is now equivalent to the physiologic status at age 65 in, say, 1982—then a large portion of the fiscal burden of population aging could be addressed. Indeed, given restrictions on the ultimate size of human populations, improvements in health at advanced ages may be an economic necessity in the United States and other developed nations with rapidly changing population age structures.

KEY POINTS

The Future of Old Age

- Population aging
- Morbid conditions prevalent at advanced ages
- Centenarians and growth of extreme elderly
- Barker's hypothesis
- Nutritional supplementation and exercise as modifiers of aging
- Biologic inputs to aging and drug therapies
- Regenerative medicine: hormonal modulation
- Epidemiologic transition
- Disability prevalence declines
- Mortality declined in the second half of the twentieth century

Evolution Theory and the Mechanisms of Aging

Thomas B. L. Kirkwood

The question “Why does aging occur?” calls for answers both at the level of proximate, physiological mechanisms and also at the level of ultimate, evolutionary origins. This chapter provides an understanding of why aging has evolved and examines what evolution theory can tell us about the kinds of mechanisms we might regard as prime candidates to explain senescence.

Evolution theory is well recognized as a powerful tool with which to inquire about the genetic basis of the aging process.¹⁻⁴ Although human aging has its roots long ago in our past, the study of its evolution can throw important light on key present-day challenges. For example, a range of population-based studies, including one based on genealogical analysis of the entire population of Iceland, has shown consistent evidence for a generic contribution to human longevity.⁵ There is growing interest in knowing how many and what kinds of genes are likely to be involved in this heritability.^{6,7} There is also interest in human genetic disorders such as Werner’s syndrome and Hutchinson-Gilford progeria that are characterized by acceleration of many aspects of the senescent phenotype (see Chapter 11).

Before addressing questions about the evolutionary origin of aging it is important to be precise about how the term “aging” is to be understood. In this chapter, aging is defined as “a progressive, generalized impairment of function, resulting in a loss of adaptive response to stress and in a growing risk of age-related disease.” The overall effect of these changes is summed up in the increase in the probability of dying, or age-specific death rate, in the population.

This definition of aging—in terms of a mortality pattern showing progressive increase in age-specific mortality—allows comparisons to be made even among species where the detailed features of the aging process may differ markedly. In phylogenetic terms, aging is widespread but by no means universal.⁹⁻¹² The fact that not all species show an increase in age-specific mortality indicates that aging is not an inevitable consequence of wear-and-tear. On the other hand, the fact that very many species do show such an increase is evidence that the evolution of aging has occurred under rather general circumstances.

EVOLUTION OF AGING

Theories on the evolution of aging seek to explain why aging occurs through the action of natural selection. The decline in survivorship, which is often also accompanied by a decline in fertility, means that there is an age-associated loss of Darwinian fitness that is clearly deleterious to the organism in which it occurs. Natural selection acts to increase fitness, so it is at once clear that selection should be expected, other things being equal, to oppose aging. The challenge to evolution theory is thus to explain why aging occurs in spite of its drawbacks.

Programmed or “adaptive” aging

It is sometimes suggested that despite its disadvantages to the individual, aging is beneficial and even necessary at the species level, for example, to prevent overcrowding.^{13,14} In this case, genes that actively cause aging might have evolved specifically to program the end of life, in the same way as genes program development.

The difficulty with this view is that there is little evidence that intrinsic aging serves as a significant contributor to mortality in natural populations,¹⁵ which means that it apparently does not play the adaptive role suggested for it. The theory also embodies the questionable supposition that selection for advantage at the species level will be more effective than selection among individuals for the advantages of a longer life. Aging is clearly a disadvantage to the individual, so any mutation that inactivated the hypothetical adaptive aging genes would confer a fitness advantage, and therefore, the nonaging mutation should spread through the population unless countered by selection at the species or group level. Conditions under which “group selection” can work successfully are highly restrictive,¹⁶ especially when there is selection in the opposite direction acting at the level of the individual. Briefly, it is necessary that the population be divided among fairly isolated groups, and that the introduction of a nonaging genotype into a group should rapidly lead to the group’s extinction. The latter condition is necessary to provide the selection between groups that might, in principle, counter the tendency for selection at the level of individuals to favor the spread of nonaging mutants. Although theoretical special cases have been constructed that might permit the selection of genes to cause aging, it appears unlikely that the necessary conditions will be met with sufficient generality to explain the evolution of aging.

Selection weakens with age

An observation of central importance to the evolution of aging is that the force of natural selection—that is, its ability to discriminate between alternative genotypes—weakens with age.^{15,17-20} Because natural selection operates through the differential effects of genes on fitness, its discriminatory power must decline with age in proportion to the decline in the remaining fraction of the organism’s lifetime expectation of reproduction. This is true whether or not the species exhibits aging.

The attenuation in the force of natural selection with age means inevitably that there is only loose genetic control over the later portions of the life span. For this reason it has been suggested that aging might be due to an accumulation in the germ line of mutations, which potentially are deleterious but are not expressed, or which produce no phenotypic effect until late in life.¹⁵

The idea is that if deleterious mutations are expressed so late that most individuals will already have died from some other cause, such as predation, even though the genes involved have the potential to cause harm they will be subject

to very little selection against them. Over the generations, a large number of such genes might accumulate. These would cause aging and death only when an individual is removed to a protected environment, away from the hazards of the wild, and so lives long enough to experience their negative effects.

A stronger version of this theory was proposed by Williams,¹⁸ who suggested that because of the declining force of natural selection with age, any gene that conferred an advantage early in life would be favored by selection even if the same gene had deleterious effects at older ages. Such "pleiotropic" genes could explain aging. The decline in the force of natural selection with age would ensure that even quite modest early benefits would outweigh severe harmful side effects, provided the latter occurred late enough.

Disposable soma theory

The disposable soma theory^{1,4,21–23} explains aging through asking how best an organism should allocate its metabolic resources, primarily energy—between, on the one hand, keeping itself going from one day to the next, and on the other hand producing progeny to secure the continuance of its genes when it has itself died. No species is immune to hazards such as predation, starvation, and disease. All that is necessary by way of maintenance is that the body remains in sound condition until an age after which most individuals will have died from accidental causes. In fact, a greater investment in maintenance is a disadvantage because it eats into resources that, in terms of natural selection, are better used for reproduction. The theory concludes that the optimum course is to invest fewer resources in the maintenance of somatic tissues than are necessary for indefinite survival (Figure 4-1). The result is that aging occurs through the gradual accumulation of unrepaired somatic defects, but the level of maintenance will be set so that the deleterious effects do not become apparent until an age when survivorship in the wild environment would be extremely unlikely.

Comparison of the evolutionary theories

The adaptive program theory is in a category of its own and support for this theory is weak; it will not be considered further in this chapter. The disposable soma and pleiotropic genes theories are adaptive in the sense that aging is the result of positive selection for aspects of the organism's life history, but the essential difference is that aging itself is

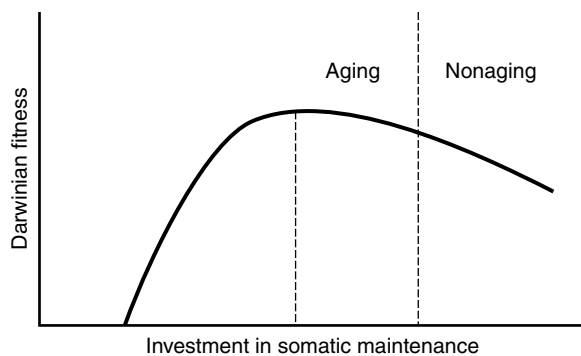

Figure 4-1. Relation between Darwinian fitness and investment in somatic maintenance predicted by the disposable soma theory of aging. Fitness is maximized at a level that is less than that which would be required for indefinite longevity (nonaging).

not adaptive but is a negative trait that arises only as a by-product or tradeoff of some other benefit. The late-acting deleterious mutations theory assumes an essentially neutral evolutionary process, the accumulation of mutations reflecting the inability of natural selection to maintain tight control over the later portions of the life span.

Among the nonadaptive theories there is a common strand, namely that old organisms count less. This is not due to any implicit assumption of frailty or obsolescence (this would render the theories circular), but to the simple mathematics of mortality. Even if old organisms retain exactly the same vigor as young ones, to the extent that old and young are physiologically indistinguishable, the fact that each cohort becomes numerically attenuated with age means that the selection force weakens. The nonadaptive theories are not mutually exclusive. Therefore, aging might in principle be due to a combination of any of them.

As regards the nature of gene action, the disposable soma theory is the most specific of the evolutionary theories, for it suggests not only why aging occurs but also predicts that the genetic basis of aging is to be found in the genes that regulate levels of somatic maintenance functions. Neither the pleiotropic genes theory nor the late-acting deleterious mutations theory is specific about the nature of the genes involved.

GENETICS OF LIFE SPAN

This section looks at the genetics of life span, first from the point of view of interspecies comparisons. That is, it will ask the question Why do species have the life spans they do? It will then look at intraspecies variation and heritability of life span. Finally, there is a brief discussion of human progeroid syndrome, such as Werner's and Hutchinson-Gilford progeria, as models of genetically accelerated senescence.

Species differences in longevity

In addition to explaining why aging occurs, evolution theory also must account for differences in species life spans. This raises basic questions about the genetic control of aging: specifically, how many genes are involved and how are these modified by selection to produce changes in life span?

For each of the nonadaptive theories, the generality of the selection forces that are involved suggests that multiple genes will be implicated. If there is a very large number of independent genes causing aging, however, the life span may be slow to change, because modifying a single gene may have little effect by itself and the probability of simultaneous independent modifications will be low. This suggests that either a reasonably small number of primary genes are responsible for aging, or that there exists some mechanism for coordinate regulation.

The evolution of increased life span is most readily explained if it is assumed that an adaptation occurs that results in a general lowering of the accidental (age-independent) death rate. In the late-acting deleterious mutations theory, this may result in new pressure to eliminate or postpone the deleterious gene effects. In the pleiotropic genes theory, the balance between early benefit and late cost may be shifted in favor of reducing the harmful effects on late survival. In the disposable soma theory, there may be selection to tune the optimum investment in maintenance to a higher level.

Variation within species

The variability in life span observed within a species or population clearly owes much to chance, but there is a significant heritable component as well.⁵ Martin et al³ have applied the terms “public” and “private” to denote genetic factors related to aging that may either be specific to individuals or shared across a population (perhaps even across species). Late-acting deleterious mutations are strong candidates for private genes because the fate of such alleles is determined largely by random genetic drift. Public genes are more likely to be those that arise through tradeoffs. In particular, the genes involved in regulating mechanisms of somatic maintenance are likely to be public genes of considerable importance. Although these genes are “public” in the sense that all individuals have them, there may nevertheless be variations within a population in the precise levels at which these functions are set. These variations in setting may in turn be the cause of genetic variation in life expectancy.

As predicted by the disposable soma theory, the level of individual somatic maintenance systems should be set high enough so that the organism remains in sound condition through its natural expectation of life in the wild environment, but not much higher than this, or resources will be wasted. Numerous maintenance systems operate in parallel to preserve viability (Figure 4-2). Depending on the levels at which they are set, each maintenance system can be thought of as “assuring” a given span of life (see also Cutler²⁴ and Sacher²⁵ for earlier discussion of the concept of “longevity assurance”). When any one of these critical mechanisms has exhausted its potential for assuring longevity, which happens because the accumulated defects threaten survival, the organism is liable to die.

If we now recall the shape of the fitness curve in Figure 4-1, we see that its peak—the point towards which natural selection is expected to exert evolutionary pressure—is rounded instead of sharp, and so we can expect a fair amount of intra-population variance in the precise settings of maintenance processes. Selection is expected to direct these settings toward the peak, but once within the region of the peak, the fitness differences on which selection can operate become quite small.

Putting these ideas together generates the prediction summarized in Figure 4-2. On the average, we expect the longevity assured by individual maintenance systems to be similar. This is because if the setting of any one mechanism is so low that it consistently fails before any of the others, then selection will tend to increase the level at which it is set. Conversely, if any mechanism tends always to fail after the others, then to the extent that this mechanism involves a

metabolic cost, there will be selection to tune down the level at which it is set. In individuals, however, the genetic variance within the population is expected to result in variation in the extent to which the organism is predisposed to age from specific causes. For example, some individuals are likely to be less well protected against oxygen radicals than others, and these individuals will therefore experience greater oxidative damage.

Instances of extreme longevity, such as human centenarians, are of special interest for they are likely to be endowed with unusually high levels of each of the important ingredients of the cellular defense network.⁶ Such individuals may also be distinguished by their freedom from alleles that predispose toward diseases that otherwise might shorten life expectancy. Schächter et al²⁷ performed the first genetic study comparing centenarians with younger adult controls, which validated the general potential of this approach. Since then a number of further studies have been conducted to examine the genetics of human longevity.⁷

It is anticipated that the next few years will see the publication of results from several large investigations looking either at individuals of extreme longevity (e.g., centenarians) or at families where there is reason to expect that family members share a genetic endowment predisposing to above-average longevity. Examples of the latter design include studies that are recruiting nonagenarian siblings (i.e., instances where two or more members of the same family are still alive past age 90). The technological advances that are presently being made in the capacity to assess DNA samples for possession of very large numbers of genetic markers at very high speed mean that the focus is now increasingly on genome-wide association studies and the linkage analyses that can be made using family groups. Herein lies both the strength of modern human genetics and a potential difficulty when studying a trait like longevity, which is likely to prove highly polygenic. If large numbers of genetic loci contribute to the longevity phenotype, but these individually make only small contributions, the difficulty of extracting the signals from the statistical noise will be formidable.

Human progeroid syndromes

A number of inherited human diseases have been characterized as showing a phenotype of accelerated aging. The best studied of these conditions is Werner's syndrome, a rare autosomal recessive disorder affecting around 10 in 1 million people, who prematurely develop a variety of major age-related diseases, including arteriosclerosis, ocular cataracts, osteoporosis, malignant neoplasms, and type II diabetes. Cells grown from Werner-syndrome patients show reduced

Figure 4-2. Polygenic control of longevity predicted by the disposable soma theory of aging. On average, the period of longevity assured by individual somatic maintenance systems is predicted to be similar, but some genetic variance about the average is also expected, as shown.

division potential and increased chromosomal instability compared with age-matched controls, and there is evidence that the pathology associated with Werner's syndrome may be related rather generally to impaired cell proliferation.

Yu et al⁸ identified the gene responsible for Werner's syndrome as a DNA helicase, an enzyme responsible for unwinding DNA for purposes of replication, repair, and expression of the genetic material. This discovery strongly supports the concept that accumulation of somatic defects is important in aging, and it well illustrates the predicted involvement of longevity-assurance genes in determining the rate of aging. A defective helicase increases the rate of accumulation of DNA defects in actively dividing cell populations. A defect in this gene leads to accelerated aging, particularly in tissues in which cell division continues throughout life. In terms of the scheme shown in Figure 4-2, the mutation responsible for Werner's syndrome can be considered equivalent to shortening the line for longevity assurance through DNA repair. However, as Figure 4-2 illustrates, DNA repair is but part of the network of longevity assurance mechanisms that determine the overall rate of aging. It is striking that Werner's syndrome is not associated with accelerated aging in postmitotic tissues, such as brain and muscle, which is consistent with the fact that these tissues, by virtue of having little or no cell division during adult life, are relatively unaffected by having a defective DNA helicase.

Another striking example is Hutchinson-Gilford progeria. In this condition features of aging develop even faster than in Werner's syndrome. The discovery that Hutchinson-Gilford syndrome is associated with mutation in the lamin A gene, which affects the integrity of the cell's nuclear membrane, has again confirmed the association between rapid aging and accelerated accumulation of molecular and cellular damage.²⁸

TESTS OF THE EVOLUTIONARY THEORIES

A key prediction of the evolutionary theories is that altering the rate of decline in the force of natural selection will lead to the evolution of a concomitantly altered rate of aging. This has been tested by applying artificial selection on life history variables or by making comparisons within and between species on the effects of different levels of extrinsic mortality. For practical reasons, most studies have focused on short-lived species, in particular the fruit fly *Drosophila melanogaster* and the nematode worm *Caenorhabditis elegans*.

Evidence for tradeoffs between early and late fitness components, as predicted by both the disposable soma and pleiotropic genes theories, comes from the success of artificial selection for increased longevity in *Drosophila*.²⁹⁻³⁴ A general correlate of delayed senescence has been reduced fecundity in the long-lived flies. A similar tradeoff has also been reported for a human population, based on analysis of birth-and-death records of British aristocrats.³⁵

The nematode *Caenorhabditis elegans* has yielded a growing number of long-lived mutants in which increased longevity has been consistently associated with increased resistance to biochemical and other stresses. Many of the affected genes are linked to pathways that control a switch between the normal developmental process of the worm and an alternative long-lived form called the *dauer* larva, which is invoked

during times of food shortage. The emerging picture points to a fundamental link between metabolic control, growth and reproduction, and somatic maintenance.³⁶⁻³⁸ These findings are directly consistent with the disposable soma theory, which predicts that at the heart of the evolutionary explanation of aging is the principle that organisms have been acted upon by natural selection to optimize the use of metabolic resources (energy) between competing physiologic demands, such as growth, maintenance, and reproduction. Consistent with this prediction it is striking that insulin signaling pathways appear to have effects on aging that may be strongly conserved across the species range. Insulin signaling regulates responses to varying nutrient levels. Allied to the role of insulin signaling pathways is the recent discovery that a class of proteins called sirtuins appears to be centrally involved in fine-tuning metabolic resources in response to variations in food supply.³⁹ It has long been known in laboratory rodents that restricted intake of calories simultaneously suppresses reproduction and upregulates a range of maintenance mechanisms, resulting in an extension of life span and the simultaneous postponement of age-related diseases. What is not at all clear, however, is whether the large effects on life span of modulating these pathways in very short-lived animals, such as nematodes and fruit flies, will be found to operate in longer-lived species. On evolutionary grounds it seems likely that there will have been greater evolutionary pressure to evolve a capacity to produce large responses to extreme environmental variation in small, short-lived animals. Therefore the scope for such modulation in humans, including through dietary restriction, is expected to be much less. Nevertheless it will be surprising if there are no metabolic consequences of varying food supply.

From the comparative perspective, the evolutionary theories predict that in safe environments (those with low extrinsic mortality) aging will evolve to be retarded. Adaptations that reduce extrinsic mortality (wings, protective shells, large brains) are generally linked with increased longevity (bats, birds, turtles, humans). Field observations comparing a mainland population of opossums subject to significant predation by mammals, with an island population not subject to mammalian predation, found the predicted slower aging in the island population.⁴⁰

At the molecular and cellular levels, the disposable soma theory predicts that the effort devoted to cellular maintenance and repair processes will vary directly with longevity. Numerous studies support this idea. A direct relation between species longevity and rate of mitochondrial ROS production in captive mammals has been found^{41,42} as has a similar relationship between mammals and similar-sized but much longer-lived birds.⁴³ DNA repair capacity has been shown to correlate with mammalian life span in numerous comparative studies,⁴⁴ as has the level of poly(ADP-ribose) polymerase,⁴⁵ an enzyme that plays an important role in the maintenance of genomic integrity. The quality of maintenance and repair mechanisms may be revealed by the capacity to cope with external stress. Comparisons of the functional capacity of cultured cells to withstand a variety of imposed stressors have shown that cells taken from long-lived species have superior stress resistance to that of cells from shorter-lived species.^{46,47}

Tests of the evolutionary theories support the idea that it is the evolved capacity of somatic cells to carry out effective

maintenance and repair that mainly governs the time taken for damage to accumulate to levels where it interferes with the organism's viability, and hence regulates longevity.

CONCLUSIONS

Our answers to the question "Why does aging occur?" have broad implications for how we perceive the likely genetic basis of aging. Firstly, evolution theory can illuminate a long-running debate about whether programmed or stochastic events, such as DNA damage, drive the aging process. The weakness of evolutionary support for the adaptive aging genes hypothesis calls the program theory into question. Any notion of an aging "clock" needs to be qualified by recognition of this fact. The existence of temporal controls in development and in cyclic processes such as diurnal and reproductive cycles does not provide a sufficient basis to suggest the existence of a clock that regulates aging. Nor does the broad reproducibility of many features of aging provide any real evidence for an underlying active program. This is not to say, however, that the nature and rate of aging are not genetically determined. The issue that distinguishes programmed from stochastic theories of aging is not whether the factors that determine longevity are specified within the genome, but rather, how this is arranged.⁴⁸

Secondly, evolution theory clearly indicates a polygenic basis for aging. Different mechanisms and even different kinds of genes may operate together. This presents a major challenge, and progress is likely to require a combination of approaches, including (1) transgenic animal models in which candidate genetic factors are altered by genetic manipulation, (2) comparative studies to identify factors that correlate

positively or negatively with species' life spans, (3) studies of the extremely long-lived (e.g., human centenarians) to identify factors associated with above-average expectation of life, and (4) selection experiments to investigate the response of life span to artificial selection pressures.

KEY POINTS

Aging

- We are not programmed to die.
- Aging occurs because, in our evolutionary past, when life expectancy was much shorter, natural selection placed limited priority on long-term maintenance of the body.
- Aging is caused by gradual accumulation of cell and tissue damage. Much of the damage arises as a side effect of essential biochemical processes, such as the use of oxygen to generate chemical energy through oxidative phosphorylation.
- Accumulation of damage begins early and continues progressively throughout life, resulting after several decades in the overt frailty, disability, and disease associated with aging.
- Multiple processes cause the damage that contributes to aging, and multiple genes regulate the efficacy of "longevity-assurance" processes, such as DNA repair, that together influence the rate of aging.
- Nongenetic factors, such as nutrition and exercise, can have important effects in modulating the rate of buildup of damage within the body.

Methodological Problems of Research in Older People

Antony Bayer

INTRODUCTION

The relentless aging of society, the accompanying growth in age-related diseases, and the disproportionate use of health and social care resources by older people might be expected to be a powerful incentive to prioritize research into aging and geriatric medicine. However, ageist attitudes and beliefs persist among many funding agencies and researchers and some older people themselves. These, together with the many practical and methodological challenges that must be overcome to deliver high-quality studies in older people continue to act as barriers to effective delivery of research in this heterogeneous and often vulnerable population.

The difficulty of undertaking research involving older people tends to be exaggerated. It is wrongly assumed that too many will have significant comorbidity leading to a poor signal-to-noise ratio, an unacceptably high risk of adverse events, inability to complete necessary assessments, poor compliance, and high rate of drop-out. This can translate into arbitrary, unscientific, and unnecessary upper age limits. Yet many of the changes commonly attributed to aging are typically because of reasons other than chronological age, notably physical and cognitive comorbidities leading to frailty, and psychosocial factors, such as relative lack of education and cigarette smoking. Furthermore it is often the old who have the greatest morbidity and mortality associated with the condition under study and who therefore will have the greatest absolute benefit from any effective intervention.

Ethical concerns about experimenting on elderly populations, who are considered "vulnerable" on the basis only of chronological age, may be cited as justification for their exclusion, demonstrating misguided paternalism of younger research workers and ignoring the older person's right to autonomous decision making. The majority of even the oldest old will have no significant cognitive impairment and will generally have the capacity to make an informed decision about participation. The consequences of excluding older people from therapeutic research, where they are left to either receive treatments in the absence of evidence-based trials, or are denied drugs because they have been untried in their age group, might be considered especially unethical¹ and imply that clinicians have a duty to actively promote their inclusion in clinical trials.² All researchers should be careful that ageist attitudes do not influence their research design, and funding bodies and research ethics committees should challenge unnecessarily restrictive entry criteria, including inappropriate upper age limits.³

Ill-informed beliefs about the supposed high risk of developing mental incapacity and perceived low life expectancy after age 65 are sometimes used to exclude older people from longitudinal studies because it is wrongly assumed that few will stay the course. In reality, the annual incidence of dementia in those over 65 is about 1% and healthy life expectancy at age 65 in England is about 12 to 14 years.

Study Designs

The optimum choice of design to study aging and age-related conditions and to understand the mechanisms underlying change and their consequences will depend on the research question to be answered.⁴ Qualitative studies; ecologic studies using available data; and quantitative studies using cross-sectional, case-control, and cohort designs will help to generate hypotheses. These can then be tested in experimental studies, using randomized controlled trial designs. Each design presents its own challenges and limitations.

Qualitative Methodologies

Qualitative research has its roots in anthropology and sociology and is an umbrella term for a heterogeneous group of methodologies with different theoretical underpinnings.⁵ They aim to gain an in-depth understanding of peoples' behavior by exploring their knowledge, values, attitudes, beliefs, and fears. This allows subjects to give "richer" answers to questions and the researcher to explore the full complexity of human behaviors, thereby providing detailed insights that might be missed by other methods. For example, it may illuminate the reasons behind patients', carers', and clinicians' decisions about management^{6,7} or explore important issues such as dignity that may be difficult to quantify.⁸

Qualitative studies are hypothesis-generating rather than hypothesis-testing, but results can identify specific issues that need to be tested using quantitative methods or can help to explain outcomes of experimental studies. Thus the two methods can usefully complement each other and increasing numbers of studies are using "mixed" methodologies (for example, a study trying to understand the attitudes of the elderly towards enrollment into cancer clinical trials).⁹

Samples in qualitative research tend to be small and labor-intensive, with data collected usually by direct observation or active participation in the setting of interest, or by in-depth individual interviews (unstructured or semistructured), focus groups (guided group discussions), or examination of documents or other artifacts. Other methods used in qualitative research studies include diary methods, role play and simulation, narrative analysis, or in-depth case study. Although potential areas of interest may be identified beforehand, there is no predetermined set of questions, and subjects are encouraged to express their views and ideas at length. Rather than formal sample size calculations, numbers of participants may be decided by analyzing interviews alongside data collection, which is stopped when no new themes are emerging (so-called "saturation"). Sampling tends to be purposive rather than comprehensive or random, deliberately aiming to reflect a specific range of experience and attitudes judged to be of likely relevance to the research question. The results are analyzed by exploring the content and identifying patterns or themes, often through an iterative process allowing meaning to emerge from the data, rather than by the deductive statistical approach of quantitative methods.

Critics of qualitative analysis are concerned that it is too influenced by the views and attitudes of the researchers when they are collecting and analyzing data, so it introduces unacceptable bias and problems with generalization and reproducibility of findings. Qualitative research can be challenging with older people, but because it can be less intrusive than more structured quantitative methodologies, it may be especially suited to those who are frail. They may be unable or unwilling to take part in lengthy interviews because of communication deficits or fatigue and several shorter interviews may be more practical. Focus groups may work best with just four or five elderly participants and need a skilled facilitator to ensure a high level of participant interaction. Extra effort is needed to ensure representative samples and to support those who are less confident, easily fatigued, or have cognitive or physical deficits. Participant or nonparticipant observation may be especially useful in institutional settings, but time must be given to establish trust with the researcher if residents and staff are not to feel threatened. Assurances of confidentiality and commitment from management are essential. However, once trust has been established, attrition rates tend to be low as participation tends not to be burdensome.¹⁰

ECOLOGIC STUDIES

Ecologic studies use available data to characterize samples and to generate hypotheses, although evidence for causality is generally weak. Data may be aggregated, such as census data and records of disease incidence by hospital, or individual, such as hospital discharge summaries or death certificates. As the data are already available, there are advantages of speed and economy, and impact of factors operating at population level (e.g., improved access to education, banning smoking in public places) may be difficult to measure at an individual level. However, measures may not be comparable over time or place, quality is always outside the researcher's control, and the available data may be selective. Many official statistics that are broken down by age will lump all the over-65s together or will only report information on adults of working age. When older people are included, they often exclude those not living in the community and those with cognitive impairment. Nevertheless, temporal data such as the effect of daily variations in air pollution or temperature on mortality of elderly people—where individual confounding factors remain constant over time—can provide robust evidence suggesting a causal effect, and ecologic data are also of value in studying the effects of early life factors on later health or disease in “life course epidemiology.”¹¹

CROSS-SECTIONAL STUDIES

Cross-sectional studies record information over a short period of time and are suited to report prevalence and the relationship between variables and age or dependency. They are relatively fast and simple to conduct as each subject is examined only once and several outcomes or diseases can be studied simultaneously. For example, recent data from the Health and Retirement Study of 11,000 adults aged 65 years or older (representing the 34.5 million older Americans) highlighted the important finding that common geriatric conditions (cognitive impairment, falls, incontinence, etc.) were similar in prevalence to common chronic diseases, such as heart disease and diabetes in older adults, and strongly

and independently associated with dependency in activities of daily living.¹² However, cross-sectional studies give no information about incidence or causality and are of limited value when studying rare conditions or acute illness.

Data can be presented as the mean value for each age group, or age can be used as a continuous independent variable in a regression analysis, with the outcome of interest as the dependent variable. Associations can be confounded when the variable of interest affects the survival of subjects, with selective mortality leading to a survival bias.

Misinterpretation can also arise from birth cohort effects, with associations and differences not arising due to age differences, but due to the era in which people were born and brought up. Sometimes such differences from one generation to the next are of particular interest and a time series design may then be appropriate, sequential samples of a particular age group being studied every few years. For example, comparison of comparable datasets from the Health and Retirement Study in 1993 and 2002 suggests a falling prevalence of dementia in the United States.¹³ Selection of subjects needs to ensure that they are well matched at each time point and methodologies need to be identical to ensure that differences are solely due to temporal changes and not to selection bias.

CASE CONTROL STUDIES

Case control studies choose groups with (cases) and without (controls) the outcome of interest and look back at what different exposures they may have had to identify possible risk factors. Case control studies have been widely used in genetic studies to identify susceptibility genes and are the best design to study rare conditions, as they are efficient in use of time and money, collecting a lot of relevant information on targeted individuals. Case control studies may be “nested” within cohort studies.

Bias can be introduced when cases and controls differ in ways other than just the outcome of interest (selection bias) or when cases are not “typical” (representativeness bias). Given the increasing heterogeneity characteristic of aging, bias can be a significant problem and care needs to be taken to well match cases and controls. Recall bias may arise because subjects are able to remember events better because of their significance, or unintentionally they may be prompted to remember by investigators, who should therefore be blinded to whether the person is a case or control when assessing exposures. People who have died do not make it into case control studies and their representatives are likely to be less reliable than the person themselves at remembering exposures, introducing a potential survival bias. Although case control studies can play a pivotal role in suggesting important associations, as in the original studies linking cigarette smoking and lung cancer,¹⁴ confounding can also lead to highly misleading conclusions, as in the observational studies of combined hormone replacement therapy and cardiovascular disease in postmenopausal women.¹⁵

COHORT STUDIES

In a cohort or longitudinal study, a group of subjects are followed over time as they age to determine who develops a particular outcome or the rate at which a variable changes. Prominent cohort studies relevant to old people include the Baltimore Longitudinal Study of Aging,¹⁶ the Rotterdam

study,¹⁷ and the Caerphilly cohort study.¹⁸ Along with risk, the number of people who actually develop the outcome of interest can be calculated (incidence). Inevitably such studies take a long time and often require a large sample size (the rarer the outcome, the larger the sample needs to be) and so are expensive. The frequency of testing needs to be decided, based on the rate of change, the precision of the measures being used, available resources, and the stamina of both researcher and research subjects. Analysis of longitudinal data by slope analysis or other techniques is likely to require specialist knowledge.

Recall bias is avoided as subjects are enrolled before the outcome(s) and the sequence of events can be more clearly established, although the possibility of reverse causality must always be considered. Cohort effects are minimal because all the subjects are generally from a single birth cohort. Ideally, longitudinal aging studies would follow subjects from birth to the grave, but this is unlikely, as they would then outlive the research team. When age range in a longitudinal study is wide, cohort effects can be identified by plotting rates of change within age groups and seeing if the plots join up smoothly (a true age effect), or are a disjointed group of line segments similar to that often seen in repeated cross-sectional studies.

Potential bias may arise when outcomes are not measured or not recorded in a consistent fashion over time, with small changes in methodology such as new equipment, a change in assay technique, or differences in study personnel appearing to suggest age-related changes (detection bias). Ensuring a common period of training for all involved in the research, with periodic refresher courses and measures of interrater and intrarater reliability, can minimize problems, but researchers must stay alert to possible methodological error throughout data collection and analysis.

Important outcomes may be missed if follow-up is too short or too long, so that subjects die before they are reassessed. Inevitably, some subjects will drop out or be lost to follow-up (excursion bias), and there are various approaches to dealing with missing data by imputing values based on available records.

CLINICAL TRIALS

A clinical trial is the methodology of choice to examine causality, with the randomized controlled trial (RCT) acknowledged as the gold standard experimental design.¹⁹ In a RCT, the researcher controls exposure to a single variable, the risk or treatment, by randomly assigning subjects to one group (intervention) or another (control, often involving a placebo intervention) and all subjects are then followed up to determine the outcome. When an effective intervention exists already, a placebo control is unethical and the new experimental intervention is then compared against an active control (the current standard of care). In rare cases, when the size of the treatment effect relative to the expected prognosis is dramatic, randomization may not be necessary or ethical, and historical controls (apparently similar, past patients) may be used.²⁰

Parallel group RCT designs are generally preferred, intervention and control groups being treated simultaneously. Thus half the subjects receive treatment A (intervention) and the other half receives treatment B (control). In a crossover design, subjects swap groups half way through the study

(half the subjects receiving treatment A followed by treatment B, with the other half receiving treatment B then A) and so each subject can act as their own control, assuming that there are no carry-over or seasonal effects. In a factorial design, two (and occasionally more) interventions, each with their own control, are evaluated simultaneously in the one study. For example one group tests treatment A, another tests treatment B, a third group tests A and B combined, and the control group tests neither A nor B. Such designs are used already extensively in cancer and cardiovascular studies and are likely to be needed increasingly in other conditions with multiple therapeutic options. Although they are an efficient method to test therapies in combination, achieving two comparisons for little more than the price of one, interactions between the interventions can complicate analysis of the outcomes and their interpretation.

Bias in clinical trials is reduced by the use of random allocation and blinding. Randomization increases the likelihood (but does not assure) that the groups will be well matched except for the intervention, distributing potential confounders both known and unknown between the intervention and control groups. Stratified randomization can be used to ensure particular groups (for example, the very old) are evenly distributed. Cluster randomization designs randomize groups of individuals (e.g., all those in a ward or nursing home) rather than individuals themselves and are increasingly common in health services research. Blinding means that the subject or investigator ("single-blind"), or both ("double-blind"), do not know to which group the subject is assigned. This prevents people from being treated differently in any way other than the intervention itself and helps to ensure that outcome assessments are unbiased.

National regulatory authorities, such as the U.S. Food and Drug Administration (FDA) and European Medicines Agency (EMA), require positive outcomes from RCTs before a drug or medical device is given marketing approval for patient use. They will have been preceded by extensive preclinical *in vitro* (laboratory) and *in vivo* (animal) testing that, when appropriate, may include studies with nonhuman primate models of aging or transgenic animal models of disease. Clinical trials then progress through an orderly series of steps, commonly classified into Phases I to IV. Recently the concept of preliminary Phase 0 trials has also been introduced to describe exploratory, first-in human studies using single subtherapeutic (micro-doses) of study drug or agent, designed to confirm that the drug broadly behaves in man as predicted from preclinical testing.

In Phase I trials, the study drug or agent is tested in a small group of subjects (20 to 80) in single ascending dose (SAD) and multiple ascending dose (MAD) studies to assess a safe dosage range, the best method of administration and tolerance and safety (pharmacovigilance). The changes in the pharmacokinetics and pharmacodynamics of many drugs in older people, especially the frail, may significantly impact on the choice of dose and dosing frequency for clinical use. A Phase I trial usually recruits healthy young adults and so care must be taken with extrapolating results to elderly patients. When the study indication is common in older people, Phase I trials may recruit elderly healthy volunteers or patients with the relevant condition (e.g., as happened in initial studies of immunotherapy for Alzheimer's disease).

In Phase II trials, the study drug or agent is given to a larger group of subjects (100 to 300), generally patients with the study indication, to further assess safety and dosing requirements (Phase IIA) and to undertake preliminary studies of efficacy (Phase IIB). Usually these “proof of concept” studies recruit a homogeneous group of younger subjects to maximize the chances of success and minimize adverse events related to altered pharmacokinetics and pharmacodynamics, comorbid conditions, and drug interactions more characteristic of older patients. However, there have been recent calls for regulatory authorities to require performance of Phase II studies of new agents in individuals aged 70 and older.²¹

In Phase III trials, the efficacy and safety of the study drug or agent is evaluated in RCTs, usually two positive trials being required to gain approval from regulatory authorities. These require the recruitment of up to several thousand patients from multiple centers and generally last for 6 months to several years depending on the study indication. It is at this phase that arbitrary exclusion criteria based on chronologic age is especially difficult to justify. Randomization, stratified by age, and predetermined subgroup analysis will allow any issues specific to the elderly patients to become apparent. Phase IV (postmarketing) trials are designed to provide additional information about benefits and risks of treatment in long-term use in clinical practice. Serious adverse effects identified at this late stage in elderly patients have resulted in withdrawal or restricted use of several prominent drugs.

The carefully controlled nature of RCTs may themselves mean that they have limited generalizability as subjects are often a very well-defined, highly selected group. Extensive lists of inclusion and exclusion criteria may exclude those with other comorbidities or those taking other medications and the resulting trial population can end up bearing little resemblance to patients normally presenting in the clinic. This can result in unintended harm to future patients.^{22,23} Certainly perceived gains from narrow eligibility criteria are often outweighed by the loss in generalizability and clinical applicability of the results and less opportunity to test preplanned subgroup hypotheses (including any effect of age).²⁴ Pragmatic clinical trials tend to take all comers and best reflect the effectiveness rather than merely the efficacy of an intervention.

Exclusion of older people from research

Elderly people, especially the frail and the very old, are too often excluded from RCTs, usually inappropriately and without justification.^{25,26} A review of eligibility criteria of RCTs published in high-impact medical journals from 1994 to 2006 found that, after inability to consent, age was the second commonest exclusion criterion, with 38% of trials excluding the over-65s.²⁷ Similarly, an analysis of research papers published in four major medical journals in 1996 and 1967 found that one third of studies excluded subjects over 65 without providing justification,²⁸ although when the analysis was repeated in 2004 the proportion had fallen to 15%, with 5% of trials specific to older people.²⁹ The age bias can be present in clinical trials in most common conditions of older people, including cancer,^{30,31} cardiovascular disease,^{32,33} Parkinson's disease,³⁴ and urinary incontinence.³⁵ A search for RCTs specifically involving very elderly subjects identified only 84 trials published between 1990 and 2002, but concluded that their methodological quality did not differ from comparable trials in the general population.³⁶

Reasons given for excluding elderly subjects from research include concerns about gaining consent, protocol eligibility criteria with restrictions on comorbidities and concomitant medications, worries about poor compliance, and high attrition and fears of an unacceptable level of adverse events. However, many of these concerns are unfounded or can be easily overcome.^{37,38} A systematic review³⁹ examining participation of elderly patients in Phase III publicly funded RCTs in cancer between 1955 and 2000 found that in those trials with sufficient numbers of elderly enrollees, survival, event-free-survival, and treatment-related mortality outcomes were similar to outcomes reported in the remainder of the studies, with the authors concluding that the similarity in these two groups showing that the enrollment of elderly in experimental RCTs is not associated with increased harm. A review⁴⁰ of patients with various solid tumors entering Phase II cancer trials in Europe concluded that, compared with younger patients, the old did not have an increased risk of more severe or frequent adverse effects and there was no difference in response rate. However, doses did need more frequent adjustment in elderly patients and treatment discontinuation increased with age because of greater loss to follow-up and treatment refusal.

Informed consent

Seeking truly informed and freely given consent is fundamental to all research involving human subjects. The research participant must be able to retain and understand the relevant facts explained to them, be allowed sufficient time to weigh the benefits and risks to make a choice (without coercion), and then be able to communicate their decision to the researcher.⁴¹ Consent is more than getting a signature in triplicate on a consent form and should be regarded as a continuous process involving ongoing open dialogue between researchers and participants.

Elderly patients may have more difficulty comprehending consent information (mainly because of education differences rather than age itself), and particular attention should be given to compensating for communication and sensory deficits, improving readability of information sheets and consent forms, and considering the use of innovative consent procedures. However, most older people are cognitively intact and, in empirical studies of competency to consent to medical treatment, elderly control individuals were nearly all judged fully capable using various legal standards.^{42,43} Gaining informed consent may require more time because of characteristics of the older person and his or her wish to involve family members in the decision.

Those with cognitive impairment and the institutionalized are especially vulnerable to exploitation and require special consideration and management, although even then, lack of capacity should not be assumed.^{44–46} The MacArthur Competence Assessment Tool for Clinical Research (MacCAT-CR)⁴⁷ is a semistructured assessment of a potential research subject's decision-making capacity to choose, understand, appreciate, and reason through information needed to make an informed decision and can be a useful aid, although it is time-consuming to administer and requires specialist training. Simple cognitive screens, such as the Mini Mental State Examination (MMSE),⁴⁸ are very imprecise guides to judging capacity.⁴⁹ If a prospective research participant is considered incapable of giving consent, the relevant legal framework must be followed.^{50,51} Generally, research is allowed to go

ahead with the subject's permission, an appropriate surrogate decision maker (usually the patient's next of kin) providing proxy consent, ethics committee approval, and if the study has the potential to benefit the subject (so called "therapeutic research") or when the research entails minimal risk and burden and cannot be undertaken with individuals able to consent ("nontherapeutic research"). Research advance directives or advance decisions clearly document an individual's views on research participation, but have not been widely adopted.⁵²

Recruitment and retention

Research is dependent on recruiting and retaining sufficient numbers of suitable study subjects. There is no consistent evidence that chronologic age influences recruitment rate into trials.^{53,54} Rather, the problem is that elderly patients are not given sufficient encouragement to take part. Thus a study of breast cancer trials found that older age remained predictive of not being invited to take part after adjustment for comorbidity, cancer stage, functional status, and race, yet a similar proportion of younger and older patients were recruited when they were asked.⁵⁵ As well as ageism, clinician apathy and inexperience of research may also contribute to the exclusion of older patients. A survey of French geriatricians found that nearly all considered that RCTs including very elderly subjects were scientifically necessary, but less than half of the elderly participated actively in such studies and many were never approached to do so.⁵⁶ Researchers have the greatest motivation and are therefore the most efficient recruiters. Elderly patients themselves do not appear to actively seek clinical trials, possibly because of a lack of knowledge, and are dependent on others to inform them of what is available.⁹ Inclusion of people living in nursing homes is especially challenging given the particular issues around consent, loss of autonomy and negative staff attitudes, confidentiality, and resident rights.⁴⁶ Involving older people themselves as active partners in research design and conduct has become a policy requirement in the United Kingdom and may be helpful, although little is known about how involvement changes the research process.^{57,58}

Although curiosity may prompt the initial interest of patients in research, anticipated personal benefits, such as health screening and regular monitoring and the possibility to help others, are the most important motivators for subsequent enrollment and for continued participation.^{54,59} The main reasons for refusing enrollment are inconvenience and not wanting to be experimented upon or a self-perception of not being a suitable research candidate. Older research participants are more motivated than the young by feelings of altruism and "paying back" those who treat them and are less concerned about financial compensation for volunteering.⁶⁰ Studies in which all patients receive the active treatment, as part of a crossover design or open label extension after a placebo control phase, seem to be preferred.

A systematic review of factors that limit the quality, number, and progress of RCTs (in all age groups) identified many clinician- and patient-based barriers to participation (Table 5-1) but no effective strategies to improve recruitment,⁶¹ a finding similar to that of a recent Cochrane Review.⁶² An earlier literature review specific to older people had identified a number of factors open to modification to increase their participation in research studies. These included positive attitudes of staff toward research, acknowledgement of altruistic motives, gaining approval of family members, protocols

Table 5-1. Barriers to Participation in a Randomized Controlled Trial⁶¹

Clinician Based
<ul style="list-style-type: none"> • Time constraints • Lack of staff and training • Worry about the impact on doctor-patient relationship • Concern for patients • Loss of professional autonomy • Difficulty with the consent procedure • Lack of rewards and recognition
Patient Based
<ul style="list-style-type: none"> • Additional procedures and appointments for patient • Additional travel problems and cost for patient • Patient preferences for a particular treatment or no treatment • Worry about uncertainty of treatment or trials • Patients' concerns about information and consent • Protocol causing problem with recruitment • Clinician concerns about information provided to patients

designed for patient rather than staff convenience, and having a physician rather than a nurse approach the patient.⁶³ In a study of recruitment of frail older adults living at home into a RCT of geriatric assessment, yield (defined as the percentage of individuals contacted who later enrolled) was highest from community physician solicitations and presentations to religious or ethnic groups and lowest from media and mailing (and often problematic because of frequent misunderstandings).⁵³

Once entered into a study, maintaining good communications—primarily by regular face-to-face or telephone contacts with the researchers, but also using regular newsletters about study progress and lunchtime meetings to meet staff involved and other participants—will aid subject retention.⁵⁹ Token gifts—such as study-related calendars, fridge magnets, and pens and pads—can also be given, but can be counterproductive if they appear too costly. Test sessions should aim to last no longer than 1 to 2 hours to prevent fatigue, and spacing data collection over multiple visits should be considered. Time must be allowed for social interaction and refreshments to stop contacts from becoming too impersonal. It should be remembered that most older people (and their accompanying caregivers) have other commitments and timing of research sessions should fit around these.

Transport provision is critically important. Mobility and cognitive problems may make travel more difficult and distance from home to the research center influences recruitment of older persons more than the young.^{64,65} A prepaid taxi to and from the research center has many advantages. When research participants make their own travel arrangements, they should be reimbursed and convenient car parking ensured. Consideration should be given to easy access to the research office, which should be wheelchair-friendly and with suitable areas for accompanying relatives and caregivers to wait. Assessments that can be reliably performed by telephone or at the subjects' homes may be preferable to visits to the research center and are more likely to ensure that the subject is at ease. However, it is more difficult for researchers to set the agenda when they are guests in the subject's home, and ensuring that well-meaning relatives and pets do not interrupt testing sessions can be challenging. Regular delivery of study medication by mail may reduce the number of necessary visits. A formal "thank you" when the study ends and feedback of the final outcome is appreciated and expected.

Outcomes

Along with the standard outcome measures of morbidity and mortality, research in older people commonly needs to consider broader issues that impact quality of life, especially

Table 5-2. Checklist When Choosing Outcome Measures

- Is the measure proven to be valid and reliable in the study population?
- Is the measure responsive to clinically significant change?
- Is it acceptable to research subject and user? Could presentation be improved?
- Who is administering? Training need? Can a proxy respondent complete reliably?
- How long does it take to administer? Is the environment appropriate?
- Is scoring simple and are results presented ready for analysis?
- Has the measure been piloted in the study population?

Table 5-3. The 25-Item GMDS

- A. General Parameters**
- I. Full medical record including all past and present diseases, organ impairments, fractures, and surgical interventions.
 - II. Full drug history, including number and type of generic medications and adverse effects reported.
 - III. Charlson index
 - IV. Vision and hearing evaluation
 - V. EuroQol
- B. Cardiovascular Risk Factors**
- I. Assessment of diabetes and hypertension
 - II. Assessment of alcohol and smoking habits (pack years)
 - III. Blood pressure (BP) and heart rate (HR) in both sitting and standing positions measured at minutes 1 and 3
- C. Functional Status**
- I. Katz index (B-ADL)
 - II. Lawton's instrumental activities of daily living (I-ADL)
 - III. Timed Up and Go
 - IV. Falls: 3 months recall record of the number, frequency, time of the day, and mechanisms of falling, assistive devices, pain, and fear of walking
 - V. Frailty index
- D. Cognitive and Psychological Status**
- I. Years of schooling and educational level
 - II. MMSE
 - III. NPI
 - IV. 15-item Geriatric Depression Score
- E. Nutritional Status**
- I. MNA-SF followed by MNA if at risk
 - II. BMI
 - III. Weight loss measured as 4% in 1 year or 5 kg in 6 months
- F. Biologic Parameters**
- I. Electrolytes (sodium, potassium creatinine, glucose), hepatic function (GGT, ASAT, ALAT), lipids (T-Chol, HDL-Chol, LDL-Chol), thyroid function, vitamin B₁₂ and folic acid, albumin, and total protein levels, Hb A_{1c}, CRP, hemoglobin level, red and white blood cell count, and platelets
 - II. Creatinine clearance by Cockcroft formula
- G. Social Status**
- I. Housing status
 - II. Caregivers: number and type of formal/informal caregivers
 - III. Time spent on formal care giving measured as hours per week

From Abellan van Kan G, Sinclair A, Anreieu S, et al. The geriatric minimum data set for clinical trials (GMDS). *J Nutr Health Aging* 2008;12:197–200.

functional, cognitive, and social outcomes. Chosen measurement instruments must be valid (recording the attribute that it purports to measure), reliable (recording consistent results under varying conditions of measurement), and responsive (able to detect change). Other factors to be considered when selecting an instrument are whether it is self-administered or researcher-administered, whether it measures capability (what can be done relevant to experimental designs) or performance (what is done, relevant in pragmatic studies), and, perhaps most importantly, how long it takes to complete. Attention should also be given to the readability and style of self-completed questionnaires (Table 5-2).

The lack of validation of measurement instruments for use in elderly populations is a problem. Scales must be able to encompass the heterogeneity that is characteristic of elderly populations, avoiding floor and ceiling effects, and they must be acceptable to the study subjects. Even an apparently simple measure such as height becomes an issue when the person cannot stand. Use of validated alternatives such as knee-floor height then need to be considered, perhaps even in those who can stand, to ensure consistency across the whole study population.

KEY POINTS

Methodological Problems of Research in Older People

- Elderly people are too often excluded from research because of concerns about gaining consent, unnecessarily strict protocol restrictions on comorbidities and concomitant medications, worries about poor compliance and high attrition, problems with assessments and fears of an unacceptable level of adverse events. Many of these concerns are unfounded or may be easily overcome.
- Optimum choice of design to study aging and age-related conditions depends on the research question to be answered. Qualitative studies, ecologic studies using available data and quantitative studies using cross-sectional, case-control, and cohort designs, will help to generate hypotheses. These can then be tested in experimental studies, ideally using randomized controlled trial designs.
- Curiosity, anticipated personal health benefits, and the possibility to help others are the most important motivators for enrollment and for continued participation in research. The main reasons for refusing are inconvenience and not wanting to be experimented upon or a self-perception of being unsuitable. Older research participants are more motivated than the young by feelings of altruism and “paying back” those who treat them and are less concerned about financial compensation.
- Cognitively intact older people may have more difficulty comprehending consent information and special attention should be given to compensating for communication and sensory deficits, improving readability of information sheets and allowing sufficient time for the consent process. People with cognitive impairment and those in institutions may require alternative consent procedures.
- Once entered into a study, retention is promoted by maintaining good communications, good transport provision, and test sessions that are no longer than necessary and arranged at times to suit the participant. Outcome measures must be acceptable, valid, reliable, and responsive and focus on quality of life, especially functional, cognitive, and social outcomes, along with morbidity and mortality.

Experience with measures in younger, fit subjects cannot reliably be extrapolated to older patients with their higher prevalence of mobility, sensory, and communication deficits. When norms for the over-65s are available, they may be derived from small numbers of atypical, healthy, young-elderly subjects and of little relevance to the frail octogenarian in a nursing home. Ideally, reliability should be established in each population sample where the measure is to be used. Certainly all raters need to be trained to ensure consistency (interrater and intrarater reliability) and to help minimize bias. Piloting of all outcome measures in the population to be studied will ensure that the final choice is feasible and reduce the number of subsequent subject dropouts.

There are a growing number of measurement instruments that have established validity and reliability in elderly and frail subjects, with some approaching the status of gold standard. Examples are the Mini Mental State Examination (MMSE) for cognition,⁴⁸ the Geriatric Depression Scale (GDS),⁶⁷ the Barthel index,⁶⁷ and Katz index⁶⁸ for basic activities of daily living, the Lawton and Brody index for instrumental activities of daily living,⁶⁹ the frailty index,⁷⁰ the Mini Nutritional

Assessment (MNA),⁷¹ the timed up-and-go test (TUG) for falls risk,⁷² and the Zarit Burden scale for caregiver burden.⁷³ Clinical trials in dementia have their own extensive battery of assessment measures.⁷⁴

Recently, expert groups on both sides of the Atlantic have considered suitable functional outcome measures for clinical trials in frail older people.^{75–77} The GerontoNet collaboration of leading European geriatric research centers has developed and piloted a 25-item geriatric minimum data set (GMDS).⁷⁷ This aims to achieve a uniform nomenclature and standardization of the assessment tools that will act as the minimum set of information to be included in future clinical studies involving older people. It claims to be straightforward, rapid to complete, easily accessible on the Internet, inexpensive, valid in a wide spectrum of research areas, and has been translated into the common European languages (Table 5-3).

INTRODUCTION

For this discussion about the biology of aging, we begin with a definition of what is meant by aging and the aging process. There are many definitions proposed, but the one provided by Richard Miller of the University of Michigan seems particularly useful for this chapter in a textbook on geriatric medicine.¹ He defines aging as the “process that progressively converts physiologically and cognitively fit healthy adults into less fit individuals with increasing vulnerability to injury, illness, and death.” Thus the two most important general problems to overcome during human aging are (1) the increasing loss of physical and cognitive function with increasing age, and (2) the increasing susceptibility to a variety of morbid conditions.

The study of the biology of aging began with discovery research, which mostly focused on describing and cataloging aging changes. To understand how these age-related changes relate to Miller's definition, the challenge is then to distinguish among:

- Pathologically neutral age-related changes, such as the graying of hair
- Changes such as the accumulation of oxidatively damaged molecules or senescent cells that are believed to contribute to the development of one or more adverse age-related conditions
- Changes that cause overt pathology, such as the development of plaque and tangles in the brain of Alzheimer's disease patients
- Changes that are the result of such pathology

Three very important milestones occurring during the early discovery phase of aging research include the observations that: (1) restricting caloric intake increases longevity and delays the onset of age-related disease in rodents²; (2) oxygen radicals are produced *in vivo* and continuously damage cellular macromolecular components³; and (3) when human fibroblasts are grown in culture they have a finite life span.⁴ Although these three concepts still provide much of the basis for biogerontologic research, so much progress has been made in fleshing out the details that *Cell* devoted its entire February 25, 2005, issue to reviews of basic aging research. Even so, in its July 1, 2005, issue, *Science* included the question “How much can human life span be extended?” as one of the 125 major scientific puzzles driving basic research today.⁵

Over the years a large number of theories of aging have been proposed to explain how age-related changes promote aging,⁶ but the complexity of the process diminishes the possibility that any one theory will completely explain aging. The concept that aging is due to both genetic and environmental/stochastic factors is now generally accepted, but it remains difficult to distinguish between the process of aging itself, and the effects due to age-related diseases.

The chapter will first focus on cellular pathways now known to regulate longevity in a variety of animal model organisms. This knowledge resulted from the ability to isolate

long-lived mutants of short-lived species such as nematodes, fruit flies and mice, which in turn has been greatly facilitated by success in sequencing the human genome and the genomes of these popular model organisms. We then discuss age-related changes related to cell proliferation and age-related changes due to damage to important cellular macromolecules, such as DNA, proteins, and lipids. These include, but are not limited to, free radical damage to DNA, proteins, and lipids³; DNA repair⁷; nonenzymatic glycation⁸; protein cross-linking and protein turnover. Such stochastic changes can become important risk factors in the development of the many degenerative age-related processes and diseases that must be dealt with by geriatricians. Beckman and Ames have written an excellent review of the free radical theory of aging,⁹ which includes a discussion of many aspects of these overlapping phenomena, but a recent review of oxidative stress in transgenically altered mouse models by Han et al¹⁰ argues that the level of damage and its relationship to late-life pathology, such as cancer, is still poorly understood. However, the chapter then includes one example of an age-related condition, sarcopenia, which may be at least partly due to oxidative damage to skeletal muscle proteins. The chapter concludes with a brief discussion of the general value of research on the basic mechanisms of aging.

THE INSULIN-SIGNALING PATHWAY AND LONGEVITY REGULATION

Our understanding of the molecular and genetic basis of aging has witnessed a significant advance in the last decade. The prevailing view until the mid-1980s¹¹ was that aging was stochastic and genetics probably played little direct role in a process that occurred after the reproductive period, and therefore beyond the power of genetic selection. However, hundreds of genes with effects on longevity have been uncovered in a variety of organisms. This was done partially as a result of the Longevity Assurance Genes Initiative of the National Institute on Aging. Genetically tractable species such as nematodes (*Caenorhabditis elegans*), fruit flies (*Drosophila melanogaster*), and yeast have been used extensively to interrogate the genetics of the aging process. Although phylogenetically far away from humans, these models have been chosen primarily because of their ease of manipulation, powerful genetics, and short life span. The earliest gene that was found to control the rate of aging in any organism was the *age-1* gene in *C. elegans*,¹² and subsequent work by several laboratories identified *daf-2* and *daf-16* as additional genes controlling life span in nematodes.^{13–15} As it turned out, these genes all cluster within the insulin-signaling pathway: *daf-2* is the nematode homolog of the insulin/IGF-like receptor, *age-1* codes for the catalytic subunit of PI3K, and *daf-16* codes for a forkhead transcription factor whose nuclear translocation is under the control of the insulin receptor/PI3K axis (Figure 6-1). In nematodes, binding of the Daf-2 receptor by any or some of the 38 known ILPs (insulin-like peptides) activates a signal transduction cascade that negatively regulates the activity of Daf-16. Under basal

conditions, Daf-16 is phosphorylated and sequestered in the cytoplasm, and decreased activity of the Daf-2 pathway results in its dephosphorylation and subsequent translocation to the nucleus where it acts as a transcription factor, and activates a series of genes primarily involved in stress resistance, metabolism, and development. This pathway is inhibited by another gene involved in longevity regulation, *daf-18*, which is the nematode homolog of PTEN.

After this seminal work in *C. elegans*, the insulin/IGF pathway has been confirmed to play a role in regulating life span in other organisms, including *Drosophila* and mice. *Drosophila* has 7 different Dilps (*Drosophila* ILPs), and mutation of the insulin receptor substrate (IRS) chico leads to increased longevity. Mice (and humans) have a family of insulin-like receptors, including the insulin receptor (InsR) and the insulin-like growth factor receptors I and II (IGFR). Because neither *Drosophila* nor *C. elegans* has an "IGF receptor," it becomes relevant to establish which of the two pathways, insulin or IGF, is relevant to aging in mammals.

Several mouse models with increased longevity due to changes in the Ins/IGF pathway have been described. Most studied are the Ames¹⁶ and the Snell¹⁷ dwarf mice. These have mutations in the *Prop-1* and *Pit-1* genes, respectively, both of which are required for pituitary development, thus leading to a disruption of the somatotrophic axis, which through the action of growth hormone (GH) regulates IGF-I levels. Furthermore, it has been observed that GH receptor knockouts¹⁸ and IGF-1 receptor heterozygotes¹⁹

are also long-lived. Many of these models have compensatory changes in both the insulin and IGF pathways, so the results are still not fully clear about the relative role of each of these pathways in longevity regulation. Interestingly, a recent report suggests that disruption of insulin signal in the brain through heterozygote deletion of one of the two IRS species, IRS2, leads to an extension of life span (18%) comparable to that observed by systemic IRS2 deletion.²⁰ These observations suggest a central control of insulin/IGF action that affects animal longevity, but the results have been contested by another group.²¹ Further details are provided by the work of Conover and Bale,²² which has shown that reduction of bioavailable IGF-1 (by deletion of PAPP-A, a protease that cleaves an IGF binding protein) also leads to an extension of life span. Certainly, many details still remain to be elucidated, but the available data support the hypothesis that the longevity extension Daf observed in nematodes through manipulation of the Daf-2/Daf-16 pathway holds true in mice as well. Humans display an age-related decrease in GH release and IGF-1 synthesis, and the data from animal models leave open the possibility that this decrease in the activity of this axis might in fact be a protective mechanism. Indeed, supplementation of normal aged individuals with recombinant GH has resulted in significant adverse effects, with no clear benefits.²³ On the other hand, recent studies suggest that centenarian Ashkenazi Jews have a mutation in the IGF-I receptor, which in vitro correlates with a decrease in IGF signaling.²⁴

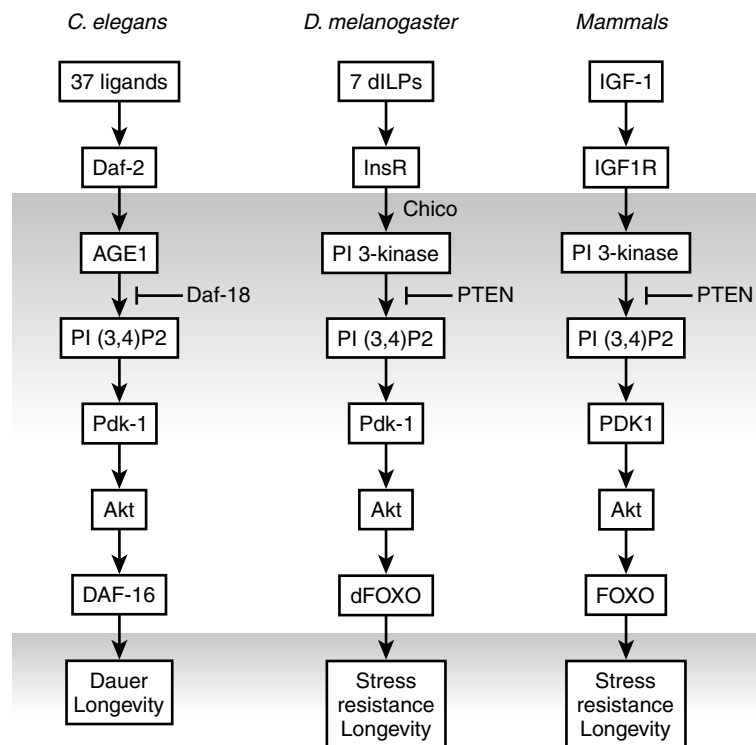

Figure 6-1. The insulin/IGF pathway is evolutionarily conserved, and has been shown to regulate longevity in several species, including *C. elegans*, *D. melanogaster*, and mammals. The figure depicts the similarities among the pathways in these three species. Of note, in both *C. elegans* and *D. melanogaster* there is only one pathway, whereas in mammals this has evolved into two separate ones, the insulin pathway and the IGF pathway. Although there is some debate, much of the evidence favors the IGF pathway as being relevant to longevity, and it is depicted here. There are also differences in the effectors that activate the pathways: in mammals there is only insulin and two IGFs, but in the lower species there are several ligands. The relative relevance of each of these ligands on aging has not yet been elucidated.

How does the insulin/IGF pathway regulate longevity? As mentioned above, the final result of the signal transduction cascade initiated at the receptor affects the translocation of Daf-16 to the nucleus. Daf-16 is the nematode homolog of mammalian FOXO (see Figure 6-1), and translocation of FOXO has been shown to be affected by several additional pathways involved in longevity.²⁵ Thus in addition to phosphorylation via the InsR/Akt pathway, FOXO phosphorylation is inhibited by a lipophilic signal sent from the gonads, and it is phosphorylated by activated AMP kinase in response to low energy, a pathway that could link FOXO to the mechanism of caloric restriction. FOXO is also modified in response to oxidative damage, both by phosphorylation through the JNK pathway and deacetylation by SirT1.²⁵ Thus it appears that FOXO lies at a nodal point that regulates organismal longevity in response to a variety of cues, both internal and external.²⁶ After translocation to the nucleus, FOXO acts as a transcription factor, upregulating the expression of a variety of genes involved in regulating the stress response, energy metabolism, cell proliferation, inflammation, and others.^{27,28} It should be noted that nuclear translocation does not seem to be a *sine qua non* for FOXO's role in longevity. An increase in nuclear Daf-16 is not observed in *age-1* mutants, and constitutive nuclear localization of the transcription factor does not result in increased life span.²⁹

It is important to keep in mind that although these genetic studies are aimed at unraveling the molecular mechanisms underlying the aging process, genetic manipulation of humans with the goal of extending life expectancy poses considerable ethical issues and is not the goal of aging research. Nevertheless, an understanding of the genetic basis of aging can provide valuable targets for therapeutic intervention and a solid theoretical foundation for age-delaying strategies (see later discussion under Why invest in basic aging research—the longevity dividend).

CELL PROLIFERATION, TELOMERASE, AND TELOMERE FUNCTION

The early work of Leonard Hayflick⁴ has been interpreted by some to mean that aging itself is programmed. Although the number of doublings a cell can undergo may have a genetic basis, the number of doublings a cell actually undergoes is subject to stochastic events. This aspect of aging is discussed below.

Telomere structure and replicative senescence

The mechanistic basis of Hayflick's observation that human cells grown in culture have a limited life span remained a mystery until Harley et al³⁰ demonstrated that telomeres shorten each time a cell divides. Telomeres are the structures at the ends of chromosomes containing long noncoding repetitive sequences, and they are synthesized by a special enzyme called telomerase.³¹ Telomerase consists of a catalytic protein complexed with a template strand of RNA that determines the repeating sequence of the telomeric DNA. Because most somatic cells do not express telomerase, as these cells continue to divide, the length of the telomeric DNA gradually shortens until a lower limit is reached (called the Hayflick limit), at which point proliferation ceases. This nonproliferative state is referred to as cell or replicative

senescence. The idea that telomere length is critical to the proliferative potential of cells was strengthened by the observation that increasing cellular telomerase activity transgenically also increases the number of doublings a cell can undergo before reaching the senescent state.³²

Telomeres consist of more than the long noncoding repetitive sequence at the 5' end of each DNA strand. The telomeric DNA binds a large number of proteins that are important in the multiple functions of telomeres.³³ These proteins are not only involved in DNA replication, but they also protect the coding sequences near the ends of chromosomes, and prevent the recombination of chromosome ends with each other or with the double-stranded DNA ends transiently produced during the normal metabolism of DNA.

Telomere length and telomerase activity can impact human health in at least three general ways. One is through the altered phenotype of senescent cells, but negative effects can also be observed if there is either too much or too little telomerase activity present in the cell.

Altered phenotype and cancer

Phenotypical changes due to replicative senescence are best understood in the human fibroblast. Whereas fibroblasts normally facilitate the synthesis of the basement membrane that helps to repress the proliferation of the cells attached to it, senescent fibroblasts secrete enzymes that degrade this matrix material.³⁴ This degradation destroys the regulatory properties of the membrane, and Krtolica et al³⁵ have directly demonstrated that the presence of senescent cells promotes carcinogenesis of nearby preneoplastic cells. Thus replicative senescence is an example of antagonistic pleiotropy by preventing uncontrolled proliferation of cells in young animals,^{36,37} but promoting cancer in their vicinity, a process of potential relevance as senescent cells accumulate with increasing age.³⁸

Too much telomerase activity and cancer

Telomeres progressively shorten with time in proliferating human cells because most human cells contain little if any telomerase activity. Thus every time a cell proliferates, the telomeres get shorter because the cell replicative machinery cannot replace the little bit of DNA lost during the initiation of DNA synthesis. Exceptions include germ cells and stem cells,³⁹ lymphocytes,⁴⁰ and transformed cells.^{41,42} Thus high telomerase activity is associated with the proliferative potential of cells and is considered to be a possible biomarker for cancer. The details of what actually causes telomerase activity to reappear in cancer cells, thus maintaining uncontrolled cancerous growth, remain to be worked out, but developing cancer drugs that inhibit telomerase is still a sought-after therapeutic intervention.

Too little telomerase activity and aging

Too little telomerase can also be a problem even though most human somatic cell types do not have significant levels of telomerase activity. The ability to replace damaged cells well into late life depends upon having robust stem cell pools, as the stem cells in these pools divide asymmetrically to produce the needed replacement cells. Telomerase activity is required to maintain the telomere length of the original mother cell. Individuals born with a mutation in either the telomerase catalytic protein or the associated template

RNA are defective in telomerase activity, and develop a condition known as dyskeratosis congenita (DC) because of their abnormal skin pigmentation. These patients may also present with nail dystrophy, premature hair graying, anemia, and/or bone marrow failure.^{43,44} Bone marrow is a good source of hematopoietic and mesenchymal stem cells, so it is perhaps not surprising that defective telomere maintenance in stem cells might be associated with bone marrow failure. If failure to maintain tissue homeostasis contributes to the development of aging phenotypes, then decreased telomerase activity in stem cells is likely to accelerate aging indirectly because of decreased regenerative capacity of the pools.⁴⁵

Rudolph et al⁴⁶ generated mice deficient in the RNA component of telomerase, and therefore lacking telomerase activity. Because mice have much longer telomeres than humans, the first three generations of these mice were fairly normal. However, by the sixth generation the mice were infertile, and their life span was reduced to 75% of normal. The sixth generation mice also had a reduced capacity to respond to stress or to repair wounds; they exhibited premature hair graying and had a higher spontaneous cancer incidence. Although increased telomerase activity is associated with cancer in humans, the loss of telomerase activity can also lead to genetic instability and cancer, indicating the complex and poorly understood relationships among telomere structure, cancer, and aging.

At least one other protein found in these telomeric complexes is related to a premature aging syndrome. Patients with Werner's syndrome (WS) lack a DNA helicase activity that results in growth retardation and early development of age-related pathologies beginning in the late teenage years.⁴⁷ Neither the role this DNA helicase plays in telomere structure and function, nor why its absence leads to premature aging, is known, but patients with WS typically develop cancer and osteoporosis prematurely, and die in their early fifties.

Telomere length as a biomarker of physiologic age

A surprising number of studies have reported an association between telomere length in lymphocyte DNA and some independent measure of human health and well-being. These include mortality,⁴⁸ Alzheimer's disease status,⁴⁹ exposure to psychologic stress,⁵⁰ cardiovascular disease,⁵¹ and parental life span.⁵² In every case these studies report a positive correlation between telomere length and healthy aging.⁵³ Neither the mechanistic basis for these associations, nor why these phenotypes correlate with telomere length in lymphocyte DNA, is well understood. However, they do support the concept that environmental factors also have an impact on aging.

CELL DEATH AND CELL REPLACEMENT — A CRITICAL ROLE FOR STEM CELLS?

Oxidative damage to cell components is random, although it may be concentrated in certain organelles such as the mitochondria, where most oxygen free radicals are generated. If the damage is severe enough, subsequent repair may be inadequate and apoptotic death may result, particularly mediated through the action of the p66^{shc} and ATR

proteins.^{54,55} Cells lost through apoptosis must be replaced either through division of a nearby somatic cell, by a progenitor cell resident in the tissue where the cell has been lost, or by recruitment of a stem cell from an appropriate niche. Progenitor cells have long been known to be present in skeletal muscle in the form of satellite cells, but it has become clear that progenitor cells reside even in brain tissue.⁵⁶ Sharpless and DePinho⁴⁵ have recently proposed that "... ageing—once thought to be degenerative—might reflect a decline in regenerative capacity of resident stem cells across many tissues." Such an idea is certainly consistent with the time dependence of appearance of the many age-related pathologies that humans experience: osteoporosis, diabetes, sarcopenia, neurodegenerative diseases, end-stage renal disease, etc. It is not known why mesenchymal-derived tissues seem to be particularly vulnerable during aging.

An important question is whether the stem cell deficiency is quantitative (number of stem cells) or qualitative (function of stem cells). Available data suggest it may be either or both, depending on the tissue, the niche, and other signals and variables. For example, hematopoietic stem cell (HSC) number may be maintained, while HSC function declines.⁵⁷ Similarly, Conboy et al⁵⁸ showed that mouse satellite cells from old donors are rejuvenated in young recipients. These results suggest that stem cell function may decline during normal human aging. Such a decline could reflect either an altered ability to differentiate normally⁵⁹ or simply the decreased ability to replicate at all.⁶⁰ Recent evidence suggests that such declining stem cell functionality can be caused by DNA damage leading to excessive apoptosis,⁶¹ and genetic mouse models also link this to premature aging phenotypes.^{62,63} Excessive apoptosis forcing increased proliferation of stem cells to maintain tissue homeostasis, even in the absence of external DNA-damaging agents, can thus have adverse effects on stem cell niches resulting in accelerated aging.^{33,45,55} In contrast, the presence of an overactive p53 protein^{64,65} appears to cause premature aging by attenuating stem cell proliferation, leading to development of aging-related phenotypes, presumably due to inadequate cell replacement from stem cell niches.

In humans, telomerase activity is normally found only in the germline, stem cell niches, and activated lymphocytes. It would be of interest to know whether decreasing telomerase function is a factor in stem cell aging. Telomerase deficiency does lead to the development of age-related phenotypes in mice, but not until telomeres have been shortened by serial breeding of telomerase-deficient mice,⁴⁶ and replicative life span of hematopoietic stem cells is decreased by telomerase deficiency.^{33,66}

PROGEROID SYNDROMES AND NORMAL AGING

Much progress in understanding human disease has been made by studying mouse models of the disease. Similar arguments can be made to support studies of aging of short-lived animal models such as yeast, nematodes, fruit flies, and mice. What is less accepted is whether there are appropriate accelerated human aging syndromes that may be informative about normal aging, in particular Werner's

syndrome and Hutchinson-Gilford progeria syndrome (HGPS). Despite obvious differences with normal aging, these and other progeroid syndromes may provide uniquely informative opportunities to formulate and test hypotheses regarding the biology of aging and age-related diseases.^{47,67} The phenotypes of these syndromes emerge at well-defined ages and include progressively degenerative changes similar to those observed during normal aging. The most common feature of both human and mouse mutations that accelerate the appearance of progeroid features is dysfunctional DNA metabolism, including replication, transcription, repair, and recombination. It remains to be determined whether such DNA dysfunction, and the cell death it may subsequently trigger, explains the time dependence of the appearance of progeroid phenotypes, and whether similar mechanisms are afoot although at a slower pace during normal aging. Such models may also provide clues about why mesenchymal stem cells might be particularly vulnerable in HGPS, as suggested by Halaschek-Wiener and Brooks-Wilson.⁶⁸

PROTEIN DAMAGE AND SARCOPENIA— DOES PROTEIN OXIDATIVE DAMAGE PLAY A CAUSAL ROLE?

Aging is associated with a progressive decline of muscle mass, strength, and quality, a condition described as sarcopenia. The prevalence of sarcopenia in older adults is about 25% under the age of 70 years, and increases to 40% in adults 80 years or older.⁶⁹ Sarcopenia is a risk factor for frailty, loss of independence, and physical disability.⁷⁰ Sarcopenia and its detrimental correlates have an immense economical impact.⁷¹ Thus understanding the mechanisms leading to muscle dysfunction (e.g., weakness) at advanced age represents a high public health priority.

The *free radical theory* of aging, formulated 50 years ago, proposes that aging can be attributed to deleterious effects of reactive oxygen species.³ This hypothesis has been extensively investigated and debated, and although oxidative damage may not be the only cause of adverse age-related changes, it clearly has been linked to a number of them.⁹ Overall, the *oxidative stress theory* states that a chronic state of oxidative stress exists in cells even under normal physiologic conditions because of an imbalance between prooxidants and antioxidants. This imbalance results in a net accumulation of oxidative damage in a variety of cellular macromolecules. Such oxidative damage increases during aging, which results in a progressive loss in the functional efficiency of various cellular processes.⁷² Three tenets of this theory include: (1) there are many oxygen-derived metabolites and reactive nitrogen species produced during normal metabolism; (2) these metabolites damage the phospholipids, proteins, and DNA of the mitochondria and other critical cellular components; and (3) oxidative stress influences signaling, transcriptional control, and other normal processes within cells.

Skeletal muscle is particularly vulnerable to oxidative stress, due in part to the rapid and coordinated changes in energy supply and oxygen flux that occur during contraction, resulting in increased electron flux and leakage from the mitochondrial electron transport chain. Skeletal muscle also contains a high concentration of myoglobin, a heme-containing protein known to confer greater sensitivity to

free radical-induced damage to surrounding macromolecules by converting hydrogen peroxide to other more highly reactive oxygen species.⁷³ Fundamental differences in skeletal muscle fiber type metabolism (slow-twitch aerobic fibers and fast-twitch glycolytic fibers) may confer differing degrees of susceptibility to oxidative stress and may be mechanistically related to the aging phenotype. The extent and time course of the deterioration of muscle function depend on many factors, such as the fiber type composition of the specific muscle studied and the selected age group. There is significant muscle atrophy, reductions in the force-generating capacity, slowing of contraction, and alterations in protein structure in fast-twitch fibers with normal aging.^{74,75} In contrast, the age-associated atrophy and significant functional declines of the slow-twitch fibers occur later (well into senescence).⁷⁶

The hypothesis that age-related deterioration of muscle function involves oxidative damage of muscle proteins by reactive oxygen and nitrogen (ROS and NOS) species⁷⁷ was suggested by a series of *in vitro* studies showing that ROS and NOS—such as peroxynitrite, hydroxyl radicals, H₂O₂, and nitric oxide—inhibit force production and induce changes in the regulation of calcium metabolism in skeletal muscle.^{78–84} Studies on *in vivo* oxidative modifications of specific muscle proteins such as sarcoplasmic Ca²⁺-ATPase (SERCA), actin, and myosin focused on a few selected markers, such as nitration of tyrosine (3-NT), formation of HNE (4-hydroxy-2-nonenal) adducts, oxidation of cysteine side chains, and glycation.^{85–88}

The SERCA protein is probably the most extensively investigated muscle protein. These investigations focus on what sites are vulnerable to oxidative stress, and how the modification or damage alters protein function with increasing age. Normal aging of skeletal muscle is associated with increased nitration; in particular, specific nitration of the SERCA2a isoform in slow-twitch muscle.^{85,89} Nitration can alter protein function and is associated with acute and chronic disease states.⁹⁰ 3-NT is formed when tyrosine is nitrated by peroxynitrite, a highly reactive molecule generated by the reaction of nitric oxide with superoxide. Muscle fibers are exposed to periodic fluxes of nitric oxide and superoxide, thus providing favorable conditions for the formation of peroxynitrite. Tyrosine nitration has the potential to inhibit protein function by altering protein conformation, imposing steric restrictions to the catalytic site, and preventing tyrosine phosphorylation.⁹¹ Moreover, the functional significance of tyrosine nitration depends on both the site of modification and the extent of the protein population containing functionally significant modifications. Tyrosine nitration increases by at least threefold in skeletal muscle during normal aging, and correlates with a 40% loss in Ca²⁺-ATPase activity during normal aging. Mass spectrometry analysis reveals an age-dependent accumulation of 3-NT at positions 294 and 295 of the SERCA2 protein, suggesting that these tyrosines play a critical role in muscle function. *In vitro* studies also demonstrate that SERCA2a is inherently sensitive to tyrosine nitration with concomitant functional deficits.^{85,89} Because the physiologic role of the Ca-ATPase is to mediate muscle relaxation, the consequence of nitration-induced inhibition of SERCA2a most likely explains the slower contraction and relaxation times observed in skeletal muscle with normal aging.

Aging also leads to a partial loss of SERCA1 isoform activity, and a molecular rationale for this phenomenon may be the age-dependent oxidation of specific cysteine residues. Mapping of the specific cysteine residues reveals nine cysteine residues targeted by age-dependent oxidation *in vivo*, and six cysteine residues partially lost upon oxidant treatment *in vitro*.⁹² Interestingly, the residues affected *in vivo* do not completely match those targeted *in vitro*, suggesting that modification of some residues do not contribute significantly to the loss of SERCA function with age. Taken together, these studies provide some insights about the molecular mechanisms responsible for age-related alterations in calcium regulation in skeletal muscle.

Myosin and actin are two key contractile proteins responsible for force generation and contraction speed. Age-related oxidative damage of myosin and actin are probably increased by decreased muscle protein turnover.⁹³ In the presence of reactive oxygen and nitrogen species, force is inhibited and contraction speed is altered.^{78,79,94} Studies of *in vivo* oxidative modifications of myosin and actin have focused on selective markers of oxidative damage, such as nitration, formation of HNE adducts, and oxidation of cysteines.^{86,88} During normal aging, myosin and actin do not significantly accumulate 3-NT or HNE-adducts. In contrast, an age-related decrease in cysteine content is detected in myosin, but not in actin with increasing age. Because the physiologic role of myosin and actin is to produce force and speed, the lack of accumulation of these oxidative stress markers is unlikely the explanation for age-related inhibitory changes in muscle contractility.

Another possible explanation of age-related inhibitory effects in muscle proteins is glycation. Accumulation of advanced glycation end products (AGEPs) resulting from the Maillard reaction alters the structural properties of proteins and reduces their susceptibility to degradation.⁹⁵ Decreased susceptibility of glycated proteins to degradation by the proteasome, the function of which is also compromised during aging,^{96,97} might also contribute to the buildup of damaged proteins. Generally, muscle shows the least glycation of biologic tissues, with a basal level of glycation in muscle protein of 0.2 mmol/mol lysine,⁹⁸ but normal aging of skeletal muscle is associated with a tenfold increase in the percentage of fibers containing glycated proteins.⁸⁷ Subsequent mass spectrometry analysis identified the glycated proteins as creatine kinase, carbonic anhydrase III, β -enolase, actin, and voltage-dependent anion channel 1, with β -enolase showing an accumulation of CML with age in muscle. β -enolase may be a scavenger of AGE because lysines are at the exposed surface of the protein. This scavenging process may spare other proteins from AGE-modification and consequent functional impairment. β -enolase is a good candidate for this role because glycation of this protein has only a limited impact on cell physiology. Indeed, although glycation leads to a decrease in β -enolase activity, no changes were detected in glycolytic flux.⁹⁹ The significance of glycation of other skeletal muscle protein on muscle function is unknown, yet *in vitro* studies show that glycation decreases myosin and actin interactions.¹⁰⁰

Taken together, these studies provide some insights about potential molecular mechanisms responsible for age-related

alterations in contractility. An important limitation in the characterization of damaged proteins from muscle tissue is the fact that the data provide only a snapshot of a dynamic process because proteins are constantly being synthesized and degraded in most tissues. Furthermore, current knowledge about posttranslational modification due to oxidative stress, and the techniques available to measure them, may not permit the quantitative analysis of all potential modifications of a given protein of interest and its functional characterization. It is likely that the future will see a significant increase in the number of specific modifications of proteins known, and an increase in our ability to associate them with specific aging phenotypes.

In summary, reduced muscle function and its attendant decrease in physical performance with age is a significant public health problem. Sarcopenia affects more than half of Americans older than age 50,¹⁰¹ at an estimated annual cost of \$18.5 billion.⁷¹ The cumulative effect of the reductions in skeletal muscle mass and function with age is a decrease in the capacity for physical work. This manifests as an inability to perform simple tasks of everyday life^{101–105} and has been shown to contribute to disability,^{69,101,106,107} greater risk for falls and fractures,⁶⁹ increases in all-cause mortality,¹⁰⁸ and, in general, a poor quality of life. People 85 and older are the fastest growing segment of the U.S. population, and estimates indicate that by 2030 almost 1 in 5 Americans, or 72 million people, will be 65 years or older (U.S. Census Bureau, 2005). Thus the incidence and prevalence of age-related decrements in muscle performance will increase, necessitating greater health care expenditures for supportive services and long-term care. Oxidative damage to key skeletal muscle proteins may be a contributing factor in sarcopenia. However, conclusive results require a more complete determination of the extent and location of oxidized sites, with parallel assessment of functional interactions of the proteins. Thus future research in the field of sarcopenia will attempt to identify and quantify all of the posttranslational modifications that a specific muscle protein accrues *in vivo*, and determine their functional implications.

WHY INVEST IN BASIC AGING RESEARCH?—THE LONGEVITY DIVIDEND

Much of current research into the biologic mechanisms of aging use death (life span) as an end point. Most biogerontologists agree that this is not the ideal end point, but it is used because we currently do not have any good biomarkers of the process, and ascertaining biologic age, as opposed to chronologic age, in laboratory animals is not an easy task. As a corollary to that choice, some believe that the purpose of basic aging research should be to increase human life span. Not only is that perception incorrect, but it is also dangerous. Indeed, it has been a long-held view that increasing the life span of humans will lead to a dramatic increase in the incidence of disease and disability.¹⁰⁹ If modern medicine succeeds in increasing life span without a concomitant increase in health span, the result could be a society of sick and infirm individuals, with poor quality of life, who will exert an enormous pressure on the economy by increasing the investment required for pensions, retirement, and health care costs.

Unfortunately, that is what appears to have happened during the last century, when median life span in the United States increased from 47 to 77.8 years, and at the same time, there has been a dramatic increase in the number of people with chronic disabilities and disease. As an example, Alzheimer's disease was not even described until 1907, and currently more than 4 million Americans have been diagnosed with the disease. So the prevalent view is that increasing the human life span any further will only lead to an ever more crippled society.

Most of the efforts of modern medicine are focused on addressing (and hopefully defeating) each of the major diseases burdening our population. For the aged, major fatal chronic diseases include cardiovascular diseases, cancer, dementias, and diabetes, but the quality of life is also impoverished by nonfatal diseases and conditions, such as osteoporosis, arthritis, sarcopenia, and others.¹¹⁰ Enormous progress has been made in understanding and treating several (but not all) of these disorders. Although such treatments and cures "benefit" a few individuals (those afflicted), it has been calculated that curing any of the major fatal diseases will only have a marginal impact on median life span, usually in the order of 3 to 6 years.¹¹¹ Furthermore, the benefit to those cured may be only relative because usually the elderly suffer from multiple disease conditions in parallel (comorbidities), so that curing any one of them will still leave them exposed to the ravages of the others. As an example, let us imagine that suddenly all cardiovascular diseases are conquered, and no one will ever again die of this. Many people who currently have semiclogged arteries would be elated by the news, and many of them would indeed go on to live useful lives for a few extra years. But the preponderant majority of individuals currently affected by cardiovascular disease are in a general state of diminished health and comorbidities, and the extra years of life are more than likely to be spent in an ever more frail state, as other age-related diseases (diabetes, Alzheimer's) take hold. Thus the increase in life span observed in the last century has led to an increase in the incidence of these other diseases. We have indeed conquered a major previous killer, infectious disease, and that led to the increased incidence of previously uncommon illnesses, such as cancer, diabetes, Alzheimer's.

What is then to be done? Aging is the major risk factor for most, if not all, age-related diseases.¹¹² For example, a high cholesterol diet will have only a minor immediate impact on the health of a young individual, but could be fatal for an older one (or for the same young individual, once he or she ages). If we accept that age is a major risk factor for these diseases, then as a corollary, slowing the rate of aging should be expected to result in a delay in the appearance of all or most age-related diseases, conditions, and ailments.^{113,114} If instead of addressing one disease at a time, as if their causes were independent, we recognize that age-related biologic changes are the main cause behind most age-related illnesses, then addressing the biologic changes that drive the process of aging is much more likely to have beneficial effects for humanity.¹¹⁵ In effect, it has been calculated that a small decrement in the slope of the aging rate curve could result in a significant increase in the proportion of our life span spent in a healthy, disease-free state. A delay of just 7 years in the appearance of major age-related illnesses could result in a net increase in health span of 50% based on the fact that

age-related decline rises exponentially with age, with a doubling time of approximately 7 years.¹¹⁶

At this time, such a goal seems within reach based on results obtained in animal models. Although much longevity research is performed in *C. elegans*, with few exceptions¹¹⁷ there is a clear scarcity of reports dealing with physiologic data in these animals, so we cannot ascertain for sure whether or not extension in life span in this model occurred in a healthy or diseased state. On the contrary, a more modest but generally reproducible increase in both median and maximal life span has been observed in rodents subjected to caloric restriction by 40%.² It is not clear whether a similar increase can be obtained in humans, but the observations in a variety of mammals indicate that the increase in life span afforded by caloric restriction is accompanied by a general delay in the aging process, such that restricted animals show a delay in the appearance of most age-related declines and diseases measured, both at the physiologic and pathologic level. Independently of whether caloric restriction (or a mimetic thereof) will work in humans, the data show that the rate of aging can be externally manipulated. Thus by delaying the onset of age-related decline, it is possible to postpone the entire range of age-related ailments, leading to a significant extension of the period of healthy living. This concomitant effect at a host of different levels has been termed *The Longevity Dividend*.^{5,6}

Interestingly, the longevity dividend concept extends well beyond health and well-being. A significant concern in many societies is the potential economic impact of the oncoming onslaught of age-related disease and disability, which threatens to break our pension and health care systems. The longevity dividend concept predicts that by addressing the basic mechanisms of aging, humans could live longer productive lives. This would translate into tangible economic benefits because people would be able to stay in the workforce longer (thus allowing for further wealth production and savings), and would withdraw less funds from pensions and the health care system. The economic implications of the longevity dividend have been explored in further detail elsewhere.¹¹³

KEY POINTS

Biology of Aging

- Decreasing the activity of the insulin-signaling pathway at any one of many steps, in a variety of animal models (fruit flies, nematodes, mice), shifts the focus of the organism from growth and reproduction to stress response and survival, thereby increasing its longevity.
- Damage to critical proteins changes their structure and compromises their function, and unless repaired or replaced, ultimately may decrease tissue function.
- Damage to DNA sufficient to block one of its critical functions (replication, transcription, repair, or recombination) may lead to cell death, and the need to replace that cell from a relevant progenitor cell pool.
- Excessive cell death can ultimately lead to exhaustion of the relevant progenitor cell pools responsible for maintaining tissue homeostasis in the presence of stress.
- Elucidating the biologic causes of aging is inherently important because aging is a major risk factor for development of most age-related pathology.

If we do manage to postpone aging, are there new diseases that will appear? Yes, that is a distinct possibility and a caveat to what has been exposed above. Even though so far we have been unable to increase maximal life span in humans,¹¹¹ modifying the aging process in animal models (e.g., by caloric restriction) does achieve that goal. If this is extrapolated to humans, it is indeed possible that currently rare or even new ailments will make their mark, just as defeating infectious diseases and many causes of childhood deaths did lead to an increase in the incidence of what we now call age-related diseases and conditions. Similarly, significantly extending median and maximal life span might lead to an increase in the prevalence of now rare diseases, such as liver

amyloidosis. In this context, it is relevant to note that in studies conducted to date, it has been observed that most centenarians and super centenarians die of the same array of causes as younger individuals (with maybe a slightly lower incidence of cancer).¹¹⁸ Nevertheless, if half of the human population reaches 100 years, and then are afflicted by these diseases, we still would have achieved an important goal: keep them healthy until their 90s. That could be one goal of modern medicine.

INTRODUCTION

Our society is experiencing unprecedented demographic changes where improvements in health care and living conditions together with decreased fertility rates have contributed to the aging of the population and a severe demographic redistribution.¹ Over the last 50 years, the ratio of people aged 60 years and over to children younger than 15 increased by about half, from 24 per hundred in 1950 to 33 per hundred in 2000. Worldwide by the year 2050, there will be 101 people 60 years and older for every 100 children 0 to 14 years old,² and many people over age 60 suffer from chronic illnesses or disabilities.³ Therefore, to better understand the mechanisms of aging and the genetic and environmental factors that modulate the rate of aging, it is essential to cope with the impact of these demographic changes.⁴ Aging can be defined as “a progressive, generalized impairment of function, resulting in an increased vulnerability to environmental challenge and a growing risk of disease and death.”⁵ It is generally assumed that accumulated damage to a variety of cellular systems is the underlying cause of aging.⁵ To date, a large proportion of aging research has focused on individual age-related disorders compromising adult life expectancy and healthy aging, including cardiovascular disease (heart disease, hypertension), cerebrovascular diseases (stroke), cancer, chronic respiratory disease, diabetes, mental disorders, oral disease, and osteoarthritis and other bone/joint disorders. Environmental factors, such as diet, physical activity, smoking, and sunlight exposure, exert a direct impact on these disorders, whereas significant genetic components make separate contributions. Although individual genetic factors could be small differences in DNA sequences—single nucleotide polymorphisms or small insertions/deletions—in both the nuclear and mitochondrial genomes, the overall genetic contribution to aging processes is polygenic and complex.

The complexity of aging is reflected in that numerous models have been proposed to explain why and how organisms age and yet they address the problem only to a limited extent. The models that are more widely accepted include: (1) the oxidative stress theory implicating declines in mitochondrial function⁶; (2) the insulin/IGF-1 signaling (IIS) hypothesis suggesting that extended life span is associated with reduced IIS signaling⁷; (3) the somatic mutation/repair mechanisms focusing on the cellular capacity to respond to damage to cellular components, including DNA, proteins, and organelles⁸; (4) the immune system plays a central role in the process of aging⁹; (5) the telomere hypothesis of cell senescence, involving the loss of telomeric DNA and ultimately chromosomal instability¹⁰; and (6) inherited mutations associated with risk for common chronic and degenerative disorders.^{11,12} In this work we will elaborate on the genetic component of each of these six hypotheses and the need for a more integrative approach to aging research.

MITOCHONDRIAL GENETICS, OXIDATIVE STRESS, AND AGING

The central role of mitochondria in aging, initially outlined by Harman,¹³ proposed that aging, and associated chronic degenerative diseases, could be attributed to the deleterious effects of reactive oxygen species (ROS) on cell components. As the major site of ROS production, the mitochondrion is itself a prime target for oxidative damage. Moreover, this is the only organelle in animal cells with its own genome, (mtDNA), which is mostly unprotected, closely localized to the respiratory chain, and subject to irreversible damage by ROS. Specifically, accumulation of mtDNA somatic mutations, shown to occur with age,¹⁴ often map within genes encoding 13 protein subunits of the electron transport chain (ETC) or 24 RNA components vital to mitochondrial protein synthesis. Not surprisingly, this mtDNA damage has been associated with deleterious functional alterations in the activity of ETC complexes. These mutations, whether single point mutations or deletions, have been shown in many studies to be associated with aging and with multiple chronic and degenerative disorders.¹⁵ An early report examining the integrity of mtDNA found accumulated mtDNA damage more pronounced in senescent rats compared with young animals.¹⁶ Other reports followed, including age-associated decreases in the respiratory chain capacity in various human tissues.¹⁷ Hypotheses put forward stated that acquired mutations in mtDNA increase with time and segregate in mitotic tissues, eventually causing decline of respiratory chain function leading to age-associated degenerative disease and aging.¹⁷ Furthermore, mtDNA haplotypes are associated with longevity in humans.^{18,19} In sum, this mitochondrial genome–ROS production theory of aging is mechanistically sound and appealing.²⁰

Deletions are the most commonly reported mtDNA mutations accumulating in aging tissues, and evidence for their role in aging is considered supporting.²¹ In order to solidify the importance of mtDNA damage in aging, Trifunovic et al²² developed a mouse model that indicated a causative link between mtDNA mutations and aging phenotypes in mammals. This “mtDNA mutator” mouse model was engineered with a defect in the proofreading function of mitochondrial DNA polymerase (Polg), leading to the progressive, random accumulation of mtDNA mutations during mitochondrial biogenesis. As mtDNA proofreading in these mice is efficiently curtailed, a phenotype develops with a threefold to fivefold increase in the levels of point mutations.²² However, the abnormally higher rate of mutation took place during early embryonic stages, and mtDNA mutations continued to accumulate at a lower, near normal rate during subsequent life stages.²³ Although these mice display a completely normal phenotype at birth and in early adolescence, they subsequently acquire many features of premature aging, such as weight loss, reduced subcutaneous fat, alopecia, kyphosis, osteoporosis, anemia, reduced fertility, heart disease,

sarcopenia, progressive hearing loss, and decreased spontaneous activity.²² Such results confirm that mtDNA point mutations can cause aging phenotypes if present at high enough levels, but alone do not prove that the lower levels measured in normal aging are sufficient to cause aging phenotypes. Hence, attention turned to the focal distribution of mtDNA mutations rather than the overall amount as key in disrupting the efficiency of the respiratory chain and thus driving the observed aging phenotypes. To prove this hypothesis, Müller-Höcker examined hearts from individuals of different ages and reported focal respiratory chain deficiencies in a subset of cardiomyocytes in an age-dependent manner.²⁴ This was subsequently supported by evidence from a number of other cell types.^{25–27} In sum, intracellular mosaicism, resulting from uneven distribution of acquired mtDNA mutations, can cause respiratory chain deficiency and lead to tissue dysfunction in the presence of low overall levels of mtDNA mutations.

The mitochondrial hypothesis of aging is conceptually straightforward, but in reality is much more complex²⁸ because a minimal threshold level of a pathogenic mtDNA mutation must be present in a cell to cause respiratory chain deficiency, and this threshold may vary between experimental models.²⁹ With 100 to 10,000 mtDNA copies per cell, mtDNAs that are mutated and normal at a given position coexist within a cell, tissue, or organ—a condition termed heteroplasmy. Different types of heteroplasmic mtDNA mutations have different thresholds for induction of respiratory chain dysfunction.¹⁷ Moreover, subjects carrying heteroplasmic mtDNA mutations often display varying levels of mutated mtDNA in different organs and even in different cells of a single organ.¹⁷ Furthermore, the intracellular distribution of mitochondria could play a role in the manifestation of the effects of mtDNA mutations.³⁰

Although significant advances in our understanding of the role of mitochondria in aging have been made, it is likely that current theories will be revised as the link between mtDNA mutations and ROS production is more deeply probed.³¹ Moreover, as the role of mitochondria in the response to caloric restriction is gaining relevance, available data are contradictory and not easily reconciled.³² Thus research efforts will continue to describe the role of the mitochondrion in influencing the mechanisms of aging, but several boundaries should be heeded: (1) the difference in complexity between humans and model organisms at genetic, cellular, and organ levels; (2) the particular life span of each species, especially as medicine has allowed humans to live beyond a “normal” age of death; (3) the genetics of inbred animals often used in experiments contradicts humans who are highly outbred; and (4) the environmental conditions in which animals (highly standardized) and humans (quite different for anthropologic and cultural reasons) live.³³

CHROMOSOMAL GENE MUTATIONS AND AGING

Genetic factors associated with human longevity and healthy aging remain largely unknown. Heritability estimates of longevity derived from twin registries and large population-based samples suggest a significant but modest

genetic contribution to human life span of about 15% to 30%.³⁴ However, genetic influences on life span may be greater as an individual ages.³⁵ Moreover, the reported magnitude of the genetic contribution to other important aspects of aging such as healthy physical aging (wellness), physical performance, cognitive function, and bone aging are much larger.³⁴ Both exceptional longevity and a healthy aging phenotype have been linked to the same region on chromosome 4,^{36,37} suggesting that although longevity per se and healthy aging are different phenotypes, they may share some common genetic pathways.

A number of potential candidate genes in a variety of biologic pathways have been associated with longevity in model organisms. Most of these genes have human orthologs and thus have potential to yield insights into human longevity.³⁸

First, the most prominent hypothesis of aging states that mutants with decreased signaling through the insulin/IGF-1 signaling (IIS) pathway have extended life span. This pathway is evolutionarily conserved from nematodes to humans.³⁹ Thus genes of this pathway are promising candidate genes for influencing human longevity and healthy aging. Several studies have reported the association between genetic variants at *IGF1R* and *PI3KCB* and reduction of insulin-IGF-1 activation and longevity.^{40,41} The finding that a nonsynonymous mutation in *IGF1R* was found to be over-represented in centenarians of shorter stature when compared with controls⁴² supports a role for the IIS pathway in life-span extension in humans, thus extending observations in model organisms.

Second, macromolecule repair mechanisms regulate the process of aging.⁶ Dysfunctional systems for damage repair to cellular constituents, such as DNA, proteins, and organelles, could curtail life span. These repair mechanisms are evolutionarily conserved across species.⁴³ Many studies support the detrimental effects of defective repair on reduced life span. Examples are human premature aging patients with mutations in a RecQ helicase, a crucial enzyme responsible for DNA strand break repair.⁴⁴ Variation at this gene has shown association with cardiovascular diseases.⁴⁵ However, few studies have demonstrated that an enhanced repair ability increases life span.⁴⁶ In addition, the altered protein/waste accumulation in the process of aging could aggravate cellular damage.¹⁰ Thus dysfunction in clearance of cellular waste, which is also called autophagy, would accelerate aging. Downregulation of autophagy gene expression, such as *Atg7* and *Atg12*, has shortened the life span of both wild type and *daf-2* mutant *C. elegans*.⁴⁷

Third, the immune system plays a central role in the process of aging.⁹ Although inflammation is an essential defense of immune systems, chronic inflammation often leads to premature aging and mortality.⁴⁸ One key player of inflammation is the cytokine interleukin 6 (*IL6*). *IL6* overexpression has been linked to many age-related that such as rheumatoid arthritis, osteoporosis, Alzheimer disease, cardiovascular diseases, and type 2 diabetes.^{49,50} Human studies have also demonstrated that *IL6* genetic variation is associated with longevity.^{51,52}

Finally, cardiovascular disease is the major cause of morbidity and mortality in industrialized countries and thus a major obstacle to healthy aging and longevity. Much attention has been placed on genes encoding proteins functioning in lipid metabolism. Plasma lipid levels are highly dependent

on age, gender, nutritional status, and other behavioral factors. It is therefore difficult, at least in cross-sectional studies, to determine to what extent a particular lipoprotein phenotype is causally associated with aging. One way to circumvent this issue is to rely on long-term prospective studies or to perform family-based studies.¹¹ Well-designed case-control genetic studies may also be advantageous because identification of particular variants associated with longevity may provide some hints to the biologic pathways leading to exceptional longevity. To that end, a large number of allelic variants in genes encoding apolipoproteins (*APOE*, *APOB*, *APOC1*, *APOC2*, *APOC3*, *APOA1*, and *APOA5*), transfer proteins (microsomal transfer protein [MTP], cholesteryl ester transfer protein [CETP]), proteins associated with HDL particles (PON1), and transcription factors involved in lipid metabolism (peroxisome proliferator-activated receptor gamma [PPARG]) have been examined in elderly populations. Similar to many other aspects of lipoprotein metabolism and cardiovascular disease risk, the most explored locus in terms of associations with longevity has been that of the *apolipoprotein E* (*APOE*) gene. Since the initial observation by Davignon et al,⁵³ reports from different parts of the world have observed a higher frequency of the *APOE4* allele in middle-aged subjects compared with older subjects (octogenarians, nonagenarians, and centenarians), concluding that the presence of the *APOE4* allele was associated with decreased life span.⁵⁴

To summarize, data accumulated so far illustrate that a variety of genes are involved in several mechanisms of aging, age-related diseases, and to a certain extent with longevity. Although thus far tenuous, there are a number of clues indicating that there is crosstalk between genes involved in longevity and those involved in age-related diseases that could be involved in longevity beyond effects on healthy aging.

Genetics is a valuable tool to expand our understanding of the molecular basis of aging. However, most studies published so far have been limited by design (i.e., cross-sectional study, small sample size, limited SNP coverage of a small number of candidate genes, interethnic differences) and so results have been inconsistent.⁵⁵ Most recently, genomewide association studies (GWAS) offer a more comprehensive and untargeted approach to detect genes with modest phenotypic effects that underlie common complex conditions.⁵⁶ Some notable findings are emerging from GWAS with a focus on aging-related phenotypes.^{34,57,58} However, to benefit fully from the contribution of genetics, large prospective studies need to be undertaken and fully supported by extensive genotyping and analytical capacities to collect adequate phenotype data. Even more important is the urgent need for a reliable intermediate phenotype for aging, both for genetic studies and for therapeutic interventions.⁵⁷

Telomeres and aging

Telomeres are repetitive DNA sequences that are wrapped in specific protein complexes and located at the ends of linear chromosomes. Telomeres distinguish natural chromosome ends from DNA double-stranded breaks and thus promote genome stability.⁵⁹ Although traditionally considered as silent structural genomic regions, recent data suggest that telomeres are transcribed into RNA molecules, which remain associated with telomeric chromatin, suggesting RNA-mediated mechanisms in organizing telomere architecture.⁶⁰

Telomere length has been proposed as a potentially reliable marker of biologic age, shorter telomeres reflecting more advanced age. Thus telomeres fit within mechanisms explaining the Hayflick limit⁶¹ because they shorten progressively with each cell division. When a critical telomere length is reached, cells undergo senescence and subsequent apoptosis. Initial telomere length is mainly determined by genetic factors.^{62,63} Although telomere shortening may be a normal biologic occurrence with each cell division, exposure to harmful environmental factors may affect its rate, accelerating telomere shortening.⁶⁴ To counter telomere shortening, telomerase, a cellular reverse transcriptase, promotes maintenance of telomere ends in human stem cells, reproductive cells, and cancer cells by adding TTAGGG repeats onto the telomeres. Moreover, recent studies suggest the existence of chromosome-specific mechanisms of telomere length regulation determining a telomere length profile, which is inherited and upheld throughout life.⁶⁵ Telomerases also may be involved in several essential cell signaling pathways without apparent involvement of well-established functions in telomere maintenance.⁶⁶ However, most normal human cells do not express telomerase and thus each time a cell divides some telomeric sequences are lost. When telomeres in a subset of cells become short (unprotected), cells enter an irreversible growth arrest state called replicative senescence.⁶⁷ The crucial role of telomeres in cell turnover and aging is highlighted by patients with 50% of normal telomerase levels resulting from a mutation in one of the telomerase genes. Short telomeres in such patients are implicated in a variety of disorders, including dyskeratosis congenita, aplastic anemia, pulmonary fibrosis, and cancer.⁶⁸ In addition to this manifestation in rare genetic disorders, short telomeres have been reported in the general population for several common chronic diseases, such as cardiovascular diseases^{69,70} hypertension,⁷¹ diabetes,⁷² and dementia.⁷³ With respect to cancer⁷⁴ dysfunctional telomeres activate the oncoprotein p53 (TP53) to initiate cellular senescence or apoptosis to suppress tumorigenesis. However, in the absence of p53, telomere dysfunction is an important mechanism to generate chromosomal instability commonly found in human carcinomas.⁷⁵ Telomerase is expressed in the majority of human cancers, making it an attractive therapeutic target. Emerging antitelomerase therapies, currently in clinical trials, might prove useful against some human cancers.⁷⁶

Based on current evidence, telomere shortening clearly accompanies human aging, and premature aging syndromes often are associated with short telomeres. These two observations are central to the hypothesis that telomere length directly influences longevity. If true, genetically determined mechanisms of telomere length homeostasis should significantly contribute to variations of longevity in the human population. Unraveling cause versus consequence of telomere shortening observed in the course of many aging-associated disorders is not an easy task. In addition, it remains unclear whether the biomarker value in a particular disease depends on shorter telomere length at birth or rather if it is merely a reflection of an accelerated telomere attrition during lifetime, or a combination of both. Although the importance of telomere attrition is supported by cross-sectional evidence associating shorter telomeres with oxidative stress and inflammation, longitudinal studies are required to

accurately assess telomere attrition and its presumed link with accelerated aging.⁷⁷

Epigenetics and aging

There is wide recognition that the fetal environment may strongly influence the risk of cardiovascular diseases and diabetes, both age-related disorders, as supported by epidemiologic data in humans and experimental animal models. It has been widely assumed that these long-lasting consequences of early-life exposures depend on the same mechanisms as those underlying “cellular memory” (i.e., epigenetic inheritance systems). There is a growing body of evidence that environmentally induced perturbations in epigenetic processes (such as DNA methylation and histone modification) can determine different aspects of aging, and the etiology and pathogenesis of age-related diseases.⁷⁸ Moreover, epigenetic alterations, such as global hypomethylation and CpG island hypermethylation, are progressively accumulated during aging and contribute to cell transformation, a hallmark of cancer.⁷⁹ Epigenetic tagging of genes controls expression of the genome and maintains cellular memory after many cellular divisions. Thus there is great importance in studying the epigenome to better comprehend genome health and the genetic mechanisms of aging. Moreover, tagging can be modulated by the environment, implying that environmentally induced changes in the epigenome could decrease or accelerate the process of unhealthy aging.⁸⁰

An integrative approach to aging mechanisms

Caloric or dietary restriction (CR or DR)⁸¹ is considered a universal mechanism that prolongs the life span of many organisms.⁸² Although there is no unified explanation, multiple mechanisms and networks are thought to be involved. First, CR can extend life span through shifting energy metabolism. Although yeast under CR display enhanced respiration and decreased fermentation,⁸³ CR-mammals shift energy expenditure toward metabolizing fat and glycogen over glucose. One molecular mechanism potentially linking caloric restriction with longevity involves the PPARC pathway, possibly via lipid metabolism.⁸⁴ Picard et al⁸⁴ have shown that Sirt1 (sirtuin 1), the mammalian SIR2 ortholog, promotes fat mobilization in white adipocytes by repressing the effects of PPARC. Second, CR can extend life span by reducing ROS-mediated damage. Upon CR, SIRT1 also activates peroxisome proliferator-activated receptor gamma-coactivator-1 α (PPARGC1A), which regulates a series of nuclear receptors and controls mitochondrial function, oxidative phosphorylation, and cellular energy metabolism.⁸⁵ Upregulation of PPARGC1A reduces ROS production,⁸⁶ thus limiting mtDNA damage. PPARGC1A variants are associated with type 2 diabetes, CVD, DNA damage, and high blood pressure in humans.^{87,88} Third, CR-animals are resistant to stress and inflammation through Foxo1 and Sirt1 inhibition of NF- κ B signaling.⁸⁹ The most likely mechanism of CR-extension of life span adopts the hormesis hypothesis, a positive response of the organism to a low-intensity stressor.⁹⁰ CR is an evolutionarily conserved stress response using stress-responsive survival pathways that evolved long ago to provide for increased likelihood of survival in diverse environments.⁸² Therefore, it is important to recognize the

complexity of mechanisms involved in aging and the need to integrate several pathways and cellular mechanisms in understanding healthy aging. The term *network theory of aging* has been proposed⁹¹ to overcome the reduction nature of individual models and to allow for interactions between individual contributing mechanisms. A proof of concept example is to consider interactions between two individual mechanisms that contribute to aging: DNA damage response and telomere maintenance. The key framework for considering these interactions is the integrative model, which predicts that telomere maintenance is an integral part of DNA damage response machinery. The integrative model predicts the dual phenotype, namely dysfunctional DNA damage response and dysfunctional telomere maintenance, where one of these mechanisms is the cause of aging. In line with this prediction, between 87% and 90% of mouse models and human examples of premature aging show this dual phenotype. Hence the integrative model is consistent with the network theory of aging. Others have provided evidence suggesting the connection between DNA damage in telomeres and mitochondria during cellular senescence.⁹² Accordingly, improvement of mitochondrial function results in less telomeric damage and slower telomere shortening, whereas telomere-dependent growth arrest is associated with increased mitochondrial dysfunction. Moreover, telomerase, the enzyme complex known to re-elongate shortened telomeres, also appears to function independently of telomeres to protect against oxidative stress. Together, these data suggest a self-amplifying cycle between the genetics of the mitochondrion and the telomere: DNA damage during cellular senescence promotes aging and age-related disorders.

KEY POINTS

Genetic Mechanisms of Aging

- Important links between ROS production, mtDNA mutations, and aging, while strong, require further research.
- The mitochondrial role in the response to caloric restriction is coming to light.
- A number of nuclear encoded genes and their genetic variants affect any of several mechanisms of aging and longevity
- Genomewide association studies hold promise to identify genetic variants pertinent to aging, but intermediate biomarkers of aging are critically needed.
- Shorter telomeres accompany human aging, and premature aging syndromes often associate with telomere shortening but deciphering the causal role of telomere length in aging remains.
- The environment affects epigenetic processes and can influence the progression of aging and age-related diseases.
- The network theory of aging serves to link the genetic aspects of mtDNA damage, telomere maintenance with aging and age-related disorders.

This chapter is an account of the subcellular mechanisms that are currently believed to have a major role in age-associated changes in cells that will ultimately result in cell death. Research into aging at a cellular level has burgeoned in recent years and is currently gathering pace as more and more is revealed about the causes and consequences of aging at this level. It is now generally accepted that age-associated cellular damage principally affects membrane lipids, proteins involved in metabolic and structural roles, nuclear and mitochondrial DNA, and intracellular signaling processes. There is also a reduction in aging of cellular maintenance and repair as a result of which cells are unlikely to recover from age-associated damage. It is also becoming clear that many cellular mechanisms of aging are closely tied to and interface with cellular mechanisms of diseases such as cancer and of certain degenerative diseases.

DESTRUCTIVE AGENTS IN CELLULAR AGING

Environmental agents

Ultraviolet (UV) solar radiation, the amount of which reaching the surface of the earth is increasing, causes damage to DNA, proteins, and lipids in the skin; and in the cornea, lens, and retina of the eye. DNA bases absorb UV light, resulting in structural changes that can be mutagenic such that a base becomes noncoding or miscoding.¹ Furthermore other abundant UV-induced mutagenic or lethal base lesions are cyclobutane-pyrimidine dimers and 6-4 photoproducts, which are potentially lethal because they can inhibit DNA polymerases from successful transcription.¹ An early cellular response to UV-induced DNA damage is by UV-damaged, DNA-binding proteins, which bind selectively to UV-irradiated DNA to switch on the cell's response to radiation damage.² UV-induced protein damage results in the accumulation of high molecular weight aggregates and reduced protein synthesis. Plasma membrane lipid damage by UV is mainly photo-oxidation of thiol groups and peroxidation of lipids themselves. UV-induced molecular mutations are greatly enhanced by the presence of oxygen. Thus, although oxygen is essential to life, it is the source of potentially damaging reactive oxygen species (ROS) that are found in the environment. Many sources of ROS are present in the environment ranging from exposure to additional ionizing radiation (from industry, nuclear radiation, and medicinal X-irradiation), ozone and nitrous oxide (primarily from automobile emissions), heavy metals (mainly cadmium, mercury, and lead), cigarette smoke (from both active and passive exposure), unsaturated fats, and many other chemicals intentionally or unintentionally present in foodstuffs.

Reactive oxygen species

The generation of reactive oxygen species (ROS) is a continuous process and a normal part of metabolism, especially the oxidative phosphorylation that takes place in mitochondria for the production of ATP. Thus the moment a new cell

comes into existence following cell division, it will become a source of ROS production. ROS (originally called free radicals) were suggested to be a fundamental source of subcellular damage leading to cellular aging by Harman³ more than 50 years ago and have come to be accepted as major, proven agents of such age-associated damage. ROS are ubiquitous and are extremely reactive clusters of atoms on account of the fact that they have an unpaired electron in the outermost shell of electrons. This is an extremely unstable configuration and they search for stability by rapidly extracting an electron from another molecule to achieve the stable configuration of four pairs of electrons in the outermost shell; thus they are very short-lived species. ROS, as indicated above, are formed by the interaction of many environmental factors with biologic molecules or as an unavoidable byproduct of cellular respiration. Four main sites of ROS generation are generally cited in the literature (the mitochondrial electron transport chain, cytochrome P-450 reactions, peroxidation of fatty acids, and phagocytic cells), but to this list must now be added skeletal muscle contraction,^{4,5} which causes a widespread increase in ROS levels. The major source of ROS is mitochondria, where oxygen is partially reduced in the electron transport system at the NADH dehydrogenase stage and at the ubiquinone/cytochrome b intersection. However, mitochondrial electron transport does not work perfectly and a single electron reduction of oxygen to the superoxide anion O_2^- takes place. Enzymatic dismutation of the O_2^- by Mn-superoxide dismutase (SOD) in mitochondria and Cu-Zn-SOD in the cytoplasm leads to the formation of hydrogen peroxide (H_2O_2). Thus the generation of O_2^- and H_2O_2 is a major byproduct of oxidation reduction reactions. It is also possible to remove H_2O_2 from tissues by catalases or by glutathione peroxidase. Unlike the O_2^- anion, H_2O_2 easily crosses plasma membranes. If it is not removed and free Fe^{2+} ions are locally present in the cytoplasm, H_2O_2 can generate the hydroxyl radical ($\cdot OH$), which can be regarded as the most damaging and reactive member of the ROS family compared with hydrogen and superoxide. The hydroxyl radical has a very short half-life, and does much damage to proteins, lipids, and DNA close to its site of production, but it can penetrate deep within cells unlike O_2^- , which is more likely to damage plasma membranes. The reaction that forms $\cdot OH$ is a two-stage process called the iron-catalyzed Haber-Weiss or Fenton reaction, which can be summarized:

Another highly reactive ROS is peroxynitrite ($ONOO^-$), which is derived from the reaction of nitric oxide (NO) (produced by inducible, constitutive, or neuronal nitric oxide synthase) and O_2^- . The reaction is extremely fast, exceeding the ability of SOD to break $ONOO^-$ down. Again, $ONOO^-$ is a strong oxidant and the $\cdot OH$ radical formed when it breaks down is highly reactive.

An example of the damaging effects of ROS, at a molecular level, is that of an $\cdot OH$ radical removing a hydrogen

atom from one of the carbon atoms in a side chain of a fatty acid forming a molecule of water. The carbon atom is left with an unpaired electron, which is very likely to react with a molecule of oxygen to form a peroxy radical. The peroxy radical can steal a hydrogen atom from a nearby side chain, thus making it into a radical. Thus, in interacting with other molecules to attain stability, ROS turn their target molecules into a radical. This initiates a chain reaction that will continue until two radicals encounter one another and each contributes its unpaired electron to form a covalent bond to link the two.

ROS derived from the mitochondrial electron transport chain at complex I (NADH dehydrogenase) and at complex III (ubiquinone-cytochrome *c* reductase), the process that consumes about 90% of a cell's oxygen intake, takes place on the inner membrane of the mitochondria and is at a very high level even in a state of low cellular activity. It has been estimated that about 1% to 2% of the oxygen intake is converted into ROS in mitochondria,⁶ but this is a constant, unremitting source of ROS production. In addition, increased ROS production can result from disorders of the respiratory chain and cause an increase in the expression of Mn²⁺-superoxide dismutase (MnSOD) leading to the production of H₂O₂. Although mitochondria are the prime site of ROS production, they possess antioxidant defense mechanisms such as MnSOD and glutathione peroxidase (GSH). The increase of oxidation of GSH that occurs in aging and in certain diseases of the liver and skeletal muscle⁷ results in an increase of oxidation of mitochondrial DNA. Evidence such as this contributes to the concept that mitochondria are a prime source of ROS in aging.⁸

Among other subcellular sources of ROS are (1) cytochrome *P*-450 enzymes, which use a wide variety of endogenous and exogenous compounds as their substrates in many metabolic processes throughout the body. They are also involved in the oxidative metabolism of many drugs that in turn may increase or decrease their activity. Cytochrome *P*-450 enzymes are located in mitochondria and on the endoplasmic reticulum. Their most common reaction is a mono-oxygenase reaction, but they can reduce O₂ to O₂⁻, possibly leading to oxidative stress. (2) Peroxisomes are organelles present in all cell types and whose role is to metabolize fatty acids. Peroxisomes contain high concentrations of oxidative enzymes whose activity generates H₂O₂ as a byproduct, which can leak out into the cytoplasm. However, they contain catalase, which can theoretically restrict the potential for damage by H₂O₂. Catalase levels, however, have rarely been shown to decrease in aging; in elderly humans higher plasma catalase activity has been reported,⁹ suggesting that compensatory antioxidant mechanisms may be present. (3) Phagocytic activity, induced by whatever pathologic reason, employs a combination of ROS and oxidants in large amounts and this activity generally increases with age. (4) ROS production as a result of the contraction of skeletal muscle has been shown to increase with age^{4,5} and its release into the extracellular space suggests the potential for inflicting more distant tissue damage. (5) In the brain the metabolism of dopamine by monoamine oxidase produces H₂O₂, which has been implicated in the dopaminergic cell loss that is characteristic of Parkinson's disease. Indeed mesencephalic dopamine cells are particularly sensitive to H₂O₂-induced cell death.¹⁰

Molecular targets of ROS production and activity are principally proteins, lipids, and DNA and it is now well documented that such ROS-inflicted damage and its functional consequences increases with age. Peroxidative chain reactions of lipids eventually yield unsaturated aldehydes, which are highly reactive, inactivating enzymes, damaging DNA, and reacting with proteins to form cross-links. Evidence that lipid peroxidation increases with age is provided by the increase in the amount of lipofuscin (age pigment) in aged cells, representing a visible biomarker of aging. The most important consequence of lipid peroxidation is to decrease plasma membrane fluidity, thereby altering membrane properties and affecting membrane bound proteins. This will tend to have deleterious effects on the proper functioning of ion pumps and channels, receptors and/or their subunits and transmembrane molecules, such as integrins and other adhesion proteins by which cells interact with the extracellular environment. It may be significant that there is a correlation between the higher content of oxidation-resistant phospholipids in the plasma¹¹ and mitochondrial¹² membranes with greatly increased longevity in certain rodent species. A more widespread consequence of the oxidation of low-density lipoproteins at a cellular level is the formation and buildup of atherosclerotic plaque in the arterial system. ROS damage proteins by oxidizing individual amino acids, resulting in the induction of protein-protein cross-links and changing the conformation of proteins such that their function is impaired. Conformational changes of proteins with aging include those of structural proteins affecting cell shape or functions (such as axoplasmic transport in neurons), specific activities, and efficiencies of enzymes and membrane-bounded receptors. Proteins—such as myosin, creatine kinase, and ATPases, which are high in -SH groups—are particularly susceptible to oxidation by ROS as is the conversion of histidine residues to asparagine on account of the proximity of histidine residues to metal-binding sites of proteins. It should not be forgotten that age-associated damage as a result of ROS also causes cross-linking in extracellular proteins such as collagen. Nucleic acids are particularly vulnerable to damage by ROS, in particular by the superoxide radical, which can attack individual bases and sugars and cause several variants of DNA strand breaks and alterations that have mutagenic potential (see later discussion). Estimations of the amount of ROS-induced DNA damage can be made by assaying levels of the DNA oxidation product 8-hydroxydeoxyguanosine (8-OHdG), which has been shown to increase with aging. In relation to this, levels of DNA repair glycosylases such as those specific for 8-OHdG are positively correlated with longevity. DNA, however, possesses a wealth of repair mechanisms (see later discussion) that constantly attempt to repair ROS-induced damage.

In summary, the constant generation of ROS leads to molecular damage, which will cause damage to subcellular organelles leading to dysfunction at the cellular level and eventually to cell death. Together with ROS-induced damage to extracellular molecules, tissue and organ damage will eventually occur. As ROS generation commences with the formation of a zygote, it could be argued that cellular aging begins at conception! It is important to note that ROS can induce apoptosis in cells or activate nuclear transcription factors leading to the upregulation of death proteins or inhibition of survival proteins as part of the turnover of cells

during the course of life. ROS-induced cell damage or death is implicated in a wide spectrum of age-related disorders, particularly of the nervous and musculoskeletal systems. The effects of ROS-induced damage on the life span has been demonstrated in wild-type and short-lived mutants of the nematode *Caenorhabditis elegans*, which can be extended by less than 50% after treatment with a synthetic antioxidant ROS scavenger.¹³

The damaging effects of ROS can be counteracted by antioxidants, which either occur endogenously or can be supplied exogenously. Antioxidants act by combining with ROS, thereby inactivating them and breaking ROS chain reactions. The cellular antioxidant capacity is, however, not 100% efficient. Naturally occurring, endogenous antioxidants vary in their concentrations from one cell type to another, between species and with age. Their concentrations do not necessarily decline with age because age-associated elevations of some antioxidants occur in organs such as the brain. The main endogenous antioxidants are enzymes such as (1) superoxide dismutase (SOD), which occurs in two forms—a mitochondrial form containing Mn^{2+} (MnSOD) and a cytoplasmic form containing Cu^{2+} and Zn^{2+} (CuZnSOD), which converts superoxide anions into H_2O_2 ; (2) catalase, which converts H_2O_2 to molecular oxygen and water; and (3) GSH, which is a selenium (Se)-containing glycoprotein occurring in both the cytoplasm and in mitochondria (where it is imported from the cytoplasm) that also breaks down H_2O_2 . The antioxidant defense provided by GSH is most important for mitochondria and for other cytoplasmic components.

Certain micronutrients, such as vitamins C, E, and β -carotene, have long been regarded as potent antioxidants. Consequently, health promotion advice is constantly given for individuals to eat plenty of prunes, blueberries, spinach, strawberries, and hazelnuts to boost vitamin E intake because it is the most abundant fat soluble antioxidant. Similarly intake of fruits with high vitamin C levels is highly recommended. More recently α -lipoic acid, which inactivates hydroxyl and superoxide radicals and is claimed to protect both lipoproteins and membranes, unlike other antioxidants.¹⁴ α -Lipoic acid is involved in carbohydrate metabolism. It is easily reduced to dihydrolipoic acid, which stabilizes peroxy and peroxy nitrite radicals. Both α -lipoic acid and dihydrolipoic acid regenerate by redox cycling other antioxidants, such as vitamins C and E, and increase intracellular glutathione levels, making it theoretically the perfect antioxidant. However, as endogenous levels are low, dietary supplementation is required and this has proved an effective antioxidant strategy.^{15,16} The list of antioxidants is constantly increasing: β -carotene and lycopene, reddish plant pigments present in red fruit and vegetables, are also potent antioxidants; estrogens are antioxidants that have protective effects on the nervous system; curcumin oil, which is extracted from turmeric, induces the enzyme hemoxygenase (HO-1), which is a potent antioxidant.

When there is a shortfall in the levels of the naturally occurring antioxidants or an increase in the production of ROS, a state of "oxidative stress" can occur in which permanent damage to proteins, lipids, and DNA results. Aged cells, particularly those exposed to UV light, show increased ROS generation and an increased tendency toward oxidative stress as judged by increased amounts of protein, lipid, and

DNA damage.¹⁷ The cellular response to a state of oxidative stress can be summarized as: (1) an increase in the expression of antioxidant enzymes; (2) increased expression of genes encoding chaperones (heat shock proteins); (3) expression of immediate early genes (such as cFOS); (4) increased expression of genes encoding DNA repair enzymes; and (5) increased expression of genes encoding apoptosis-related proteins. Aged cells are less able to respond in these ways and consequently have a reduced potential for antioxidant capabilities and therefore in their ability to repair ROS-induced damage. Thus the effects that ROS production on a wide range of genes whose expression is vital for normal cell function and survival is now considered to be an important factor in determining longevity.¹⁸

Intracellular calcium homeostasis

The intracellular concentration of free calcium (Ca^{2+}) is instrumental in many processes of normal cellular activity and can be responsible for dysfunctional changes in cell function. The regulation of the passage of Ca^{2+} into a cell and throughout the cytoplasm has to be strictly regulated for normal cellular activity to continue. In aging cells, Ca^{2+} homeostasis involves many different mechanisms including calcium channels, pumps, transporters, and intracellular buffers and binding proteins; one or more of these mechanisms may be disrupted with potentially fatal consequences.^{19,20,21} Ca^{2+} homeostasis has been extensively studied in mammalian neurons where it is intimately involved in neuron-specific activities such as the synaptic release of neurotransmitters and the regulation of genes encoding cytoskeletal elements essential for the elaborate morphology of neurons and the conduction of action potentials.

Extracellular Ca^{2+} levels are approximately 2 mM, whereas intracellular Ca^{2+} levels are 100 nM. Voltage operated Ca^{2+} channels (VOCCs) and nonspecific cationic channels are the key types of channels involved in the influx of extracellular Ca^{2+} . Of the six known VOCCs, the L-type VOCC is the main channel involved in events associated with aging and neurodegeneration. The very low intracellular Ca^{2+} levels are maintained by uptake into smooth endoplasmic reticulum (SER) involving Ca^{2+} ATPase activity, into mitochondria through the activity of Ca^{2+} uniporters and by Ca^{2+} binding proteins and Ca^{2+} ATPases in the plasma membrane. Additionally the endoplasmic reticulum is involved in the release of Ca^{2+} via the inositol 1,4,5-triphosphate pathway or through ryanodine receptors. If intracellular Ca^{2+} is elevated it can cause cytotoxic cell death, particularly if the cell is hypoxic. This is a common feature of all cell types but neurons are more vulnerable to this as many CNS neurons have nonspecific cationic channels, such as NMDA (*N*-methyl D aspartate) and AMPA ligand-gated glutamate receptors in their plasma membranes, which promote the influx of Ca^{2+} into the neuronal cytoplasm. Age-associated ROS damage to plasma membranes, ion pumps, and channels, coupled with altered gene expression for receptor and channel subunits, will all contribute to the challenge of maintaining low intracellular Ca^{2+} levels.

Increased intracellular Ca^{2+} leads to increased ROS generation and to the activation of the calmodulin-dependent enzyme nitric oxide synthase (NOS). NO interacts with the superoxide radical to produce peroxy nitrite. Peroxy nitrite levels therefore increase intracellularly and it

diffuses rapidly to other neurons and causes cell damage by oxidizing lipids, proteins, and DNA (i.e., it is highly and rapidly cytotoxic). In astrocytes, age-associated depletion of glutathione in mitochondria greatly increases the sensitivity of astrocytes to peroxynitrite. It is critical for a cell to maintain and control a submicromolar Ca^{2+} level since the level of Ca^{2+} has important roles in many physiologic processes, controlling for example hormone secretion, ion channel activity, enzyme activity, assembly of the cytoskeleton, and also in the expression of many of the genes involved in these processes.²² The regulation and/or restoration of Ca^{2+} levels is energetically demanding for a neuron because it is a highly ATP-dependent process. ROS damage to mitochondria results in a disruption of oxidative phosphorylation and in consequence reduced ATP production, which is likely to be the underlying source of perturbed Ca^{2+} regulation. With increased age there is a decrease in the mitochondrial membrane potential, which results in Ca^{2+} leaking out into the cytoplasm. Recently it has been confirmed in peripheral neurons that, with increasing age, the ability of the SER to take up Ca^{2+} decreases.²³ This can be demonstrated by depleting Ca^{2+} stores with caffeine and then measuring the reuptake by the SER. Ca^{2+} flow in and out of the SER is mediated by ryanodine receptors and, with age, the expression and numbers of these receptors is reduced.²³

Decreases in intracellular calcium binding proteins (CBP)—such as calbindin-D28k, calretinin, and parvalbumin, which regulate the amount of calcium free in the cytoplasm—may also contribute age-associated changes in intracellular Ca^{2+} concentrations in neurons. There is much variation in the age-associated changes in CBPs in differing parts of the CNS: their levels are unchanged in the cerebellum but reduced in the hippocampus, retina, and in lower motor neurons. Changes such as these have been implicated in motor neuron disease where neuron death has been linked to disruption of intraneuronal Ca^{2+} buffering. In the peripheral nervous system, there are striking differences in the effects of age on CBPs in postganglionic neurons. Many, but not all, sympathetic but not parasympathetic ganglionic neurons contain calbindin-D28k and the number of neurons containing calbindin falls by 50% in aged rats. On the other hand, all neurons of the rat major pelvic ganglion contain neurocalcin and there is an equal decrease in neurocalcin-positive neurons in both the sympathetic and parasympathetic neuron populations of this ganglion in old age.²⁴

CELL SENESCENCE

Cultured cells normally only divide a limited number of times after which they enter a growth-arrested state called replicative senescence.²⁵ They do not produce any new DNA by replication but they do not die, remaining metabolically active *in vitro* for several months. Human diploid fibroblasts taken from a 40-year-old and cultured *in vitro* cease dividing after about 40 mitotic divisions, but those taken from an 80-year-old can only manage about 30 mitoses. The phenomenon of adult cells undergoing fewer mitotic divisions than cells from younger donors, originally described by Leonard Hayflick,²⁶ has given rise to the concept of the Hayflick limit and has been reported in human cells taken from a wide variety of tissues.²⁷ It is also well documented

that cultured cells from short-lived species enter replicative senescence after fewer mitotic divisions than cells from longer-lived species, suggesting that replicative senescence is an indicator of longevity. But how may replicative senescence contribute to human aging? There are two possibilities: either on account of a cell's exhaustion of the capacity to divide or altered cell biology. Many organs, such as skin, the intestinal lining, the liver, the immune system, and hair follicles, rely on cell division for day-to-day functioning to replace naturally occurring cell loss. In such instances a decrease in cell division will have a serious impact on the proper functioning of the organ in question. Also, some tissues retain the ability for cell division in response to damage or cell loss (a burst of cell division is a major feature of wound healing); however, lower rates of wound healing is a feature of elderly humans. The effects of replicative senescence on cell biology may be manifested by differing patterns of post-mitotic gene expression, which is often represented by an overexpression of proteins (e.g., aged human dermal fibroblasts increase their production of collagenase, which leads to the breakdown of the extracellular matrix [ECM] which damages the skin contributing to formation of the wrinkles seen with increasing age).

In vitro experiments have proven very productive in aging research but *in vivo* experiments present a greater challenge in detecting and evaluating age-associated cellular changes, particularly in a very long-lived species such as man. In consequence a significant proportion of aging research is conducted on short-lived species such as the fruit fly *Drosophila melanogaster* and the nematode *Caenorhabditis elegans*. However, there is a marker for human senescent fibroblasts—an abnormal form of the enzyme galactosidase—that is expressed late in a cell's life called senescence-associated β -galactosidase (SA- β -gal), which is a lysosomal enzyme.²⁸ Detecting SA- β -gal by histochemistry²⁹ has demonstrated that there are almost no senescent skin cells in people in their thirties but those in their 70s have clusters of SA- β -gal-positive cells in the dermis and epidermis. Senescent cells are, in addition, characterized by the production of high levels of ROS and consequent DNA damage,³⁰ increased levels of p53 tumor suppressor protein in response to DNA damage and high content of lipofuscin (age pigment). Senescent cells are generally harmful to an organism: senescent skin cells produce increased amounts of collagenase (metalloproteinase) as mentioned above and less TIMPS (tissue inhibitors of metalloproteinases) and other ECM degrading proteases, and senescent endothelial cells produce the cytokine interleukin-1 α , which causes inflammation. Perhaps the most significant factor associated with dysfunctional senescent cells is that they increase in number with aging, possibly contributing to the greater incidence of tumors in the elderly.

What is the cellular mechanism that stops cells from dividing so that they enter the nondividing state of replicative senescence? A possible solution is the existence of one or more mutated genes that prevent mitosis from taking place and interrupting the cell cycle, perhaps by suppressing genes responsible for the synthesis of certain growth factors. Alternatively or additionally, ROS-induced metabolic changes that influence the synthesis or adversely affect critical signaling molecules and the inability of aged cells to activate antioxidant defense mechanisms may well be

contributory factors. Most interest has, however, focused on telomeres, the repeat sequence DNA terminal regions of chromosomes that gradually shorten with successive mitotic divisions.

Telomeres and telomerase

Telomeres are nucleoprotein complexes that contain hexanucleotide repeat sequences of DNA at each end of a chromosome. They are required for successful replication of chromosomes during mitosis because they maintain chromosome length and protect chromosomes against damage. Telomeres are made up of tandem repeats of the bases TTAGGG whose nucleotides are complexed with specific telomere repeat-binding factors and another enzyme called tankyrase to form a cap at the end of the chromosome. The hexanucleotide repeats are added to the ends of the chromosomes by an enzyme called telomerase, which uses an RNA template and a reverse transcriptase (TERT) in contrast to the normal DNA polymerase. Thus telomeres are not replicated in the same way as the rest of the chromosomal DNA. Telomere replication is not as accurate as true DNA replication and the number of repeats in the telomeric DNA will decrease over time. Telomere length is also aided by a repair (recombination) protein called RAD51D (normally associated with the repair of double strand breaks in DNA) but this mechanism acts independently of telomerase. Cell senescence is associated with the gradual reduction in the number of TTAGGG repeats as cells continue to divide and the telomeres become so shortened and worn that eventually the chromosomes lose their ability to replicate and the DNA is thus at risk of being damaged by not being replicated. However, the gene which codes for the synthesis of telomerase at the same time helps to prevent the telomeres from shortening. In most cell types in man, this gene is rarely switched on to produce the enzyme. Therefore the cells become deficient in telomerase and gradually lose their ability to divide (i.e., they enter the state of replicative senescence). It was first demonstrated by Harley³¹ that the telomeres in human cultured fibroblasts become shorter as a function of age, and from this arose the idea that measurement of shortening telomeres represented a "biologic clock" ticking away on a cell's journey toward replicative senescence. Oxidative stress has been shown to speed up telomere shortening as telomeric DNA is less well repaired than the remainder of the nuclear DNA.³² The part of the telomerase enzyme that actually synthesizes the TTAGGG repeats is called TERT. Is it possible to insert the TERT telomerase gene by gene therapy so that the telomeres do not shorten and cells never enter the senescent state? This cellular immortalization has been attempted on cultures of skin fibroblasts from Werner's syndrome (progeroid) patients and on adult smooth muscle cells with success. Moreover, such immortalized cells have not shown any changes indicating that they have developed a cancer cell phenotype. Telomere shortening is not a characteristic of all cell types. In germ cells, cell division continues for decades and the telomeres never shrink because the telomerase gene is always active and the telomeres are constantly being replaced/synthesized. Germ cells can therefore be regarded as having been immortalized. Also the immune system relies on the constant and rapid production of T and B cells for which maintenance of telomeres is

absolutely vital. It is thought that T-cell aging, combined with telomere shortening, may lead to increases in autoimmune responses and explain the increased susceptibility to inflammatory diseases in the elderly. In certain very active tumor cells, the telomerase gene is switched on and consequently the cells' ability to divide is maintained and tumors continue to grow. Cells with artificially lengthened telomeres live longer in culture and there are DNA-like molecules that make cancer cells grow much longer telomeres, thereby doubling their life span and potentially slowing down the rate of growth of tumors.

The contribution of telomere shortening to the other factors previously mentioned as leading cells into the state of replicative senescence clearly indicates that this is a very complex cellular process in aged cells. In view of the increased numbers of senescent cells with increasing age, Von Zglinicki³² suggested that "telomeres act as cellular 'sentinels' for genomic damage and remove 'dangerous' cells from further proliferation." Whether this anthropomorphic idea is correct or not, there is no doubt that the genome is at great risk on account of telomere shortening and that it will have a profound effect on the proper functioning of the aging cell.

Genomic instability DNA MUTATIONS

The declining force of natural selection in postreproductive life applies to senescent cells (i.e., as there are no further meiotic cell divisions, the opportunity for beneficial gene mutations for passing on to successive generations to occur has passed). On the other hand senescent cells may generate deleterious DNA mutations that, unlike DNA damage, are irreversible and may cause cellular or metabolic damage likely to decrease longevity. Using the mouse lacZ reporter gene, it has been possible to quantify point and rearrangement DNA mutations³³ in the heart and liver of young and aged mice where approximately threefold increases in mutation frequency occurred with age. The increase in the mutation frequency in the aged small intestine was even higher.

GENE REPRESSION

Gene repression is the switching off of individual genes whose products are needed to maintain the function of the cell such as the production of vital enzymes or cofactors. This is especially important if the products of such genes are not long-lived and deteriorate, or are metabolized. Unless these products can be supplied in the diet, the decrease in concentration will inhibit functioning dependent on a particular gene product. In senescent human fibroblasts, there is a range of genes that are repressed or underexpressed. The genes include, among others, those involved in signaling pathways, transcription factors, heat shock proteins, TIMPS, cytokines, and DNA polymerases. Gene repression is distinct from gene silencing where regions of chromosomal DNA become transcriptionally inactive on account of the tight wrapping of the histone proteins that prevent access to DNA polymerases, which would normally align the nucleotides into a new nucleic acid chain. In yeasts, aging may be regulated by DNA silencing³⁴ that is undertaken by several "silent information regulator" (Sir) proteins or sirtuins—the evolutionarily conserved lysine deacetylase Sir2 together

with its partner proteins Sir3 and Sir4. In mammals the number of sirtuins increases to seven, indicating a more complex process of DNA silencing.

GENE OVEREXPRESSION

Gene overexpression is the switching on of genes in aging cells. Most of these have been demonstrated in senescent human fibroblasts and are functionally associated with the degradation of the ECM and the production of cytokines (i.e., these are deleterious functions that will lead to tissue damage). Gene dysregulation, where regions of chromosomes are activated inappropriately leading to the dysfunctional expression of certain genes, may be a contributory factor in age-associated gene overexpression. The use of high-density oligonucleotide microarrays provides a powerful method to visualize gene-expression profiles in tissues. This methodology has been used to investigate age-associated changes of thousands of genes simultaneously. Among many tissues examined, the gene-expression profile in aged mouse skeletal muscle was generally indicative of a lower expression of metabolic and biosynthetic genes.³⁵ In the neocortex and cerebellum of aged mice, the gene-expression profile indicated inflammatory responses, oxidative stress, and a reduction of neurotrophic support,³⁶ very similar to that seen in neurodegenerative diseases of the human brain. In a large study on the human frontal cortex in brains from individuals ranging in age from 26 to 106 years,³⁷ transcriptional profiling indicated downregulation of genes involved in synaptic transmission, Ca²⁺ homeostasis, signaling pathways, and mitochondrial function among others. Among the genes that are upregulated in this study were those involved with stress responses, antioxidant defenses, and DNA repair. These results raise the following questions: why is it that certain genes are selectively vulnerable to aging, what controls this vulnerability, and to what extent can the compensatory upregulation of defensive/repair gene activity be effective?

The effects of dietary (caloric) restriction on aging cells is normally associated with reduced metabolic rate and a decrease in the amount of ROS produced. However, dietary restriction has been shown to have distinct effects on gene expression that are beneficial to mice. Lee et al³⁶ and Weindruch et al³⁵ demonstrated that more than 100 genes were switched on as mice aged—many being genes that are activated when cells are damaged but in mice that had been fed a low calorie (but vitamin and protein supplemented) diet, less than a third of these genes were switched on, supporting the theory that dietary restriction is beneficial at the level of the genome.

GENOMIC DNA DAMAGE

Genomic or nuclear DNA is a highly complex and inherently unstable molecule and is susceptible to damaging agents, such as UV, ROS, and environmental chemicals. As the basis for the genome, it is a prerequisite that DNA is absolutely stable and perfectly aligned to ensure accurate replication, transcription, and minimalization of mutations. DNA strand breaks, which may occur spontaneously, are very prone to recombination and fusion with other chromosomes, thereby disrupting part of the genome. Thus DNA requires constant maintenance to repair the damage that occurs spontaneously and frequently. DNA is the only molecule in cells that is actively scanned to detect errors in synthesis and for DNA damage for which a multiplicity of repair mechanisms exists.

If the repair mechanisms fail, then a mutation is more likely to occur and because of that potential threat, it is clear that the stability of the genome depends on DNA repair. Some of the changes in DNA structure that can be induced by ROS UV radiation (mainly hydroxyl radicals) can be listed as follows:

1. Point mutations (base deletion or substitution). The most common is the oxidation of guanine to 8-oxoguanine, which pairs with adenine rather than cytosine.
2. Translocation or transposition of a segment of DNA from one chromosome to another
3. Inversions — removal of a DNA segment and its reinsertion in reverse order
4. Double-stranded DNA breaks resulting in fragmented chromosomes
5. Insertion of nonchromosomal (usually viral) DNA
6. Deletion of whole genes
7. Single-stranded DNA breaks will interfere with gene transcription during replication

Among the DNA protective mechanisms, GSH is present in the nucleus and is important in protecting not only DNA from ROS attack but also the nuclear membrane itself. Specific repair of oxidative damage of DNA by enzymes is now evident. In the human genome, there are 130 DNA repair genes which are classified as follows:

1. Base excision repair genes which encode for enzymes that excise and replace damaged DNA purines and pyrimidines. Specific enzymes such as glycosylases recognize damaged or deficient C, G, T, and A bases and remove them. DNA repair polymerases and DNA ligases, normally involved in DNA replication, resynthesize a new strand using the undamaged one as a template. This is similar to DNA "proofreading," which is a very energy-demanding process that slows down replication but one that has evolved over time; nevertheless it is not a 100% perfect mechanism. One of the unsolved mysteries of this process is how the glycosylases detect damaged bases that are located deep within the DNA helix.
2. Nucleotide excision repair genes express enzymes that excise a series of adjacent nucleotides of a particular sequence.
3. Mismatch repair genes can rectify errors of DNA replication and recombination. Some enzymes are specialized for distinct types of mismatch.
4. Double-stranded breaks can be repaired by genes that encode proteins that are involved in strand pairing during recombination such as RAD51D, which is also involved in protecting telomeres.
5. Translesional DNA repair deals with damaged bases that impede the progression of a replicating DNA polymerase.

With regard to DNA repair in the aging cell, there is good evidence (by 8-OHdG measurement) that DNA damage is increased, that long-lived species have more efficient DNA repair mechanisms than short-lived ones, and that aged cells are less efficient at DNA repair. In general the machinery for selective gene expression, determined by chromosomal DNA, leading to the normal phenotype, changes little during life thanks to DNA repair.

MITOCHONDRIAL DNA

Mitochondrial DNA (mtDNA), attached to the inner mitochondrial membrane, codes for 13 of the 60 polypeptides of the mitochondrial respiratory complexes and is therefore an integral part of mitochondrial function. It is much more easily damaged than nuclear DNA due to its proximity to ROS production from oxidative phosphorylation and the fact that it is naked, lacking the protection of histone proteins. It is likely that the components of the electron transport chain most susceptible to ROS are Complex I (NADH ubiquinone reductase) and Complex IV (cytochrome oxidase). However, a beneficial effect of this location is that confining oxidative phosphorylation to mitochondria may reduce mitochondria-derived ROS from gaining access to the cytoplasm, entering the nucleus, and damaging nuclear DNA. Unlike nuclear DNA, mtDNA lacks repair mechanisms but mitochondria have their own antioxidant defenses, including GSH and MnSOD, both of which decrease in content in aging⁶ as does total mtDNA content in a variety of tissues.^{38,39} Consequently, 10 to 20 times more mtDNA bases are modified or deleted by ROS in aging compared with nuclear DNA, resulting in a reduction of mitochondrial transcripts and proteins derived from mtDNA. Levels of 8-OHdG are higher in mtDNA than in nuclear DNA. Because 8-OHdG is mutagenic, mtDNA mutations increase with age, and it is likely that this may be a factor contributing to the determination of life span⁴⁰ and rate of aging.⁴¹ The rates of mitochondrial ROS production and accumulation of mtDNA mutations are higher in short-lived as opposed to long-lived mammals.

PROTEIN SYNTHESIS AND DEGRADATION

Cellular proteins are in a constant state of turnover involving synthesis and degradation, with individual proteins having half-lives that vary from a few minutes to several days. Overall there is a general reduction in protein synthesis and content in aging, but this masks the fact that synthesis of some proteins decreases, for others it remains static, and for other proteins, levels of synthesis increase with age. Also levels of protein synthesis vary with aging from one tissue to another and between species. Age-associated levels of proteins may not only relate to levels of synthesis but to malfunctioning of the mechanisms for protein breakdown. Proteins are integral to all aspects of cell function as they interact with all other macromolecules and are required for every aspect of cellular maintenance and repair. The integrity of the cytoskeleton, vital for giving a cell its shape and for processes such as axoplasmic transport, is also dependent on proper protein turnover. Many proteins that are not turned over rapidly undergo posttranslational modifications, such as phosphorylation, oxidation, glycation, or methylation; such altered proteins, which tend to accumulate in the cytoplasm with age, are implicated as the cellular basis of a range of pathologic conditions.

Although there is only one process for protein synthesis, there are multiple subcellular processes for the degradation of proteins. Protein degradation is a highly complex and tightly regulated process that plays major roles in a variety of basic cellular processes during the life and death of cells, and hence in both health and disease. The two main pathways are the lysosomal pathway and the ubiquitin-proteasomal

pathway. A third proteolytic mechanism, however, exists involving the calpains (calcium dependent neutral proteases). The lysosomal pathway is mainly an indiscriminate cellular pathway for proteolysis that contributes to the general maintenance of a cell, resulting eventually in the formation of lipofuscin (age pigment), which tends to accumulate in cells with age. Lipofuscin is formed by ROS-induced oxidation of macromolecules derived from subcellular organelles. Some cell types are particularly prone to lipofuscin accumulation with aging, of which cardiac myocytes are a prime example in which almost a fifth of the cell volume may become occupied by lipofuscin in old age. Although regarded as being chemically inert, the disruptive effect on efficient contraction of the myofibrils may well contribute to myocardial dysfunction in old age. The accumulation of lipofuscin with age can be reduced by the antioxidant vitamin E, thus implicating ROS in lipofuscin formation. The efficiency of the lysosomal pathway declines with age as the binding of macromolecular targets to the lysosomal membranes and their transport into the lysosome becomes less effective^{42,43} and there is leakage of certain lysosomal enzymes into the cytoplasm.⁴⁴

In the ubiquitin-proteasome pathway, proteins are first covalently tagged by ubiquitins, which are small (76 amino-acid) proteins that control the system responsible for degradation of proteins. The ubiquitinated protein can then be recognized by a 26S proteasome complex (of a 20S proteasome and a 19S cap). These are barrel-shaped, widely distributed cytosolic organelles that act effectively as a protease complex into which tagged proteins pass. The proteins have to unfold themselves as far as possible to enter the pore of the proteasome after which the ubiquitins are recycled. Proteasomes are large complexes of proteolytic enzymes that have three main types of proteolytic activity: chymotrypsin-like, trypsin-like, and caspase-like activity. The degraded proteins (i.e., amino acids or small peptides) can then be recycled. During aging, proteasomal function becomes impaired, with chymotrypsin-like activity in particular decreasing, but that of catalase-like activity not declining.

The third proteolytic pathway—the calpains (calcium dependent neutral proteases), which are ATP- and Ca²⁺-dependent—have specific substrates in both the cytoplasm and the nucleus. In the event of oxidative stress-induced elevations of intracellular Ca²⁺ concentrations, the amount of DNA damage and repair, as indicated by reduced levels of 8-OHdG, implicates calpain-mediated degradation.⁴⁵ Given the trend toward increased oxidative stress and consequent perturbations of intracellular Ca²⁺ homeostasis in aging, the proteolytic involvement of calpains, which are very widespread, is also likely to be revealed as a major contributor. That there is an overall decrease with age in proteolytic activity is not disputed but the exact contribution made by the different pathways for protein degradation has yet to be resolved. Nevertheless the age-associated (and pathologic) aggregation of and cytoplasmic accumulation of oxidized or otherwise transformed proteins is not in doubt.

The tertiary structure of large protein molecules is achieved not by "self-assembly" because linkages between certain surfaces or polypeptide chains are necessary to attain the correct molecular configuration. Assistance in the noncovalent folding of polypeptide chains is supplied by molecular chaperones. Heat shock proteins (HSPs) are a group of such proteins that bind to such surfaces during assembly of large molecules

and prevent the occurrence of incorrect union/interactions between parts/surfaces of the molecules. Many molecular chaperones are also HSPs, in that they are proteins expressed in response to raised temperatures or other cellular stressors,⁴⁶ but are not expressed when cells are performing their normal biologic functions. A major function of chaperones is to prevent newly assembled polypeptide chains from aggregating into nonfunctional structures such as protein aggregates that characterize some neurodegenerative diseases.⁴⁷ Chaperones also help in restoring correct conformation if a large protein becomes distorted during a biosynthetic process such as protein synthesis or during passage through a narrow membrane channel or pore. Chaperones are also involved in the constant removal and replacement of damaged proteins that occurs during the continual remodeling of cell structure by protein turnover. As proteins are turned over rapidly, the continued expression of chaperones is vital for normal cellular functioning. Chaperone expression is induced by stress such as a decrease in temperature, which reveals the need for chaperone production to cope with intracellular damage. When not required, chaperone expression decreases.

In aging cells ROS-induced DNA damages genes encoded to produce chaperones. Reduced levels of HSP expression occur in aged cells such as fibroblasts, which have lower expression of Hsp70—a collagen-specific chaperone—and also of Hsp90, which is required for the assembly and functioning of telomeres.⁴⁸ Chaperone-mediated autophagy (CMA) is a selective pathway for the degradation of damaged proteins in lysosomes. The processes whereby the proteins are targeted by the lysosome and cross the lysosomal membrane are aided by chaperones, can be induced by oxidative stress, and are adversely affected by aging.^{49,50} The importance of molecular chaperones in cellular aging is indicated by the extension of life span that has been demonstrated in mice, *C. elegans*, and in *Drosophila* by the overexpression of chaperones or by the reduction in life span following inhibition of HSP translation and expression.⁴⁸

SIGNALING PATHWAYS

Cells interact with their environment and respond to changing environmental conditions. Most stimuli are chemical ligands that bind to receptors in the plasma membrane but a much smaller number of stimuli, such as gases and steroid hormones, cross the plasma membrane and interact with intracellular receptors. Activation of a receptor by the bound ligand transduces the stimulus into an intracellular chemical signal, which can act as a messenger. The messenger molecule usually amplifies the signal and in turn activates some form of effector system for the cell to make the appropriate response to the initial stimulus. This process is known as a signaling pathway or signal transduction pathway. As most of the molecules involved in signaling pathways are proteins and the biology of proteins is adversely affected by many factors associated with cellular and molecular aging, such as ROS, DNA damage, gene expression, mRNA translation, and Ca^{2+} levels, it is to be expected that signaling pathways will also be affected in aging. Two of the most significant signaling pathways that have been shown to be involved in aging are the:

1. Insulin/IGF-1 pathway. This pathway is involved in the regulation of life span and is evolutionarily

conserved.⁵¹ Reduced receptor and PI3 kinase function impair insulin/IGF-1 signaling, resulting in a dramatically extended life span.⁵²

2. Target of rapamycin (TOR) pathway. The TOR nutrient sensing pathway is an important regulator of cell growth, development, and aging, which interacts with processes such as transcription, mRNA translation protein turnover, and cytoskeletal organization.⁵³ TOR signaling generally conserves cellular energy, which can be diverted to cellular maintenance and repair mechanisms that will be beneficial to aging cells.

EXTRACELLULAR MATRIX

The interaction between cells and their immediate environment can be vital for their survival. Integrins, for example, are transmembrane molecules that are attached directly to the ECM and crucial to the cell's survival. Other molecules of the ECM are involved in relaying signals from cytokines or growth factors to receptors in the plasma membrane. There is some evidence for alterations in membrane properties and in the number and type of receptors with age. The process of glycation is a factor that causes changes in large proteins, such as collagen, with increasing age and in certain progressive diseases of aging—such as atherosclerosis, joint stiffness, arthritis, urinary incontinence, and congestive heart failure. Essentially, blood sugars chemically bond to proteins and DNA. Over time they become chemically modified to form advanced glycation end products (AGEs). AGEs interfere with the proper functioning of proteins and some form covalent cross-links with adjacent protein strands in the case of collagen and elastin. The mechanical result is that formerly flexible or elastic tissues become stiff. Also the chemical changes due to glycation and cross-linking can initiate harmful inflammatory and autoimmune responses. In addition, one of the effects of mechanical stress or inflammation on chondrocytes is to induce the production of ROS and as chondrocytes are isolated from one another in cartilage, they cannot be replaced and cartilage will degenerate.

KEY POINTS

Cellular aging is characterized by:

- The generation of reactive oxygen species (ROS)
- Damage to molecules and organelles by ROS
- Variably effective cellular antioxidant defense mechanisms
- Dysregulation of intracellular calcium homeostasis
- Alterations in telomere structure and telomerase expression
- Genomic DNA damage affecting gene expression
- Mitochondrial DNA damage affecting ATP production
- Alterations in protein synthesis and degradation
- Alterations in molecular chaperone activity
- Alterations in signaling pathways
- Alterations in cellular relations with the extracellular matrix

CONCLUSION

The cellular mechanisms of aging described above may provide a convincing account of the cellular processes that determine the length of survival and fate of a cell as individuals grow older. Accumulated molecular and cellular damage by UV, ROS, Ca^{2+} , and changes in genomic function can be demonstrated in aging cells. However, some of the scientific literature of the twenty-first century questions whether theories of aging such as accumulated oxidative damage are universally applicable across the animal kingdom.⁵⁴ Clearly these complex theories of aging at a cellular level are far

from being completely understood. Another emerging realization is the close connection between perceived cellular mechanisms of aging with those underlying the development of cancer, for which increasing age is the largest risk factor.⁵⁵ This realization should, ideally, focus the minds of investigators in both fields in their quest for complete understanding of the mechanisms underlying these two critically important cellular processes.

When broadly defined, aging refers to all time-associated events that occur during the life span of an organism. During this time, many changes occur in the physiologic processes. These changes may be beneficial, neutral, or deteriorative. During the developmental period of life, most changes are due to the maturation of the physiologic processes and tend to be beneficial. However, during the postmaturational period of life, most changes are detrimental, although some may be neutral, such as the graying of the hair. Indeed, the term “senescence” is used to specifically denote this postmaturational deterioration. Senescence is defined as the deteriorative changes with time during postmaturational life that underlie an increasing vulnerability to challenges, thereby decreasing the ability of the organism to survive. Although senescence is a subset of aging, in common usage, aging is often used to only mean senescence. Unfortunately, this specialized meaning is usually not explicitly stated. In this chapter, aging and senescence will be used as synonyms, a usage particularly appropriate in a textbook of geriatric medicine.

This brief chapter can cover only concepts and provide a limited number of examples. Section 11 of the *Handbook of Physiology* series published by the American Physiological Society is dedicated to the physiology of aging.¹ That volume provides in-depth coverage of most age changes in the physiologic systems and should be consulted by readers who desire further information in a particular subject area.

PHYSIOLOGIC DETERIORATION AND THE AGING PHENOTYPE

A major characteristic of the aging phenotype is the deterioration of the physiologic processes exemplified by comparing elderly people with young adults. Indeed, physiologic deterioration plays an important role in the age-associated increase in the age-specific mortality rate. Thus, knowledge of the age changes in the physiologic systems is invaluable for both the geriatric physician tending elderly patients and the biologic gerontologist in the quest for an understanding of the biologic nature of aging.

Causes of age-associated physiologic deterioration

The progressive deterioration with age of the physiologic systems that starts during young adulthood is caused by the many damaging processes and agents that organisms encounter during life. Apparently, repair systems during postmaturational life are not able to fully eliminate the damage. The result is a progressive functional inadequacy of the physiologic systems due to the accumulation of damage. The extent of this functional inadequacy and its rate of occurrence vary among species and among individuals within a species, and among the physiologic systems of an individual. It is convenient to classify the damaging processes responsible for the age-associated physiologic deterioration in the following three categories: (1) damage resulting from intrinsic living processes, (2) damage caused by extrinsic factors, and (3) damage resulting from age-associated diseases.

DAMAGE RESULTING FROM INTRINSIC LIVING PROCESSES

Many of the processes essential to life also have damaging aspects. For example, aerobic metabolism, which enables organisms to readily generate metabolic energy from ingested nutrients, has the negative aspect of the generation of highly reactive compounds, such as superoxide radicals, hydroxyl radicals, and hydrogen peroxide because of the univalent reduction of oxygen. These oxygen-containing compounds are potentially highly damaging. Protection from, and repair of, damage due to these substances has evolved, but is not totally effective. Therefore, an accumulation of oxidative damage with increasing age occurs.² The extent of protection and the ability to repair damage varies among species. Thus, it is not surprising that there is interspecies variation in the rate of accumulation of oxidatively damaged macromolecules. Another example involves glucose, a most important fuel for most organisms. However, in addition to serving as an energy source, glucose also participates in the glycation and glycoxidation of proteins and nucleic acids and, in this way, alters their biologic functions.³ Again, there are protective mechanisms and processes that eliminate the damaged macromolecules, which vary in efficacy among species. Probably there is no intrinsic living process that does not also have the ability to cause damage.

DAMAGE CAUSED BY EXTRINSIC FACTORS

There is general agreement that extrinsic factors contribute to the aging phenotype. Despite this, many do not subscribe to the view that these extrinsic factors are part of the aging process. This view is based on long-held criteria for aging processes enumerated by Strehler⁴ in 1977. One of the criteria is “intrinsicity,” the view that aging is entirely an intrinsic phenomenon. Busse⁵ recognized the conceptual difficulty that this criterion caused and tried to resolve the problem by proposing the concept of primary and secondary aging. Primary aging was defined as universal changes occurring with age within a species or population, changes not caused by environment. Secondary aging was defined as changes as a result of the interactions of primary aging with disease processes and environmental factors. This concept may be faulty for two reasons. First, if aging results from progressive accumulation of unrepaired damage, it is irrelevant whether that damage originates from intrinsic processes or is caused by extrinsic agents. Second, extrinsic agents cause damage only because of interactions with biologic structures and processes. For example, it has been shown that the effect of genes on the life span and aging of *Drosophila melanogaster* is dependent on environmental interactions.⁶

In a sense, all damage is intrinsic whether it originates as a result of basic living processes or from reactions to extrinsic factors. However, this view downplays the importance of environmental factors that are not desirable because such factors can be modified and thus should be the focus of research on aging interventions.

Indeed, the notable effect that environmental factors can have on the aging process is particularly well illustrated by the

Figure 9-1. Survival curves for ad libitum-fed male F344 rats (group A, $n = 115$) and rats restricted to 60% of the mean ad libitum intake (group R, $n = 115$). (Reprinted with permission Yu BP, Masoro EJ, Murata I, et al. Life span study of SPF Fischer 334 male rats fed ad libitum or restricted diets: longevity, growth, lean body mass and disease. *J Gerontol* 1982;37:130–141, Fig 6.)

effects of long-term restriction of food intake by laboratory mice and rats.⁷ Restricting the food intake by 30% to 50% of that eaten by ad libitum-fed animals markedly increases longevity (see Figure 9-1 for its typical effect on population survival characteristics⁸), prevents or delays age-associated disease, and maintains a broad array of physiologic processes in a youthful state until very advanced ages. Examples of the scope of these beneficial effects include: immune function,⁹ cardiac function,¹⁰ female reproductive function,¹¹ and gene expression.¹² Indeed, reduction of food intake retards most, but not all, age-associated changes in physiologic processes of rats and mice that have been studied. It has been established that the reduction in energy (calorie) intake is the dietary factor responsible for this retardation of age changes in the physiologic systems.⁷ Thus, this phenomenon is often referred to as caloric restriction (CR). Although there is no evidence that CR during the adult life of humans would globally retard age-associated physiologic deterioration, it has been shown to influence the physiologic systems of non-human primates in a fashion similar to its effects on mice and rats.¹³ Moreover, there is evidence that CR influences the occurrence and progression of age-associated human disease processes,¹⁴ such as atherosclerosis,¹⁵ hypertension,¹⁵ and insulin resistance and impaired glucose tolerance.¹⁶

The lifestyle factor that has received the most attention relates to the fact that with increasing age many people become increasingly sedentary.¹⁷ Studies on the effect of exercise training in old human subjects indicate that some of the decline in physiologic function with advancing age in sedentary people is due to the effects of exercise deficiency and probably can, at least in part, be reversed by physical activity even at advanced ages.¹⁸ Skeletal muscle mass and strength decrease with increasing age,¹⁹ and both the mass and the strength can be increased by resistance training even at very advanced ages.²⁰ It is likely that the frequently occurring increase in body weight in people between the ages of 20 and 70 years is primarily the result of a sedentary lifestyle.²¹ Exercise has also been found to attenuate the age-associated increase in body fat content.²² Most importantly, exercise improves the distribution pattern of body fat in elderly men and women.²³ There is also evidence that exercise increases

insulin sensitivity and thereby alleviates insulin resistance and impaired glucose tolerance that commonly occur with advancing age.²⁴ There is little doubt that the increasingly sedentary lifestyle with advancing age contributes greatly to the deterioration of physiologic functions observed in old people.

There is no clear demarcation between lifestyle factors and personal habits. For example, exposure to the sun results in changes in skin structure and function,²⁵ referred to as photoaging by dermatologists and commonly viewed as a marker of aging by laypersons. Excessive sun exposure may be an inevitable consequence of the occupation of a person or of the climatic conditions of the geographic region in which the individual resides. If so, the effect of excessive skin sun exposure probably should be in the lifestyle category. However, recreational choice leading to excessive skin sun exposure such as sunbathing can be viewed either as lifestyle or as personal habit. A personal habit that has received much attention in regard to aging is cigarette smoking. It is established that aging of the skin is promoted by smoking.²⁶ Also, age-associated diseases that cause notable physiologic deterioration are promoted by smoking. Examples are chronic obstructive lung disease²⁷ and atherosclerosis.²⁸

Psychosocial factors such as engaging in social activities have been shown to significantly lower the age-specific mortality rate of people in the retirement age range.²⁹ Since this type of engagement has also been found to enhance the execution of activities of daily living (ADL), it is likely that it retards or reverses age-associated deterioration of the physiologic system. Indeed, there is clear evidence that social support retards age-associated decline in cognitive function.³⁰ Although these psychosocial findings are intriguing, remarkably little is known regarding the underlying biologic mechanisms. Indeed, our understanding of this intriguing subject has progressed little since the last edition of this book.

DAMAGE RESULTING FROM AGE-ASSOCIATED DISEASES

Age-associated diseases are generally viewed as the cause of much of the physiologic deterioration that occurs with advancing age.³¹ These diseases usually cause morbidity and mortality at advanced ages and are chronic or when acute are the result of long-term processes, such as bone loss or atherogenesis. It is also recognized that the occurrence and progression of age-associated diseases are strongly influenced by age-associated physiologic deterioration. However, there is disagreement regarding two fundamental questions. Are age-associated diseases an integral part of the aging process? Is there a fundamental difference between the aging of physiologic processes and the progression of what are called pathophysiologic processes?

In addressing these questions, the concept of "normal aging" has emerged³¹ and is widely used by those conducting physiologic studies on aging humans. It is defined as senescence in the absence of disease; probably more appropriately, it should be called "atypical aging" rather than "normal aging." Most elderly people have one or more age-associated diseases. Moreover, Scully³² points out that any definition of disease is problematic because what is called a disease is influenced by medical advances and societal culture. For example, Lakatta and Levy³³ view hypertension as a disease and point out that a systolic blood pressure of 140 to 160 mmHg

is now considered to be hypertension, whereas in 1990 it was considered to be in the normal range. Indeed, it is to be expected that the fraction of the elderly free of age-associated disease will become vanishingly small as advances in medicine increasingly uncover occult disease. Moreover, to study what many investigators call "normal aging," great effort is made to exclude from the population to be studied subjects with age-associated disease. Although such studies are invaluable by providing a reductionist approach to the study of aging, a powerful tool in dissecting the details of the aging processes, they provide little assessment of what is occurring as the general population ages.

Furthermore, the view that normal aging does not involve the occurrence of age-associated disease is not conceptually sound in terms of basic biology. Evolutionary biologists propose that aging (senescence) occurs because of the decline in the force of natural selection with advancing age.³⁴ Thus, biologic processes that result in detrimental effects expressed late in life cannot be selected against. It is for this reason that physiologic deterioration increases with increasing age, and it is for the same reason that age-associated disease increasingly expresses with advancing age. It is true that some people (a very small subset) may age without evidence of discernible age-associated disease, but this may relate more to the fact that the distinction between age-associated disease and age-associated physiologic deterioration is arbitrary. For example, loss of bone mass is a well-recognized age-associated physiologic deterioration and osteoporosis is a major age-associated disease; the boundary in this case of when to label a physiologic change as a disease is arbitrary.

For all of the above reasons, in this chapter, deterioration of physiologic systems secondary to age-associated disease will be considered to be an integral part of aging. Of course, it is always important to know the specific reason for the altered physiology, and when age-associated disease is the major immediate cause, it should be identified.

INTERSPECIES AND INTRASPECIES VARIATION IN AGE-ASSOCIATED PHYSIOLOGIC DETERIORATION

In general terms, mammalian species are remarkably similar in that a progressive, but usually not linear, deterioration in the physiologic systems occurs with advancing postmaturational age.³⁵ However, there is considerable interspecies variation in the details of these physiologic changes.

There is also great intraspecies heterogeneity in age changes in the physiologic systems, a phenomenon that has been well characterized in humans. Rowe and Kahn³⁶ have developed the concept of "usual aging" and "successful aging" for considering the differences among individuals in age changes in physiologic functions. "Usual aging" refers to elderly who are functioning well but are at risk for disease, disability, and premature death. They may exhibit modest increases in systolic blood pressure and abdominal fat, and deterioration of one or more physiologic systems. "Successful" aging refers to a small group of disease-free elderly people who exhibit the following characteristics:

- Low risk of disease or disability
- High level of mental and physiologic function
- Active engagement in life

Rowe and Kahn focus on environment and lifestyle as the major determinants for achieving "successful aging" and point to adequate physical exercise, good diet, good personal habits (not smoking or abusing drugs and using alcohol in moderation), and good psychosocial environment as being particularly important. Surprisingly, they barely mention the role of genetics in achieving "successful aging."

Although the concept of "successful aging" is provocative, there are questions regarding its value and usefulness. One question is how common is "successful aging" now or is it likely to become if most people were to live in a good environment and adhere to an appropriate lifestyle. As of now, only a small fraction of those in the eighth decade of life would meet the criterion of being free of chronic disease (i.e., almost all suffer from one or more of the following diseases: osteoarthritis, coronary heart disease, cerebrovascular disease, congestive heart failure, dementia, type II diabetes, Parkinson's disease, cancer, benign prostate hyperplasia, and cataracts).³¹ And this does not fully cover the list of such diseases.

A related question is what fraction of those who meet the criteria of "successful aging" in the eighth decade of life will continue to when in the ninth and tenth decades of life or when they are centenarians. If most of them undergo notable physiologic deterioration before death, what does the concept of "successful aging" provide in addition to the well-known fact that individuals age at different rates? The concept of biologic age as distinct from chronologic age was proposed long ago.³⁷ Thus the question arises as to whether the concept of "successful aging" is useful or misleading. It is likely that most centenarians were in the "successful aging" category when in the eighth decade of their lives. However, they exhibit notable physiologic deterioration, which must have occurred progressively during the ninth and tenth decades of life culminating after becoming centenarians.³¹ It seems more appropriate to say that these centenarians undergo a slow rate of aging rather than "successful aging." This is not merely an academic issue but also one with societal implications because "successful aging" implies that physiologic deterioration due to aging can be prevented rather than merely delayed. Such a view may misguide public policy based on the view that an appropriate lifestyle and environment will enable people to reach very old age without the disabilities that are so costly in the use of societal resources. Unfortunately, it is possible that the environment and lifestyle advocated for "successful aging" may have just the opposite effect. Indeed, centenarians have greatly increased in numbers during the twentieth century³⁸ and may become commonplace during the twenty-first century. Furthermore, since the environment and lifestyle advocated for the achievement of "successful aging" is likely to increase the number of centenarians, it may result in an increase in the fraction of the population that consume societal resources because of notable physiologic deterioration.

AGE CHANGES IN THE PHYSIOLOGY OF SPECIFIC ORGANS AND ORGAN SYSTEMS

All organs and organ systems exhibit age-associated physiologic deterioration, if not in all individuals, at least in a significant fraction of the population. This subject area is so

vast that it cannot begin to be covered in this brief chapter. The volume on aging¹ of the *Handbook of Physiology* series of the American Physiological Society provides a systematic and extensive coverage for those needing in-depth information about a particular organ or organ system. Also many other chapters in this textbook provide a substantial discussion of age changes in the physiology of specific organs and organ systems relevant to the subject matter of the chapter. In this chapter a few specific examples have been selected for discussion solely for the purpose of illustrating general concepts.

Before starting this discussion, it is important to point out that most of the studies on age changes in the physiology of organs and organ systems have used the cross-sectional study design. The interpretation of cross-sectional studies is often confounded by factors not related to aging.³⁹ What are called "cohort effects" is a major confounder.⁴⁰ For example, during the twentieth century, the number of years of education progressively increased in the developed nations.⁴¹ Therefore, when comparing cognitive abilities of 30-year-olds and 80-year-olds in a cross-sectional study, the difference in educational levels confounds any conclusions about the effects of aging. What is referred to as "selective mortality" is the other major type of confounder of cross-sectional studies.⁴² The older the age group being studied, the smaller is the fraction of its birth cohort still alive. Members of the birth cohort with risk factors for fatal diseases tend to die at younger ages than others in the birth cohort. Thus, for example, a difference in the blood level of HDL-cholesterol between those in the age range of 80 to 90 years compared with those in the age range of 50 to 60 years may relate more to "selective mortality" than to aging.

Aging broadly affects the cardiovascular system, ranging from structural and functional alterations of the heart and vasculature to changes in the neural reflexes regulating cardiovascular functioning.⁴³ Left ventricular hypertrophy commonly occurs with advancing age and its extent varies among individuals.⁴⁴ Notable left ventricular hypertrophy is associated with heart failure, coronary heart disease, and stroke. Left ventricular compliance commonly decreases with advancing human age and may be a contributor to heart failure.⁴⁵ The ability to increase heart rate in response to exercise-induced peak oxygen consumption declines with increasing human age.⁴⁶ Also, there is a decrease with advancing age in the ability of β -adrenergic agonists to increase heart rate.³³ There is an age-associated decrease in left ventricular contractility during maximal exercise and this is also a manifestation of reduced β -adrenergic responsiveness.⁴⁷ With increasing age, the large arteries dilate, stiffen, and the intima thickens.⁴⁸ Systolic blood pressure and pulse pressure commonly increase with increasing age, a phenomenon primarily due to age-associated arterial structural changes.⁴⁹ The extent of the increase in pulse pressure is a strong predictor of risk of cardiovascular disease.

Many of these age-associated changes in cardiovascular physiology may underlie the occurrence of cardiovascular disease, while cardiovascular disease may play an important role in many of the age changes in cardiovascular function. Moreover, lifestyle and other environmental factors undoubtedly are major players in the physiologic

deterioration of the cardiovascular system and in the progression of cardiovascular disease. Of course, some of the deterioration may be due to intrinsic aging processes and thus inevitable. However, it is difficult to identify such processes with certainty because one cannot be sure that they do not arise from yet-to-be-recognized extrinsic factor or disease. Moreover, it is important to emphasize that those age changes in cardiac function that are secondary to lifestyle and other environmental factors are not inevitable and may be modifiable even at advanced ages, at least to some extent. Lakatta⁵⁰ points out that the cardiovascular age-changes are being studied at the molecular level in rodent and nonhuman primate models and that the findings of these studies hold promise for developing interventions for even the intrinsic aging processes underlying cardiovascular disease.

Cross-sectional studies of apparently healthy human populations report a decrease in kidney function after age 40, with the glomerular filtration rate decreasing about 1% per year of age increase.⁶¹ However, a longitudinal study⁵² conducted on subjects of the Baltimore Longitudinal Study of Aging has revealed that not all people exhibit an age-associated decline in glomerular filtration rate (Figure 9-2). The mean decrease in creatinine clearance in 446 male subjects followed over a 23-year period was 0.87 mL per minute per year. However, one third of the subjects showed no decline in creatinine clearance. Others in this study exhibited a small but statistically significant decline and still others had a notable decline in creatinine clearance. It is interesting to note that the mean decline in creatinine

Figure 9-2. Age changes in creatinine clearance of male subjects studied serially in the Baltimore Longitudinal Study of Aging. The top panel presents the findings of six subjects from the group who exhibited notable decreases in creatinine clearance with increasing age; the middle panel presents the findings of six subjects from the group who exhibited a small but significant decrease in creatinine clearance with increasing age; the bottom panel presents the findings of six subjects from the group who exhibited no decrease in creatinine clearance with increasing age. (From Lindeman et al⁵² with permission of Blackwell Science Inc.)

clearance of the subjects in this study group was similar to what has been observed in many cross-sectional studies. The reasons for the differences among people in changes with age in kidney function have not been established. Lindeman⁵¹ has suggested that the decline in renal function noted in cross-sectional studies may be due to the fact that many in the populations studied suffered from undetected pathologic processes and that a decrease in glomerular filtration rate is not an inevitable involuntal process. Indeed, it has been shown that elevated blood pressure accelerates the age-associated decline in renal function.⁵³ It is also possible that lifetime dietary preferences play a role since excessive dietary protein is believed to promote renal functional deterioration. Indeed, if the deterioration of renal function with age is primarily due to disease and/or environmental factors, then it is potentially modifiable by public health measures.

The appearance of the skin is widely used as an indicator of the age of a person. The skin, indeed, undergoes many structural and functional age-associated changes.⁵⁴ The skin wrinkles, loses elasticity and is increasingly more fragile. The barrier function of the skin is compromised, as is its immune function. The loss of sebaceous glands leads to dry skin and the loss of melanocytes causes alterations in pigmentation. There is a decrease in subcutaneous fat, which adversely affects the ability to cope with cold environments. However, the magnitude of most of these changes does not result from intrinsic aging processes but is the result of cumulative sun damage since their extent is much reduced in skin areas protected from the sun.²⁵ Cigarette smoking is the other major factor that promotes skin aging.²⁶ Indeed, sun exposure and cigarette smoking appear to act synergistically to promote skin aging.²⁶ Thus, commonly used skin markers of aging have little relation to intrinsic processes but primarily relate to environmental factors and can be readily modified by altering lifestyle.

These three examples make clear that many age changes are not primarily because of intrinsic aging processes but, to varying degrees, are secondary to (or are at least promoted by) age-associated disease or extrinsic factors or both. To view them as not being part of the aging process removes from consideration major problems that confront aging individuals nor is there any biologic basis for such a view. It is true that deterioration due to disease or extrinsic factors may be preventable and, in some cases, reversible, but that hardly lessens their involvement in aging. Indeed, much of what we currently consider to be intrinsic may ultimately be found to be of extrinsic origin or at least influenced by extrinsic factors. And what is considered to be extrinsic has its actions by interacting with intrinsic processes. Indeed, what is considered to be lifestyle may have a strong intrinsic basis (e.g., the sedentary lifestyle adopted by many people as they age also occurs in laboratory rats,⁵⁵ which in the case of the rodent is probably better viewed to be intrinsic rather than a lifestyle choice). Moreover, as discussed earlier, there are strong reasons to believe that most age-associated diseases are part of the aging process, making their separation from other aspects of aging arbitrary.³¹ Nevertheless, identification of age-associated diseases is obviously essential in the practice of geriatric medicine and is also invaluable in experimental biogerontology by providing the detailed information needed for interpretation of the findings of human and animal studies.

AGE CHANGES IN ORGANISMIC FUNCTION

Given the many deteriorative changes that occur in the physiology of organs and organ systems, it is to be expected that the functional competence of the organism is compromised with advancing age. Indeed, organismic functional deficits occur that can be classified in the following way: (1) decreased ability to cope with challenges, (2) reduced functional capacity, and (3) altered homeostasis. A few examples of these organismic functional deficits are presented next.

Ability to cope with challenges

The reduced ability to cope with challenges, or what are often called stressors, is a hallmark of the aging phenotype.⁵⁶ It is well known that secretion of glucocorticoids by the hypothalamic-hypophyseal-adrenocortical system and increase in the activity of the adrenal medullary-sympathetic nervous system are responses common to all stressors, and that they play an important role in enabling mammalian organisms to cope with all stressors.⁵⁷ Also, induction of the heat shock protein system is a common response, enabling organisms of almost all species to withstand many different cellular stressors.⁵⁶ Of course, in addition to these general responses, there are defenses that are specific for particular stressors or challenges. However, because the loss with advancing age in ability of organisms to cope appears to occur with all types of stressors, it might be expected that there is deterioration of one or more of the general mechanisms. The currently available evidence does not indicate that the ability of the hypothalamic-hypophyseal-adrenocortical system to respond to challenges by increasing the secretion of glucocorticoid hormone is compromised by aging.⁵⁸ Of course, that does not rule out the possibility of a reduced ability of the glucocorticoid target site to respond to the hormone, but studies designed to address this possibility have yet to be done. There is some indication that the response of the adrenal medullary-sympathetic nervous system to challenges may be attenuated with advancing age,⁵⁹ but these findings are hard to interpret because basal levels of catecholamines are elevated with increasing age. There is also evidence that there is a blunting with age of at least some adrenergic responses in target tissues (e.g., the heart as discussed previously). Nevertheless, based on current information, it does not seem that an inadequate response of the adrenal medullary-sympathetic nervous system plays a major role in the age-associated reduction in the ability of the organism to meet challenges. In contrast to these neuroendocrine responses, the evidence is clear that the ability to induce heat shock proteins in response to cellular stressors markedly decreases with the increasing age of mammals,⁵⁶ and this may play a major role in the loss in ability to cope with stressors. However, because the physiologic deterioration occurs with advancing age in most organs and organ systems, functional deficits in specific responses may underlie the reduced ability to deal with a broad scope of challenges. A case in point is the decrease in the ability of the immune system to protect the organism from damage due to infectious agents.⁶⁰ Thus, although it has long been known that successfully meeting challenges is compromised with advancing age, the basis of this deficit remains to be fully elucidated.

Aerobic exercise capacity

The capacity of the cardiopulmonary system to supply oxygen to exercising muscles along with the capacity of the muscles to use this oxygen in energy metabolism is referred to as the aerobic exercise capacity. It is a measure of the maximum ability to carry out exercise and is determined by measuring the maximum rate of oxygen consumption attainable when performing an exercise test of increasing intensity that requires a large proportion of the total muscle mass. Aerobic exercise capacity decreases in healthy sedentary men and women at the rate of about 10% per decade.⁶¹ Since physical fitness markedly influences aerobic exercise capacity, some of this decrease may be a result of the fall in physical activity with advancing age. The loss of aerobic exercise capacity is associated with a decrease in forced expiratory volume per second (FEV₁) and maximum heart rate. Hollenberg et al⁶¹ believe that these pulmonary and cardiovascular changes play the major role in the age-associated decrease in aerobic capacity. Thus it is not surprising that the decline in aerobic exercise capacity is much greater in elderly people suffering from chronic disease, particularly atherosclerotic disease. Well-trained endurance athletes at all ages have a higher aerobic exercise capacity than untrained people of the same age.⁶² Katzel et al⁶² carried out a longitudinal study on the changes in aerobic fitness in endurance athletes of advanced ages. They found that some exhibited a greater longitudinal decline in aerobic exercise capacity than what was observed in sedentary people of the same age. Other old endurance athletes exhibited a very small longitudinal decline in aerobic exercise capacity. The former group was found to have decreased the magnitude of their endurance training during the course of the study, whereas the latter group had not. Katzel et al concluded that the rate of decline in aerobic exercise capacity in older endurance athletes is highly dependent on the intensity of their training. The aerobic exercise capacity of elderly sedentary men and women can be increased by physical training.⁶³

Acid-base homeostasis

It has long been held that healthy elderly people have no problem maintaining normal acid-base balance when living the usual relatively unchallenged existence.⁶⁴ However, a careful meta-analysis of published data has challenged this view.⁶⁵ It was found that there is a progressive increase in blood hydrogen ion concentration and a progressive decrease in the blood concentration of bicarbonate ion and carbon dioxide from age 20 to 80 years. The apparent steady-state plasma concentration of hydrogen ion was found to increase by 6% to 7% and the bicarbonate ion to decrease by 12% to 16%. It is likely that an age-associated deterioration of kidney function is responsible for the increase in the blood hydrogen ion because, when challenged with an acid load, the ability of the kidneys to excrete the acid load decreases with advancing age.⁵¹

Fat-free mass (FFM)

Body mass is divided into two components: fat mass and FFM. The constituents of FFM are skeletal muscle mass, body cell mass, total body water, and bone mineral mass. In men, peak FFM is reached in the mid-30s and progressively declines thereafter; in women, it is stable in young adulthood until about age 50 when it begins to progressively decline with

advancing age.⁶⁶ Clearly, the homeostatic system regulating FFM is deranged at advanced age. An important component in the age-associated decrease in FFM is the loss of skeletal muscle mass, an important factor in the decrease in muscle strength with age.⁶⁶ Although physical exercise with an emphasis on weight-training can decrease the loss of muscle mass in the elderly, even individuals who maintain their fitness have some age-associated loss of muscle.⁶⁷

Fat mass

Body fat mass increases with age in both men and women through middle age; a slow decrease occurs after age 70.⁶⁶ Even in those people whose body weight does not increase with age, body fat increases as lean body mass decreases. The homeostatic regulation of fat mass becomes faulty with advancing age. Sedentary lifestyle plays a role in the age-associated increase in fat mass since exercise is associated with a decrease in fat mass in the elderly.⁶⁸ However, exercise attenuates but does not totally prevent the age-associated increase in body fat. There is also a redistribution of fat to the abdominal region with increasing age.⁶⁶ Exercise not only decreases the age-associated increase in body fat but, most importantly, it also preferentially attenuates the disproportionate increase in abdominal fat.⁶⁹ The great concern about abdominal fat is due to the extensive evidence indicating that it is a risk factor for several age-associated pathologic problems such as coronary heart disease and type 2 diabetes.⁷⁰ Indeed, abdominal fat mass is positively associated with mortality in the elderly.⁷¹ Thus interventions aimed at preventing the abdominal accumulation of fat with advancing age are most important to develop.

Bone mass

Bone mineral density (BMD), which accounts for 70% of bone strength, declines in both men and women starting in midlife.⁷² Osteoporosis refers to a disease condition in which the extent of the decrease in BMD makes the individual prone to bone fracture; the age-associated decrease in BMD is probably the major reason that about 75% of all hip, spine, and distal forearm fractures occur in persons older than 65. In many women there is an age-associated postmenopausal increased rate of bone loss that can last for years.⁷³ Since women also have a less massive skeleton than men, it is not surprising that elderly women are more prone to bone fracture than elderly men. Middle-aged and older blacks of both genders have greater bone mass than whites.⁷⁴ They also have a substantially lower fracture rate, which is only partly due to maintaining a higher BMD. Cross-sectional studies have shown a positive correlation between exercise and BMD.⁷⁵ Although in postmenopausal women, low dietary calcium intake increases the risk of osteoporosis, this effect is often countered by such women having an increased body mass index.⁷⁶ Cigarette smoking lowers the BMD.⁷⁷

Hormone replacement therapy has been the primary method for retarding bone loss in postmenopausal women. Treatment with low-dose conjugated estrogens or low-dose estradiol increases BMD in postmenopausal women.⁷⁸ Recent concern about the nonskeletal risks associated with long-term use of estrogens (e.g., breast cancer and cardiovascular disease) has lessened the enthusiasm for hormone replacement.

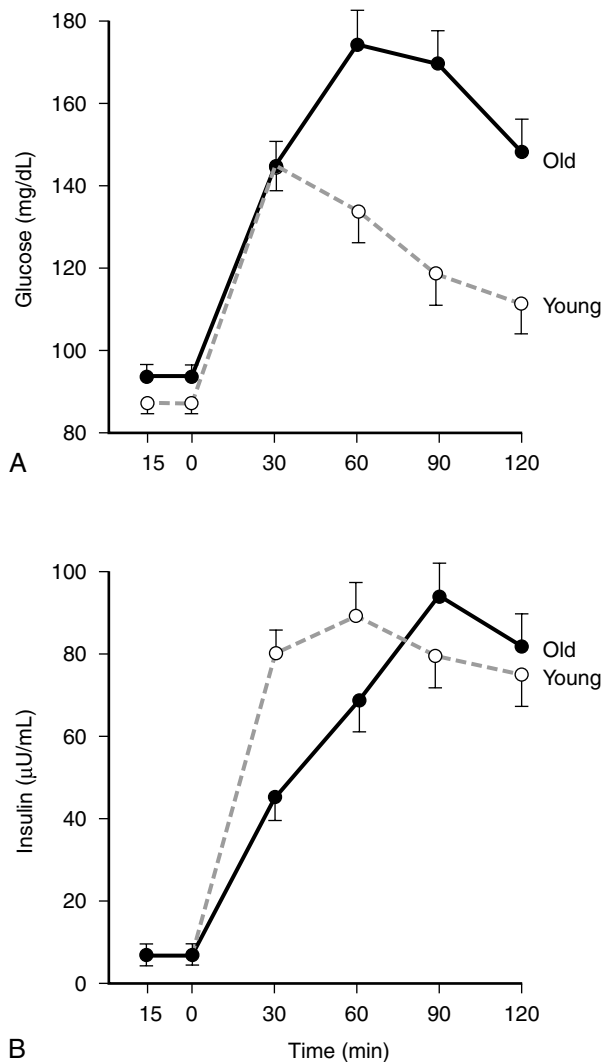

Figure 9-3. Influence of age on the response of plasma glucose and insulin concentration to an oral load of glucose. Young and old healthy human subjects were given 100 g of glucose orally. (From Chen et al⁸⁶ with permission of Blackwell Science Inc.)

Body temperature

The thermoregulatory system has the following components: thermal sensors (cutaneous and central); afferent neural pathways; central system integration; efferent neural pathways (somatic and autonomic); effectors (skeletal muscle shivering thermogenesis, brown adipose tissue nonshivering thermogenesis, cutaneous vasomotor activity, sweat gland activity). With increasing age, there are deficiencies at several levels of the thermoregulatory system.⁷⁹ Aging is associated with a progressive deficit in the ability to sense heat and cold, and also a reduced ability to generate heat (lower muscle mass for shivering thermogenesis) and dissipate heat (alterations in cardiovascular function and atrophy of sweat glands).⁸⁰ Also, there is impairment in nonshivering thermogenesis due to a decreased quantity of brown adipose tissue with advancing age.⁸¹ The circadian rhythm of core temperature deteriorates at advanced ages.⁸² Unlike in young men, body temperature in old men continues to increase following the cessation of a submaximal exercise.⁸³ Indeed, the deterioration of the thermoregulatory system

makes old people extremely vulnerable to high and low environmental temperature.⁸⁴

Glucose homeostasis

A diminished homeostatic regulation of plasma glucose concentration is a common characteristic of the aging phenotype.⁸⁵ When this regulatory ability declines sufficiently, a diagnosis of type II diabetes is made—a common age-associated disease. A major tool for examining glucose homeostasis has been the oral glucose tolerance test. Typical of the findings are those reported by Chen et al (Figure 9-3).⁸⁶ They administered orally 100 g of glucose to groups of healthy old and young subjects; plasma glucose rose to higher levels and remained elevated longer in the old than in the young, whereas the rise in plasma insulin level was delayed in the old, but with time reached that of the young. With increasing age, there is a reduced ability to secrete insulin⁸⁷; however, it is not known how important a role it plays in the alteration in glucose homeostasis with age. In contrast, there is strong evidence that an increased resistance to insulin action is a major factor in the diminished homeostatic glucose regulation in old people.⁸⁸ As discussed previously, people become increasingly sedentary and have increased body fat, particularly in the abdominal region, with advancing age; these two factors are known to increase insulin resistance and to blunt the glucose homeostatic responses. Indeed, the effect of aging on glucose homeostasis can be ameliorated by increasing physical activity and in so doing decreasing adiposity, particularly in the abdominal region.⁸⁹ It is the increase in visceral fat that appears to be the major factor in increasing insulin resistance with advancing age.⁹⁰ Indeed, probably exercise increases insulin sensitivity⁹¹ because it decreases abdominal fat.

KEY POINTS

Physiology of Aging

- Physiologic deterioration occurs during the adult life of most, if not all, mammalian species.
- The rate of age-associated physiologic deterioration and its character varies among species and among individuals within species.
- Age-associated physiologic deterioration results from the following three sources of damage: intrinsic living processes, environmental factors, and age-associated disease.
- Whether age-associated disease is an integral part of aging is a fundamental question that has yet to be resolved.
- Whether the concept of “normal aging,” defined as aging in the absence of disease, is useful or misleading is an open question as is the related concept of “successful aging.”
- The cross-sectional design has been used in most studies on the physiology of human aging; such studies can be confounded by factors other than aging, which makes it imperative that the possibility of confounders be carefully evaluated when interpreting the findings.
- The ability to cope with stressors is diminished with advancing adult age.
- The capacity to carry out activities (e.g., the aerobic exercise capacity), declines with advancing adult age.
- Homeostatic regulation deteriorates with advancing adult age.

SUMMARY AND CONCLUSIONS

Physiologic deterioration is a hallmark of the aging phenotype. This deterioration is caused by (1) damage resulting from intrinsic living processes; (2) damage due to extrinsic factors, such as diet, lifestyle, personal habits, and psychosocial factors; and (3) age-associated diseases. Although mammalian species are similar in that all show a progressive deterioration of physiologic processes with advancing age, the details of this deterioration vary among species. Thus the detailed characteristics of the deterioration probably have a strong genetic component. There is also a considerable intraspecies variation in the rate and character of physiologic deterioration with advancing age. Many of the differences among individuals of the same species appear to relate to extrinsic factors. Age-associated deterioration occurs in all organs and organ systems. The extent to which extrinsic factors and age-associated disease play a role varies among organ systems and among individuals but, in most cases, one

or both appear to have a major role. These age changes in the physiology of organs and organ systems compromise the functional abilities of the organism and underlie the decreasing ability to survive with advancing age. The physiologic deficits of the aging organism can be summarized as (1) a reduced functional capacity, (2) a decreased ability to cope with challenges, (3) an altered homeostasis. Because much of the physiologic deterioration with advancing age is caused by extrinsic factors, aging can be modified by altering lifestyle and environmental factors. Also, the large role that age-associated disease plays in the physiologic deterioration can be modulated by presently available medical and public health measures and undoubtedly much more by those that will be developed in the future.

A Clinico-Mathematical Model of Aging

Kenneth Rockwood
Arnold Mitnitski

INTRODUCTION

Overview of frailty

Geriatricians have an affinity for frail elderly people, or should. The complex care of elderly people who are frail is argued—including in the Foreword of this book—to be the very stuff of geriatric medicine.¹ This chapter, building on recent reviews,^{2,3} addresses the issue of frailty in relation to complexity to argue that the formal assessment of complexity can usefully be employed to understand the scientific basis of the analyses of frailty, with insights for the practice of geriatric medicine.

Frail, elderly patients are at an increased risk—compared with others of the same chronologic age—as a consequence of having multiple, interacting, age-related physiologic impairments, some of which cross clinical thresholds to be recognized as diseases and others as disabilities. These impairments, diseases, and disabilities typically interact with various social vulnerability factors, which commonly travel with the frail to further increase the risk of adverse health outcomes.

The view of frailty as a multiple-determined at-risk state is reasonably noncontroversial.^{4–8} By contrast, how best to operationalize frailty is more controversial. As outlined in various reviews, some of the proposed operational definitions receive more widespread support than others. In particular, the “phenotypic” definition of frailty used in the Cardiovascular Health Study (CHS)⁹ has been endorsed at consensus conferences^{6,7} and employed by several groups.^{10–13} Indeed, it has even been claimed that the terms “frail” and “frailty” should be avoided except when used in the context of a CHS assessment.¹⁴

Overview of complexity

The idea of complexity is proving to be one of the most important conceptual advances in science.¹⁵ Briefly, complexity arises from systems. Systems can be defined in many ways because there is an irreducible extent to which the definition of a system depends on the context in which it is considered. To start, it might work best to contrast a *system* with a *set of elements*. The elements of a set exist as members of the set because of some shared characteristic, but they do not become a system until there is interconnectedness between them. Interconnectedness exists when changes in one element result in changes in other elements, and these changes result in further changes, and so forth. It is the nature of the interrelated changes that defines complexity: complexity is the phenomenon of dynamic interactions in the elements of a system. The goal of complexity analyses is to quantify and summarize these changes.

The use of complexity analyses in aging has not been noncontroversial. For example, in 2002, an entire issue of *Neurobiology of Aging* was devoted to complexity. Some of the papers in the special issue gave examples in which complexity, as measured in one specific context, appeared to decrease with aging,¹⁶ whereas others gave opposite examples.¹⁷ Although some commentators despaired,¹⁸ this result is typical when complex systems are first investigated. Commonly, with better specification of the context, (e.g., specification of

intrinsic dynamics or of the time scale under consideration) apparent contradictions resolve. Such specification can lead to the implementation of new interventions that are based on a better appreciation of changes in dynamic complexity of biologic variability, such as the application of subsensory noise to the feet to improve postural stability in older adults.¹⁹

It is evident that aging humans constitute aging systems, both as individuals and as groups, and that within the human organism, there are different organ systems, although their specification—where does the vascular system end and the immunologic system begin?—often results in some arbitrariness. Such arbitrariness is best not ignored when considering a phenomenon as all-encompassing as the passage of time. How to specify the interconnectedness of the organs in the body as people age is not clear. It is clear, however, that there is (there must be, if it is a system) interconnectedness of health characteristics (interdependence of variables). One way to specify the interconnectedness of health characteristics is by the use of connectivity graphs (Figure 10-1). Such graphs are constructed to represent interconnectedness between variables, so that a line between variables is portrayed when some specified level of connectivity—say a correlation >0.2 exists. As the graph illustrates, some variables are more highly connected than others (i.e., some have more lines between them than others do.²⁰ (It is this high connectivity between some items more than others, that means that the items of the frailty index do not need to be weighted—an issue to which we will come.)

The connectivity graph illustrates two fundamental points about complex states, which are multiplicity and interconnectedness. Another way to think about interconnectedness is that a system is “more than a sum of its parts”; this is sometimes referred to as the system having “emergent properties.” (The idea of emergent properties is controversial and need not be considered further here.) What will be evident is that an individual’s state of health can be summarized by a single number—it is what we will refer to later as the frailty index—and that the properties or behavior of that number (for example, how the frailty index changes with age) can be considered as an area of investigation in and of itself. To continue that example, we have shown that the distribution of the frailty index with age has distinctive characteristics.²¹ These characteristics can be studied using network models, which offer an apparatus for such analyses, based on stochastic dynamics.^{22–28} One example is the idea that heterogeneity (here, of the distribution of the frailty index with age)^{21,26} arises as a consequence of the stochastic dynamics of complex systems. This approach to studying heterogeneity is readily summarizable using a network approach, and has had wide applicability from cortical networks in Alzheimer’s disease²⁹ to capital markets,³⁰ to gas furnace pressures.³¹ Finally, the connectivity graph also shows that a complex system is summarizable. We will refer to this later, in terms of both the frailty index, and of the more general case of a clinical state variable. For now, we will simply note that a complex system can be summarized in ways that are not necessarily

Figure 10-1. Connectivity graph. Nodes indicate the deficits (codes correspond to the deficits listed in reference 20) and edges indicate statistically significant relationships between deficits (i.e., when the conditional probability of one deficit, given another is statistically different ($p < 0.05$; t -test) from the unconditional probability of the first deficit. It is clear that not all elements are equally well connected. (Copyright A Mitnitski et al, used with permission.)

complicated. That is the goal of the bulk of initiatives in bringing the tools of complexity analysis to studying what happens as people age and become frail. As a start, the simplicity of the output of these analyses is a good measure by which the merit of the analyses might be judged.

THE PHENOTYPIC DEFINITION OF FRAILTY

A very popular approach to defining frailty is by means of a clinical phenotype. This operational definition, developed by a consensus and tested in the Cardiovascular Health Survey,⁹ has been validated in several studies^{12,13,32-39} and endorsed by several groups.⁶⁻⁸ The phenotypic definition concentrates on five clinical characteristics: a self-report of exhaustion, self or observer report of a decline in activity level, demonstrated or reported weight loss, impaired strength (commonly operationalized as impaired grip strength using a dynamometer), and slow gait (e.g., defined as the slowest 20% of the population was defined at baseline, based on time to walk 15 feet, adjusting for gender and standing height).⁹ People who have none of the five characteristics are said to be robust, and those with three or more are said to be frail. People who have only one or two problems are at an intermediate risk grade, referred to as being "prefrail." In several studies, the three groups have been shown to have ascending levels of risk of a number of adverse health outcomes, including worsening mobility, falls, disability, fracture, mortality, and institutionalization.^{9,12,32-35,37}

A comprehensive series of studies have evaluated a wide range of markers that are seen in association with increasing grades of frailty. People who are frail have been found to have, among other impairments, higher levels of inflammatory markers,⁴⁰⁻⁴² worse glucose control⁴³ and lower antioxidant¹³ and hemoglobin⁴⁴ levels.

The ready operationalization of the phenotypic definition, especially in epidemiologic studies, is a clear asset. So too has

been the attempt to disentangle physical frailty from disability and comorbidity.⁴⁵ On the other hand, the phenotype has been criticized for an artificial distinction between physical and cognitive (including affective) states,⁴⁶ for requiring performance tests that can be impracticable in the clinical setting⁴⁷ and for problems of both sensitivity and specificity in relation to both mortality prediction⁴⁸ and to what many experienced clinicians would accept as frail.⁴⁶

Frailty in relation to deficit accumulation

Our group has proposed that frailty can be understood in relation to deficit accumulation.⁴⁹ The fundamental idea to this approach is that the more deficits that people have (the more things people have wrong with them), the more likely they are to be frail. We have been encouraged to continue with this approach by the insights that can be gained from the study of the frailty index itself. Our group, and others^{48,50} have described how the frailty index changes in characteristic ways. These changes are susceptible to precise analyses, which we will outline below, and which also appear to have useful clinical implications. In this way, we hope to move beyond cartoon models of frailty. For example, Figure 10-2 is one such cartoon model.⁵¹ It represents frailty as a state that arises from a dynamic interplay between a variety of factors. When people are well, their assets outweigh their deficits. As they experience illness, the balance can shift, but as this is a dynamic state, it can shift back. The model also suggests that people with, for example, many social assets, will be harder to tip into frailty than those with fewer social assets.

Although cartoon models have many uses, and the advantage of readily illustrating complicated ideas, they cannot offer the precision of formal, quantitative models, as depicted in Figure 10-3.⁵² It demonstrates changes in frailty states, from having n deficits at baseline, to k deficits at follow-up. The formal model shows that these probabilities can be modeled as a modified Poisson distribution. Here is what the formula says: the chance of having k deficits at follow-up is a function of the number of deficits n , at baseline. First, we must consider that to have k deficits at follow-up, the person must be alive, so the chance of moving from n to k must be adjusted for the chance of surviving. The term P_{nd} is the chance of dying during the interval between baseline and follow-up (or between any two consecutive assessments) so $1 - P_{nd}$ is the chance of surviving. For any given n state (e.g., $n = 1$, $n = 2$, etc.), the chance of having any k deficit proceeds in a highly ordered way, with incremental change (this is what is implied by the Poisson distribution). For example, for most baseline states, the single most likely number of deficits that an individual will have at follow-up is one more than they had at baseline. (Formally, this can be summarized as saying that the mode of k is $n + 1$.) There is a slightly smaller chance of staying the same and about the same chance of having two things wrong more than at baseline, a smaller chance again of improving and so on. The probabilities of achieving any given k therefore arise as a function of n , and follow an ordered set of changes. On average, n increases, but for virtually any value of n , there is a chance of improvement (or stabilization or decline). Large jumps in n to k states are uncommon; when large changes in the value of n do occur, they usually go from a low n state (i.e., few deficits, good health) to a high k state.

Two other points are especially of note. One is that the chance of moving from any given n state to any k state

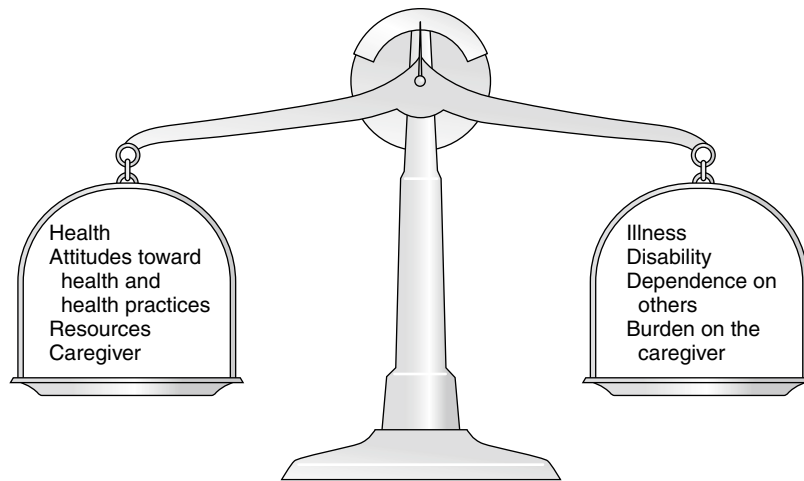

Figure 10-2. The balance beam model of changes in frailty states. The beam illustrates a multicomponent, dynamic state. (Copyright CMAJ and used with permission.)

$$P_{nk} = \frac{\rho_n^k}{k!} \exp(-\rho_n)(1 - P_{nd})$$

Figure 10-3. A formal mode of changes in frailty states, expressed as the probability of a person with n deficits at baseline surviving to have k deficits at follow-up. P_{nd} is the chance of dying; $P_{nd} = P_{od} \exp(b_2 n)$. Note that $\{I\} \rho_n = \rho_0 + b_1 n \{I\}$; $\{I\} \rho_0 \{I\}$ and P_{od} are the characteristic risks associated with no deficits. The two parameters b_1 and b_2 describe, respectively (given the current number of deficits, n), the increments of their expected change, and the risk of death. Note that the model can be elaborated to include the effects of specific covariates, such as age, sex, or social vulnerability. In that case, the antilog of the ratio of the regression coefficients associated with each covariate is an estimate of the relative risk associated with that coefficient.

depends on both the present value of n , and the general (or ambient, or background) changes in that environment. This is captured in the formula by saying that $\{I\} \rho_n = \rho_0 + b_1 n \{I\}$, where $\{I\} \rho_0 \{I\}$ describes the chance of accumulating deficits for people who have nothing wrong at baseline (i.e., who at baseline are in the “zero [deficit] state.”) The parameter b_1 describes, given the current nonzero number of deficits, the increments of their expected change.²⁵ Of course, the same obtains for the risk of death [i.e., $P_{nd} = P_{od} \exp(b_2 n)$]; P_{od} is the chance of dying for people who have nothing wrong at baseline. Here, parameter b_2 describes, again given the current (nonzero) number of deficits, the associated risk of death.²⁵ In this way, it can be seen that the zero state appears to be informative about the environment in which a given population ages. Finally, we note that this is a simplified model, which can be adjusted to evaluate the impact of various covariates. For example, to understand the impact of high versus low level of education, we can evaluate its impact on $\{I\} \rho_0 \{I\}$ and P_{nd} .

The move from the operationalization of the concepts of deficits in dynamic balance in Figure 10-2 to the terms specified in Figure 10-3 took place over some years, but each agrees on the following essential points: Frailty is a multiply with agreement on determined state of risk that is complex (component parts which interact in ways that are not always summarizable at the level of the individual parts) and dynamic (the interactions produce further interactions, and change with time). In Figure 10-2, items that relate to health are envisaged as weights on the balance beam. For example, various health assets, such as a positive health

attitude⁵³ or positive health practices such as exercise,⁵⁴ fit on the left hand side of the balance, giving positive weight to assets. Others, such as illness, and the particular illnesses which give rise to disabilities, and the particular disabilities that result in dependence on others are seen to weigh on the negative side. As more health deficits mount up and a person becomes more frail, the assets and deficits come into a precarious balance. In this context, an acute illness can be an important deficit, and can even “tip the balance” between assets and deficits. As attractive as this model is—it is easy to understand, accommodates multiple factors, and is complex and dynamic—unless and until it can be quantified, it cannot rise beyond the status of a metaphor. (In its earliest operationalization, the deficits were quantified as grades of disability, cognitive impairment, and poor health attitude.)^{55,56}

By contrast, Figure 10-3 proposes that changes in health status—changes in grades of frailty—occur as a function of the number of things that people have wrong with them. It says that the chance that people with that number of things wrong with them will change their health status in relation to a known distribution of the range of chances. These changes can be stability, worsening, or improvement. The distribution suggests that most people do not change their health status that much (i.e., a person with n things wrong with them is most likely, when followed up, to have $n+1$ things wrong, or to show a slight worsening) but also could stay at just n things wrong, or improve to $n-1$ things wrong. For most people, the chance of improvement to $n-1$ is about the same as the chance of worsening to $n+2$ things wrong. But those discrete states (slightly better, the same, or 1 or 2 more things wrong) consist of over half of the possible outcomes. The model assigns all possible outcome states (better, same, worse, or dead) typically with high precision based on just four parameters—a staggering degree of dimensionality reduction compared with most multivariable models. As the equation shows, each of the four parameters becomes an object of investigation, in and of itself. So the motivation to continue this line of inquiry is very strong.

Even so, most readers—especially most medical readers, for whom the mathematics is stereotypically not their strong suit—will worry that whatever apparent precision in these

estimates might be obtained by the quantitative model, it comes at a very high price of comprehensibility. The balance beam is much easier to understand. For now, we will make the claim that almost everything that is in the balance beam can be included in the quantitative model: the model helps us understand how to quantify what our clinical intuition tells us is the case. An important addendum—what compels us to say “almost everything” and not “everything” is that some elements that are important in the balance beam need a more elaborate model to achieve full specification. For example, the balance beam posits an interaction between so-called “medical” and “social” factors. As covered in a later chapter of this textbook on social vulnerability, social deficits appear to operate in a way that has much in common with frailty, but at a level that is separable from it.⁵⁷

A useful way to understand the dynamics of deficit accumulation is to consider what Benjamin Gompertz quantified in 1825⁵⁸: the older people are, the more likely they are to die, as a precise function (+/- one or two error terms)^{59,60} of the logarithm of their age (see Figure 10-3). But it is not as though people suddenly drop dead as they age. Instead, before death, they accumulate deficits, and they accumulate them exponentially with age.⁶¹ In fact, it is the deficit count, more than chronologic age, which correlates most with the risk of death at any age.^{48,49,61,62} The deficits that we can see accumulate clinically—the symptoms, signs, diseases, disabilities, and laboratory abnormalities that we typically count in frailty indices—presumably begin as subcellular impairments.⁶³ So the line of reasoning goes that barring sudden death or accidents, the more impairments people have, the more deficits they have; the more deficits they have, the more frail they are; and the more frail they are, the more likely they are to die.

DEVELOPMENT OF A FRAILTY INDEX BASED ON COMPREHENSIVE GERIATRIC ASSESSMENT

We began work on the frailty index by counting deficits in existing databases, chiefly epidemiologic ones. Over the years, we have collaborated with several groups to build a frailty index in their databases, usually epidemiologic, not clinical ones. This has justifiably caused concern in some quarters about the clinical usefulness of the approach,⁶⁴ especially as an optimal frailty index should contain no fewer than 30 to 40 items. (The lowest practical limit seems to be about 10, although at that point, selection of which items are to be counted becomes more important.)⁶⁵ Most recently, we have begun to build a frailty index prospectively from the standardized comprehensive geriatric assessment form that is used on all clinical geriatric medicine services at the Capital District Health Authority in Halifax, Nova Scotia. The CGA form (Figure 10-4) is the basis of our consultation assessment on the consultation services, and of care planning on each of our inpatient services (acute and rehabilitation services) and the day hospital. It is worth noting that the form readily can count up to 50 items (+10 items relating to social vulnerability) but can still fit on a single page.

The frailty index that is derived from the CGA form is built like any other, which is to say that it counts deficits. (We have built other frailty index measures based on CGA.)^{66,67} In a recent open access journal publication, we have spelled out how to create a frailty index.⁶⁸ A video is also available at

<http://geriatricresearch.medicine.dal.ca>. By convention, we give any deficit a score of 1 if it is present and 0 if it is absent. On the CGA form, for example, under the section “Communication” we would give 1 point each for problems of vision, hearing, and speech. Similarly, we would give a point for impaired mobility or a recent fall. In addition, we count each of the comorbidities that an individual might have and score one point for each. We count additional deficits for every five medications prescribed beyond five (5 through 9 medications, one deficit; 10 through 14 medications, two deficits, and so on). Any asymptomatic risk factor where modification would have a mortality benefit (e.g., hypertension or antiplatelets in secondary vascular prevention) would be considered as a further deficit if left untreated.

An important point about the frailty index-CGA is that almost all deficits can be measured in every patient, so there should be few missing data—typically less than 5% for any given item. This requirement has the effect of excluding many performance-based measures from frailty index variables, at least from survey data in which they typically have considerably more than 5% missing data.⁴⁷ If they are to be included, then it seems to be useful to assign missing data the score associated with worst performance status.⁴⁷

Validation of the frailty index

The frailty index has been validated by our group and by others, typically using a three-part approach that considers content, construct, and criterion validity.⁶⁹ The content validity of a measure that counts what people have wrong with them, and assumes that the more they have wrong with them, the more likely they are to be frail, seems secure. In addition, it offers the idea of grades of frailty. On the other hand, many commentators have been concerned about the idea that the frailty index weights all items equally. A common specific objection is that it seems implausible that both “cancer” and “skin disease” should have the same weights (i.e., “0” if absent and “1” if present). The usual rejoinder is that although cancer more often is more lethal than skin disease, not all cancers are lethal, and not all skin diseases are benign. When skin disease is lethal (e.g., psoriasis with vasculitis and skin breakdown), it will have more deficits associated with it. The same would hold for a cancer that impacted the overall state of health. This detection of multiple deficits has the effect of weighting more serious illness higher, regardless of the cause of the illness.

Construct validity has been tested chiefly by convergent construct correlation (i.e., by correlating the frailty index with other frailty measures, and measures of disability, cognitive impairment, and comorbidity).⁷⁰ Correlations between the frailty index and other measures of frailty—including the phenotypic definition—typically run in the range of ~0.6 to 0.8. As reviewed elsewhere^{2,3} slightly lower correlations (in the range of ~0.4 to 0.6) typically are seen with global measures of function, comorbidity, and cognition.

One aspect of construct validation that lends some insight into the nature of frailty is the relationship between the frailty index and age (Figure 10-5). Consistently in epidemiologic samples, we have found that the average value of the frailty index is highly associated with age (correlation coefficients >0.95).^{2,3} Although the average value of the frailty index increases with age (typically about 3% per year on a log scale—see Figure 10-5, lower best fit line), individuals have variable numbers of deficits at any given age. People who have a large number of deficits (e.g., people with a frailty index score of more than 0.5,

The individual items on it can be scored to derive a frailty index based on the CGA (FI-CGA). (Copyright Geriatric Medicine Research Unit, Dalhousie University, Halifax, Nova Scotia, Canada. Used with permission.)

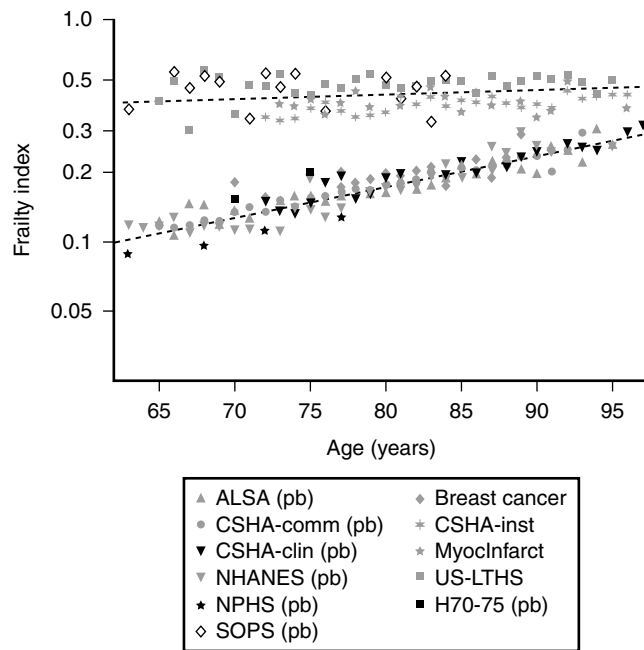

Figure 10-5. The relationship between the frailty index and age. Across several surveys, the frailty index accumulates in community dwelling older adults at a rate of about 3% per year, on a log scale (lower line). By contrast, in clinical samples and among institutionalized older adults, the values of the frailty index are much higher on average and show almost no accumulation with age.

and who had half or more of all deficits that were measured) typically show no mean accumulation with age; that is, they have, on average, about as many deficits as they can tolerate, so that if more deficits occur, they die. This is also typical of the mean value of people who come from clinical and institutional samples (see [Figure 10-5](#), upper best fit line).^{61,71}

Even though the average value of the frailty index increases with age, there is considerable individual variability, so that some people are well above and others well below the mean value. If the frailty index quantifies a risk state, then people with high frailty index values should have a higher risk of death than people with lower frailty index values. As noted, this is the case; it also holds for institutionalization,^{65,72} health service use,⁶⁷ and worse health status.^{52,73,74} In each case, the higher the frailty index count, the more likely the person is to experience an adverse outcome. The relationship between the frailty index and the risk of death, like the relationship between age and the risk of death, is also exponential.

The frailty index as a clinical state variable

If variation in grades of the frailty index reflects variation in the risk of adverse health outcomes, then it is reasonable to suppose that these grades in the frailty index represent different states of health. To this end, we have proposed that the frailty index can be considered as a clinical state variable.² A state variable is one that quantitatively summarizes the state of an entire system; a classic example is temperature, which can be measured has a single number on a graded scale. The number has a known meaning, as the average of the kinetic energies of the molecules which make up a given system. These individual kinetic energies are indeterminate. By contrast, temperature is more stable, and can behave in ways that can be known with precision. An important trait of a state variable is that it can be described using plain language

descriptions. Temperature can be meaningfully communicated as, for example, hot, warm, cool, cold, or freezing. These descriptions can also be contextualized. In a biologic context, scalding would have a precise clinical meaning. These attributes appear to be particularly worthwhile in grading frailty and allow some precision to be brought to the question of what procedures might safely be entertained in a "frail" patient. This grading of risk in relation to the severity/load of the intervention and the responsiveness/frailty of the individual is an active area of inquiry. For now, the interim answer seems to be to translate the frailty index into terms used. One aspect of the frailty index as a clinical state variable that has yet to be fully explored is its translation into plain language: what is the analog to "hot" versus "tepid" with respect to frailty? Pending this answer being fully worked out, the high correlation between the frailty index and the Canadian Study of Health and Aging Clinical Global Frailty Scale⁷⁰ makes that measure seem to be a reasonable way to quickly grade degrees of fitness and frailty ([Table 10-1](#)).

Another consequence to flow from the idea that the frailty index defines discrete health states is that how these states change might be informative. As noted, this appears to be the case (see [Figure 10-3](#)). The probability for a given individual of a change in the number of deficits that they have depends on two factors. The first is the number of deficits that that individual has at baseline and the number of deficits that are accumulated, on average, by a person who has no deficits at baseline. Another notable feature of the reproducibility of the changes in health states represented by variable deficit counts/grades of frailty is that these estimates are very robust. The estimates noted above do not just come from different countries, but were developed using different versions of the frailty index, which typically has not been constructed in the same way in any two studies (see [Figure 10-5](#)). The examples quoted above employ iterations of the frailty index that use different types of variables (e.g., self-reported in the NPHS, clinically assessed [CSHA, H-70], or laboratory data H-70), and often different numbers of variables (from 39 in the NPHS to 70 in the CSHA to 100 in H-70).

The frailty index has often been referred to as a measure of biologic age.^{20,50,75} If we consider that biologic age derives its rationale not as time since birth—that is already well handled by chronologic age—but as the time to death, then the high correlation between the frailty index and mortality can be usefully exploited to calculate biologic age. Here is how. Consider two people ("A" and "B") of the same chronologic age, say 80 years old ([Figure 10-6](#)). One has a frailty index score of 0.11, which by interpolation we can see is the mean value on average of the frailty index at age 65. We can this say that this person has a biologic age of 65 years. The second person has a frailty index value of 0.28, which corresponds to the mean value of the frailty index at age 95, meaning that this person has a biologic age of 95. In multivariable models, which include both chronologic age and the frailty index, each contributes independently, but with more information typically coming from the frailty index.^{48,49} In addition, people who accumulate deficits more quickly have a higher mortality rate.

The frailty index-CGA is one instance of a clinical state variable, with a single number summarizing the overall clinical state of the individual. Other candidate clinical state variables can be considered. Recalling that a system is different from a set of elements by virtue of its interconnectedness,

Table 10-1. Clinical Frailty Scale

Grade	Plain Language Descriptor	Common Characteristics	Usual Frailty Index Values
1	Very fit	Robust, active, energetic, well motivated, and fit; these people commonly exercise regularly and are in the fittest group for their age. Commonly describe their health as "excellent."	0.09 (0.05)
2	Well	Without active/symptomatic disease, but less fit than people in category 1.	0.12 (0.05)
3	Well, with treated comorbid disease	Disease symptoms are well controlled compared with those in category 4.	0.16 (0.07)
4	Apparently vulnerable	Although not frankly dependent, these people commonly complain of being "slowed up" or have disease symptoms or self-rate health as "fair," at best. If cognitively impaired, do not meet dementia criteria.	0.22 (0.08)
5	Mildly frail	Shows limited dependence on others for instrumental activities of daily living.	0.27 (0.09)
6	Moderately frail	Help is needed with both instrumental and some personal activities of daily living. Walking commonly is restricted.	0.36 (0.09)
7	Severely frail	Completely dependent on others for personal activities of daily living.	0.43 (0.08)
8	Terminally ill	Terminally ill	

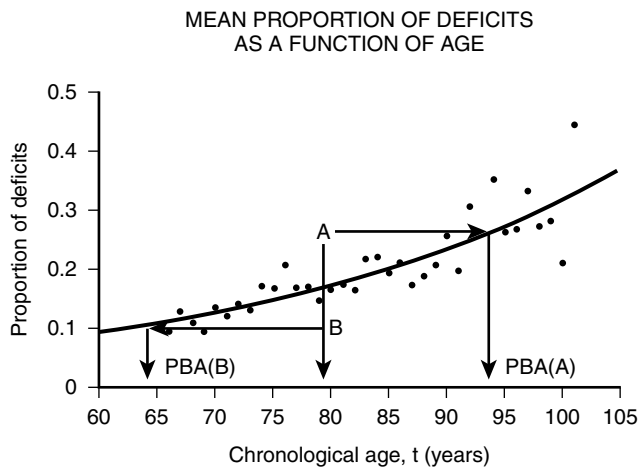

Figure 10-6. Personal biologic age. Because the mean value of the frailty index is so highly correlated with mortality (r^2 typically >0.95), it can be used to estimate personal biologic age, understood as a measure of the proximity to death. Consider two men, each with the same (chronologic) age of 78 years. Person A has a value of the frailty index that corresponds to the mean frailty index value for 93-year-olds. In that sense he has a personal biologic age of 93 years. By contrast, person B has a value of the frailty index that is seen, on average, at age 63 years. That person would have a mortality risk that corresponds to that of 63-year-olds.

clinical state variables need to integrate information about connectedness of the component parts. In this way, decline in connectivity can be considered as a manifestation of frailty, a point that can be illustrated with connectivity graphs.²⁰ In this way too, it is evident that any clinical state variable should represent the functioning of a system, so from that standpoint must be high order. For humans, the evolutionary high order functions are upright bipedal ambulation, opposable thumbs, divided attention, and social interaction. In consequence, candidate clinical state variables logically can be sought in measures of mobility and balance, function, divided attention, and social withdrawal. Any geriatrician will recognize in this a short list of important "geriatric giants," those being impaired mobility ("taking to bed," "off legs"), falls, functional decline, and social withdrawal, or caregiver distress. This textbook has chapters on each topic and each is moving toward better quantification of the underlying phenomena. The valuation

of mobility and balance appears to hold particular promise as a candidate for a clinical state variable that changes acutely.⁷⁶ Recently, too, a frailty index has been employed using data available in the emergency department record.⁷⁷

Good geriatric medicine has always had an intuitive grasp of the nature of complexity as manifest in the frail elderly patients for whom geriatricians are privileged to care. The intent in making the analysis of complexity explicit is to build on this intuition, not substitute for it. As has been argued, providing a scientific basis for the specialty of geriatric medicine, rather than it existing as a set of utilitarian values (we do these things because they seem to work), is essential to advancing the care of frail elderly patients with complex needs.⁷⁸

KEY POINTS

Models of Aging

- Frailty is an important issue for geriatricians; geriatric medicine chiefly consists in the complex care of elderly people who are frail.
- Frailty is a state of increased risk of adverse health outcomes.
- Operationalization of frailty is controversial, with three approaches to measurement: classification from preset descriptors; criteria based on the idea of common frailty phenotypes, and a count of deficits.
- An attractive feature of the deficit count approach is that it allows insights from formal analyses of complexity to be applied to clinical problems associated with frailty.
- One insight from complexity analyses is the notion of clinical state variables (i.e., single numbers that allow the overall clinical state to be summarized). The frailty index, a deficit count, is one example of the chronic health state. Mobility and balance, appropriately measured, appears to be another clinical state variable, more applicable for acute changes in health.
- Another idea that can be imported from complexity analyses is that instruments meant to convey information should be presented in ways that allow for easy pattern recognition.
- The formal analysis of complexity also makes clear why comprehensive geriatric assessment, and the evaluation of delirium, falls, and immobility are intrinsic to geriatric medicine. Each is a response to the analysis of complex systems at high risk for failure.

The Premature Aging Syndrome Hutchinson-Gilford Progeria: Insights Into Normal Aging

Leslie B. Gordon

INTRODUCTION

Hutchinson-Gilford progeria syndrome (HGPS) is an extremely rare, uniformly fatal, segmental “premature aging” disease in which children exhibit phenotypes that may give us insights into the aging process at both the cellular and organismal levels. This chapter will compare HGPS with normal aging with respect to its genetics, biology, clinical phenotype, clinical care, and treatment. By looking carefully at one of the rarest diseases on earth, we gain novel and important insight into the most common conditions affecting quality and longevity of life—aging and cardiovascular disease.

HGPS: disease description

Hutchinson-Gilford progeria syndrome is, in most cases, a sporadic, autosomal dominant, “premature aging” disease in which children die of heart attacks or strokes at an average age of 13.^{1,2} Children experience normal fetal and early postnatal development. Between several months and 1 year of age, abnormalities in growth and body composition are readily apparent (Figure 11-1). Severe failure to thrive ensues, heralding generalized lipoatrophy,^{3,4} with apparent wasting of limbs, circumoral cyanosis, and prominent veins around the scalp, the neck, and trunk. Children reach a final height of approximately 1 m and weight of approximately 14 kg. Bone and cartilaginous changes include clavicular resorption, coxa valga, distal phalangeal resorption, facial disproportion (a small, slim nose and receding mandible), and short stature. Dentition is severely delayed.^{5,6} Eruption may be delayed for many months, and primary teeth may persist for the duration of life. Secondary teeth are present, but may or may not erupt. Skin looks thin with sclerodermatous areas and almost complete hair loss.^{7–9} Skin findings are variable in severity and include areas of discoloration, stippled pigmentation, tightened areas that can restrict movement, and areas of the dorsal trunk where small (1 to 2 cm) soft bulging skin is present. Joint contractures, due to ligamentous and skin tightening, limit range of motion. Intellectual development is normal in HGPS. Transient ischemic attacks and strokes may ensue as early as 4 years of age, but more often they occur in the later years. Death results from sequelae of widespread arteriosclerosis between the ages of 8 and 21 years, almost exclusively from myocardial infarction or stroke.^{1,2,10}

Molecular genetics and cell biology

LAMIN A

HGPS is a member of the family of genetic diseases known as the laminopathies, whose causal mutations lie along the *LMNA* gene (located at 1q21.2).^{11–13} The *LMNA* gene codes for at least four isoforms, of which only the lamin A

isoform is associated with mammalian disease.^{14,15} The lamin proteins are the principal proteins of the nuclear lamina; a structure located inside the inner nuclear membrane.¹⁶ Lamin A, like all lamin molecules, contains an N-terminal head domain, a coiled-coil α -helical rod domain, and a carboxy terminal tail domain¹⁷ (Figure 11-2). It is derived from a larger molecule, prelamin A, which undergoes multistep proteolytic processing, which includes the addition and then cleavage of a farnesyl group to become mature lamin A.^{18–20} The loss of the farnesyl anchor presumably releases prelamin from the nuclear membrane, rendering it free to participate in the multiprotein nuclear scaffold complex just internal to the nuclear membrane, affecting nuclear structure and function.¹⁹ The integrity of the lamina is crucial to many cellular functions, including mitosis, creating and maintaining structural integrity of the nuclear scaffold, DNA replication, RNA transcription, organization of the nucleus, nuclear pore assembly, chromatin function, cell cycling, and apoptosis.

MUTATIONS IN *LMNA* CAUSE HGPS

HGPS is almost always a sporadic autosomal dominant disease, with only one proven case of mosaicism.²¹ Ninety percent of HGPS patients have a single C to T transition at nucleotide 1824, which activates a cryptic splice site^{22–24} (Figure 11-2). Translation followed by posttranslational processing of this altered mRNA produces a shortened abnormal protein with a 50 amino acid deletion near its C-terminal end, henceforth called “progerin.” The 50 amino acid deletion does not affect the ability of progerin to localize to the nucleus or to dimerize because the necessary components for these functions are not deleted.¹⁹ Importantly, however, it does remove the recognition site that leads to proteolytic cleavage of the terminal 18 amino acids of prelamin A (see Figure 11-2), along with the phosphorylation site(s) involved in the dissociation and reassociation of the nuclear membrane at each cell division.^{18,19}

The multisystem and primarily postnatal disease manifestation in HGPS is not surprising, since lamin A is normally expressed by most differentiated cells, preserving function in undifferentiated cells that dominate fetal development.¹⁶ Lamin A expression is developmentally regulated and displays cell and tissue specificity, primarily in differentiated cells including fibroblasts, vascular smooth muscle cells, and vascular endothelial cells.^{14,25,26} Although the alternate splicing in HGPS leads to decreased levels of lamin A, this does not seem to affect cell function at all. In fact, a mouse model entirely lacking lamin A shows no signs of disease.²⁷ HGPS is therefore a *dominant negative* disease; it is the action of progerin, not the diminution of lamin A, that causes the disease phenotype.

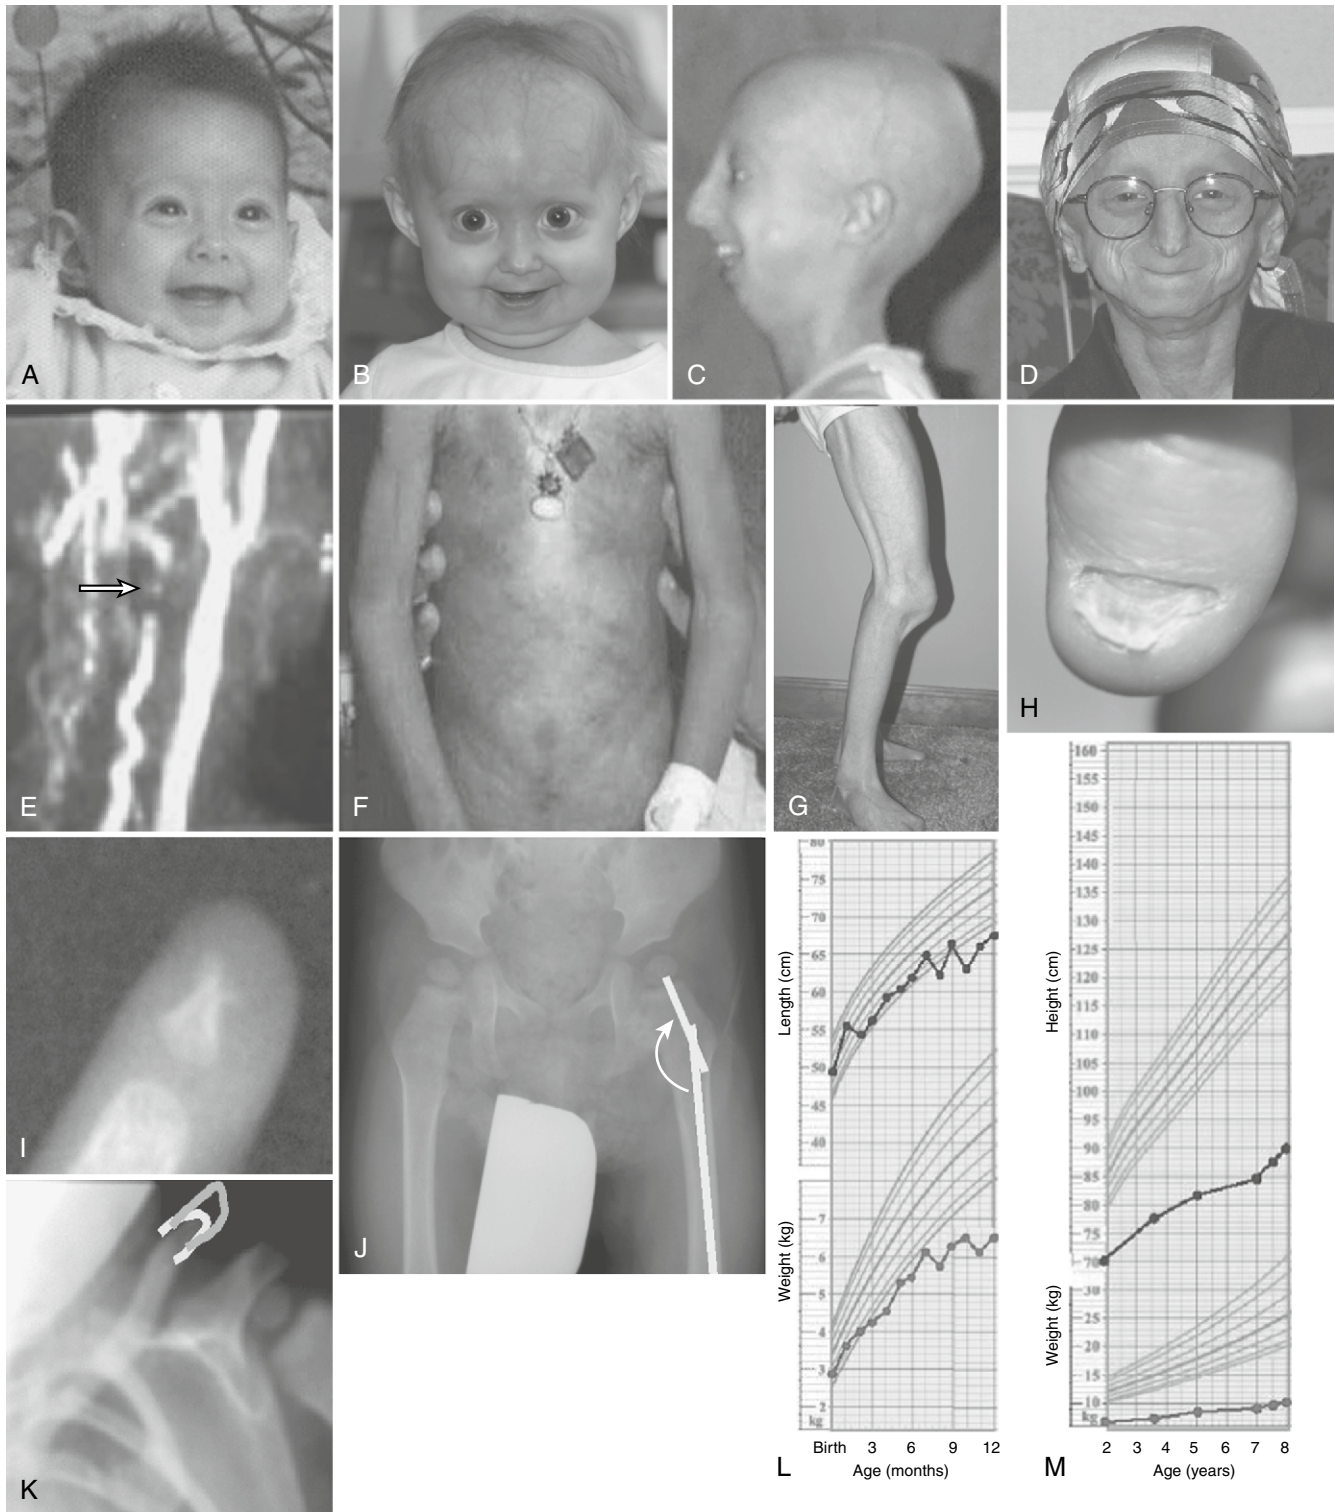

Figure 11-1. Physical characteristics of HGPS: Four different children at ages (A) 3-month-old female, (B) 2.2-year-old female, (C) 8.5-year-old male, and (D) 16-year-old male. (E) Carotid artery MRI with contrast in a 4-year-old with HGPS demonstrates patency of right common carotid artery, and 100% occlusion of left common carotid artery (arrow). (F) Truncal skin showing areas of discoloration, stippled pigmentation, tightened areas that can restrict movement, and areas of the dorsal trunk where small (1 to 2 cm) soft bulging skin is present in a 7-year-old male. (G) Knee joint restriction in a 12-year-old male. (H) Nail dystrophy and distal phalangeal tufting in a 10-year-old male. Typical x-ray findings: (I) acro-osteolysis of the distal phalange, (J) clavicular shortening, (K) coxa valga. Growth characteristics showing normal birth weight and length, followed by failure to thrive. Average length (blue) and weight (black) for age for 10 females during (L) birth to 12 months and (M) 2 to 8 years. Standard deviation less than 6% for each data point. Data for males is not significantly different from those of females ($p < 0.05$) (data not shown). (Photos courtesy from The Progeria Research Foundation. Data courtesy from the PRF Medical and Research Database. Growth charts adapted from those developed by the National Center for Health Statistics in collaboration with the National Center for Chronic Disease and Health Promotion, published May 30, 2000, www.cdc.gov/growthcharts.)

Figure 11-2. Abnormal splicing in HGPS and normal *LMNA*. (A) Sequences in bold and italics represent potential splice donor sequence. Partial DNA sequence for ideal consensus splice donor sequence (seven bases, *Top line*), which shares six of seven bases with HGPS (*Middle line*), and five of seven bases with normal *LMNA* (*Bottom line*). Codes for glycine are underlined. Mutant transition (C to T) in red. Vertical red line represents splice point used variably in HGPS, and in normal cells (less frequently). (B) Representation for mutant splicing that results in 50 amino acid deletion from lamin A, thus creating progerin. (C) Translation of the *LMNA* gene yields the prelamin A protein, which requires posttranslational processing for incorporation into the nuclear lamina. The prelamin A protein has the amino acids CSIM at the C terminus. This comprises a CAAX motif (where C is cysteine, A is an aliphatic amino acid, and X is any amino acid), which signals for isoprenylation (in this case, the addition of a farnesyl group to the cysteine by the enzyme farnesyltransferase [FTase]). After farnesylation, the terminal three amino acids (SIM) are cleaved by the ZMPSTE24 endoprotease, and the terminal farnesylated cysteine undergoes carboxymethylation. A second cleavage step by ZMPSTE24 then removes the terminal 15 amino acids, including the farnesyl group. This final cleavage step is blocked in Hutchinson-Gilford progeria syndrome. (Copyright 2006. *Nature Reviews Genetics*.)

FARNESYLATION AND HGPS

A key to disease in HGPS is the presumably persistent farnesylation of progerin,²⁴ which renders it permanently intercalated into the inner nuclear membrane, where it can accumulate and exert progressively more damage to cells as they age. That the failure to remove the farnesyl group is at least in part responsible for the phenotypes observed in HGPS is strongly supported by studies on both cell and mouse models, which have either been engineered to produce a nonfarnesylated progerin product, or treated with a drug that inhibits farnesylation, rendering a non-farnesylated progerin product. Drugs tested include farnesyltransferase inhibitors, statins, and nitrogen-containing *bis*-phosphonates, all of which work at different points along the pathway leading to farnesylation of the abnormal lamin A proteins produced in progeria.²⁸ By preventing the initial attachment of the farnesyl group to newly synthesized preprogerin molecules, progerin is thought to be unable to effect its aberrant function at the inner nuclear membrane. In many *in vitro* and mouse model studies, some or all of the phenotypes of HGPS were reversed toward normal.

This included reversing vascular disease in an HGPS mouse model that mimics progressive arteriosclerosis,²⁹ increased life span by 50%, fewer bone breaks, and increased size using farnesyltransferase inhibitor (FTI),³⁰ and increasing life span by 80%, improved growth, hair, and bone breakage in a ZMPSTE24^{-/-} model.³¹

Aging and HGPS

HGPS is described as a "segmental" premature aging syndrome because it shares some phenotypes with normal aging, but not all. Cancer, Alzheimer's disease, and various other sequelae of aging are not present in HGPS. Clinical characteristics common to both, but accelerated in HGPS, include progressive vascular disease, bone loss (osteopenia or osteoporosis), loss of subcutaneous fat (lipoatrophy), and hair loss. A number of laminopathies have both progeroid and nonprogeroid phenotypes, but HGPS is the best studied for its commonalities with aging, senescence, and arteriosclerosis.²⁸

HGPS and aging share a variety of cellular elements key to aging at the cellular level, including decreased resistance

to oxidative stress, increased DNA damage, and decreased ability to repair that damage; abnormal nuclear shape (blebbing) (Figure 11-3; see also color plate 11-3); decreased resilience in response to mechanical strain; and a host of signaling pathways that change with senescence and age, including the Notch pathway.³² Perhaps our most exciting new clue to the aging process is the presence of progerin protein at increasing concentrations as both HGPS and normal cells age.

Normal fibroblasts senesce, but HGPS fibroblasts senesce more rapidly (i.e., usually within 15 passages³³). Oxidative stress, in the form of superoxide radicals and hydrogen peroxide, has been found to induce senescence and apoptosis and is implicated in the cause of atherosclerosis³⁴ and normal aging.^{35,36} Antioxidants such as superoxide dismutase, catalase, and glutathione peroxidase help eliminate superoxide radicals and hydrogen peroxide. Yan et al³⁷ demonstrated significantly decreased glutathione peroxidase, magnesium superoxide dismutase, and catalase levels in HGPS fibroblast cultures compared with normal control cultures. Normal cellular senescence is also marked by increasing rates of DNA damage and a decline in the ability to repair this damage.³⁸ Progeria cells accumulate double stranded DNA (dsDNA) breaks and impaired DNA repair³⁹⁻⁴¹ Aberrant nuclear shape (called blebbing or lobulation) occurs in normal fibroblasts undergoing apoptosis as an antecedent to apoptosis and senescence¹⁶ (see Figure 11-3; see also color plate 11-3). A consistent phenotype in HGPS cells is the same aberrant shape of their nuclei, which is readily detected following staining with antilamin antibodies.^{16,24} The blebbing

is a structural sign of cellular decline in both normal and HGPS cell cultures. Another structural weakening associated with aging cells, development of cardiovascular disease, and HGPS is the response to mechanotransduction (applied force).^{42,43} When strain is applied to early passage wild-type fibroblast nuclei, they remain stiff.⁴⁴ Although progeria fibroblasts show normal rigidity at early passages (when progerin levels and nuclear blebbing are at a minimum), late passage nuclei show dramatically *increased* rigidity over wild-type fibroblasts. In addition, whereas wild-type cells enter S phase and G2 phase in response to mechanical stretch, HGPS cells do not proliferate in response to stretch. Microarray studies have revealed significant overlap between cell signaling in senescing cells and HGPS fibroblasts as compared with early passage normal cells.⁴⁵⁻⁴⁷ The Notch regulatory pathway in particular stands out because Notch is important for maintenance of stem cells (including mesenchymal stem cells), differentiation pathways, and cell death. Significantly, both HGPS cells and non-progeria cells induced to produce progerin display up-regulation of three genes in the Notch pathway: Hes 3, Hes 4, Hey 1.

The discovery that progeria is caused by a mutation in lamin A, which had not previously been implicated in mechanisms of aging, brought in an entirely new question: Are defects in lamin A implicated in normal aging? The first positive evidence was reported by Scaffidi et al in 2006,⁴⁹ who showed that cell nuclei from normal individuals have acquired similar defects as progeria patients, including changes in histone modifications and increased DNA damage. Younger cells

Figure 11-3. Nuclear blebbing and presence of progerin in HGPS and aging. Fibroblast nuclei stained with antilamin antibody (A) passage 4 HGPS, (B) passage 10 normal, (C) passage 40 normal; skin biopsies stained with antiprogerin antibody and shown here at 40 \times for (D) HGPS donor age 10 years old; (E) normal newborn, (F) normal, donor age 90 years old.

show considerably less of these defects. They further demonstrated that the age-related effects are the result of the production of low levels of progerin mRNA produced by activation of the same cryptic splice site that functions at much higher levels in progeria, and is reversed by inhibition of transcription at this splice site. Cao et al,⁵⁰ studying the same phenomenon, showed that among interphase cells in fibroblast cultures, only a small fraction of the cells contained progerin. The percentage of progerin-positive cells increased with passage number, suggesting a link to normal aging. Notably, McClintock et al found progerin in skin biopsies of older donors, while young donors had no detectable progerin. This is the first human *in vivo* demonstration of a buildup of progerin with normal aging⁵¹ (see Figure 11-3; see also color plate 11-3). The newly discovered relationship between HGPS and lamin A has opened the doors of scientific exploration into how lamins play a role in heart disease and aging in the general population. Scaffidi et al⁴⁹ have shown that normal fibroblasts also produce some progerin by using this same splice site to a lesser degree than do HGPS fibroblasts.

A key element when considering treatment for HGPS, or for arteriosclerosis and normal aging, is progerin's dosage effect. In HGPS, the nonmutated *LMNA* gene splices normally produce full length lamin A, and only rarely uses the cryptic splice site to produce progerin. The other (mutated) *LMNA* gene produces both progerin in substantial amounts and a minor amount of lamin A. Reddel and Weiss showed that the mutant allele in cultured HGPS fibroblasts uses the cryptic splice site 84.5% of the time.⁵² Different individuals may produce more or less progerin, and within an individual, different cell types may produce varying amounts of progerin versus normal lamin A. In normal fibroblast cells in culture, the cryptic splice site is used about fiftyfold less as compared with HGPS fibroblasts. However, because progerin protein accumulates with increasing age in skin biopsies⁵¹ (see Figure 11-3; see also color plate 11-3) and *in vitro* with increasing passage number,¹⁶ the influence of progerin on health in the general population probably also increases as we age. Clinical support for the dosage effect hypothesis is found in the study of a 45-year-old man with a progeroid laminopathy, whose mutation in T623S produced a cryptic splice site abnormality in *LMNA*, but the splice site was used 80% less frequently than in classic HGPS.⁵³ His phenotype mimicked HGPS, but to a milder degree. Therefore we can assume that decreasing the levels of progerin by a relatively modest percentage will significantly ameliorate disease. In addition, it is highly possible that one component of genetic predisposition to arteriosclerosis lies in the amount of progerin that an individual accumulates in his or her lifetime.

OVERLAP BETWEEN HGPS AND ARTERIOSCLEROSIS OF AGING

Individuals with HGPS develop premature severe arteriosclerosis in childhood and frequently succumb to resulting heart attacks or strokes in the second decade of life.^{1,54} Hypertension, angina, cardiomegaly, and congestive heart failure are common end-stage events.⁵⁵⁻⁵⁸ The disease progression of progeria blood vessels does not fit the typical atherosclerotic description, which includes intima-media thickening, atherosclerotic plaque (rich lipid core) with

ruptured cap and superimposed thrombosis, inflammation and endothelial destruction, and proliferating medial smooth muscle cells. In HGPS, intima-media thickness of the carotid artery is normal⁵⁹ as are cholesterol, low-density lipoprotein (LDL), and high sensitivity C-reactive protein levels—all factors in chronic lipid-driven inflammation of atherosclerosis.⁶⁰

Instead, the HGPS vascular phenotype resembles an arteriosclerosis, which is characterized by hardening of the vessels (decreased compliance) in medium and large vessels, and affects millions of aging individuals. Meredith et al, studying a cohort of 15 patients with HGPS, found that younger children displayed normal vascular compliance but that, with age, compliance decreased, and in a number of children this led to left atrial enlargement.⁵⁹ Blood pressure and heart rate were in the normal range in younger children, whereas the older children had increasing blood pressures and variable heart rates. Electrocardiograms were normal in most, although a few had long Q-T intervals suggesting fibrosis of the conduction system.

Gordon et al⁶⁰ found serum levels of cholesterol, triglyceride (TG), LDL, and C-reactive protein (a mediator of inflammation) within normal limits in 19 patients, but showed decreasing high-density (HDL) and adiponectin (a secretory product of adipose tissue) with increasing age in HGPS. In fact, adiponectin values exhibited a strong positive correlation with HDL values in progeria children. Declines in HDL and adiponectin have been implicated in other lipodystrophic syndromes and lipodystrophy associated with type 2 diabetes.⁶¹⁻⁶⁵ Adiponectin is emerging as an independent cardiovascular risk factor, which may directly regulate endothelial function⁶¹⁻⁶⁵ and which also correlates with HDL in type 2 diabetes.⁶⁶

The fewer than 20 autopsies on children with HGPS have revealed focal plaque throughout large and small arteries, including all coronary artery branches.^{1,57,58,67-70} The plaque is markedly calcified and contains cholesterol crystals and a nearly acellular hyaline fibrosis. Vessel cross-sections at autopsy of one 22-year-old woman with clinical features of HGPS revealed no indication of vasculature inflammation.⁵⁴ The vascular media no longer contained smooth muscle cells and the elastic structure was destroyed and replaced with extracellular matrix or fibrosis, with profound adventitial thickening and a depleted media. Presumably the primary loss of smooth muscle cells initiates vascular remodeling by secondary replacement with matrix in large and small vasculature.

Apoptosis occurs in vascular smooth muscle cells before the development of calcification,⁷¹ and may even be required for calcification to occur. Since vascular calcification is a requisite event in plaque formation,⁷² apoptosis may be a key element in the development of disease in HGPS and arteriosclerosis.^{33,42,73}

HGPS is a disease involving abnormalities in the extracellular matrix, with increased collagen and elastin secretion, disorganized dermal collagen, decreased decorin, and increased aggrecan and ankyrin G compared with normal controls.^{45,47,74-77} Extracellular matrix molecules have both structural and cell signaling functions in skin, bone, and the cardiovascular system,⁷⁸⁻⁸⁴ all of which are severely affected in HGPS. In pathologic and clinical studies, mesoderm-derived tissues and their extracellular matrices are targets of

principal defects. Gene expression studies of HGPS fibroblasts are consistent with these findings.^{46,85} Aneurysms, noted in several cases of HGPS,^{10,67,70} derive from medial necrosis, which could reflect either a connective tissue problem and concurrent death of smooth muscle cells.

In summary, the study of HGPS has provided a completely new molecule, progerin, which may play an integral role in general vascular biology and health. The progeria vasculature is characterized by global stiffness, tortuosity, and a loss of smooth muscle cells in the media with subsequent extracellular replacement. Biochemical abnormalities include progressively decreasing HDL and adiponectin. Smooth muscle cell dropout is unique to progeria, whereas global stiffness and tortuosity, decreased HDL, and adiponectin are observed in arteriosclerosis and type 2 diabetes in the normal aging population. Although progerin was found in arterioles of an HGPS patient,²⁵ future studies in this young field will need to assess for the presence of progerin in non-HGPS vasculature, and its potentially causal relationship to cardiovascular disease with aging.

Clinical care

DIAGNOSTICS AND GENETIC COUNSELING

Initial indications for HGPS include failure to thrive, skin signs, stiffened joints, delayed dentition, gradual hair loss, and subcutaneous loss of fat with normal developmental milestones. Average age at diagnosis is 2 years (see www.genetests.org). The Progeria Research Foundation (www.progeriaresearch.org) is the only patient advocate organization worldwide that is solely dedicated to discovering the cause, treatments, and cure for progeria. The organization provides services for families and children with progeria, such as patient education and communication with other progeria families. It serves as a resource for physicians and medical caretakers of these families via clinical care recommendations, a diagnostics facility, a clinical and research database, and funding for basic science and clinical research in progeria.

CARDIAC CARE AND LOW-DOSE ASPIRIN

Children with HGPS are at high risk for heart attacks and strokes at any age. The earliest published incidence of stroke is at the age of 4 years.⁵⁹ In one case, seizures were the presenting cerebrovascular event.¹⁰ Importantly, stroke (cerebral infarction) may occur while the child exhibits a normal EKG and may be caused by occlusion of a small cerebral vessel in the absence of large-vessel intracranial blockages.⁸⁶

Studies in adults have shown that the benefits of low-dose aspirin therapy increase with increasing cardiovascular risk.^{87,88} Recommendations here are extrapolated from this evidence in adults. *Low-dose aspirin should be considered for all children with HGPS at any age, regardless of whether the child has exhibited overt cardiovascular abnormalities or abnormal lipid profiles.* Low-dose aspirin may help to prevent atherothrombotic events, including transient ischemic attacks (TIA), stroke, and heart attacks, by inhibiting platelet aggregation. Dosage is determined by patient weight, and should be 2 to 3 mg/kg given once daily or every other day. This dosage will inhibit platelet aggregation but will not inhibit prostacyclin activity.

Once a child begins to develop signs or symptoms of vascular decline, such as hypertension, TIA, strokes, seizures,

angina, dyspnea on exertion, EKG changes, echocardiogram changes, or heart attacks, a higher level of intervention is warranted. Antihypertensive medication, anticoagulants, antiseizure and other medications usually administered to adults with similar medical issues have been given to children with HGPS. All medication should be dosed according to weight, and carefully adjusted according to accompanying toxicity and efficacy.

INTUBATION

Intubation is difficult in the child with progeria due to the small oral aperture with retrognathia, little flexion or extension in the cervical spine, relatively large epiglottis, and small glottic opening. Nasal fiberoptic may be difficult to place because of an unusual glottic angle. Intubation with direct visualization is recommended because glottic angle may make fiberoptic intubation difficult. For nonoral procedures, mask ventilation, or laryngeal mask airway is recommended over intubation.

PHYSICAL THERAPY (PT) AND OCCUPATIONAL THERAPY (OT)

Children with progeria need PT and OT as often as possible (optimally two to three times each per week) to ensure maximum range of motion and optimal daily functioning throughout their lives. The role of PT and OT is to maintain range of motion, strength, and functional status. Proactive PT and OT are important since all children with progeria develop restrictions in range of motion in a progressive manner (see Figure 11-1). Bony abnormalities are almost always evident in x-rays by the age of 2 years.⁸⁹⁻⁹³ Range of motion may be restricted because of progressive joint contractures, primarily in the knees, ankles, and fingers as a result of tendinous abnormalities; hip abnormalities due primarily to progressive coxa valga; and shoulder restrictions due to clavicular resorption. Tightened skin can also restrict range of

KEY POINTS

The Premature Aging Syndrome Hutchinson-Gilford Progeria

- HGPS is a rare segmental premature aging syndrome in which children die of heart attacks or strokes between ages 7 and 20 years.
- HGPS is an autosomal dominant disease caused by a single base mutation in *LMNA*, leading to a silent mutation that creates a cryptic splice site.
- Lamin A is an inner nuclear membrane protein that is central to cellular structure and function, primarily in differentiated cells.
- The abnormal lamin A protein produced in HGPS, called progerin, is not only generated in HGPS, but is also generated to a lesser extent in the normal population.
- Cardiovascular disease in HGPS resembles arteriosclerosis of aging, with hypertension, vascular stiffening, vessel wall remodeling with abnormal extracellular matrix, plaque formation in the face of normal cholesterol levels, and finally stroke and heart attacks.
- Progerin accumulates with increased age and is likely associated with cellular aging and vascular disease in the general population.
- Preclinical studies show that preventing farnesylation of progerin improves disease phenotype both in cell culture and in mouse models, including reversal of vascular disease.

motion. Skin tightening can be almost absent in some children, or can be severe and restrict chest wall motion and gastric capacity in others.

Each regimen should be tailored to the child's individual needs, and tailored according to cardiac status in consultation with the child's physician. Any child who develops dyspnea (shortness of breath), angina (chest pain), or cyanosis (blue discoloration of lips and skin) during exertion should stop immediately. If symptoms do not rapidly resolve, the child should receive emergency medical care. If oxygen is available, it should be administered. Therapy personnel should be trained in cardiopulmonary resuscitation and have access to an automated external defibrillator with pediatric capability.

Common protocols for PT and OT include but are not limited to the following: Tracking progress through regular joint range of motion measurements is advised at least every 3 to 4 months. Due to the orthopedic conditions commonly seen in the hip and shoulder, range of motion in these joints should be closely monitored. Tightness is also seen in the heel cords, low back muscles, finger flexors, and triceps muscles. To maintain range of motion, a combination of myofascial release techniques followed by more traditional passive, active, and active-assisted stretching exercises are

effective. Due to the possibility of weakened joint integrity due to coxa valga in the hips and clavicular resorption in the shoulders, it is advisable to avoid passive stretching in these joints and instead focus on active stretching. Weight-bearing activities in hands and knees are helpful for stretching finger flexors. To help maintain range of motion, traditional stretching can be followed by functional activities. Strengthening activities should target core strengthening for the hips and abdominals with activities such as sit-ups, bridges, and leg lifts. Due to orthopedic deformities, tendinous, and muscular and skin tightness, gait deviations often occur. It is advisable to focus on maintaining heel cord flexibility and hip internal rotation to minimize gait deviations.

ACKNOWLEDGMENT

I wish to gratefully acknowledge the children with progeria and their families, for participation in progeria research. Thank you to Frank Rothman, PhD, for review of the chapter and helpful suggestions.

Aging is a continuous process that constitutes a cycle studied with events that affect all systems in the body, including the connective tissues. The interrelationship between the aging process and connective tissues is complex, involving a variety of factors and interactions acting in a reciprocal fashion. One could inquire into the effects of aging on connective tissues and, conversely, one may ask how the components of connective tissue contribute to the aging process. To answer these questions, it is important to have some understanding of the structural biochemistry of connective tissues, some knowledge of the processes involved in their biosynthesis, modification, extracellular organization, and molecular genetics, and the factors affecting the properties of connective tissue cells and the extracellular matrix (ECM). In the period since the last edition, new data became available which highlight the progress made in the area of the mechanisms responsible for the alterations in connective tissue components in diseases associated with aging. Armed with this knowledge, it becomes apparent that there can be a huge number of events in the development of connective tissues that may be associated, directly or indirectly, with the processes or effects of aging. These have been and continue to be areas of intensive research.

This chapter presents an abbreviated discussion of the various components of the ECM, their structure, molecular organization, biosynthesis, modification, turnover, and molecular genetics. It discusses some concepts on the effects of aging on the ECM and the effects of aging on the properties of various connective tissues and the involvement of connective tissue physiology on diseases associated with aging.

THE PROPERTIES OF CONNECTIVE TISSUES

The properties of connective tissues are derived primarily from the properties of the components of the ECM surrounding, and secreted by, the cells of those tissues. Some connective tissues, such as cartilage or tendons, may be composed primarily of a single-cell type (e.g., chondrocytes or fibroblasts), whose synthesis and secretion of ECM and other factors largely determine the properties of the tissue. Some tissues, such as bone, blood vessels, and skin, contain a number of different connective tissue cell types (e.g., osteoblasts and osteoclasts) in bone, endothelial, and smooth muscle cells in blood vessels, and fibroblasts and epithelial cells in skin, which contribute to both their structural and functional properties. Other tissues, such as cardiac muscle and kidney, may have properties dependent upon connective tissue components whose biologic roles are separate from the major physiologic function of the tissue and which may have influence over the properties of that tissue during the process of aging. Different cell types will exhibit different phenotypic patterns of ECM production, which in turn will influence the structural properties of a given connective tissue.

The major components of the ECM fall into three general classes of molecules: (1) the structural proteins, which

include the collagens (of which there are now 28 types recognized) and elastin; (2) the proteoglycans, which contain several structurally distinct molecular classes, such as heparan sulfate and dermatan sulfate; and (3) the structural glycoproteins, exemplified by fibronectin (FN) and laminin (LM), whose contribution to the properties of connective tissues has been recognized only within the past 35 to 40 years. The interactions among these materials determine the development and properties of the connective tissues.

The collagens

STRUCTURE

The collagens are a family of connective tissue proteins having a triple-stranded organization and containing molecular domains within which the strands are coiled around one another in a triple helix. The reader is referred to two recent reviews on collagen biochemistry.^{1,2}

The genes of at least 28 distinct collagen types have been characterized.³ The interstitial collagens—types I, II, III, and V—exist as large, extended molecules that tend to organize into fibrils.¹ There may be more than one collagen type within these fibrils.⁴ Type IV collagen, also known as *basement membrane (BM) collagen*, does not exist in fibrillar form, but rather in a complex network of collagen molecules linked by disulfide and other cross-linkages and associated with non-collagenous molecules, such as LM, entactin, and proteoglycans, to form an amorphous matrix.^{5,6} Although at least 28 collagen types are recognized, the protein of only the first 11 collagens has been isolated from tissues.

There are 46 genes corresponding to the α chains of 28 collagen types.³ Collagen type I is the most abundant collagen and the most abundant protein in the body. The basic unit of the type I collagen fibril is a triple helical heterotrimer, tropocollagen, consisting of two identical chains, termed $\alpha 1(I)$, and a third chain, $\alpha 2(I)$.¹ The other collagen types have been given similar designations; however, some of the types are homotrimers containing three identical chains and some contain three genetically distinct α chains.

The collagen α chain has a unique amino acid composition with glycine occupying every third position in the sequence. Thus the collagenous domains consist of a repeating peptide triplet, -Gly-X-Y-, in which X and Y are amino acids other than glycine. A large percentage of amino acids in the Y position is occupied by proline. In addition, collagen contains two unique amino acids derived from posttranslational modifications of the protein, 4- and 3-hydroxyproline and hydroxylysine. The presence of 4-hydroxyproline provides additional sites along the α chain capable of forming hydrogen bonds with adjacent α chains, which are important in stabilizing the triple helix so that it maintains its structure at body temperatures. If hydroxyproline formation is inhibited, the triple helix dissociates into its component α chains at 37° C.

The presence of glycine in every third position, along with the extensive hydrogen bonding, provides the triple helix with a compact protected structure resistant to the action of most proteases. The α chains of the collagen superfamily

are encoded with information that specifies self-assembly into fibrils, microfibrils, and networks that have diverse functions in the ECM.⁶ The structures of collagens can be stabilized further through the formation of covalent cross-linkages derived from modification and condensation of certain lysine and hydroxylysine residues on adjacent α chains.² Cross-linkage formation is important in stabilizing collagen fibrils and contributes to their high tensile strength.

BIOSYNTHESIS⁷

Type I collagen α chains are synthesized as a larger precursor, procollagen, containing noncollagenous sequences at their C and N termini. As each pro- α chain is synthesized, intracellular prolyl and lysyl hydroxylases act to form hydroxyproline and hydroxylysine. The triple helix is formed intracellularly and stabilized by the formation of interchain disulfide bonds near the carboxyl termini of the component pro- α chains. After secretion of the triple helical collagen, procollagen peptidases remove most of the noncollagenous portions at each end of the procollagen. Extracellular lysine and hydroxylysine oxidases oxidize the amino groups of lysine or hydroxylysine to form aldehyde derivatives, which can go on to form Schiff base adducts, the first cross-linkages. These can rearrange and become reduced to form the various other cross-linkages. Increased numbers of collagen cross-linkages have been reported in a pathologic state known as scleroderma.

DEGRADATION OF CONNECTIVE TISSUE COMPONENTS

The role played by matrix metalloproteinases (MMPs) in connective tissue turnover has gained prominence in the past 35 years as information on the mechanisms by which MMPs mediated synovial joint inflammation and ECM turnover in arthritides became available.⁸ Extracellular degradation of collagen is accomplished by enzymes known as tissue collagenases. These enzymes cleave triple helical collagen at a site three quarters from the amino acid terminus, resulting in the formation of two triple helical fragments (225 nm plus 75 nm respectively), which denature at temperatures above 32° C to form nonhelical peptides that can be degraded by tissue proteinases. Cleavage by tissue collagenase is considered to be the rate-limiting step in collagenolysis of triple helical collagen. Collagenolysis is the subject of reviews by Kleiner and Stetler-Stevenson⁹ and Tayebjee et al.¹⁰

Collagenolysis is an important physiologic process responsible to a large extent for the repair of wounds and processes of tissue remodeling in which undesired accumulations are removed as new connective tissue is laid down. However, in conditions such as rheumatoid arthritis, osteoporosis (OS), and aging, the production of collagenases may be stimulated, resulting in an elevated degradation of synovial tissue or bone.

Degradation of elastin by elastases—belonging to a family of serine—metalloproteinases, or cysteine proteinases, gives rise to the generation of elastin fragments, designated as elastokines.¹¹

Tissue collagenases are secreted by connective tissue cells as a precursor, procollagenase, which must be activated to become enzymatically active. This can be

achieved *in vitro* by the action of trypsin on the latent enzyme. Other proteinases, including lysosomal cathepsin B, plasmin, mast cell proteinase, and plasma kallikrein, also can activate latent collagenases. Thus inflammatory cells can secrete factors that lead to collagenase activation, accounting for the inflammatory sequelae of the arthritides. Collagenases are also under the influence of plasma inhibitors, of which α 2 macroglobulin accounts for most of the inhibitory process. In addition, inhibitors of plasminogen activation can indirectly prevent the activation of procollagenases by plasmin. Fibroblasts and other connective tissue cells also secrete inhibitors of collagenases, suggesting a complex system of extracellular control of collagenolysis.^{9,10}

Elastin

The biochemistry and molecular biology of elastin have been subjects of excellent reviews.^{12,13} As in interstitial collagens, glycine makes up about one third of the amino acid content of elastin. Unlike collagen, however, glycine is not present in every third position. In addition, elastin is an exceedingly hydrophobic protein, with a large content of valine, leucine, and isoleucine.

Elastin is synthesized as a precursor molecule, tropoelastin, with a molecular weight of about 70 kDa. However, in tissues, elastin is found as an amorphous, macromolecular network. This is due to the condensation of tropoelastin molecules through the formation of covalent cross-linkages unique to elastin. These cross-linkages arise through the condensation of four lysine residues on different tropoelastin molecules to form the cross-linking amino acids, desmosine and isodesmosine, characteristic of tissue elastin. The reader is referred to reviews by Bailey et al² and Wagenseil and Mecham¹³ for discussions of the details of collagen and elastin cross-linking.

The hydrophobicity, together with the formation of cross-linkages, endow elastin with its elastic properties and an extreme insolubility and amorphous structure. Elastin accounts for most of the elastic properties of skin, arteries, ligaments, and the lungs. The presence of elastin has been demonstrated in other organs, such as the eye and the kidney. In most tissues, elastin is found in association with microfibrils, which contain several glycoproteins, including fibrillin. Microfibrils have been identified in many tissues, and the importance of their assemblies as determinants of connective tissue architecture has been brought into focus by the identification of mutations in fibrillin in the heritable connective tissue disorder Marfan syndrome.¹⁴

An elegant review summarizes the current knowledge of the structure of the elastin gene, including consideration of the heterogeneity observed in immature mRNA as a result of alternative splicing in the primary transcript.¹⁵ Analysis of the bovine and human elastin genes revealed the separation of those exons coding for distinct hydrophobic and cross-linking domains. Comparison of the cDNA, genomic sequences, and S1 analyses demonstrated that the primary transcript of both species is subject to considerable alternative splicing. It is likely that this accounts for the presence of multiple tropoelastins found in several species. It is suggested that the differences in alternative splicing may be correlated with aging.¹⁵

The proteoglycans

Proteoglycans are characterized by the presence of highly negatively charged, polymeric chains (glycosaminoglycans or "GAGs") of repeating disaccharide units covalently attached to a "core" protein. The disaccharide units comprise an *N*-conjugated amino sugar, either glucosamine or galactosamine, and a uronic acid, usually *D*-glucuronic acid or—in the instances of dermatan sulfate, heparan sulfate, and heparin—*L*-iduronic acid. In cartilage and in the cornea, another GAG, keratan sulfate, containing *D*-glucose instead of a uronic acid has been demonstrated. The amino group of the hexosamine component is usually acetylated and the GAGs are usually *O*-sulfated in hexosamine residues with some *N*-sulfation, instead of acetylation, in the instances of heparan sulfate and heparin. Depending on the source and type of proteoglycan, the number of GAGs attached to the core protein can vary from three or four all the way up into the twenties, with each GAG having a molecular size in the tens of thousands of daltons. In addition, as in the case of the cartilage proteoglycans, there may be more than one type of GAG attached to the core protein. In cartilage, several proteoglycan molecules may be associated with another very large GAG, hyaluronic acid, consisting of disaccharide units of glucuronyl *N*-acetylglucosamine. The compositional structure of the GAGs is summarized in Table 12-1.

The overall effect of these structures is the creation of huge, negatively charged highly hydrophobic complexes. The hydration and charge properties of these complexes cause them to become highly extended, occupying a hydrodynamic volume in the tissue much larger than would be predicted from their chemical composition. In the instance of synovial cartilage, it is suggested that the hydration endows the tissue with shock-absorbing properties in which applied pressure to the joint is counteracted by the extrusion of water from the complex, forcing a compression of the negative charges within the molecule. Upon the release of pressure, the electronegative repulsive forces drive the charges

Table 12-1. Properties and Tissue Distribution of Glycosaminoglycans

GAGs	Composition	Tissue Distribution
Hyaluronic acid	<i>N</i> -acetylglucosamine <i>D</i> -Glucuronic acid	Blood vessels, heart, synovial fluid, umbilical cord, vitreous
Chondroitin sulfate	<i>N</i> -acetylgalactosamine <i>D</i> -Glucuronic acid 4- or 6- <i>O</i> -sulfate	Cartilage, cornea, tendon, heart valves, skin, etc.
Dermatan sulfate	<i>N</i> -acetylgalactosamine <i>L</i> -Iduronic acid 4- or 6- <i>O</i> -sulfate	Skin, lungs, cartilage
Keratan sulfate	<i>N</i> -acetylglucosamine <i>D</i> -Galactose <i>O</i> -sulfate	Cornea, cartilage, nucleus pulposus
Heparan sulfate	<i>N</i> -acetylglucosamine	Blood vessels, basement membranes, lung, spleen, kidney
Heparin	<i>N</i> -sulfaminoglucos- amine <i>D</i> -Glucuronic acid <i>L</i> -Iduronic acid <i>O</i> -sulfates	Mast cells, lung, Glisson membranes

apart with a concomitant influx of water to restore the initial hydrated state. The metachromatic staining properties of connective tissues are due mainly to their proteoglycan content. Several excellent reviews of proteoglycan biochemistry have already been written.¹⁶⁻¹⁸

In recent years, several proteoglycans have been identified in the pericellular environment, either associated with cell surfaces or interacting with ECM components such as interstitial collagens, FN, and TGF- β . Current reviews by Groffen et al¹⁶ and Schaefer and Iozzo¹⁷ describe the structures of the protein cores, their gene organization, their functional characteristics, and tissue distribution. Several of the proteoglycans described by Schaefer and Iozzo on the list constitute a group of small leucine-rich proteoglycans (SLRP). Notable among them are decorin¹⁸ and perlecan.¹⁹ They are multidomain assemblies of protein motifs with relatively elongated and highly glycosylated structures having several protein domains shared with other proteins. In their review, Groffen et al¹⁶ discuss the role of perlecan as a crucial determinant of glomerular BM permselectivity and suggest that the additional presence of agrin, another heparan sulfate proteoglycan species, makes the latter an important contributor to glomerular function.

Lumican, one of the leucine-rich proteoglycans, is found in relative abundance in articular cartilage,¹⁸ which, along with its size, varies with age. In adult cartilage extracts, it exhibited a molecular size in the range of 55 to 80 kDa. Extracts from juvenile cartilage had a more restricted size variation corresponding to the higher molecular size range present in the adult. In the newborn, the sizes were in the range of 70 to 80 kDa.

The biosynthesis of proteoglycans begins with the synthesis of the core protein. The sugars of the GAG chain then are sequentially added to, in most instances, serine residues of the protein, using uridine diphosphate conjugates of the component sugars, with sulfation following as the chain elongates. Most of the chain elongation and sulfation is associated with the Golgi apparatus. The degradation of proteoglycans is mediated through the action of lysosomal glycosidases and sulfatases specific for the hydrolysis of the various structural sites within the GAG chain. Genetic abnormalities in the production or synthesis of these enzymes have been shown to be the main causes of "mucopolysaccharidoses," whose victims may exhibit severe tissue abnormalities and a high incidence of mental retardation.

The structural glycoproteins

In addition to the collagen and elastin components of connective tissues, there are groups of glycoproteins, the structural glycoproteins, that have important roles in the physiology and structural properties of connective and other types of tissues. These proteins, which include FN, LM, entactin/nidogen, thrombospondin (TSP), and others, are involved during development, in cell attachment and spreading, and in tissue growth and turnover.

FIBRONECTIN

One of the best characterized of the structural glycoproteins is fibronectin (FN). It was originally isolated from serum where it was referred to as "cold-insoluble globulin" (CIG). As it became recognized that FN was an all important secretory product of fibroblasts and other types of cells, and

was involved in cell adhesion, the term "FN" replaced CIG. Comprehensive reviews on the structure and function of FN have been published by Lafrenie and Yamada²⁰ and Mao and Schwarzbauer.²¹

FN exists as a disulfide-linked dimer with a molecular weight of about 450 kDa, each monomer having a molecular size of 250 kDa. FN exists in at least two forms, a tissue form and plasma FN. Plasma FN is somewhat smaller and is more soluble at physiologic pH than the cellular form. Spectrophotometric and ultracentrifugal studies indicate that both forms are elongated molecules composed of structured domains separated by flexible, extensible regions. Limited proteolytic digestion has revealed the presence of specific binding sites for a number of ligands, including collagen, fibrin, cell surfaces, heparin (heparan sulfate proteoglycan), factor XIIIa, and actin.

FN plays a role in blood clotting by becoming cross-linked to fibrin through the action of factor XIIIa transamidase, which catalyses the final step in the clotting cascade.²² Fibroblasts and other cell types involved in the repair of injury adhere to the clot by interacting with the cell-binding domain of FN. FN also enables cells to migrate in developing embryos. FN contains a unique peptide sequence, arginylglycylaspartylserine (RGDS or RGD), that binds to specific cell surface proteins (integrins), which span the plasma membrane.²¹ Purified RGD can inhibit FN from binding the cells and can even displace bound FN. The integrins have a complex molecular organization and appear to interact with certain intracellular proteins, thereby providing a mechanism for the control of a number of events by components of the extracellular environment.

FN is encoded by a single gene and its complete primary structure has been determined by the DNA sequencing of overlapping cDNA clones.²³ From such studies, it became recognized that there are peptide segments derived from alternative splicing of FN mRNA at three distinct regions, termed extra domain A (ED-A), ED-B, and connecting segment (III CS). A middle region of the polypeptide containing homologous repeating segments of about 90 amino acids, called type III homologies, has been identified.^{24,25} Using immunologic techniques with monoclonal antibodies, it was shown that the ED-A exon is omitted during splicing of the FN mRNA precursor in arterial medial cells, while the expression of FN containing ED-A is characteristic of modulated smooth muscle cells, such as those in culture or those involved in intimal thickening and atherosclerotic lesions. It would appear that this process of alternative splicing is used during embryonic development or tissue repair as a mechanism to generate different forms of FN in the ECM by the inclusion or exclusion of specific segments. This could be the source of differences between the plasma and cellular forms of FN. This phenomenon of alternative splicing may also be involved in the synthesis of collagens and elastin, and may well be implicated in processes of aging.

LAMININ

Laminin (LM) is the major structural glycoprotein of BMs. In addition to its association with the molecular components of BMs (e.g., type IV collagen, entactin/nidogen, and heparan sulfate proteoglycan), it plays an important role in cell attachment and neurite growth.²⁶⁻²⁸ LM is difficult to isolate from whole tissues or from BMs owing to its poor solubility,

and so most of our knowledge of it is derived from extracts of tumor matrices.

LM is a very large complex composed of at least three protein chains associated by disulfide linkages. The largest of these, the $\alpha 1$, has a molecular weight of about 440 kDa, whereas the smaller units, $\beta 1$ and $\gamma 1$ chains, have molecular weights of about 200 to 250 kDa. Several LM isoforms have been described in recent years,²⁸ necessitating a new nomenclature of its component chains.²⁹ The authors describe 15 isoforms of LM. The first new chain $\alpha 2$ has been found in preparations from normal tissues but is absent from those from neoplastic tissues.^{30,31} LM has been shown to have a twisted cruciform shape consisting of three short arms and a single long arm with globular domains at the extremities of each arm. In several of the newer isoforms of LM, the $\alpha 1$ chain has a smaller molecular size, lacking a portion of its amino terminus.

LM can influence processes of differentiation, cell growth, migration, morphology, adhesion, and agglutination. It plays a major role in the structural organization of BMs.³² LM exhibits a preferential binding to type IV collagen compared with other collagen types. LM contains domains similar to those of FN that bind to different proteins, and cell surface components containing an RGD sequence on the $\alpha 1$ chain and a YIGSR sequence on the $\beta 1$ chain, both of which bind to different integrins on the cell surface and are involved in cellular attachment and migratory behaviors.

ENTACTIN/NIDOGEN

Entactin/nidogen, a novel sulfated glycoprotein, is an intrinsic component of BMs. Entactin was first identified in the ECM synthesized by mouse endodermal cells in culture.³³ Subsequently, a degraded form, termed nidogen, was isolated from the Englebreth-Holm-Swarm sarcoma and mistakenly identified as a new BM component.³⁴ Both terms, entactin and nidogen, are used interchangeably in the modern literature. Entactin-1/nidogen-1 and entactin-2/nidogen-2 are differentially expressed in myogenic differentiation.³⁵

Entactin/nidogen forms a tight stoichiometric complex with LM. Rotary shadowing electron microscopy has revealed its association with the $\gamma 1$ chain of LM. Entactin/nidogen has been shown to promote cell attachment via an RGD sequence, and calcium ions have been implicated in its properties.³⁶ Its role along with LN in BM assembly and in epithelial morphogenesis has already been noted in the previous section. It has been shown that entactin-1/nidogen-1 regulates LM-1 dependent mammary specific gene expression.

THROMBOSPONDIN

Thrombospondins (TSPs) are a family of extracellular, adhesive proteins that are widely expressed in vertebrates. Five distinct gene products—designated TSP 1-4 and cartilage oligomeric matrix protein (COMP)—have been identified. TSP-1 and -2 have similar primary structures. The molecule (450 kDa) is composed of three identical disulfide-linked protein chains. It is one of the major peptide products secreted during platelet activation, and it is also secreted by a diversity of growing cells. TSP has 12 binding sites for calcium ion and depends upon it for its conformational stability. It binds to heparin and heparan sulfate proteoglycan

and to cell surfaces, and appears to modulate a number of cell functions, including platelet aggregation, progression through the cell cycle, and cell adhesion and migration.^{37,38} Recent genetic studies have shown associations of single nucleotide polymorphisms in 3 of the 5 TSPs with cardiovascular disease.³⁷ Both TSP 1 and 2 are best known for their antiangiogenic properties and their ability to modulate cell-matrix interactions.³⁸

INTEGRINS AND CELL ATTACHMENT PROTEINS

As indicated above, cell surfaces contain groups of proteins, the integrins, that mediate cell-matrix interactions. The integrins behave as receptors for components of the ECM and interact with components of the cytoskeleton.³⁹ This provides a mechanism for the mediation of components of the ECM of intracellular processes, including control of cell shape and metabolic activity. The integrins exist as paired molecules containing α - and β -subunits. They appear to have a significant degree of specificity for ECM proteins, which apparently is conferred by combination of different α - and β -subunits.

In addition to the integrins, cell attachment proteins (CAMs) are present on the cell surface. These confer specific cell-cell recognition properties. For reviews on integrins and CAMs, see Albelda and Buck,³⁹ Danen and Yamada,⁴⁰ Takagi,⁴¹ and Lock et al.⁴²

AGING AND THE PROPERTIES OF CONNECTIVE TISSUES

From the foregoing discussion, it becomes apparent that there can be a multitude of possible loci in the development, structural organization, metabolism, and molecular biology of connective tissues for the introduction of alterations in the properties of these tissues. For a given tissue, changes in the composition of the ECM or changes in the factors that control the production of ECM can feed back through complex mechanisms to induce changes in the properties of the tissue. The process of aging may well involve some of these factors. It is probable that, during the aging process, the phenotypical expression of ECM (i.e., the patterns of ECM composition) will change. It is also probable that many of the components of the ECM may evolve with time as a function of their long biologic half-lives and the enzymatic and nonenzymatic modifications that take place. These can include processes of maintenance and repair, responses to inflammation, nonenzymatic glycosylation, cross-linkage formation, etc.

In a sense, it may be important to differentiate between those processes of senescence that are genetically programmed (i.e., innate senescence), and the contributions to aging induced by "environmental" factors. However, it becomes difficult to distinguish whether a given alteration is an effect or a cause of aging.

In this section an attempt is made to discuss some of the factors and conditions involving connective tissues that may be associated with the aging process. These include aspects of cellular senescence, inflammatory and growth factors, photoaging of the skin, diabetes mellitus, nonenzymatic glycosylation, the cause of OS, osteoarthritis (OA), atherosclerosis, Werner's syndrome (WS), and Alzheimer's disease (AD).

Cellular senescence

A large body of research has established conclusively that normal diploid cells have a limited replicative life span and that cells from older animals have shorter life spans than those from younger animals. Thus the process of aging could be attributed to cellular senescence. A number of observations suggest that connective tissue proteins may be affected during cellular senescence. In an extensive study on the properties of murine skin fibroblasts, van Gansen and van Lerberghe⁴³ concluded that among the main effects of cellular mitotic age were a depression of chromatin plasticity, changes in the organization of cytoplasmic filaments, and changes in the organization of the ECM. They implicated an involvement of collagen fibers in the intracellular events both *in vivo* and *in vitro*. Although senescent fibroblasts may not be dividing, they are biosynthetically active, showing an increased synthesis of FN and increased levels of FN mRNA. However, both senescent and progeroid cells demonstrated a decreased chemotactic response to FN and developed a much thicker extracellular FN network than did young fibroblasts.⁴⁴ There is some indication that, with increasing age, cells become less able to respond to mitogens, which may have a bearing on age-related differences in wound healing.⁴⁵ It was also shown that the presence of senescent chondrocytes increases the risk of articular cartilage degeneration that is associated with fibrillation of the articular surface and increased collagen cross-linking.⁴⁶ Thus it would appear that there is some correlation between cellular senescence and changes in the regulation of connective tissue metabolism and cellular interactions.

Inflammatory and growth factors

One of the active areas of contemporary connective tissue biology is the study of the influence of inflammatory and growth factors on the properties of connective tissues. It is well recognized that inflammatory cells accumulate in damaged and infected tissues as part of the inflammatory response. These cells secrete lymphokines, such as the interleukins, and other factors which may influence connective tissue metabolism. In addition, a number of growth factors, including epidermal growth factor (EGF), platelet-derived growth factor (PDGF), fibroblast growth factors (FGFs), and transforming growth factors (TGFs), can have extensive control over connective tissue metabolism. As indicated earlier, senescent cells may not respond to these factors as do young cells. In addition, it is possible that stimulation of cell replication by certain of these factors may accelerate the progression of cells toward senescence. To add to the complexity are the findings that many cells can synthesize certain of these factors including interleukin-1, PDGF, FGFs, and TGFs, endowing the cellular components of tissues with autocrine and paracrine properties.

In studies reported by Furuyama et al,⁴⁷ alveolar type II epithelial cells cultured on collagen fibrils in a medium supplemented with TGF- β -1 synthesized a thin continuous BM. Immunohistochemical studies revealed the presence of type IV collagen, LM, perlecan, and entactin/nidogen. Similar stimulatory effects of TGF- β -1 on BM protein synthesis in rat liver sinusoids were reported by Neubauer et al.⁴⁸ The role of a variety of growth factors and cytokines in the development of inflammatory synovitis accompanied by

destruction of joint cartilage was demonstrated in studies by Gravalles.⁴⁹ Recent studies by Takehara⁵⁰ suggest that the growth of skin fibroblasts is regulated by a variety of cytokines and growth factors with a resultant increase in ECM protein production.

The extent of involvement of these interacting factors in the aging process is not clear, but it is probable that they contribute to the process.

Mechanisms of cutaneous aging

Cutaneous aging is a complex biologic activity consisting of two distinct components: (1) intrinsic, genetically determined degeneration, and (2) extrinsic aging due to exposure to the environment, also known as "photoaging." These two processes are superimposed in the sun-exposed areas of skin, with their profound effects on the biology of cellular and structural elements of the skin.^{51,52} The symptoms of photoaging are different from those of intrinsic aging, and evidence suggests that these two processes have different mechanisms.

A variety of theories have been advanced to explain aging phenomena and some of them may be applicable to innate skin aging as well. It was postulated that diploid cells, such as dermal fibroblasts, have a finite life span in culture.⁵⁰ This observation, when extrapolated to the tissue level, could be expected to result in cellular senescence and degenerative changes in the dermis. Others have suggested that free radicals may damage collagen in the dermis,⁵³ and a third theory implicates nonenzymatic glycosylation of proteins, such as collagen, leading to increased cross-linking of collagen fibrils. It is postulated that this process is the major cause of dysfunction of collagenous tissues in old age.⁵⁴ Finally, cutaneous aging may be attributed to differential gene expression of ECM of connective tissue. It has been demonstrated that the rate of collagen biosynthesis is greatly reduced in the skin of elderly people.⁵⁵ Collectively, the observations on dermal connective tissue components in innate aging suggest an imbalance between biosynthesis and degradation, with less repair capacity in the presence of ongoing degradation.

Additional changes in the aged dermis concern the architecture of the collagen and elastin networks. The spaces between fibrous components are more compact owing to a loss of ground substance. Collagen bundles appear to unravel and there are signs of elastolysis. Scanning electron microscopic studies of the three-dimensional arrangement of rat skin from animals ranging in age from 2 weeks to 24 months showed that, during postnatal growth, there was a "dynamic rearrangement" of the collagen and elastic fibers, with an ordered arrangement of mature collagen bundles being attained by producing distortions of relatively straight elastic fibers. During adulthood, there is a tortuosity of these elastic fibers coupled with an incomplete restructuring of the elastic network that was deposited to interlock with the collagen bundles.

The effects of photodamage on dermal connective tissue are exemplified in the histopathologic pictures of photoaging. The hallmark of photoaging is the massive accumulation of the so-called "elastotic" material in the upper and middermis. This phenomenon, known as "solar elastosis," has been attributed to changes in elastin.⁵⁶ Solar elastotic material is composed of elastin; fibrillin; versican,

a large proteoglycan, and hyaluronic acid. Even though the elastotic material contains the normal constituents of elastic fibers, the supramolecular organization of solar elastotic material and its functionality are severely perturbed. It was also known that elastin gene expression is notably activated in cells within the sun-damaged dermis. In addition, it has been shown that accumulation of elastotic material is accompanied by degeneration of the surrounding collagen meshwork. Parallel studies provide evidence implicating MMPs as mediators of collagen damage in photoaging.⁵⁵

It would appear that the main culprit in photoaging appears to be the UV-B portion of the ultraviolet spectrum, although UV-A and infrared radiation also contribute to the damage. In UV-A irradiated hairless mice, there appears to be alteration in the ratio of type III to type I collagen in addition to the elastosis. It has been shown that UV irradiation of fibroblasts in culture enhances expression of MMPs.⁵⁵ There is also an increase in the levels of the components of the ground substance in photoaged skin (predominantly dermatan sulfate, heparan sulfate, and hyaluronic acid). In human aged skin, mast cells are numerous and appear to be degranulated. These cells are known to produce a variety of inflammatory mediators so that photoaged skin is chronically inflamed. In innate aging, the skin tends to be hypocellular. The microcirculation of the skin is also affected, becoming sparse, with the horizontal superficial plexus almost destroyed. Although atrophy may be presented in end-stage photoaging in the elderly population, ongoing photoaging is characterized by more, not less.

The effects of photoaging could be totally prevented by broad-spectrum sunscreens. Although severe photoaging in humans is considered to be irreversible, in hairless mice it was found that repair could take place after the cessation of irradiation, with the newly deposited collagen appearing totally normal. A similar repair was observed in biopsies of severely photo-damaged human skin after several years of avoidance of exposure to the sun.

Diabetes mellitus

Currently two types of diabetes mellitus are recognized clinically, type-1 diabetes (DM-1), which is insulin dependent and is caused by β -cell destruction, and type-2 (DM-2), formerly known as noninsulin dependent. Diabetics often show signs of accelerated aging, primarily as a result of the complications of vascular disease and impaired wound healing so common in this disease. It is well documented that diabetics will exhibit a thickening of vascular BMs.⁵ The biologic basis for this thickening is as yet obscure, but could well be related to abnormalities in cell attachment, or the response to factors affecting BM formation to excessive nonenzymatic glycosylation of proteins, or to an abnormal turnover of BM components. Fibroblasts from diabetic individuals exhibit a premature senescence in culture.⁵⁷ The role of inhibitors of aldose reductase was investigated by Sibbitt et al.⁵⁸ They showed that, in normal human fibroblasts, the mean population doubling times, population doublings to senescence, saturation density at confluence, tritiated thymidine incorporation, and response to PDGF were inhibited with increasing glucose concentrations in the media. They found that inhibitors of aldose reductase, sorbinil and tolrestat, completely prevented these inhibitions. Myoinositol had similar effects; however, no data were presented to indicate

that aldose reductase inhibitors would reverse the premature senescence in fibroblasts from diabetic individuals. Thus it is not clear whether prevention of the formation of reduced sugars can have a therapeutic effect, nor is it clear that all of the aging effects of diabetes are mediated by reduced sugars.

One of the less known complications of DM-1 and DM-2 is bone loss. This complication is receiving increased attention because DM-1 diabetics are living longer due to better therapeutic measures; however, they are faced with additional complications associated with aging, such as OS.⁵⁹ Both DM-1 and DM-2 diabetic patients are under high risk of cardiovascular disease. Uncontrolled hyperglycemia may give rise to nonenzymatic glycosylation of proteins, which may lead to the generation of reactive oxygen species, increased intermolecular and intramolecular cross-linking with subsequent vessel damage, and atherogenesis.^{60,61}

Nonenzymatic glycosylation and collagen cross-linking

When enzymes attach sugars to proteins, they usually do so at sites on the protein molecule dictated by the specificity of the enzyme for the regional sequence to be glycosylated. On the other hand, nonenzymatic glycosylation, a process long known to cause food discoloration and toughness, proceeds nonspecifically at any site sterically available.⁶¹ The longer a protein is in contact with a reducing sugar, the greater the chance for nonenzymatic glycosylation to occur. In uncontrolled diabetics, elevated circulating levels of glycosylated hemoglobin and albumin are found. Since erythrocytes turn over every 120 days, the levels of hemoglobin A_{1c} are an index of the degree of control of hyperglycemia over a 120-day period. The same is true for glycosylated albumin over a shorter period. Proteins such as collagen, which is extremely long-lived, have also been shown to undergo nonenzymatic glycosylation. Paul and Bailey⁶² demonstrated that glycation of collagen forms the basis of its central role in complications of aging and diabetes mellitus.

The nonenzymatic reactions between glucose and proteins are collectively known as the Maillard or Browning reaction. The initial reaction is the formation of a Schiff base between glucose and an amino group of the protein. This is an unstable structure and can spontaneously undergo an Amadori rearrangement in which a new ketone group is generated on the adduct. This can condense with a similar product on another peptide sequence to produce a covalent crosslinkage.⁶⁰ Initially, glycation affects the interaction of collagen with cells and other matrix components, but the most damaging effects are caused by the formation of glucose-mediated intermolecular cross-linkages. These cross-linkages decrease the critical flexibility and permeability of the tissues and reduce turnover. Another fibrous protein that is similarly modified by glycation is elastin.⁶² Verzijl et al⁶³ have shown that, during aging, nonenzymatic glycation results in the accumulation of the advanced glycation end-product pentosidine in articular cartilage aggrecan.

The arthritides—osteoarthritis

The development of rheumatoid diseases, particularly OA, is a common event in aging individuals. The cause of OA and OS is based on a variety of factors ranging from genetic susceptibility, to endocrine and metabolic status, to mechanical and traumatic injury events.⁶⁴ With aging, the bone loss in

OA is lower compared with OS. The lower degree of bone loss with aging is explained by the lower bone turnover, as measured by bone resorption-formation parameters.⁶⁵ In the initial stages of OA, there is increased cell proliferation and synthesis of matrix proteins, proteinases, growth factors, and cytokines synthesized by adult articular chondrocytes. Other types of cells and tissues of the joint, including the synovium and subchondral bone, contribute to the pathogenesis.⁶⁶

In inflammatory arthritis, degradative enzymes including tissue collagenases and metalloproteinases are present in the rheumatoid lesion, leading to degradation of both cartilage and bone. It is believed that inflammatory factors stimulate abnormal levels of these enzymes.⁶⁷ Studies by Iannone and Lapadula⁶⁸ demonstrated that interleukin-1 (IL-1) is produced by synovial cells. IL-1, TNF- β , and other cytokines are also mitogenic for synovial cells and can stimulate the production of collagenases, proteoglycanases, plasminogen activator, and prostaglandins. It is suggested that IL-1 plays an important role in the pathogenesis of rheumatoid arthritis.

Osteoporosis

OS is a systemic skeletal disease, comprising rarefaction of bone structure and loss of bone mass, leading to increased fracture risk. The frequency of this disorder increases with aging. Twin and family studies have demonstrated a genetic component of OS regarding parameters of bone properties, such as bone mineral density, with a heredity component of 60% to 80%.⁶⁹ OS affects most women above 80 years of age; at the age of 50, the lifetime risk of suffering an OS-related fracture approaches 50% in women and 20% in men. Studies indicate that genetic variations explain as much as 70% of the variance for bone mineral density in the population.⁷⁰ The National Organization of Osteoporosis recommends bone density testing for all women over 65 and earlier (around the time of menopause) for women who have risk factors.

Viguet-Carrin et al⁷¹ demonstrated that different determinants of bone quality are interrelated, especially the mineral content and modifications in collagen. Different processes of maturation of collagen occur in bone, involving enzymatic and nonenzymatic reactions. The latter type of collagen modification is age related and may impair the mechanical properties of bone. In a study of human trabecular bone taken at autopsy, Oxlund et al⁷² examined both collagen and reducible and nonreducible collagen cross-linkages in relation to age and OS. The extractability of collagen from vertebral bone of control individuals was increased with age. Bone collagen of OS individuals showed increased extractability and a marked decrease in the concentration of the divalent reducible collagen cross-linkages compared with sex- and age-matched controls. No alterations were observed in the concentration of trivalent pyridinium cross-linkages. These changes would be expected to reduce the strength of the bone trabeculae and could explain why the OS individuals had bone fractures although the collagen density did not differ from that of the sex- and age-matched controls.

Croucher et al⁷³ have quantitatively assessed cancellous structure in 35 patients with primary OS. Their data demonstrate that, for a given cancellous area, structural changes in primary OS are similar to those observed during age-related bone loss in normal subjects. These findings strongly

implicate an abnormal increase in the activity(ies) of osteoclast-derived resorption enzymes, acting on the degradation of the ECM, in the cause of OS.

Arterial aging

In young healthy individuals, the cushioning function of elastic arteries—principally the aorta—results in optimal interaction with the heart, and optimal steady flow through peripheral resistance vessels. As the arteries age, changes in their composition and structure lead to an increase in the stiffness of their walls, resulting in increased pulse pressure, hypertension, and a greater risk of cardiovascular disease. Another effect of aortic stiffening is transmission of flow pulsations downstream into vasodilated organs, principally brain and kidney, where pulsatile energy is dissipated and fragile microvessels are damaged. This accounts for microinfarcts and microhemorrhages, with specialized cell damage, cognitive decline, and renal failure.⁷⁴

The arterial media responsible for arterial stiffness and resilience is composed of elastin, collagen, vascular smooth muscle cells, and ground substance. Elastin comprises 90% of arterial elastic fibers. The generalized age-related stiffening (arteriosclerosis) is confined primarily to the media of arteries. Although the absolute amounts of both collagen and elastin in arteries fall with age, the ratio of collagen to elastin increases. In addition, with age, elastic lamellae undergo fragmentation and thinning, leading to ectasia and a gradual transfer of mechanical load to collagen, which is 100 to 1000 times stiffer than elastin. Possible causes of this fragmentation are mechanical (fatigue failure) or enzymatically driven by MMP activity.⁷⁵ MMPs navigate the behavior of vascular wall cells in different atherosclerosis stages, in adaptive remodeling, in normal aging, and in nonatherosclerotic vessel disease.⁷⁶ In arteries, accumulation of advanced glycation end products over time leads to cross-linking of collagen and consequent increases in its material stiffness. Furthermore, the remaining elastin itself becomes stiffer, owing to calcification and the formation of cross-links due to advanced glycation end products, a process that affects collagen even more strongly.⁷⁵ These changes are accelerated in the presence of disease such as hypertension, diabetes, and uremia. Most studies show that arterial stiffening occurs across all age groups in both DM-1 and DM-2. Arterial stiffening in DM-2 results partially from the clustering of hyperglycemia, dyslipidemia, and hypertension, all of which may promote insulin resistance, oxidative stress, endothelial dysfunction, and the formation of proinflammatory cytokines and advanced glycosylation end products.⁷⁷

Although there is ample evidence for the link between arteriosclerosis and the degradation and remodeling of collagen and elastin, much remains unknown about the detailed mechanisms.

Werner's syndrome

WS is a rare autosomal recessive premature aging disease manifested by age-related phenotypes, such as atherosclerosis, cataracts, OS, soft tissue calcification, premature graying, and loss of hair, and a high incidence of some types of cancer.⁷⁸ The gene product, WRN, which is defective in WS, is a member of the RecQ family of DNA helicases.⁷⁹ Clinical and biologic manifestations in four major body systems—the nervous, immune, connective tissues, and endocrine

systems—similar to normal aging, appear at an early stage of the patient's life. WS may cause abnormalities in the cardiovascular system manifested as restrictive cardiomyopathy.⁸⁰ Ostler et al⁸¹ reported that WS fibroblasts show a mutator phenotype, abbreviated replicative life, and accelerated cellular senescence. They also demonstrated that T-cells derived from WS patients have the mutator phenotype. Increased collagen synthesis in fibroblasts from two WS patients has been reported. This was accompanied by a near doubling of the levels of procollagen mRNA over normal controls. Similarly, studies by Hatamochi et al⁸² demonstrated that WS fibroblast-conditioned medium brought about activation of normal fibroblast proliferation but failed to alter the relative rates of collagen and noncollagenous protein synthesis by such fibroblasts.

Alzheimer's disease

AD is a disease of old age. The characteristic pathophysiologic changes at autopsy include neurofibrillary tangles, neuritis plaque, neuronal loss, and amyloid angiopathy. Mutations in chromosomes 1, 12, and 21 cause familial AD. Susceptibility genes do not cause the disease by themselves but in combination with other genes modulate the age of onset and increase the probability of AD.⁸³ Significant progress has been made in identifying the mutations in the Tau protein and dissecting the cross-talk between Tau and the second hallmark lesion of AD, the A β peptide-containing amyloid plaque.⁸⁴

Recent studies with familial AD have demonstrated reduction or loss of smooth muscle actin in the media of cerebral arterioles. Intracerebral arterioles and numerous capillaries were laden with amyloid deposits. There was marked expression of collagen type III and BM collagen type IV. Fibers of both amyloid and collagen were found within the BM.⁸⁵

Clinical and experimental studies have shown that cerebral perfusion is progressively decreased during increased aging, and this decrease in brain blood flow is significantly greater in AD. Studies by Carare et al⁸⁶ have shown that capillary and arteriole BMs act as "lymphatics" of the brain for drainage of fluid and solutes. Amyloid β (A β) is deposited in BM drainage pathways in cerebral amyloid angiopathy and may impede elimination of amyloid β and interstitial fluid from the brain in AD.

The localization of BM components, such as LM, entactin/nidogen, and collagen type IV, to the amyloid plaque has suggested that these components may play a role in the pathogenesis of AD.⁸⁷ The work of Kiuchi et al⁸⁸ has shown that entactin/nidogen, collagen type IV, and LM had the most pronounced effect on preformed A β 42 fibrils, causing disassembly of amyloid β -protein fibrils. Circular dichroism studies indicated that high concentrations of BM components induced structural transition in A β 42 β -sheet to random structures.

It has been suggested that the vascular BM may serve as a nidus for senile plaque, playing a role in the development of both amyloid and neuritic elements in AD.

SUMMARY

This chapter has reviewed some aspects of biochemistry and molecular biology, and the involvement of connective tissue in the process of aging. There is a complexity

KEY POINTS

Connective Tissues and Aging

- Changes in the structural integrity and production of connective tissue macromolecules are associated with the process of aging.
- Loss of tissue function in aging is associated with increased cross-linking of collagen and elastin fibrils and subsequent decrease in their turnover.
- Alternative splicing in the mRNA of the connective tissue macromolecules has been implicated in the process of aging.
- There is a correlation between cellular senescence and changes in the regulation of connective tissue metabolism.
- Nonenzymatic glycosylation of collagen and elastin is accelerated with aging and may be associated with changes in diabetes.
- In age-related osteoporosis, a decrease in divalent reducible collagen cross-linkages may lead to reduced bone strength and may explain increased bone fractures.
- In aging and in senile dementia of the Alzheimer type, there is colocalization of type IV collagen, laminin, heparan sulfate proteoglycan and amyloid plaque in the brain vasculature.

inherent in the control of connective tissue structure, metabolism, and molecular biology, and aging might contribute to alterations in these and vice versa. Among the phenomena that may prove central to the aging process are the processes of collagen cross-linking and nonenzymatic glycosylation, alternative gene splicing, effects of solar radiation, the interplay of cytokines and growth factors on the control of connective tissue phenotype, production and action of degradative enzymes, factors that affect cell replication, connective tissue diseases, and intracellular factors that control senescence. The causes and effects of aging are an active area of contemporary research in which the involvement of connective tissue is an important element.

Clinical Immunology: Immune Senescence and the Acquired Immune Deficiency of Aging

Mohan K. Tummala
Dennis D. Taub
William B. Ershler

As a fundamental organ necessary for the maintenance of life, the immune system first appeared in primitive organisms about 480 million years ago.¹ The intricate relationship between acquired immunity and infection was apparent early in recorded history. Observing an epidemic of plague in 430 BC, Thucydides reported that anyone who had recovered from the disease was spared during future outbreaks. The era of modern immunology was launched with Jenner's report in 1798 of an effective vaccine employing cowpox pustules to prevent smallpox in humans. Improved understanding of immunity and infection continued throughout the nineteenth and twentieth centuries. For example, identification of bacterial organisms ultimately resulted in the discovery of antibodies that could neutralize these microbes and/or their toxins, eventually leading to endorsement of the concept of vaccination. The discovery of antibody structure during the 1960s finally began the era of modern immunochemistry. With regard to cellular immunity, despite the early work of Metchnikoff and his followers, the role of cells in acquired immunity was not truly appreciated until the 1950s. Although theories of "self-recognition" and "autoimmunity" appeared early in the twentieth century, autoimmune diseases remain incompletely understood.

As a concept, immunogerontology is a relatively recent focus of interest. In 1969, Walford proposed that declining immune function contributes to the biologic processes of aging.² He speculated that disorders in the immune system that occur with aging account for three major causes of disease in old age: (1) increased autoimmunity; (2) failing surveillance allowing the expression of cancers; and (3) the increased susceptibility to infectious diseases. Current evidence supports the notion that the decline in immune function with aging may be viewed as a form of acquired immunodeficiency of modest dimension. Complicating the assessment of aging on immune function, older people are more likely to have diseases, conditions, or exposures that contribute to declining immune function.³

CHANGES IN THE HUMAN IMMUNE SYSTEM WITH AGING

Nonspecific host defense

Primary (innate) immunity is the first line of defense against invading pathogens. It differs from secondary (acquired) immunity in that it does not require sensitization or prior exposure to offer protection. Primary immunity involves tissues (e.g., mucocutaneous barriers), cells (monocytes, neutrophils, natural killer [NK] cells) and soluble factors (cytokines, chemokines, complement) coordinated to mediate the nonspecific lysis of foreign cells.

A feature of innate immunity is the detection of pathogens using pattern recognition receptors such as Toll-like receptors (TLRs) that recognize specific molecular patterns present on

the surface of pathogens triggering a variety of signaling pathways. After processing of antigen by the antigen presenting cells, the peptide fragments are presented along with major histocompatibility (MHC) class II molecules to CD4⁺ T cells or with MHC class I molecules to CD8⁺ T cells to generate efficient T-cell responses. The antigen presenting cells also provide additional co-stimulatory stimulus (e.g., ligation of B7.1 or CD80 on antigen-presenting cells with CD28 on T cells) to lower the threshold of T-cell activation and survival following the recognition of antigens. The ligation of TLRs on antigen presenting cells enhances the phagocytosis of the pathogen through the release of chemokines and other peptides, which then result in activation and recruitment of immune cells to the sites of infection.

Phagocytosis

Phagocytosis involves the engulfment and lysis and/or digestion of foreign substances. The capacity of neutrophils, macrophages, and monocytes for phagocytosis is determined by their number and ability to reach the relevant site, adhere to endothelial surfaces, respond to chemical signals (chemotaxis), and complete the process of phagocytosis.⁴ The study of alterations in phagocytosis with age must then involve examinations of each of these steps, and are inherently more difficult in human populations than in disease-free inbred animals. Extrapolation of studies of senescent mice to humans suggests age itself does not attenuate response to bacterial capsular antigens in a well-vascularized area such as the lung.^{5,6} Niwa et al reported a deterioration in neutrophil chemotaxis and increase in serum lipid peroxidase in the nonsurviving cohort of a 7-year longitudinal study, suggesting a preterminal but not necessarily "normal" aging alteration in these factors.⁷ However, age-related effectiveness in chemotaxis may be reduced in less vascular tissues *in vivo*, such as in the skin, which also has a number of other changes that may impair the ability of cells in the vascular compartment to reach a site of infection.⁸ Although elderly persons preserve the number and overall phagocytic capacity, *in vitro* neutrophil functions (including endothelial adherence, migration, granule secretory behavior such as superoxide production, nitric oxide, and apoptosis) appear to be reduced with age,⁹⁻¹¹ and significantly fewer neutrophils arrive at the skin abrasion sites studied in older people.¹² How this translates to immune response and immune-mediated repair in infected or otherwise physiologically stressed older people remains unknown. Although the expression of TLRs and GM-CSF receptors are not diminished, ligation of these receptors results in altered signal transduction. With aging, alterations in signal transduction of these receptors may be involved in the defective function of neutrophils with decreased response to stimuli such as infection with gram positive bacteria.^{13,14} These changes in the elderly, unlike in the young, could be the result of changes in the recruitment

of TLR4 into lipid rafts and no-raft fractions (the domains on plasma membrane that play an important role in cell signaling) with LPS stimulation.¹⁵ And similarly, the activation through GM-CSF on the surface of these cells is also altered in the elderly because of an age-related presence of a phosphatase in the lipid raft blocking cell activation and contributing to decreased response to GM-CSF in neutrophils from older people.¹⁶

Macrophage activation also appears to change with age; this may be partially attributable to a reduced gamma interferon signal from T lymphocytes.^{17,18} A decrease in the number of macrophage precursors and macrophages is observed in bone marrow.¹⁹ Although it is not clear if there is an age-associated decrease of TLR on the surface of aged macrophages, defective production of cytokines has been observed after TLR stimulation, possibly due to altered signal transduction.^{20,21} With aging, there is diminished expression of MHC class II molecules both in humans and in mice, resulting in diminished antigen recognition and processing by these antigen presenting cells.^{19,22} In addition, activated macrophages from humans and mice produce higher levels of prostaglandin E₂, which may negatively influence antigen presentation.¹⁹ Fewer signals at the site of infection may be a consequence of reduced numbers of activated T cells locally due to reduced antigen processing capacity of macrophages. Fewer T cells and the defective expression of homing markers to attract T cells from peripheral blood into inflamed tissues²³ suggests that increased susceptibility of old mice to, for example, tuberculosis, reflects an impaired capacity to focus mediator cells and the additional cytokine they may express at sites of infection (see more on T-cell changes with age in later discussion). These observations may help explain why late-life tuberculosis or reactivation tuberculosis occurs and remains clinically important in geriatric populations. The change in function of antigen-presenting dendritic cells (DC) with aging is less well defined. A decrease in number and migration of Langerhans cells in skin has been described in elderly people,²⁴ but their function remains sufficient for antigen presentation.²⁵ In contrast, DCs from the elderly who are considered "frail" have been demonstrated to have reduced expression of costimulatory molecules, secrete less interleukin (IL)-12, and stimulate a less robust T-cell proliferative response when compared with those who are not "frail."²⁶

Cell lysis

Cell lysis is mediated through a variety of pathways, including the complement system, natural killer (NK), macrophage/monocyte, and neutrophil activity. Complement activity does not appear to decline significantly with age, and neutrophil function also appears intact. However, in longitudinal studies of nonhuman primates, NK activity does appear to be affected by age²⁷ and acute stressors such as illness.²⁸ The functioning status of NK cells is dependent on a balance of activating and inhibitory signals delivered to membrane receptors.²⁹ A well preserved NK cell activity is observed in healthy elderly individuals³⁰ explaining, in part, a lower incidence of respiratory tract infections and higher antibody titers after influenza vaccination.³¹ However, elderly individuals with chronic diseases and frailty are characterized by lower NK cytotoxicity and a greater predisposition to infection and other medical disorders.^{32,33}

Although little is known about any changes in expression of activating and inhibitory receptors in the elderly, NK activation and cytotoxic granule release remain intact.^{30,34} Secretion of IFN- γ after stimulation of purified NK cells with IL-2 shows an early decrease, which can be overcome with prolonged incubation.³⁵ IL-12 or IL-2 can upregulate chemokine production, although to a lesser extent than that observed in young subjects.³⁶ These observations suggest that NK cells have an age-associated defect in their response to cytokines with subsequent detriment in their capacity both to kill target cells and to synthesize cytokines and chemokines.

Specific host defense

There are well-defined alterations in both cellular and humoral immunity with advancing age. In the cellular immune system, most studies show no significant changes with human aging in the total number of peripheral blood cells, including total lymphocytes, monocytes, NK cells, or polymorphonuclear leukocytes.^{35,37–41} The appearance of lymphocytopenia is associated with mortality in elderly people, but is not an age-related finding.^{42–44} Most studies show no changes in the percentages of B- and T-lymphocyte populations in the peripheral blood,^{45,46} although chronically ill elderly people may particularly have a decline in total T-cell numbers. Equivocal changes in the ratio of helper cells to suppressor cells (T₄/T₈) occur in normal aging.^{39,40,45,47,48} These findings are in contrast to human immunodeficiency virus (HIV)-induced acquired immunodeficiency syndrome (AIDS) associated with a decreased T₄/T₈ ratio. Finally, there is a specific age-related increase in memory cells, cells that express the CD45 surface marker.^{49–52}

Qualitative changes in T-cell function

The function of lymphocytes is altered with aging. This may be a consequence of decreased thymic function, an important factor for age-related changes in thymic dependent immunity-adaptive T-cell immunity. Declines in serum thymic hormones precede the decline in thymic tissue. By the age of 60, few of the thymic peptides are measurable in human peripheral blood,⁵³ and the thymus undergoes progressive reduction in size associated with the loss of thymic epithelial cells and a decrease in thymopoiesis. Thymic hormone replacement may improve immune function in old age,^{54,55} but there are no current clinical indications in this regard.

T cells may be considered either "naïve" or "memory" on the basis of prior antigen exposure, and with advancing age, there has been noted a relative expansion of the memory T-cell pool. The competency of adaptive immune function declines with age primarily because of a dramatic decline in production of naïve lymphocytes because of a decline in thymic output and an increase in inert memory lymphocytes (see later discussion). Naïve CD4⁺ T cells isolated from aged humans and animals display a decreased *in vitro* responsiveness and altered profiles of cytokine secretion to mitogen stimulation and expand poorly and give rise to fewer effector cells when compared with naïve CD4⁺ T cells isolated from younger hosts. Naïve CD4⁺ T cells from aged animals produce about half the IL-2 as young cells on initial stimulation with antigen-antigen presenting cells. Also the helper function of naïve CD4⁺ T cells for antibody production is

also decreased.⁵⁶ But newly generated CD4⁺ cells in aged mice respond quite well to antigens and are able to expand with adequate IL-2 production with good cognate helper function. Thus these age-related defects in naïve CD4⁺ T cells appear to be a result of the chronologic age of naïve CD4⁺ T cells rather than the chronologic age of the individual. These aged naïve CD4⁺ T cells proliferate less and produce less IL-2 in response to antigenic stimulation than naïve CD4⁺ T cells that have not undergone homeostatic divisions in the peripheral blood. The mechanism underlying homeostasis associated dysfunction of naïve CD4⁺ T cells is not known. But in contrast to naïve cells, memory CD4⁺ T cells are long lived, maintained by homeostatic cytokines, and are relatively competent with age. Isolated CD4⁺ T cells from healthy elderly human and old mice are normal in antigen proliferation in vitro.⁵⁷ Memory CD4⁺ T cells generated from young age respond well to antigens over time, whereas memory CD4⁺ T cells derived from older age respond poorly.⁵⁸ Memory T cells generated from aged naïve T cells, upon stimulation, survive and persist well, but they are markedly defective in proliferation and cytokine secretion during recall responses with impaired cognate help for humoral immunity. Healthy elderly are able to mount a CD4⁺ T-cell response comparable to that observed in younger individuals when vaccinated with influenza, but they exhibit an impaired long-term CD4⁺ T-cell immune response to the influenza vaccine.⁵⁹ Vaccination with influenza results in increased IL-2 secretion in response to viral antigen in vitro.^{60,61} But the number of influenza-specific cytotoxic T cells declines with age, with no increase after vaccination.⁶²

Alteration in cell surface receptor expression (e.g., the loss of costimulatory receptor CD28 on the surface of CD8⁺ T cells) is one of the most prominent changes that occur with aging. CD28-CD8⁺ T cells are absent in newborns but become the majority (80% to 90%) of circulating CD8⁺ T cells in the elderly. Functionally, these CD28-CD8⁺ T cells are relatively inert and have a reduced proliferative response to TCR cross-linking, but maintain their capacity for cytotoxicity and are resistant to apoptosis.⁶³ This loss of CD28 expression is associated with a gain of expression of stimulatory NK cell receptors in CD28-CD8⁺ memory T cells, enabling their effector function as a compensation for impaired proliferation.⁶⁴

There is a reduction of naïve CD8⁺ T cells with some degree of oligoclonal expansion of CD8⁺ T cells with age observed in the healthy elderly.⁶⁵ This expansion may reflect a compensatory phenomenon to control a latent viral infection or to fill available T-cell space as a result of diminished output of naïve T cells from the thymus. When this clonal expansion reaches a critical level, the diversity of T-cell repertoire is reduced and its ability to protect against new infections is compromised as seen when elderly humans are exposed to new antigens. For example, the effect of host age was studied in the recent severe acute respiratory syndrome (SARS) outbreak, and it was discovered that the antigen recognition repertoire of T cells was approximately 10⁸ in young adults but only 10⁶ in the elderly.⁶⁶ Notably, most of the SARS mortality was observed in infected persons over the age of 50 years. Accumulation of CD28-CD8⁺ T cells are also found in viral infections, such as CMV, EBV, and hepatitis C, so CD28-CD8⁺ T cells may be derived from CD28-CD8⁺ T cells after repeated antigenic stimulation.⁶⁷

This clonal expansion of CD28-CD8⁺ T cells appears to be associated with increased infections and failed response to vaccines in the elderly. As a result of the combination of thymic involution, repeated antigenic exposure and alteration in susceptibility to apoptosis (increased for CD4 and decreased for CD8), the thymic and lymphoid tissue in the aged host becomes populated with anergic (nonresponsive) memory CD8⁺CD28⁻ T cells resulting in impaired cell mediated immunity. The potential for far-reaching effects of the presence of senescent T cells is illustrated by the correlation between poor humoral response to vaccination in the elderly and an increase in the proportion of CD8 T cells that lack expression of CD28.^{68,69}

There is also a decline in delayed-type skin hypersensitivity (DTH)⁷⁰⁻⁷³ and the assessment of this has become a useful measure of cell-mediated immunity. Generally, a battery of skin test antigens (usually four to six antigens) is required to adequately assess DTH. The number of skin test positive reactions declines with age from more than 80% in young individuals to less than 20% in older individuals.⁷³ As with most functional measures in geriatric populations, there is remarkable heterogeneity. In one study,⁷² 17.9% of subjects over age 66 years and living at home were anergic compared with 41% who were living in a nursing home but able to care for themselves and 60% who were functionally impaired and living in a nursing home. Although skin testing is a good indicator of cell-mediated immunologic health, it is heavily influenced by both acute and chronic illnesses and the component of anergy because of "aging" is difficult to discern. Furthermore, concomitant in vitro testing suggests that not all anergic patients have impaired in vitro responses,^{37,74} suggesting that some of the observed skin test anergy may be either technical (i.e., due to difficulty in intradermal injection in the skin of elderly people) or because of a deficit in antigen presentation, as described above. Thus both in vivo cutaneous DTH assessment and in vitro lymphocyte testing may be necessary to more adequately identify individuals who are truly anergic and presumably immunodeficient. The relevance of this type of determination is apparent by the repeated demonstrations of an association between anergy and mortality.^{43,72,73,75-77}

The issue of an age-associated decline in DTH has particular relevance for the testing of past or current tuberculosis exposure.⁷⁸⁻⁸² Acknowledging the high incidence of anergy in elderly patients, care must be given to assess response to control antigens, such as *Candida*, mumps, or streptokinase-streptodornase (SKSD) before concluding a negative tuberculin reaction indicates absence of TB exposure. Furthermore, for the healthy elderly, false positive skin tests may be observed in those who have had repeated testing ("booster" effect).⁸²

Qualitative changes in B-cell function

In the humoral immune system, there are no consistent changes in the number of peripheral blood B cells with age. The decline in antibody production following vaccination in the elderly is the result of reduced antigen-specific B-cell expansion and differentiation, leading to production of low titres of antigen-specific IgG. Most studies indicate a mild to moderate increase in total serum immunoglobulin (Ig)G and IgA levels with no change in IgM levels.^{83,84} Declines in antibody titers to specific foreign antigens

have been noted, including naturally occurring antibodies to the isoagglutinins,⁸⁵ and titers of antibody to foreign antigens such as microbial antigens.^{86–90} Both the primary⁹¹ and secondary immune responses to vaccination are impaired. Elderly patients tend to have lower peak titers of antibody and more rapid declines in titers after immunization^{92,93} and the peak titer occurring slightly later (2 to 6 weeks rather than 2 to 3 weeks postvaccination) than in younger people.⁹⁴ In contrast, serum autoantibodies may have organ specificity, such as antiparietal cell, antithyroglobulin, and antineuronal antibodies.^{46,95–101} With aging, there is a decreased generation of early progenitor B cells resulting in low output of new naïve B cells with clonal expansion of antigen-experienced B cells. This results in limited repertoire in immunoglobulin generation (through class switch) in B cells as observed in elderly humans and old mice¹⁰² with limited antigen-specific B-cell expansion and differentiation, leading to production of reduced titers of antigen-specific IgG. The antibodies produced by older B cells are commonly of low affinity due to reduced class switching and somatic recombination in the variable region of the immunoglobulin gene that is necessary for antibody production and diversity. The generation of memory B cells is highly dependent on germinal centers, the formation of which are known to decline with age. The formation of germinal centers is dependent to some extent on interactions of B cells with CD4⁺ T helper cells, and the age-related quantitative and qualitative changes in T and B cells may account, in large part, for the clinically observed diminished response to vaccines. For example, although 70% to 90% of individuals less than 65 years old are effectively protected after influenza vaccination, only 10% to 30% of frail elderly are protected.¹⁰⁵

Organ-nonspecific autoantibodies, such as antibodies to DNA and rheumatoid factors, also increase with age. Circulating immune complexes may also increase with advancing age.^{95,106} The reason why auto-antibodies increase with age is not known. Several explanations are possible, including alterations in immune regulation and an increase in stimulation of B-cell clones because of recurrent or chronic infections or increased tissue degradation.

Cytokine dysregulation and aging

There has been an increased awareness of alterations in the production and degradation of cytokines with age (Table 13-1). In vitro studies to assess functional aspects of lymphocytes after stimulation with mitogens show a decline in proliferative responses possibly as a result of decreased T-cell lymphokine production and regulation, particularly interleukin-2 (IL-2).^{44,48,107,108} Decreases in the percentage of IL-2 receptor positive cells, IL-2 receptor density, and in the expression of IL-2 and IL-2 receptor specific mRNA in old humans have been reported.^{48,109} IL-2 production in response to specific antigens also declines. There is a profound decline in the proliferative capacity of T lymphocytes to nonspecific mitogens.^{46,48,73,110} In addition, antigen-specific declines in the proliferative potential of T cells have been demonstrated.^{70,111} The number and affinity of mitogen receptors on T lymphocytes do not change with age.¹¹² However, the number of T lymphocytes capable of dividing in response to mitogen exposure is reduced, and the activated T cells do not undergo as many divisions.⁸⁰

Table 13-1. Immunologic Markers of Aging

Decreased	Increased
Thymic output	Memory T and B cells
Naïve peripheral T cells	Oligoclonal expansion of memory lymphocytes
Diversity of T- and B-cell repertoire	
Co-stimulatory stimuli to T cells	CMV specific CD8 ⁺ /CD4 ⁺ T cells
CD28 ⁺ T cells	CD45 RO ⁺ T cells
CD45 ⁺ T cells	CD 28 ⁻ T cells
IL-2, INF- γ , IL-12, IL-10, IL-13	IL-6, SCF [†] , LIF [†]
Proliferation with mitogens	
Delayed type hypersensitivity	Anergic T cells
Response to vaccination	

[†]Stem cell factor

[†]Leukemia inhibitory factor

Superimposed upon the accumulation of a relatively inert naïve T-cell fraction observed with advancing age, there appears also to be a shift in predominance of helper T-cell responses from type 1 (TH1) to type 2 (TH2). Cells of the TH1 type produce IL-2, interferon- γ , and TNF- α and predominantly mediate cell-mediated immune and inflammatory responses, whereas cells of the TH2 type produce IL-4, IL-5, IL-6, and IL-10, factors that enhance humoral immunity (Figure-13-1).⁵⁶ Whereas the decline in IL-2 and IL-12 may contribute to the observed decline in cellular immune function, the increase in proinflammatory cytokines (particularly IL-6) may contribute to the metabolic changes associated with frailty. It has been proposed that a chronic exposure to such proinflammatory signals contributes to the phenotype of frailty.¹¹³ In fact, elevated IL-6 levels have been shown to correlate well with functional decline and mortality in a population of community-dwelling elderly people.¹¹⁴ Thus the inflammation-related biomarkers are powerful predictors of frailty and mortality^{115,116} in the elderly and this phenomenon is referred to as “inflammaging.”⁴⁹

In the steady state (i.e., in the absence of stress, trauma, infection, or disease), IL-6 is tightly controlled and levels in the serum are typically measured in the very low picogram range. Among the regulators of IL-6 are sex steroids (estrogen and testosterone), and, at menopause, detectable IL-6 levels appear in the blood in apparently healthy individuals. This inappropriate presence of a circulating proinflammatory molecule has garnered great interest among biogerontologists because it provides a rational explanation for many of the phenotypic features of frailty and levels associated with a number of age-associated disorders, including atherosclerosis, diabetes, Alzheimer’s disease,^{117,118} and osteoporosis.^{119,120}

CLINICAL CONSEQUENCES OF IMMUNE SENESCENCE

Autoimmunity

Waldorf⁹¹ speculated that autoimmunity plays an important role in the aging process. Cohen and others have alternatively proposed that autoimmunity may play an important physiologic role in the regenerative and reparative process that is ongoing during aging.¹²¹ Certain autoimmune diseases have

Figure 13-1. Differentiation of naïve TH cell into effector T cells. The differentiation of naïve T cells into various effector T-cell subsets occurs in response to stimulation by distinct antigen-presenting cells and cytokine exposure. These functional subsets include TH1, TH2, TH17, and Treg cells. These subsets play distinct roles in the genesis and control of cell-mediated immunity and inflammation. Traditionally, the TH1 responses have been implicated in many autoimmune and inflammatory disease states and cytokines produced by these cells, primarily IL-2, IFN- γ , and TNF- α induce both mononuclear and polymorphonuclear cell infiltration and activation in the target tissues. In this fashion, deregulated expression of proinflammatory cytokines is thought to play a central role in the development of autoimmune diseases and chronic inflammatory responses. In contrast, TH2 cells secrete IL-4 and IL-10 that promote humoral immunity and inhibit TH1 responses and have been implicated in amelioration and remission of autoimmune and inflammatory diseases. A third TH subset, named TH17, has recently been described that depends on IL-23 for survival and expansion, and has been identified as a major mediator of pathogenic inflammatory responses associated with autoimmunity, allergy, organ transplantation, and tumor development. Over the last few years, regulatory T (Treg) cells of several types have been identified and shown to play an active role to suppress autoreactive T cells; however, these cells are also capable of suppressing the host's ability to mount an optimal cell-mediated immune response to antigens and tumor cells if their numbers and activity are not controlled.

their highest incidence in old age, such as pernicious anemia, thyroiditis, bullous pemphigoid, rheumatoid arthritis, and temporal arteritis, suggesting that the age-related increase in autoantibodies may have clinical relevance,^{122–127} although this latter point remains unproven.

Autoimmunity may also play a role in vascular disease in old age.¹²⁸ Giant T-cell arteritis is a common disease in old age^{124,129} and is associated with degenerative vascular disease. Indeed, immune mechanisms may result in atherosclerosis, a final common pathway of pathology secondary to a variety of vascular insults.¹³⁰ A number of antivascular antibodies have been described in man^{131–134} that are associated with diseases of the vasculature. Antiphospholipid antibodies are associated with a variety of pathologic states of the vasculature, including stroke and vascular dementia,^{135,136} temporal arteritis, and ischemic heart disease.^{137,138} However, the exact mechanism by which antiphospholipid antibodies cause vascular injury remains unknown.¹³⁹ The increased occurrence of antiphospholipid antibodies with age^{140–142} and the association of these autoantibodies with vascular disease may represent a predisposing immunologic factor for immune-mediated vascular disease in elderly people. Autoantibodies to vascular heparan sulfate proteoglycans (vHSPG) may also be important in vascular injury in old age,¹³³ since vHSPG plays an important role in normal anticoagulation and cholesterol metabolism.¹⁴³

Immune senescence and cancer

Age is the single greatest risk for cancer.¹⁴⁴ It has long been postulated that immune mechanisms play an important role in recognizing and destroying tumor cells, and thus an age-associated decline in immune function might be invoked to explain the increased rate of cancer in old age. The problem with this hypothesis is that, as rational as it sounds,

it has been very difficult to prove (see later discussion). Furthermore, there are other explanations for the observed increased malignant disease in the elderly, not the least of which is the estimated prolonged time (measured in decades for many epithelial tumors) it takes to sustain the multiple genetic and epigenetic events required for malignant transformation and tumor growth to the point of clinical detection. An alternative explanation suggests that the host and host factors change over time, favoring progression and expression in later life. These two hypotheses to explain the increase in late-life malignancy have aptly been described as “seed vs. soil.”¹⁴⁵

From an immunologic and “soil” standpoint, there are two principal observations that relate to malignancies and age: (1) deregulation of proliferation of cells directly controlled by the immune system and (2) evidence of increased malignancies in late life that could be hypothetically restrained by nonsenescent immunity. These will be discussed sequentially.

Proliferative disorders of the lymphocyte are common in old age. Although bimodal in incidence, the peak in late-life lymphoma includes a disproportionate incidence of nodular B-cell types.¹⁴⁶ Both old humans and mice have commonly exhibited a monoclonal gammopathy (paraprotein) in the last quartile of the life span.^{47–150} Monoclonal gammopathies increase with age and may occur in 79% of sera from subjects over the age of 95 years.^{151–153} Radl¹⁵¹ has defined four categories of age-associated monoclonal gammopathy: (1) myeloma or related disorders; (2) benign B-cell neoplasia; (3) immune deficiency, with T cell greater than B-cell loss; and (4) chronic antigenic stimulation. He speculates that the third category is by far the most common, and that this is what occurs with immune senescence. It is possible that age-associated immune dysfunction is initially associated with

markers of aberrant immune regulation, such as increased levels of paraproteinemia and/or autoantibody, which may later contribute to the pathogenesis of lymphoma. Monoclonal gammopathies may cause morbidity, particularly renal disease in the absence of overt multiple myeloma.¹⁵⁴ In a minority of cases of monoclonal gammopathies, a malignant evolution may occur.^{154–156} Multiple myeloma also demonstrates an age-related increase in incidence.¹⁵⁷ Although treatment is not generally indicated for monoclonal gammopathies,¹⁵² treatment of myeloma is often useful. Another common malignant transformation of the lymphocyte in old age is chronic lymphocytic leukemia.¹⁵⁸ Non-Hodgkin's lymphoma also increases in incidence with age, whereas Hodgkin's lymphoma has a bimodal distribution.¹⁵⁹

Finally, a discussion of cancer development and aging would not be complete without considering the importance of the decline in immunity and associated failure of "immune surveillance."^{160–163} It has long been proposed that the decline in immune function contributes to the increased incidence of malignancy. However, despite the appeal of such a hypothesis, scientific support has been limited and the topic remains controversial.¹⁶⁴ Proponents of an immune explanation point to experiments in which outbred strains of mice with heterogeneous immune functions were followed for their life span.^{165,166} Those that demonstrated better functions early in life (as determined by a limited panel of assays available at the time on a small sample of blood) were found to have fewer spontaneous malignancies and a longer life than those estimated to be less immunologically competent. Furthermore, it is difficult to deny that profoundly immunodeficient animals or humans are subject to a more frequent occurrence of malignant disease. Thus it would stand to reason that others with less severe immunodeficiency would also be subject to malignancy, perhaps less dramatically so. However, the malignancies associated with profound immunodeficiency (e.g., with AIDS or after organ transplantation) are usually lymphomas, Kaposi's sarcoma, or leukemia and not the more common malignancies of geriatric populations (lung, breast, colon, and prostate cancers). Accordingly, it is fair to say that the question of the influence of age-acquired immunodeficiency on the incidence of cancer in elderly people is unresolved. There is much greater consensus on the importance of immune senescence in the clinical management of cancer, including the problems associated with infection and disease progression.

Immune senescence and infections in old age

An aging immune system is less capable of mounting an effective immune response after infectious challenge and thus infection in elderly people is associated with greater morbidity and mortality.^{167,168} Most notable in this regard are infections with influenza virus, pneumococcal pneumonia, and various urinary tract pathogens. However, older individuals are also more susceptible to skin infections, gastroenteritis (including *Clostridium difficile*), tuberculosis, and herpes zoster (shingles). There is also an increase in hospital- and nursing home-acquired infections in elderly people. These susceptibilities to infection are due to both immune senescence and other changes more common among older individuals, such as a reduced ciliary escalator efficiency and cough reflex predisposing to aspiration pneumonia; urinary

and fecal incontinence predisposing to urinary tract and perineal skin infections; and immobility predisposing to pressure sores and wound infections.

Infections in older people frequently present atypically.^{74,144,169} Old individuals may not have typical "hard" signs of infection, such as spiking fever, leukocytosis, prominent inflammatory infiltrates on chest x-rays, or rebound tenderness for those with an acute abdomen. Thus a change in mental status or mild malaise might be the only clinical indication of urinary tract infection or even pneumonia. Lower baseline temperatures may require the need for monitoring the change in temperature, rather than the absolute temperature. This is particularly true in the frail elderly, for whom infections caused by unusual organisms, recurrent infections with the same pathogen, or reactivation of quiescent diseases such as tuberculosis or herpes zoster virus can be counted on to present atypically and also to be resistant to standard therapy.

Influenza

Most of the significant morbidity and excess mortality during influenza epidemics occurs in older adults.¹⁷⁰ Age itself, in addition to and separate from the many comorbid conditions of older people, is a significant risk factor for severe complications of influenza.¹⁷¹ It is widely held that much of the increased susceptibility of elderly people to influenza and its complications are attributable to immunologic factors, including reduced antibody responsiveness and influenza-specific cell-mediated immunity as discussed above. The role of humoral immunity, especially in the form of neutralizing antibodies, is perhaps most important for preventing and limiting the initial infection¹⁷² rather than promoting recovery. T-cell-mediated responses appear to be more important and primarily involved in postinfection viral clearance and recovery; influenza-specific cytotoxic T lymphocyte (CTL) activity correlates with rapid clearance of virus in infected human volunteers, even in the absence of detectable serum antibody.¹⁷³ This has been experimentally confirmed in several studies through the adoptive transfer of influenza-specific CTLs in mouse models.^{174,175} No doubt influenza-specific antibody declines with age, whether because of natural infection or vaccination,^{176–178} and this presumably translates to an increased risk of influenza infection. However, and perhaps equally important, CTL,^{62,179} human leukocyte antigen (HLA) restriction by influenza-specific T-cell clones, and lymphocyte proliferative responses also decline with age. T cell-mediated cytokine responses, most notably IL-2, also decrease with age, although this has not been as clearly established for healthy elderly people⁶¹ as it has been for frail elderly people.⁶⁰ Together these observations account for much of the age-related increase in influenza susceptibility and morbidity. Furthermore, although influenza in otherwise healthy unvaccinated elderly people leads to an illness that lasts nearly twice as long as their younger counterparts, influenza illness duration in those elderly people previously vaccinated (i.e., vaccine failures) is comparable to the illness duration in vaccinated healthy young adults. This observation remains true when the vaccine-to-circulating strain match is poor, negating poor vaccine match as a reason not to vaccinate seniors annually. In the long-term care setting, influenza vaccination was found to be effective in reducing influenza-like illness and preventing pneumonia, hospitalization, and deaths (both

infectious and "all cause" mortality). Among the elderly residing in the community setting, the benefits of annual vaccination have been demonstrably modest in some studies,¹⁸⁰ and more effective in others.^{81,182} Among many efforts to increase the immune response and hence protection from influenza vaccination in the elderly, component hemagglutinin dose within the vaccine and higher doses were found to be more immunogenic.¹⁸³ It is important to note that, despite all of the changes occurring with age and comorbid conditions of age, influenza vaccine still is highly cost-effective in reducing influenza-related infections and complications, especially in the high-risk elderly population.^{171,182,184}

Pneumococcal disease

Reduced immune competence, whether due to age, disease, or drug therapy, introduces risk for complications from pneumococcal disease. For example, one study found the incidence of pneumococcal disease to be 70 cases per 100,000 in individuals over the age of 70 compared with 5 cases per 100,000 in younger adults.¹⁸⁵ *Streptococcus pneumoniae* is a gram-positive lancet-shaped diplococcus that normally colonizes the nasopharynx and was present in up to 70% of individuals in the preantibiotic era. The pathogenic form is encapsulated, and antigenic variants of the polysaccharide capsule are sufficiently immunogenic to be useful as vaccine targets. The rising prevalence of penicillin-resistant *Pneumococcus*¹⁸⁶ renders infection treatment more difficult and reinforces the need for prevention as a primary management strategy for pneumococcal disease.

Pneumonia is the most prevalent expression of infection with *S. pneumoniae* but other sites of infection are also clinically important. These include otitis media, sinusitis, meningitis, septic arthritis, pericarditis, endocarditis, peritonitis, cellulitis, glomerulonephritis, and sepsis (especially postsplenectomy). Chronic obstructive pulmonary disease is an independent risk factor for occurrence of and complications from pneumococcal infection, and this might relate to the altered mechanics of clearing secretions and altered immunity within the lung itself. Risk factors for pneumococcal infections also include conditions that predispose an individual to aspiration of pneumococci, such as swallowing disorders, a feature not uncommon in stroke survivors.

Prevention is the best form of defense, and the polysaccharide antigens of the pneumococcal vaccine have been used to generate T-cell independent responses, a theoretical advantage for older adults because immune senescence is thought to primarily perturb T-cell more so than B-cell responses (see previous discussion). Yet, studies on pneumococcal vaccine efficacy in disease prevention often have been disappointing or inconclusive,^{178,187} with more recent studies suggesting efficacy and cost-effectiveness.^{188–191} Consequently, underuse of pneumococcal vaccine has been held accountable for the development of outbreaks in nursing facilities in which vaccination rates were low.^{192,193} Currently, revaccination is recommended for persons aged 65 and older if they received vaccine 5 or more years prior and were less than 65 years of age at the time of vaccination. Meanwhile, new vaccine designs aim to better stimulate the immune response in older adults by recruiting T-cell help through polysaccharide conjugation with a peptide combined with cytokine¹⁹⁴ or by using a peptide target.¹⁹⁵ Whether these approaches

are superior for an immune senescent patient remains to be defined.

Varicella-zoster virus

Herpes zoster (shingles) is caused by varicella zoster virus (VZV) and is increasingly prevalent with advancing age, as are its severity and complications.^{196–200} The majority of cases occur after the age of 60 years²⁰¹ and by 80 years, the annual attack rate is 0.8%. Two major complications of herpes zoster, postherpetic neuralgia and cranial nerve zoster (often of the ophthalmic nerve, and not infrequently resulting in lower motor neuron paresis), are the most disabling. Postherpetic neuralgia occurs in more than 25% of patients 60 years and older and is strongly associated with sleep disturbance and depression.^{202–206} Bell's palsy²⁰⁷ and Ménière's²⁰⁸ disease, both conditions associated with advanced age, have also been linked to herpes zoster. VZV-specific cell-mediated immunity correlates closely with susceptibility to herpes zoster in large populations, such as patients with lymphomas, bone marrow transplant recipients, and immunocompetent elderly persons.^{209–216} Whereas a decline in VZV-specific cell-mediated immunity is a major precipitant for VZV reactivation,²¹⁷ demonstrable VZV immunity limits the viral replication and spread.²¹⁸ In a randomized clinical trial with a live attenuated VZV vaccine among adults aged 60 years and over, vaccination reduced the incidence of herpes zoster, and postherpetic neuralgia compared with those who received a placebo.²¹⁹ The magnitude of benefit with reduction in postherpetic neuralgia was more pronounced in those aged 70 years or more. This study led to approval of vaccine among the elderly greater than 60 years of age in the United States, and also in Europe and Australia.

SECONDARY CAUSES OF ACQUIRED IMMUNODEFICIENCY IN OLD AGE

In contrast to the normative changes that may result in a mild idiopathic-acquired immunodeficiency with aging, a variety of secondary causes of acquired immunodeficiency occur in elderly people that may be severe, yet reversible. The distinction between secondary causes of immune deficiency from "normal" age-related changes is an important clinical distinction. The clinician needs a high index of suspicion for acquired immunodeficiency in old age, since many causes are reversible and can be the primary reason for infection risk, altered presentation of infection, or inadequate response to usual therapy.

Malnutrition

The effects of malnutrition on the immune system may be profound, and clearly increase the risk of infection in elderly people.^{220,221} Immune deficits in undernourished ambulatory elderly people may be reversed by nutritional supplementation. Malnutrition affects up to 50% of hospitalized elderly people and is highly associated with poor acute care outcomes, including death.^{222–224} Severe protein, calorie, vitamin, and micronutrient deficiencies may cause immune impairment resulting in poor outcomes in response to infection.^{225,226} An absolute lymphocyte count below 1500 cells/mm³ often indicates some degree of malnutrition, and a count below 900 cells/mm³ is a frequent correlate of both severe malnutrition and immunodeficiency.

Comorbidity

Chronic illnesses such as congestive heart failure²³⁰ and Alzheimer's disease may be associated with progressive cachexia despite adequate food intake, and may be mediated by tumor necrosis factor or other inflammatory mediators.^{94,102} In patients with dementia, despite adequate food intake, malnutrition is common and is associated with a fourfold increase in infection.¹⁰² Diabetes mellitus, common in geriatric populations, is frequently associated with diminished immune function.

Polypharmacy

Since elderly people frequently consume a number of prescription or over-the-counter medications, drug-induced acquired immunodeficiency is probably far more common than is generally appreciated. Numerous commonly prescribed drugs cause neutropenia and lymphocytopenia. Analgesics, nonsteroidal antiinflammatory agents, steroids, antithyroids, antibiotics, antiarthritic drugs, antipsychotics, antidepressants, hypnotics/sedatives, anticonvulsants, antihypertensives, diuretics, histamine type-2 (H₂) blockers, and hypoglycemics are among a long list of commonly prescribed medications that may suppress inflammatory and/or immune responses.^{227–229} T lymphocytes also have calcium channels along with cholinergic, histaminic, and adrenergic receptors, and drugs that work on these targets may have unappreciated effects on immune function.²³⁰ Hypogammaglobulinemia may also be induced by medications.²³¹ Recent studies have also demonstrated that medications may also be associated with an impaired or enhanced response to vaccination.^{232,233}

HIV and other infections

HIV infection may be a cause of acquired immunodeficiency in elderly people and should always be considered part of the differential diagnosis of acquired immunodeficiency in elderly patients with lymphopenia and appropriate risk factors.^{234–238} The most common source of AIDS in the elderly was until recently transfusion, but now it is acquired through sexual activity.^{239–241} Dementia is often a common presenting feature of AIDS,²⁴² and AIDS should be considered part of the differential diagnosis of dementia in aged patients with appropriate risk factors. The possibility that many cases of AIDS will go undetected in the elderly has considerable implications for geriatric-health care workers. In the United States, approximately 11% of patients with AIDS are over 50 years of age—a recognized health issue in geriatric population—and age could be an independent risk factor in rapid progression of the disease.^{240,243}

Stress

Psychosocial isolation, depression, and stress are probable causes of immune dysfunction in old age.^{244,245} There is an increased incidence of cancer during periods of psychosocial stress and depression related to bereavement.^{246,247} Social isolation and marital discord may impair immune function.²⁴⁸ Chronic stress in the form of care giving for a demented spouse also reduces influenza vaccine response.²⁴⁹ Interventions to enhance social contact demonstrably improve immune function as measured by a variety of laboratory measures.²⁵⁰ Immobility may also cause immune dysfunction, and exercise may maintain function in old age

in both animals and humans.²⁵¹ These aspects of psychoneuroimmunology obviously have particular relevance in the interdisciplinary practice of geriatrics, given the high prevalence of psychosocial problems in elderly people.

Immune function assessment

The tests necessary to perform an immunologic evaluation to establish the diagnosis of acquired immunodeficiency in old age are readily available to the clinician.²⁵² The humoral immune system is readily tested by measuring total serum protein and quantitative immunoglobulin (IgG, IgA, and IgM) levels. Serum protein electrophoresis, and immunoelectrophoresis are useful to rule out monoclonal gammopathy, myeloma, and some forms of lymphoma, and may also provide clues to chronic inflammatory disease (polyclonal gammopathy, reduced albumin). Specific antibody titers such as isoagglutinins also provide additional information regarding B-cell function. The integrity of the cellular immune system is tested by blood leukocyte counts (including absolute lymphocyte counts), delayed skin test hypersensitivity employing a panel of at least six antigens, and in vitro testing such as measurements of lymphocyte subsets, the proliferative capacity of lymphocytes in response to mitogen or specific antigens, and cytokine production. The latter tests are often performed in a standard clinical immunology laboratory. Other more sophisticated immune tests are also available from the clinical immunology consultant and research laboratory.

Specific potentially reversible causes of acquired immunodeficiency, such as malnutrition or medications, should be sought in aged patients with recurrent or unusual infections, particularly those with lymphocytopenia and/or anergy. At a minimum, a medication review and a nutritional assessment should be performed, with monitoring of neutrophil or lymphocyte counts during nutritional supplementation or medication withdrawal. HIV infections should always be considered in high-risk patients, including the very old, particularly because the risks for spread of HIV among health care workers and family members caring for frail elderly persons.

Immune enhancement and other clinical strategies

Numerous interventions have been employed in an attempt to enhance immune function in old age. The use of thymic and other hormones, mediators, and cytokines have been proposed as immunoenhancing agents, but none of these has gained clinical acceptance.²⁵³ In animals, calorie restriction without undernutrition clearly prolongs life and is associated with immune competence into late life; however, the benefits of calorie restriction in man remain unknown.²⁵⁴ Supplemental zinc and other trace metals may also have benefit in some older patients in restoring lymphocyte proliferation in vitro, and in enhancing delayed-type skin hypersensitivity reactions, but their effects in preventing or reducing the morbidity of infections or other problems potentially related to immunodeficiency in old age have not been demonstrated.^{255–258} Vitamin C and other antioxidants may also have beneficial effects on immune function.^{259,260} Megadose dietary supplementation does not significantly improve immune function in the normal-aged animal.²⁶¹

Vaccinations are critically important in maintaining the health of elderly people in the face of declining immunity

and are effective in preventing pneumococcal pneumonia, influenza, and tetanus and in reducing mortality from these illnesses.^{251,262–264} Although elderly people achieve lower peak titers and more rapid declines of serum antibody levels, the majority of healthy elderly people achieve titers that are generally presumed protective.^{89,92,265,266} However, chronically ill, frail elderly people, particularly institutionalized, malnourished individuals, may not achieve adequate protective peak antibody titers against pneumococcal pneumonia or influenza when immunized with a single dose of vaccine, and supplemental doses are recommended by some experts.^{267–269} Older persons may require revaccination with tetanus toxoid more frequently than every 10 years (as currently recommended) to maintain protective levels of antibodies in the serum.^{88,270} The use of new protein conjugate and immunoconjugate vaccines may improve the response in older people.^{271–273}

CONCLUSIONS

There are mild to moderate changes within the immune system with normal aging, and these render an individual susceptible to certain infections and may also affect clinical presentation. A more profound deficit in immune function is commonly observed in geriatric populations, but when

this occurs, the clinician should be highly suspicious that secondary (i.e., causes other than just “aging”) are involved. Reversible causes of acquired immunodeficiency in this age group include comorbid diseases, malnutrition, medications, stress, and possibly infections, including HIV. Newer therapeutic approaches may ultimately be useful in the treatment of acquired immunodeficiency in elderly people, particularly in high-risk individuals who are substantially impaired by the effects of aging and diseases of old age on the immune system.

KEY POINTS

Clinical Immunology of Aging

- The immune system changes with age, primarily affecting T-cell and B-cell functions
- Changes in the immune system are relevant to the changing clinical presentation and expression of disease.
- Immune senescence affects vaccine effectiveness.

Effects of Aging on the Cardiovascular System

Susan E. Howlett

Advanced age is a major risk factor for the development of cardiovascular disease. Why age increases the risk of cardiovascular disease is debatable. The increased risk might arise simply because there is more time to be exposed to risk factors such as hypertension, smoking, and dyslipidemia. In other words, the aging process itself has little impact on the cardiovascular system. However, an emerging view is that the accumulation of cellular and subcellular deficits in the aging heart and blood vessels renders the cardiovascular system susceptible to the effects of cardiovascular diseases. Although increased exposure to risk factors likely contributes to the development of cardiovascular disease in aging, there is considerable evidence that the structure and function of the human heart and vasculature change importantly as a function of the normal aging process. These changes occur in the absence of risk factors other than age, and in the absence of overt clinical signs of cardiovascular disease.

AGING-ASSOCIATED CHANGES IN VASCULAR STRUCTURE

Studies in blood vessels from apparently healthy humans have shown that the vasculature changes with age. The large elastic arteries dilate, something that is evident to the naked eye, and that is well seen in arterial radiographic studies. These readily visible changes arise from microscopic changes in the wall structure of the centrally located, large elastic arteries.^{1,2} The arterial wall is composed of three different layers, which are known as tunics. The outermost layer, or tunica adventitia, is composed of collagen fibers and elastic tissue. The middle layer, known as the tunica media, is a relatively thick layer composed of connective tissue, smooth muscle cells, and elastic tissue. The contractile properties of the arterial wall are determined primarily by variations in the composition of the media. The innermost layer of the arterial wall, or tunica intima, consists of a connective tissue layer and an inner layer of endothelial cells. Endothelial cells are squamous epithelial cells that play an important role in regulation of normal vascular function, and endothelial dysfunction contributes to vascular disease.³ Age-associated changes in these different layers have a profound effect on the structure and function of the vasculature in older adults.

The process by which the structure of the arterial wall is modified by the aging process is known as remodeling. Structural changes due to remodeling are apparent even in early adulthood and increase with age.² Aging-related arterial remodeling is thought to provide an ideal setting in which vascular diseases can thrive. Indeed, structural changes that occur in the arteries of normotensive aging humans are observed in hypertensive patients at much younger ages.²

One of the most prominent age-related changes in the structure of the vasculature in humans is dilation of large elastic arteries, which leads to an increase in lumen size.⁴ In addition, the walls of large elastic arteries thicken with age.

Studies of carotid wall intima plus media (IM) thickness in adult human arteries have shown that IM thickness increases between twofold and threefold by 90 years of age.¹ Increased IM thickness is an important risk factor for atherosclerosis independent of age.² Thickening of the arterial wall in aging is due mainly to an increase in the thickness of the intima.¹ Whether thickening of the media occurs in aging is controversial. However, studies have shown that the number of vascular smooth muscle cells in the media declines with age, while the remaining cells increase in size.⁵ Whether these hypertrophied smooth muscle cells are fully functional or whether this is one way in which aging is deleterious to vascular function is not yet clear. The major structural changes in the vasculature with age are summarized in [Figure 14-1](#).

Age-associated thickening of the intima is due, in part, to changes in connective tissues in aging arteries. The collagen content of the intima and collagen cross-linking increase markedly with age in human arteries.^{1,3,6} However, the elastin content of the intima declines, and elastin fraying and fragmentation have been reported.^{1,6} It has been proposed that repeated cycles of distention followed by elastic recoil may promote the loss of elastin and the deposition of collagen in aging arteries.¹ These changes in collagen and elastin content are believed to have important effects on the distensibility or stiffness of aging arteries, as discussed in more detail in the “Arterial Stiffness in Aging Arteries” section.

In addition to alterations in intimal connective tissues in aging, studies in human arteries have shown that the aging process modifies the structure of the endothelial cells themselves. Endothelial cells increase in size with age or hypertrophy. In addition, endothelial cell shape becomes irregular.⁷ The permeability of endothelial cells increases with age and vascular smooth muscle cells may infiltrate the subendothelial space in aging arteries.^{1,7} There also is considerable evidence that many of the substances released by the endothelium are altered in aging arteries.⁸ The impact of these changes on vascular function is discussed in more detail in the next section.

ENDOTHELIAL FUNCTION IN AGING

Once regarded as an almost inert lining of the blood vessels, the vascular endothelium is now recognized to be metabolically active tissue involved in the many changes needed to maintain and regulate blood flow. The structure and function of the endothelium changes notably with age.^{3,8,9} In younger adults, the vascular endothelium synthesizes and releases a variety of regulatory substances in response to both chemical and mechanical stimuli. For example, endothelial cells release substances, such as nitric oxide, prostacyclin, endothelins, interleukins, endothelial growth factors, adhesion molecules, plasminogen inhibitors, and von Willebrand factor.¹⁰ These substances are involved in the regulation of vascular tone, angiogenesis, thrombosis, thrombolysis, and many other functions. There is evidence that the aging

Figure 14-1. Remodeling of the central elastic arteries with age. The layers of the arterial wall are labeled as indicated. There are marked changes in central elastic arteries as a consequence of the aging process. The diameter of the lumen increases with age. Intima plus media (IM) thickness also increases, primarily as a consequence of an increase in the thickness of the tunica intima. An increase in collagen deposition and a decrease in elastin are responsible for intimal remodeling in aging arteries. The number of vascular smooth muscle cells in the tunica media decreases, whereas the remaining cells hypertrophy. Endothelial cell hypertrophy also occurs in aging arteries.

process may disrupt many of these normal functions of the vascular endothelium.

Endothelial dysfunction is most often measured as a disruption in endothelium-dependent relaxation. Endothelium-dependent relaxation is mediated by nitric oxide, which is released from the endothelium by mechanical stimuli, such as increased blood flow (shear stress), and by chemical stimuli (i.e., acetylcholine, serotonin, bradykinin, or thrombin).¹⁰ When nitric oxide is released from the endothelium, it causes vascular smooth muscle relaxation by increasing intracellular levels of cGMP. The increased cGMP prevents the interaction of the contractile filaments actin and myosin.¹¹ Thus blood vessel relaxation is impaired with age. The age-related increase in vascular stiffness is, in part, related to the reduced ability of the vascular endothelium to produce nitric oxide as people age.¹² The decrease in nitric oxide release with age appears to be mediated by less effective acetylcholine activity.¹³

The mechanism by which nitric oxide activity is reduced in aging remains controversial. Nitric oxide is synthesized in endothelial cells by a constitutive enzyme called endothelial nitric oxide synthase (eNOS or NOS III).¹⁴ There is some evidence that the levels of eNOS are reduced in aging, which could account for the decrease in nitric oxide activity in aging vasculature.¹⁵ However, other studies suggest that factors such as the production of oxygen free radicals in aging endothelial cells may impair nitric oxide production in aging.¹³ Further studies will be needed to fully understand the mechanism or mechanisms responsible for endothelial dysfunction in aging vasculature.

There is good evidence that endothelial dysfunction is an important cause of cardiovascular disease, independent of age.^{3,8,9} Therefore age-related endothelial dysfunction is

likely to make a major contribution to the increased risk of vascular disease in older adults.

ARTERIAL STIFFNESS IN AGING ARTERIES

Aging-related remodeling of the large, central elastic arteries has a major impact on the function of the cardiovascular system. One of the best-characterized functional changes in aging arteries is a decrease in the compliance or distensibility of aging arteries.² This resistance of aging arteries to deflection by blood flow is known as an increase in arterial stiffness.¹⁶ This increase in arterial stiffness impairs the ability of the aorta, and its major branches, to expand and contract with changes in blood pressure. This lack of deflection of the blood flow increases the velocity at which the pulse wave travels within large arteries in older adults.¹⁶ An increase in pulse wave velocity is related to hypertension, but pulse wave velocity can be measured separately from blood pressure. An increase in pulse wave velocity in aging is an important risk factor for future adverse cardiovascular events.¹⁷

The structural changes in the arterial wall described above are implicated in the increase in arterial stiffness observed in central elastic arteries in the aging heart. The increased collagen content and increased collagen cross-linking that occur in aging arteries are believed to increase arterial stiffness in aging.^{1,3} Other factors such as reduced elastin content, elastin fragmentation, and increased elastase activity also are thought to increase stiffness in aging arteries.³ Changes in the endothelial regulation of vascular smooth muscle tone and changes in other aspects of the arterial wall and vascular function also may contribute to the age-associated increase in arterial stiffness.^{1,3}

Figure 14-2. The age-associated increase in central artery stiffness has important effects on peripheral pressure. **A**, In young adults, the elastic central arteries expand with each cardiac contraction, so that a part of the stroke volume is transmitted peripherally in systole and the remainder is transmitted in diastole. **B**, In older adults, stiff central arteries do not expand with each contraction, so stroke volume is transmitted in systole. This leads to an increase in systolic blood pressure and a decrease in diastolic blood pressure in older adults. (Modified from Izzo JL Jr: *Arterial stiffness and the systolic hypertension syndrome. Curr Opin Cardiol* 2004;19:341–352.)

Arterial stiffness is thought to be responsible for some of the changes in blood pressure that are reported in older adults.¹⁸ In younger adults, recoil in the elastic central arteries transmits a portion of each stroke volume in systole and a portion of each stroke volume in diastole, as illustrated in Figure 14-2, A. However, in aging arteries, the increase in stiffness of large arterial walls is thought to contribute to the increased systolic arterial pressure and the decreased diastolic pressure that are characteristically observed in aging.¹⁸ In this way, stiff central arteries can lead to an increase in pulse pressure in aging.¹⁸ These changes occur because increased stiffness abolishes elastic recoil in central elastic arteries. This means that blood flow is transmitted during systole, which leads to a high systolic pressure.¹⁸ As blood flow is transmitted in systole, the elastic recoil does not dissipate in diastole and diastolic pressure declines with age, as shown diagrammatically in Figure 14-2, B. This increase in systolic pressure with no change or a decrease in diastolic pressure leads to isolated systolic hypertension, which is the most common form of hypertension in older adults.¹⁹ Studies have shown that isolated systolic hypertension increases the risk of cardiovascular disease.²⁰ Therefore aging-related changes in stiffness of large elastic arteries can explain many of the changes in blood pressure observed in aging and may contribute to the increased risk of cardiovascular disease in older adults. In addition, this increase in central artery stiffness is thought to play a role in some of the age-associated changes in the heart, both by increasing the work of the heart and decreasing coronary artery flow, as discussed in the next section.

Age-related changes in blood vessels may vary between different vascular beds. The structural changes that lead to increased arterial stiffness are much more pronounced in large, elastic arteries, such as the carotid artery, than in smaller, muscular arteries such as the brachial artery.^{1,4} However, there are age-related changes in vascular reactivity in vessels other than the central elastic arteries. For

Table 14-1. Age-Related Changes in the Vasculature

Age-Associated Changes in Vasculature	Clinical Consequences
↑ Intimal thickness	Promotes atherosclerosis
↑ Collagen, reduced elastin, ↑ vascular stiffness	Systolic hypertension
Endothelial cell dysfunction	↑ Risk of vascular disease

example, the responsiveness of arterioles to drugs that stimulate α_1 -adrenergic receptors declines with aging.²¹ Vascular responsiveness to either endothelin or angiotensin receptor agonists also may decline with age, although this has not been extensively investigated and there is no evidence for such changes in humans.²¹ Few studies have investigated the impact of age on vascular responsiveness in veins, but most studies report that age has little impact on the responsiveness of veins to a variety of pharmacologic agents.²¹ Investigation of age-dependent alterations in vascular reactivity is an important area of inquiry; such changes would affect the responsiveness of the aging vasculature to drugs that target blood vessels in humans. Table 14-1 summarizes the major age-associated changes in the vasculature, along with the clinical consequences of these alterations.

EFFECT OF THE AGING PROCESS ON THE STRUCTURE OF THE HEART

The aging process has obvious effects on the structure of the heart at both the macroscopic and microscopic levels. At the macroscopic level, there is a noted increase in the deposition of fat on the outer, epicardial surface of the aging heart.^{22,23} Calcium deposition in specific regions of the heart, known as calcification, is commonly observed in the aging heart.²³ There also are changes in the gross morphologic structure of individual heart chambers with age. There is an age-associated increase in the size of the atria. Furthermore, the

atria dilate and their volume increases with age.²⁴ Although some studies have reported that the mass of the left ventricle increases with age, others have concluded that ventricular mass does not increase with age if subjects with underlying heart disease are excluded.²⁵ However, there is general agreement that left ventricular wall thickness increases progressively with age.^{7,24}

Age-related changes in cardiac structure are apparent not just macroscopically, but at the level of the individual heart cell. Briefly, there are fewer more active heart cells and more fibroblasts. Beginning at age 60, there is a noticeable decline in the number of pacemaker cells in the sinoatrial node, which is the normal pacemaker of the heart.²⁶ The total number of muscle cells in the heart, which are known as cardiac myocytes, also declines with age and this decrease is greater in males than in females.²² Indeed, the population of cardiac myocytes in the heart declines by approximately 35% between the ages of 30 and 70 years old.²⁷ This cell loss is thought to occur through both apoptotic and necrotic cell death.²⁸ The loss of cardiac myocytes in the aging heart leads to an increase in size (hypertrophy) of the remaining myocytes, something that is more pronounced in cells from men than in cells from women.²² This cellular hypertrophy may compensate, at least in part, for the loss of contractile cells in the aging heart. However, unlike cellular cardiac hypertrophy that occurs as a result of exercise, hypertrophy of cells in the aging heart results from the age-related loss of myocytes, which may increase the mechanical burden on the remaining cells.²⁸

In addition to the cardiac myocytes, the heart contains large numbers of fibroblasts, which are the cells that produce connective tissues such as collagen and elastin. Collagen is a fibrous protein that holds heart cells together, whereas elastin is a connective tissue protein that is responsible for the elasticity of body tissues. As the number of myocytes progressively declines with age, there is a relative increase in the number of fibroblasts.²³ The amount of collagen increases with age, and there is thought to be an increase in collagen cross-linking between adjacent fibers with aging.^{7,24,29} Increased collagen in the aging heart leads to interstitial fibrosis.³⁰ There also are structural changes in elastin in the aging heart and these changes may reduce elastic recoil in the aging heart.²³ Together with changes in the myocytes with aging, these structural changes in connective tissues increase myocardial stiffness, decrease ventricular compliance, and thereby impair passive left ventricular filling.³⁰ The impact of these changes on myocardial function is considered in more detail next.

MYOCARDIAL FUNCTION IN THE AGING HEART AT REST

There are significant age-associated abnormalities in cardiac function in older adults, especially diastolic function and especially with exercise. These changes are most apparent during exercise, although some changes are evident even at rest. When individuals are reclining at rest, the heart rate is similar in younger and older subjects. However, when older individuals move from the supine to the seated position, the heart rate increases less in older adults than in younger adults.²⁴ This decreased ability to augment heart rate in response to positional change may be

linked to the age-related impairment in responsiveness to the sympathetic nervous system discussed in the "Response of the Aging Heart to Exercise" section. In contrast, left ventricular systolic function, which is a measure of the ability of the heart to contract, is well preserved at rest in older adults.^{7,24,25} Other measures of cardiac contractile function at rest also are unchanged with age. The volume of blood ejected from the ventricle per beat (stroke volume) is generally comparable or slightly elevated in older adults when compared with their younger counterparts.^{7,24} Similarly, the left ventricular ejection fraction, which is the ratio of the stroke volume to the volume of blood left in the ventricle at the end of diastole, is unchanged in aging.^{7,24} Thus systolic function is relatively well preserved in healthy older adults at rest.

Unlike systolic function, diastolic function is profoundly altered in the hearts of older adults at rest. The rate of left ventricular filling in early diastole has been shown to decrease by up to 50% between 20 and 80 years of age.²⁴ Several mechanisms have been implicated in the reduction of left ventricular filling rate in the aging heart. It has been proposed that age-associated structural changes in the left ventricle impair early diastolic filling. The aging heart is characterized by increased collagen deposition and structural changes in elastin, both of which combine to increase left ventricular stiffness in the aging heart.²³ This increased ventricular stiffness reduces the compliance of the ventricle and impairs passive filling of the left ventricle.³⁰ An additional mechanism that has been implicated in the decrease in ventricular filling rate in aging is changes at the level of the cardiac myocytes. Uptake of intracellular calcium into internal stores is disrupted in myocytes from the aging heart.^{24,30} As a result, residual calcium from the previous systole may cause persistent activation of contractile filaments and delay relaxation of cardiac myocytes in the aging heart.³⁰ It also has been suggested that diastolic dysfunction reflects, at least in part, an adaptation to the age-related changes in the vasculature. Increased vascular stiffness leads to increased mechanical load and subsequent prolongation of contraction time.³⁰ The age-associated increase in stiffness of the aorta increases the load the heart must work against (afterload), which is thought to promote the increase in left ventricular wall thickness observed in the aging heart.²⁵ These adaptive changes may serve to preserve systolic function at the expense of diastolic function in the aging heart.

In the hearts of young adults, left ventricular filling occurs early and very rapidly, due primarily to ventricular relaxation. Only a small amount of filling occurs as a result of atrial contraction later in diastole in the young adult heart.²⁴ In contrast, early left ventricular filling is disrupted in the aging heart. This increased diastolic filling pressure results in left atrial dilation and atrial hypertrophy in the aging heart.²⁹ The more forceful atrial contraction observed in the aging heart promotes late diastolic filling and compensates for the reduced filling in early diastole.²⁴ Because the atria make an important contribution to ventricular filling in older adults, loss of this atrial contraction due to conditions such as atrial fibrillation can lead to a marked reduction in diastolic volume and can predispose the aging heart to diastolic heart failure.³⁰ Atrial dilatation also can promote the development of atrial fibrillation and other arrhythmias in the aging

heart.²⁴ Despite this evidence for diastolic dysfunction in the aging heart, left ventricular end diastolic pressure does not decline with age in older healthy adults at rest. Indeed, aging is actually associated with a small increase in left ventricular end diastolic pressure, in particular in older males.²⁴ Thus although the filling pattern in diastole is altered in aging, this does not lead to notable changes in end diastolic pressure in older hearts at rest.

RESPONSE OF THE AGING HEART TO EXERCISE

Although many aspects of cardiovascular performance are well preserved at rest in older adults, aging has important effects on cardiovascular performance during exercise. The decline in aerobic capacity with age in individuals with no evidence of cardiovascular disease is attributable in part to peripheral factors, such as increased body fat, reduced muscle mass, and a decline in O_2 extraction with age.^{29,31,32} However, there is strong evidence that age-associated changes in the cardiovascular system also contribute to the decrease in exercise capacity in older individuals. Studies have shown that the VO_{2max} , which is the maximum amount of oxygen that a person can use during exercise, declines progressively with age starting in early adulthood.^{31,32} Age-related changes in maximum heart rate, cardiac output, and stroke volume described below compromise delivery of blood to the muscles during exercise and contribute to this decline in VO_{2max} in aging.

The maximum heart rate attained during exercise decreases gradually with age in humans, a fact well known by widely distributed posters commonly seen in exercise facilities.³³ Interestingly, this decrease is not affected by physical conditioning because it is present in both sedentary and fit individuals.²⁵ Several mechanisms have been implicated in the reduction in maximum heart rate during exercise in aging. One mechanism involves a decrease in the sensitivity of the aging myocardium to sympathetic stimulation. Normally, the sympathetic nervous system becomes activated during exercise, and releases catecholamines (noradrenaline and adrenaline) to act on β -adrenergic receptors in the heart. This β -adrenergic stimulation leads to an increase in heart rate and augments the force of contraction of the heart. However, it is well established that the responsiveness of the heart to β -adrenergic stimulation declines with age.²⁴ This is thought to be due to high circulating levels of noradrenaline that are present in older adults.³⁴ These high levels of catecholamines in older adults arise from a decrease in plasma clearance of noradrenaline and an increase in the spillover of catecholamines from various organ systems into the circulation in older adults.³⁴ Chronic exposure to high levels of catecholamines may desensitize elements of the β -adrenergic receptor signaling cascade in the aging heart and limit the rise in heart rate during exercise.²⁴ An additional mechanism that is thought to limit the maximum heart rate in exercise is the decrease in the total population of sinoatrial nodal pacemaker cells in the aging heart.³¹ This decrease in the number of pacemaker cells may impair the response of the heart to sympathetic stimulation during exercise.

The decrease in maximal heart rate during exercise has a major impact on the response of the aging cardiovascular

system to exercise. Both heart rate and stroke volume are important determinants of cardiac output. Therefore a decrease in maximum heart rate during exercise would be expected to have an impact on cardiac output during exercise in older adults. Although this has not been extensively investigated, there is evidence that cardiac output during exercise is lower in older adults compared with their younger counterparts.^{7,25} This decrease in cardiac output during exercise is not attributable to age-associated alterations in stroke volume.^{7,29} However, the reduced responsiveness to β -adrenergic receptor stimulation in the heart may limit the increase in myocardial contractility in response to exercise in older adults.^{7,25,29} These changes in cardiovascular function in aging are thought to be mitigated by an increase in left ventricular end-diastolic volume during exercise in older adults.³³ This increases the amount of blood in the ventricle at the end of diastole, and increases the stretch on the heart. It is well established that an increase in the amount of blood in the ventricle at the end of diastole results in an increase in the strength of contraction of the heart, a property known as the Frank Starling mechanism. Thus an increase in the reliance on the Frank Starling mechanism may at least partially compensate for the decrease in heart rate and contractility during exercise in aging.^{7,25,33}

Although a decrease in cardiovascular performance and an increased susceptibility to cardiovascular diseases are inevitable consequences of the aging process,³⁵ there is evidence that regular exercise has numerous beneficial effects on the aging cardiovascular system. Endurance exercise blunts the decline in VO_{2max} that occurs as a consequence of the aging process.³¹ Additionally, the age-associated decline in cardiac output can be partially overcome by regular aerobic training.³¹ However, endurance training does not modify the age-related decline in maximal heart rate during exercise.^{25,31} This might occur because exercise increases the levels of circulating catecholamines, which have been implicated in the decline in maximal heart rate in older adults as discussed earlier.³¹ Regular endurance exercise also attenuates the increased arterial stiffness that is observed in central elastic arteries from sedentary older adults.³⁶ Finally, habitual aerobic exercise can protect the aging heart from detrimental

KEY POINTS

Effects of Aging on the Cardiovascular System

- The structure and function of the human heart and vasculature change as a function of the normal aging process.
- The age-associated increase in stiffness of central elastic arteries promotes systolic hypertension in older adults.
- Diastolic dysfunction in the aging heart arises from impaired left ventricular filling, increased afterload, and prolonged availability of intracellular calcium.
- Decreased responsiveness to β -adrenergic receptor stimulation limits the increase in heart rate and contractility in response to exercise in older adults.
- Despite limits on the ability of the aging cardiovascular system to respond to exercise, regular exercise attenuates the adverse effects of aging on the heart and vasculature and protects against the development of cardiovascular disease in older adults.

Table 14-2. Age-Related Changes in the Heart

Age-Associated Changes in the Heart	Clinical Consequences
↑ Collagen, changes in elastin, ↑ left ventricular wall thickness	Impairs passive left ventricle filling
Prolonged availability of intracellular calcium	Diastolic dysfunction
Left atrial hypertrophy↑ Susceptibility to atrial arrhythmias	
↓ Number of pacemaker cells in sinoatrial node	↓ Ability to elevate heart rate in response to exercise
↓ Sensitivity to β-adrenergic receptor stimulation	Impaired ability to ↑ heart rate and contractility in exercise

effects of cardiovascular diseases such as myocardial ischemia.³⁷ Therefore there is good evidence that exercise can mitigate at least some of the detrimental effects of age on the cardiovascular system. The major age-related changes in

the heart and the clinical consequences of these changes are summarized in [Table 14-2](#).

SUMMARY

There are prominent changes in the structure and function of the vasculature and the myocardium in older adults when compared to younger adults. These changes are apparent even in the absence of risk factors other than age and in the absence of overt cardiovascular disease. However, these age-related alterations in the vasculature and the heart may render the cardiovascular system more susceptible to the detrimental effects of cardiovascular disease.

Age-Related Changes in the Respiratory System

Gwyneth A. Davies
Charlotte E. Bolton

RESPIRATORY FUNCTION TESTS

The commonly used respiratory function tests are presented in this chapter. In addition, patterns of lung function abnormality seen in some of the common types of condition are also presented.

The breathing parameters are:

- Forced expiratory volume in 1 second (liters): FEV₁. This is the volume of air expired during the first second of a forced expiratory maneuver from vital capacity (maximal inspiration). Measured by spirometry.
- Forced vital capacity (liters): FVC. This is the total volume of air expired during forced expiration from the end of maximum inspiration. A slow vital capacity (SVC) is the volume of air expired, but this time through an unforced maneuver. In the young these are similar but in emphysema, where there is loss of elastic recoil, FVC may fall disproportionately more than SVC. These are also measured by spirometry.
- Peak expiratory flow rate (liters/minute): PEFr. This is the maximal expiratory flow rate measured using a peak flow meter, a more portable method; therefore serial home measurements may be requested in patients.

The following measurements require more detailed lung function testing:

- Total lung capacity (liters): TLC. The volume of air contained in the lung at the end of maximal inspiration. Measured by helium dilution or body plethysmography together with the next two tests.
- Functional residual capacity (liters): FRC. This is the amount of air left in the lungs after a tidal breath out and indicates the amount of air that stays in the lungs during normal breathing.
- Residual volume (liters): RV. The amount of air left in the lungs after a maximal exhalation. Not all the air within the lungs can ever be expired.
- Transfer factor (mmol/minute): TL_{CO}. This is a measure of the ability of the lung to oxygenate hemoglobin. It is usually measured with a single breath hold technique using low concentration carbon monoxide.
- Transfer coefficient (mmol/minute/k/Pa/L_{BTPS}): K_{CO}. This is the TL_{CO} corrected for the lung volume.

In addition, blood gas measurements are often performed to assess both acid-base balance and oxygenation. The most important measures for respiratory disease are the partial pressure of oxygen (PaO₂), partial pressure of carbon dioxide (PaCO₂), and the pH. A low PaO₂ (hypoxemia) with a normal PaCO₂ indicates type I respiratory failure. An increased PaCO₂ with hypoxemia indicates type II respiratory failure. A rapidly rising PaCO₂ will result in a fall in the pH, for example, seen in an acute exacerbation of chronic obstructive

pulmonary disease (COPD). Renal compensation occurs in response to chronically high PaCO₂ with correction of the pH to normal/near-normal levels; but this renal compensation takes several days to occur. Hyperventilation, associated with excess expiration of CO₂, as seen in anxiety attacks but also in altered respiratory control such as Cheyne-Stokes respiration, will result in an increase in pH as a result of a drop in PaCO₂. Pure anxiety-related hyperventilation will not cause hypoxemia but other causes for this altered respiratory control may cause hypoxemia.

There are two main characteristic patterns of respiratory disease based on spirometric evaluation. These are the obstructive and the restrictive patterns. The obstructive pattern, as seen in patients with asthma and COPD, is characterized by:

- Reduced FEV₁ and PEFr
- Normal or reduced FVC. (If FVC reduced, disproportionately less reduced than FEV₁)
- Reduced FEV₁/FVC ratio to less than 0.7

The restrictive pattern is characterized by:

- Reduced FEV₁
- Reduced FVC
- Normal or high FEV₁/FVC ratio

Conditions relating to both these spirometric patterns with more detail on lung function patterns and utility of other lung function parameters to characterize and diagnose conditions will be discussed in further chapters.

AGE-RELATED CHANGES IN THE RESPIRATORY SYSTEM

Lungs age over a lifetime but there is in addition an accumulation of environmental insults that an individual has been exposed to, given that the lungs have direct contact with the atmosphere. The key exposure is smoking in the form of direct smoke but also second-hand passive smoking, the impact of which is being increasingly recognized.^{1,2} A quantitative evaluation of a person's smoking habit is usually classed as pack years (20 cigarettes a day (1 pack/day) for 10 years equates to 10 pack years).

Oxidative stress is an important mechanism of lung function decline, oxidants stemming both from cigarette fumes and from other causes of airway inflammation.^{3,4} Oxidants and the subsequent release of reactive oxygen species (ROS) lead to reduction and inactivation of proteinase inhibitors, epithelial permeability, and enhanced nuclear factor κB (NF-κB), which promotes cytokine production, and in a cyclical fashion is capable of recruiting more neutrophils. There is also plasma leakage, bronchoconstriction through elevated isoprostanes, and increased mucus secretion. The lung has

its own defense enzymatic antioxidants such as superoxide dismutase (SOD), which degrades superoxide anion and catalase, and glutathione (GSH), which inactivates hydrogen peroxide and hydroperoxidases. Both are found intracellularly and extracellularly. In addition there are nonenzymatic factors that act as antioxidants, such as vitamin C and E, β -carotene, uric acid, bilirubin, and flavonoids.⁵

Recently, there has been a renewed interest in the effect of critical early life periods determining peak lung function and the subsequent “knock-on” effect on lung function in later life and the effect on the adult and the elderly lungs. If peak lung function reserve is not attained, then the “natural” trajectory of decline may lead to symptomatic lung impairment in mid or later life. Such factors in early life would include premature birth, asthma, environmental exposure, nutrition, and respiratory infection.^{6,7} In addition, the effect of environmental pollution, nutrition, respiratory infections, and physical activity on lung function decline are reported.^{8,9} The mechanisms affecting respiratory function are likely to be multiple and cumulative. Interestingly, in the Inuit community, where life-style has gradually become more westernized—with a reduction in the fishing and hunting activities and the community developing a more sedentary life-style—there has been acceleration in age-related lung function decline.¹⁰

In the aging lung, there are structural and functional changes within the respiratory system and, in addition, immune mediated and extrapulmonary alterations. These are discussed in detail in this chapter.

Structural changes

There are three main structural changes in the aging lung. These include the (1) lung parenchyma and subsequent loss of elastic recoil; (2) stiffening of the lung (i.e., reduced chest wall compliance); and (3) the respiratory muscles.

The main change is the loss in the alveolar surface area as alveoli and alveolar ducts enlarge. There is little alteration to the bronchi. The small airways suffer qualitative changes far more than quantitative changes in the supporting elastin and collagen, with disruption to fibers and loss of elasticity leading to the subsequent dilatation of alveolar ducts and airspaces known as “senile emphysema.” Alveolar surface area may drop by as much as 20%. This leads to an increased tendency for small airways to collapse during expiration because of the loss of the surface tension forces.¹¹ In a healthy elderly individual, this is probably of little or no significance but reduction in their reserve may unearth difficulties at the time of an infection or superadded respiratory complication. Amyloid deposition in the lung vasculature and alveolar septae occurs in the elderly, although its relevance is unclear. Within the large airways, with aging, there is a reduction in the number of glandular epithelial cells, resulting in a reduced production of mucus and thus impairing the respiratory defense against infection.

Chest wall compliance is decreased in the elderly. Contributing to this increasing stiffness of the lungs are loss of intervertebral disc space, ossification of the costal cartilages, and calcification of the rib articulatory surfaces, which combine with muscle changes to produce impaired mobility of the thoracic cage. In addition to these, additional insults from osteoporosis leading to vertebral collapse have been shown to result in a 10% reduction in FVC,¹² probably through developing kyphosis and increased anterior-posterior

diameter—the barrel chest. Such vertebral collapse is frequently found in the elderly, increasing with age, if sought through appropriate imaging. These structural alterations lead to suboptimal force mechanics of the diaphragm and increasing chest wall stiffness. Rib fractures, again common in the elderly, may further limit respiratory movements.

The predominant respiratory muscle is the diaphragm, making up about 85% of respiratory muscle activity; with the intercostals, the anterior abdominal muscles and the accessory muscles also contributing. The accessory muscles are used by splinting of the arms, a feature commonly associated with the emphysematous COPD patient. Inspiration leading to chest expansion is brought about by these muscles contracting, whereas expiration is a passive phenomenon. The accessory muscles are used where there is increased ventilatory demand, such as in the COPD patient. The respiratory muscles are made up of type I (slow), type IIa (fast-fatigue resistant), and type IIx (fast-fatigable) fibers. The difference in the muscle fibers is based upon the aerobic capacity and ATP activity of the myofibrils and confers differing physiologic properties. The major age-related change in the respiratory muscles is a reduction in the proportion of type IIa fibers, which thus impairs both strength and endurance.¹³ An increasing reliance on the diaphragm due to loss of intercostal muscle strength and the less advantageous diaphragmatic position to generate force add to breathlessness. Globally, there is reduced muscle myosin production and this is likely to confer disadvantage to the respiratory muscles also. Comorbid conditions, such as COPD and congestive heart failure, are associated with altered muscle structure and function as is poor nutrition.^{14–16} Physical deconditioning and sarcopenia, hormone imbalance, and vitamin D deficiency will exacerbate the age-related lung structural changes—the body becomes less adaptive to the respiratory limitations. Medications, especially oral corticosteroids, may cause problems particularly with regard to respiratory and peripheral muscle strength. Acute infection puts added demand on the respiratory system and may expose the limited respiratory reserve.

Age-related functional changes

FEV₁ and FVC fall with age. Flow within the airways also falls. The ratio of FEV₁ to FVC falls by approximately 0.2% per year as a result of a greater reduction in the FEV₁ parameter relative to FVC with time, with changes more rapid in women.¹⁷

The total lung capacity (TLC) does not change significantly with age as the loss of elastic recoil and increased elastic load of the chest wall counteract. The RV and FRC increase due to reduced elastic recoil, causing the premature closure of the airways and stiffness of the chest wall. The elderly person thus breathes at higher lung volumes, placing additional burden on the respiratory muscles and has higher energy expenditure of up to 120% that of a young adult. The closing volume is the lung volume at which the dependent airways begin to close during expiration. This is increased in the elderly because of a lack of support and tethering of the terminal airways by collagen and elastin, and may lead to closure during normal tidal breathing,¹⁸ leading to ventilation perfusion (V/Q) mismatch that may be responsible for lower resting arterial oxygen tensions.¹⁷ Although arterial oxygen tensions tend to be lower in the elderly, unless there is coexistent respiratory disease, the PaO₂ is sufficient for adequate hemoglobin saturation. There is reduced gas transfer (TLCO)

because of the aforementioned structural changes and the V/Q mismatch. There is, in addition, reduction in pulmonary capillary blood volume and density of the capillaries.

The previously mentioned impaired respiratory muscle strength and endurance may be of little or no functional significance in the healthy elderly person, but may lead to impaired reserve to combat respiratory challenges consequent upon acute respiratory disease. Measures of respiratory muscle strength, such as the maximal inspiratory pressure (MIP), maximal expiratory pressure (MEP), and sniff nasal inspiratory pressure (SNIP), fall with age.¹⁴

In the elderly there are alterations in the regulation and control of breathing. The elderly breathe with similar minute ventilation to younger subjects but at smaller tidal volumes and a higher respiratory frequency. A blunted response to both hypoxia and hypercapnia has been reported,^{19–21} with Poulin²² demonstrating impaired response to hypoxia during sustained hypercapnia. Elderly people show an increased ventilatory response to exercise,²⁰ which may be more pronounced in males.²³ Maximal oxygen uptake (VO_{2max}) declines with age with a parallel decline in exercise capacity, having reached a peak as a young adult. This is due to a combination of both cardiovascular (such as reduced cardiac output) and respiratory causes, including ventilation perfusion mismatch. The decline in maximal oxygen uptake with age can be attenuated to some degree by maintaining regular exercise.^{24,25}

Elderly people are less able to objectively perceive acute bronchoconstriction.^{26,27} Moreover, airway β_2 -adrenoceptor responsiveness is reduced in old age, as evidenced by impaired responses to β -agonists in healthy elderly subjects.²⁸ Altered chemoreceptor sensitivity to hypoxia, reduced ability to perceive elastic loads on inspiration or expiration, impaired perception of tactile sensation and joint movement, or age-associated central processing abnormalities may all be contributing factors.^{29,30} Subsequently, this is likely to mask deteriorating respiratory symptoms and may delay presentation to health care services.

Sleep disordered breathing is more common in the healthy elderly,³¹ yet older subjects appear less likely to seek medical review or have the sleep disorder diagnosed due to a high prevalence of tiredness, fatigue, and snoring in this age group generally along with concurrent other medical illness and sedating medication including benzodiazepines. Cerebrovascular disease is associated with sleep disordered breathing,³² and in fact obstructive sleep apnea in stroke patients is a predictor of death.³³ There is increased upper airway resistance in the elderly with a reduced respiratory effort to try and overcome this obstruction. There is a high prevalence of sleep disordered breathing in patients with congestive heart failure,³⁴ and it is said to be greater in patients with Alzheimer disease,³⁵ both of which are increasingly prevalent in the elderly. In addition and conversely, sleep disordered breathing can contribute to both cardiovascular disease and impaired cognitive function.^{36,37}

Effects of aging on pulmonary host defense and immune response

The immune system is described as comprising two separate but interacting components. Innate immunity is the rapid, nonspecific system which functions as the first line of defense against invading microorganisms. Adaptive (or acquired) immunity, mediated by B and T lymphocytes, is

antigen-specific and involves the development of memory cells allowing a future antigen-specific response. There is impaired immune function in the elderly, both of the innate and adaptive components.

Aging leads to breakdown of the mucosal barrier of the lung and reduced mucociliary clearance enabling invasion by pathogenic organisms. In the aged lung, the innate immune system is increasingly challenged by greater contact with pathogens and cumulative exposure to environmental insults such as smoking. There is impaired chemotaxis and phagocytosis, reduced superoxide generation, and reduced bactericidal activity of neutrophils.³⁸ Dendritic cells are less efficient at antigen presentation. In addition, although the number of natural killer (NK) cells increases with advanced age, there is a reduction in NK cytotoxicity.³⁹ In vitro evidence suggests that macrophage function is impaired with age, with a reduced capacity to generate reactive oxygen species and proinflammatory cytokines, and reduced expression of certain pattern-recognition receptors, such as Toll-like receptors.^{40,41}

Healthy elderly subjects have been shown to demonstrate a hyperinflammatory state, so-called "inflamm-aging."⁴² This is associated with increased circulating proinflammatory cytokines, such as IL-6, TNF, IL-1 β , prostaglandin E_2 , and antiinflammatory mediators, including soluble TNF receptor, IL-1 receptor antagonist and acute phase proteins (C-reactive protein, serum amyloid A). This background proinflammatory state may contribute to a poorer outcome when host defenses are challenged in the aged lung.

Alterations in cell-mediated adaptive immunity include atrophy of the thymus together with aging within the T-cell pool, including altered memory T-cell function and a shift from a TH1 to TH2 profile.⁴¹ There is a reduction in naïve T-lymphocyte production and absolute numbers of CD3⁺, CD4⁺, and CD8⁺ T cells. Other changes include a smaller T-cell receptor repertoire and reduced proliferative responses to antigens. A decrease in B-cell numbers, impaired production of memory B cells, and reduced antibody responses affect humoral immunity in the elderly.

Immunosenescence explains a large part of the increased susceptibility to lower respiratory tract infection in the elderly.

KEY POINTS

Age-Related Changes in the Respiratory System

- There are both age-related changes and true aging changes in the respiratory system.
- Most of the available information comes from cross-sectional studies rather than longitudinal studies.
- There are structural and functional changes to the lung in the elderly. In addition, there are alterations to respiratory control and immunologic alterations that can all contribute to age-related changes of the respiratory system. Such alterations may be synergistic.
- Exercise exerts additional demands on the respiratory system that may reveal respiratory limitation. In addition, although alterations in the respiratory system may not be apparent in the healthy elderly person, acute illness may unearth the diminished respiratory reserve.
- Elderly people are less able to perceive bronchoconstriction and other symptoms. In parallel, there is thus relative underreporting of symptoms.

However, causes which contribute to pneumonia risk in this population are multifactorial. Bacterial colonization of the upper respiratory tract is not uncommon in the elderly.⁴³ This may be associated with colonization of the stomach, which itself is commoner in old age and may be preceded by antacids or H₂ blockers.^{44,45} The elderly person with swallowing difficulties, particularly in association with cerebrovascular disease and other neurologic diseases where there is associated cognitive impairment, is more prone to aspiration. Similarly, tracheal intubation or the presence of nasogastric tubes increases aspiration risk. Malnutrition and the presence of chronic disease such as diabetes or renal failure will also contribute to pneumonia susceptibility. An age-related decline in

immune function leads to a reduced response to vaccination including the influenza vaccination and increased susceptibility to respiratory infection and pneumonia.

In conclusion, there are both structural and functional changes in the lungs together with alterations in the control of breathing and more general immunologic alterations in the elderly. The changes are not just a direct consequence of age but are also affected by environmental exposure and coexistent comorbidities.

Neurologic Signs in the Elderly

Rawan Tarawneh

James E. Galvin

Neurologic disorders are a common cause of morbidity and institutionalization in the elderly population.¹ Not only does advancing age increase the frequency and severity of neurologic disease, but it may also play an important role in modifying disease presentation. The geriatric neurologic examination can be challenging even for the experienced physician. Normal aging may be associated with the loss of normal neurologic signs or the exaggeration of others. It may be associated with the appearance of findings considered abnormal in younger patients or the reappearance of physical signs usually seen in infancy and early stages of development.

The geriatric neurologic examination is also influenced by involvement of other systems (e.g., rheumatologic disease), the frequent cooccurrence of multiple conditions in a single patient, and the presentation of nonneurologic disorders (e.g., myocardial infarction, urinary tract infection, fecal impaction) as neurologic signs (e.g., gait difficulty and confusion). Therefore, it is important for physicians to appreciate the multitude of age-related changes in both the central and peripheral nervous system (Table 16-1).

MENTAL STATUS

Because the frequency of cognitive disorders increases dramatically with advancing age, examination of mental status is one of the most important components of the neurologic examination. Unfortunately, it is often also one of the most difficult parts of the neurologic examination to interpret. In general, fund of knowledge continues to expand throughout life and learning ability does not appreciably decline with age. Cognitive changes associated with normal aging include a decrease in processing speed, cognitive flexibility, visuospatial perception (often in conjunction with decreased visual acuity), working memory, and sustained attention.² Other cognitive abilities such as access to remotely learned information and retention of new encoded information appear to be spared in aging, thus allowing their use as sensitive indicators for disease processes.³

Crystallized intelligence characterized by practical problem solving, knowledge gained from experience, and vocabulary⁴ tends to be cumulative and does not generally decline with aging.⁵ On the other hand, fluid intelligence characterized by the ability to acquire and use new information as measured by solutions to abstract problems and speeded performance (e.g., performance on the Raven's progressive matrices and Wechsler Adult Intelligence Scale digit symbol task) has been shown to decline gradually with aging.⁶

Longitudinal studies of memory and aging demonstrate considerable variability among cognitive abilities between different individuals (interindividual variability) and among different cognitive domains within the same individual (intra-individual variability).³ At least part of this variability may be attributed to different study designs; however, it is very important to take the intraindividual and interindividual variability into consideration when defining neuropsychological norms for the elderly.⁷ Some authors have suggested that age-weighted rather than age-corrected norms for cognition

should be used,⁸ whereas other investigators have stressed the influence of other factors such as culture, experience, educational background, and motor speed on cognitive performance.⁷ For example, although older adults generally perform less well on both the verbal and performance subtests of the Wechsler Adult Intelligence Scale compared with young adults, these differences are minimized when corrected for motor slowing and educational level. Other situational factors that may affect individual performance on cognitive tasks include fatigue, emotional status, medications, and stress. Moreover, it may be very difficult to attribute impaired cognition to aging in the presence of underlying conditions such as depression, dementia, and delirium—all of which are common, and often unrecognized, in the elderly population.

The elements of a comprehensive mental status examination include assessment of cognitive, functional, and behavioral domains. The initial contact with the patient affords the opportunity to assess whether a cognitive, attention, affective, or language disorder is present. If available, questioning of an informant may bring to light changes in cognition, function, and behavior that the patient either is not aware of or denies.

Screening for cognitive disorders in the older adult may include both performance and informant measures. Examples of brief tests of mental status include the Mini Mental State Exam,⁹ the Mini-Cog,¹⁰ and the Montreal Cognitive Assessment.¹¹ These tests compare decrements in cognitive ability to published norms, often adjusted for age and education. Decrements in cognitive ability are compared with published norms, often adjusted for age and education. Examples of other brief informant assessments include the AD8,¹² and the Informant Questionnaire on Cognitive Decline in the Elderly.¹³ These scales detect intraindividual decline by comparing current performance on cognitive and functional tasks to prior levels of performance. Combining performance and informant measures may increase the likelihood of detecting cognitive disorders.¹⁴

CRANIAL NERVE FUNCTION

Smell and taste

Normal aging is associated with decrements in olfaction at both threshold and suprathreshold concentrations. Elderly people also have reduced capacity to discriminate the degree of differences between odors of different qualities and have impaired performance on tasks that require odor identification.¹⁵ Impaired olfaction with aging may be due to structural and functional changes in the upper airway, olfactory epithelium, olfactory bulb, or olfactory nerves.¹⁵ It is important to recognize that while impaired smell can be associated with aging, it can also be the result of medications, viral infections, and head trauma. Moreover, there appears to be early involvement of olfactory pathways in neurodegenerative diseases such as Alzheimer disease (neurofibrillary tangles)¹⁶ and Parkinson disease (Lewy bodies).¹⁷ Taste, which in turn is greatly dependent on olfaction, also decreases with advanced age, with a reduced sensitivity for a broad range of

Table 16-1. Neurologic Changes Associated With Normal Aging

Psychomotor slowing
Decreased visual acuity
Smaller pupil size
Decreased ability to look upward
Decreased auditory acuity, especially for spoken language
Decreased muscle bulk
Mild motor slowing
Decreased vibratory sensation
Mild swaying on Romberg test
Mild lordosis and restriction of movement in neck and back
Depression of Achilles tendon reflex

tastes compared to young adults.^{18,19} Although the number of taste buds does not seem to be significantly decreased in the elderly, some studies have suggested decreased responses in electrophysiologic recordings from taste buds.²⁰ Multiple other factors such as medications, smoking, alcohol, and dentures may contribute to decreased taste.

Vision

Age-related changes have been documented in visual acuity, visual fields, depth perception, contrast sensitivity, motion perception, and perception of self-motion in relation to external space (optical flow).⁷ Anatomic and physiologic studies have demonstrated a gradual decline in photoreceptors after the age of 20, resulting in decreased visual acuity in elderly.²¹ This is especially apparent in conditions with low contrast and luminance.²² There is also a decline in visual field sensitivity with aging.²³ The mechanisms responsible for this are not well understood. There is also an age-related impairment in accommodation that leads to farsightedness (presbyopia) and a decrease in accommodation because of rigidity of the lens.⁷ Relaxation and accommodation times increase progressively and peak around the age of 50. Therefore, many elderly are forced to use glasses for reading. Moreover, ophthalmologic conditions, such as cataracts, glaucoma, and macular degeneration occur commonly with age and contribute significantly to decreased visual acuity seen with aging.

Pupillary abnormalities have also been described with normal aging. These include smaller pupils (senile miosis), which may be due to decreased preganglionic sympathetic tone,²⁴ sluggish reaction to light, and decrease or even loss of the near or "accommodation" response.^{25,26} Some authors have reported loss of pupillary reaction in 5%–19% of normal elderly in the absence of neurologic disease.²⁷

Age-associated changes in extraocular motility include decreased velocity of saccades, prolonged latency, decreased accuracy, and prolonged duration and reaction time. There is also an age-related limitation of upgaze,²⁸ but not downgaze, slowing of smooth pursuits, and impaired visual tracking.^{27,29–32} Vertical gaze changes begin in middle age and decline in the upward plane from 40 degrees between the ages of 5 and 14 years, to 16 degrees between the ages of 75 and 84.^{33,34} Vertical gaze palsy is an important consideration in the evaluation of driving abilities in older adults (street signs, traffic lights). Other changes of eye movements with aging include loss of Bell's phenomenon (upward and outward deviation of the eyes in response to attempted forced closure of the eyelids).

Hearing and vestibular function

Gradual loss of cochlear hair cells, atrophy of the stria vascularis, and thickening of the basement membrane may account for the impaired hearing that is commonly seen with aging. This is often referred to as "presbycusis" and predominantly affects higher frequencies.² Other changes include impaired speech discrimination, increase in pure tone threshold averages (approximately 2 dB/yr), and decreased discrimination scores.³⁵

Vestibular function may also be affected with aging. There is a decrease in vestibulospinal reflexes, and in the ability to detect head position and motion in space. These may be secondary to loss of hair cells and nerve fibers along with neuronal loss in the medial, lateral, and inferior vestibular nucleus in the brainstem.⁷

MOTOR SIGNS

There is a progressive decline in muscle bulk associated with aging, sometimes referred to as sarcopenia. This is most obvious in the intrinsic muscles in the hands and feet, particularly the dorsal interossei and thenar muscles as well as around the shoulder cap (deltoid and rotator cuff muscles). Atrophy of the thenar muscles, without weakness or fasciculations, may be present in more than 50% of elderly patients.³⁶ Results of different longitudinal studies have been inconsistent regarding the predominant fiber type affected by aging, with reports of loss of type IIb fibers or "fast twitch" fibers³⁷, reduction in the percentage of type I fibers with no change in type I or II mean fiber area, a decrease in the capillary to fiber ratio,³⁸ and an increase in the percentage of type I fibers.³⁹ The decrease in muscle mass is associated with electrophysiologic evidence of denervation and muscle fiber atrophy.⁴⁰ However, fasciculations are not a normal sign of aging, and if present, should warrant search for pathologic causes (e.g., motor neuron disease, compressive cervical myelopathy, multifocal motor neuropathy).⁷

Decrease in muscle strength often accompanies the decrease in muscle bulk.⁴¹ One study reported up to 50% decrease in maximum voluntary contraction force and twitch tension in the quadriceps in elderly patients compared with younger ones.⁴² Hand grip strength decreases significantly after the age of 50, but strength in the arms and shoulders does not change until after the age of 60. Weakening of abdominal muscles may accentuate lumbar lordosis and contribute to low back pain. Other studies have suggested that changes in muscle strength are not frequent²⁵ or significant in the absence of underlying disease states.²⁷ Differences in the results of these studies can be attributed to different evaluation techniques and the examination of different muscle groups.

In addition to motor bulk and strength, there also appears to be loss of speed and coordination of movement with aging. Speed of hand and foot tapping was found to be reduced by 20% to 23% in one study.⁴¹ A mild terminal tremor and hesitation in finger nose testing,²⁵ mild bradykinesia,⁴³ rigidity, and mild dysmetria on finger-nose and heel-shin testing have also been described in isolation in 1.8% to 44% of elderly.^{2,27,29} In one study of 467 patients, the prevalence of parkinsonian signs defined as the presence of signs of two or more categories (rigidity, bradykinesia, tremor, gait disturbance) increased gradually from 14.9% for people aged 65 to 74 to

52.4% for those 85 and older.⁴³ These may interfere with activities of daily living, such as dressing, eating, and getting out of a chair and may be an important source of disability. Another finding of that study was that the presence of parkinsonism was associated with a twofold increase in mortality mostly as a result of gait instability.

Paratonia

Paratonia (Gegenhalten) represents increased motor tone with rapid passive movements of the limbs (i.e., flexion and extension), often suggestive of deliberate resistance. Unlike the rigidity of Parkinson, it is not constant and tends to disappear with slow movements of the limbs. Paratonia can be detected when the patient's arms, suspended 15 cm above the lap, remain elevated after being released despite instructions to the patient to relax.²

The prevalence of paratonia increases with advancing age with a prevalence 4% to 21%.³¹ It is considered by some to be a postural reflex or a cortical release sign. Similar to other primitive release signs, its prevalence is higher in patients with advanced Alzheimer's and correlates with the severity of cognitive impairment. Other investigators consider paratonia as a sign of age-related changes in the basal ganglia.³²

Tremor and other abnormal movements

Physiologic tremor may occur at any age. There are different types of physiologic tremor: rest tremor with a frequency of 8 to 12 Hz, postural tremor when the patient holds out the arms during isometric contractions of the muscles against gravity (with a frequency of 8 to 12 Hz), and action or volitional tremor during isotonic contraction (with a frequency of 7 to 12 Hz).⁴⁴

The prevalence of physiologic tremor in healthy elderly is controversial.⁴⁴ Postural tremor is more likely secondary to other causes, such as medications, alcohol, disease states such as hyperthyroidism, hyperadrenergic states, or dystonia. When no obvious secondary factors are evident, essential tremor should be considered in the diagnosis. Its prevalence has been reported to range from 1.7% to 23% of healthy elderly aged 65 years or older in different studies.⁴⁵ In the absence of secondary causes for tremor, and when the tremor does not fit the criteria for essential tremor, it is often referred to as senile tremor. Senile tremor is very common, affecting 98% of elderly patients in one community-based case control study. It is often a mild asymptomatic tremor and frequently does not require treatment. It is unclear if it represents an exaggerated physiologic tremor or a mild form of essential tremor.² A rhythmic, usually asymmetric rest tremor is often indicative of Parkinson disease.⁵

Senile chorea is a rare condition with late onset of generalized chorea in the absence of dementia and absence of a family history of a similar condition. It is probably better considered a prodromal syndrome rather than a separate disease entity as many patients diagnosed with senile chorea later develop other neurologic disorders such as Huntington's disease. Some pathologic reports have demonstrated its association with abnormalities in the putamen, globus pallidum, and cerebellar nuclei.²

The frequency of idiopathic lingual-facial-buccal dyskinesia is elevated in patients over the age of 60 with a prevalence of 1.5% and can be as high as 38% in hospital-based

populations. Tardive dyskinesia associated with neuroleptic medications should be considered in the differential diagnosis.²

CHANGES IN GAIT AND STATION

There is a tendency to develop flexed posture with advanced age. This may be due to decreased neuromuscular power, increased tone (paratonia), and degenerative joint disease. Increased postural sway is a normal phenomenon in the elderly and is seen in two different frequencies. Fast oscillations are dependent on proprioceptive input from the lower extremities and slow oscillations are dependent, at least partially, on vestibular input. Looking at the feet exaggerates this normal sway by interfering with visual compensation. Postural righting reflexes may be slowed and with reduced amplitude in the elderly. Control of stance, as judged by the amplitude of sway, is poor in childhood, peaks in adulthood, and decreases with age. In one study, almost one third of patients above the age of 60 were unable to minimize their sway with visual endeavors and therefore had a significant risk for falls.⁴⁴

Examination of gait in the elderly is an essential part of the neurologic examination, given the high risk of falls in the population. Gait is composed of equilibrium (maintaining an upright posture) and locomotion (gait initiation and stepping); both of which appear to be decreased in aging.⁷ Healthy elderly people have difficulty maintaining balance on one foot with eyes closed. Quantitative studies have also shown that older people have greater body sway⁴⁶ and exhibit significant reduction in the velocity of gait and length of stride.⁴⁷ Therefore, the elderly may have difficulty with tandem gait or heel to toe walking for extended periods of time.

The term idiopathic senile gait⁴⁸ is sometimes used to describe the clinical picture of stooped posture, posteriorly rotated immobile pelvis, excessive flexion at the hips and knees, a reduced toe-floor clearance, a slightly broad base, and reduced arm swing.⁴⁹ However, this term remains poorly defined and does not include all forms of gait disorders that can be seen with aging. There is also substantial overlap with the gait associated with many pathologic conditions, such as normal pressure hydrocephalus, parkinsonism, and lacunar state.⁵⁰

Other factors that contribute to impaired gait in the elderly include decreased muscle strength, weakening of abdominal muscles, arthritis and degenerative joint disease, diminished vibration and position sense, impaired visual and vestibular systems, and impaired motor speed and coordination. Despite these multiple factors, some authors suggest that age alone does not generally affect postural righting reflexes or cause recurrent falls. If present, these should be investigated to rule out underlying disorders such as Parkinson's disease.

DEEP TENDON REFLEXES

The ability to detect reflexes can be limited by conditions such as apprehension or joint disease in the elderly. Hyporeflexia or areflexia of the ankle jerks has been reported in elderly people.⁵¹ Asymmetry of reflexes was reported in 3% of the elderly in one study. Electrophysiologic studies report both afferent and efferent limbs of the reflex to be decreased

with age.⁷ The ankle jerk is usually the first reflex to decrease or disappear with aging although, there have been reports of loss of patella tendon reflexes as well.⁴⁴

Superficial reflexes (abdominal, cremasteric, and plantar response) may become sluggish or disappear with advanced age. Corticospinal lesions above T6 may lead to loss of all superficial abdominal reflexes, whereas all are spared in lesions below T12. Lesions between T10 and T12 may lead to selective loss of the lower reflexes only with a positive Beevor's sign (upward movement of the umbilicus in a supine patient attempting to flex the head).⁷

Extension or dorsiflexion of the big toe with fanning of the toes induced by stroking the lateral aspect of the sole is called the Babinski sign. It is considered to be a primitive reflex that, when present beyond the first 2 years of life, is a reliable sign of upper motor neuron pathology. No consistent changes have been documented with normal aging, and there is often some degree of interobserver variability in eliciting this reflex.⁷

SENSORY SIGNS

The most common and evident abnormality in sensory examination associated with aging is decreased vibration and to a lesser extent proprioception. Both of these sensory modalities are carried by the dorsal column; their impairment with age may be due to proliferation of connective tissue, arteriosclerotic changes in the arterioles, degeneration in the nerve fibers,⁵² or loss of axons in the dorsal column.⁵³

Vibration sense is impaired in 12% to 68% of elderly between the ages of 65 to 85 years old and becomes more impaired with advanced age.²⁷ The loss of vibration affects both upper and lower extremities and often begins distally.² This can be demonstrated with a 128 tuning fork at the metatarsals or medial malleolus of the ankle. One study reported that vibration sense might be absent in the soft tissues of the abdomen, thighs, and legs and the plantar surfaces of the toes even when it is present over bony prominences.⁴⁴ Using quantitative measurements, it has been shown that the sensitivity of vibration decreases with age in the high frequency range but does not change in the low frequency range (25 to 40 Hz).

Proprioception is also affected to a lesser extent with a prevalence ranging from 2% to 44% in different studies.^{27,31} This often manifests as a mild sway on the Romberg test. There is paucity of data regarding the involvement of tactile sensation in the elderly. Some reports suggest that age is associated with increased thresholds for light touch.⁵⁵ However, these changes are often not significant enough to be detected clinically. Other studies found no change in quantitative measures of touch or two-point discrimination.⁴¹ The results of different studies regarding changes in thermal sensitivity have been conflicting.²

Despite an increased pain threshold in the elderly, subjective sensory symptoms such as paresthesias, formications, postherpetic neuralgia, and tic douloureux are commonly encountered in the elderly population.⁴⁴

PRIMITIVE REFLEXES

Primitive reflexes, or so called "archaic" or developmental reflexes represent loss of cortical inhibition on reflex associations present at early stages of development and later

suppressed with brain maturation. Their reappearance in adult life has been associated with atrophic changes predominantly involving the frontal lobes (e.g., dementia syndromes, demyelinating disease, or cerebrovascular disease) and are sometimes referred to as "cortical release signs." However, these reflexes are sometimes seen in otherwise healthy elderly and some (such as the palmomental reflex) can be elicited at all ages. The exact pathophysiologic mechanisms underlying these reflexes are not completely understood. In isolation, they are neither sensitive nor specific for any neurologic disease. Although some can be seen in normal aging, their occurrence in combination should necessitate investigation for underlying disease (neurodegenerative disease and dementia) and should not be attributed to normal aging alone.²

Palmomental reflex

Contraction of the mentalis muscle in the lower jaw is elicited by stroking the ipsilateral thenar eminence. It is a polysynaptic and nociceptive reflex with the afferent arm traveling through the median and ulnar nerves and the efferent arm in the facial nerve. The threshold for eliciting the palmomental reflex varies greatly between individuals.⁵⁶ The palmomental reflex is seen in up to 27% of individuals before age 50 and in more than 35% of individuals over age 85.³¹ The appearance of the palmomental reflex may reflect frontal lobe dysfunction.²

Snout or pout reflex

This is elicited by pressing or gently tapping over the philtrum of the upper lip in the midline, which results in pouting or pursing of the lips. It is a nociceptive reflex of the perioral muscles carried by the trigeminal and facial nerves for the afferent and efferent limbs. Unlike the palmomental reflex, it is generally not seen before the age of 40 to 50 according to different reports.⁵⁷ However, the incidence increases with age, with a prevalence of 73% by age 85.²⁷ The occurrence of this reflex correlates well with impaired performance on psychometric testing⁵⁸ and corresponds to loss of large pyramidal neurons in the anterior cingulate gyrus.²

Suck reflex

This is elicited by stroking the lips with the index finger or a reflex hammer. The response could be incomplete with the lips closing around the finger or object, or could be complete—resulting in sucking movements in the lips, tongue, and jaw.⁴⁴ If the stimulus is applied to the lateral margins of the lips, the head turns towards the side of the stimulus. Although it can be seen in 6% of normal elderly,⁵⁹ it is more common in the presence of dementia⁵⁸ and correlates with the severity of cognitive impairment.⁶⁰ The snout and suck reflex appear to be more common with prolonged use of phenothiazines.⁴⁴

Grasp reflex

There are three different types of grasp reflex that reflect three different levels of severity of cortical disinhibition.² The first called tactile grasp is elicited by applying firm pressure across the palm from the ulnar to the radial side while distracting the patient (e.g., asking the patient to count backwards from 20). It is considered positive if the patient grasps the examiner's fingers or flexes the fingers with adduction of

the thumb in response to stroking the palm. Traction grasp is described as the patient counter pulling when the examiner attempts to pull away from the patient's grip. Magnetic grasp is when the patient follows or reaches for the examiner's hand to grasp it. It is generally considered a pathologic sign, and often occurs as a result of contralateral or bilateral damage to medial frontal or basal ganglia structures. However, some have reported its presence in 3% to 67% of normal elderly^{27,31} and generally increases with advanced age. It is also more frequent in Alzheimer's disease⁶¹ and correlates with the degree of cognitive impairment.⁶⁰ Analogous to the grasp reflex in the hand is flexion and adduction of the toes with inversion and incurving of the foot in response to tactile stimulation or pressure on the sole. This reflex is seen invariably in neonates and may reappear in the elderly and contribute to gait difficulty.

Glabellar tap reflex

Other names for this reflex include glabella tap sign, orbicularis oculi sign, blinking reflex, and Myerson's sign. It is elicited by tapping between the eyebrows with the finger, at a rate of 2 per second and avoiding a visual threat response. A normal response consists of blinking in response to the first 3 to 9 taps, followed by cessation of the response with further tapping. It is considered positive or abnormal if blinking continues with further tapping. An abnormal glabellar tap was first described in Parkinson's disease patients and was considered to be diagnostic for that disease. However, it can occur with normal aging and other neurodegenerative disorders. It is found in more than 50% of normal older adults and it is debatable whether it becomes more prevalent with older age.^{31,32} It is different from the other primitive reflexes in that it mainly results from lesions of basal ganglia, rather than cortical disinhibition.²

CONCLUDING COMMENTS

A variety of neurologic disorders (e.g., stroke, Parkinson's disease, Alzheimer's disease) preferentially affect older adults. To document normal findings and detect abnormal signs, a comprehensive mental status and neurologic examination should be performed in every older adult.

Altered cognitive function in the setting of a clear sensorium is consistent with dementia secondary to a neurodegenerative process (Alzheimer's disease, Parkinson's disease, Pick's disease) or medical illness (cerebrovascular disease, vitamin B₁₂ deficiency, hypothyroidism). Delirium on the other hand causes alteration in sensorium and level of consciousness and may be due to medications, infection, head injury, or metabolic derangements. Associated features include disruption of sleep-wake cycle, intermittent drowsiness and agitation, restlessness, emotional lability, and frank psychosis (hallucination, illusions, delusions). Predisposing factors include advanced age, dementia, impaired physical or mental health, sensory deprivation (poor vision or hearing), and placement in intensive care units.

A functional decline in some aspects of cranial nerve function (e.g., vision, hearing, vestibular function, taste, and smell) can be readily detected on examination. In the

absence of other findings, this may be considered part of the normal aging process. However, a constellation of abnormalities usually represent a pathologic condition afflicting the nervous system. Similarly, older individuals experience decreased mobility, coordination, sensation, and strength as they age. However, more profound changes that significantly alter mobility or present as focal neurologic signs should alert the clinician to a neuropathologic disorder and warrants diagnostic testing.

In conclusion, neurologic findings of normal aging include subtle declines in cognitive function, mildly impaired motor function, and altered sensory perceptions. However, exaggerated impairments in cognitive, behavioral, motor, and sensory function suggest the onset of neurologic diseases that commonly afflict the older adult. A comprehensive mental status and neurologic examination in addition to a detailed general physical examination is the foundation for identifying neuropathologic conditions that necessitate further investigation.

KEY POINTS

Neurologic Signs in the Elderly

- Neurologic disorders are a common cause of morbidity, mortality, and institutionalization in elderly populations, not only increasing in severity of neurologic disease but modifying disease presentation.
- Because the frequency of cognitive disorders increases dramatically with advancing age, examination of mental status is one of the most important components of the neurologic examination. The elements of a comprehensive mental status examination include assessment of cognitive, functional, and behavioral domains.
- Neurologic findings of normal aging include subtle declines in cognitive function, mildly impaired motor function, and altered sensory perceptions. However, exaggerated impairments in cognitive, behavioral, motor, and sensory function suggest the onset of neurologic disease.
- A functional decline in sensory cranial nerve function (e.g., vision, hearing, vestibular function, taste, and smell), in the absence of other findings, may be considered part of the normal aging process.
- Primitive or "pathologic" reflexes (glabellar, grasp, snout, palmomental) occurring in isolation may be seen in normal aging. However, their occurrence in combination or with other neurologic signs may represent processes affecting frontal lobe function (e.g., dementia syndromes, demyelinating disease, or stroke).

Geriatric Gastroenterology: Overview

Richard C. Feldstein
Robert E. Tepper
Seymour Katz

More than 20% of our population is expected to exceed 65 years of age by 2030,¹ with the most rapidly growing segment over 85 years of age.² Of necessity, gastroenterologists will be increasingly confronted with digestive diseases in elderly patients. Gastrointestinal disease is the second most common indication for hospital admission of elderly patients,³ who account for four times as many hospitalizations as do younger patients.¹ In the outpatient setting, patients 75 and older visit internists six times more frequently than do younger adults.³

NORMAL PHYSIOLOGY OF AGING

With a few notable exceptions, the digestive system maintains normal functioning in elderly people. To distinguish between the expected age-related alterations of the gut and symptoms attributable to pathologic conditions, the clinician must have an understanding of the normal physiology of aging. One must also appreciate the interactions between the gastrointestinal (GI) tract and longstanding exposures to environmental agents (e.g., medications, tobacco, and alcohol) and chronic non-GI disease states (e.g., congestive heart failure, diabetes mellitus, chronic obstructive pulmonary disease, dementia, depression).⁴ With this knowledge, it will become apparent that most new GI complaints in otherwise healthy older people are due to disease rather than to aging alone and therefore merit appropriate investigation and treatment.

Aging is not associated with a difference in either the desire to eat or the hunger response before meal intake, but postprandial hunger and the desire to eat are reduced.^{5,6} One explanation may be that fasting and intraduodenal lipid-stimulated plasma concentrations of cholecystokinin (CCK), a physiologic satiety factor, and leptin, a hormone that functions mainly as a signal of adiposity eliciting long-term satiety, have been found to be higher in older than in younger men.^{7–10} However, anorexia in older individuals should not be attributed to advanced age alone. This symptom warrants evaluation to exclude a medical or psychological cause or a medication-induced adverse effect.⁵

Up to 40% of healthy elderly people subjectively complain of dry mouth. Although baseline salivary flow probably decreases with aging, stimulated salivation is unchanged in both healthy and edentulous geriatric patients.^{11–15} Chewing power is diminished, probably because of the decreased bulk of the muscles of mastication,^{16,17} although perhaps attributable in part to preclinical manifestations of neurologic disease rather than to the normal aging process.¹⁵ Although many older patients are edentulous to some degree, better dental care has enabled more of them to have intact teeth now than in the past.^{5,18,19}

Gustatory and olfactory sensation tend to decrease with aging.^{10,20} The ability to detect and discriminate between sweet, sour, salty, and bitter tastes deteriorates as one gets

older.^{5,10,21,20} Thresholds for salt and bitter taste show age-related elevations, whereas that for sweet taste appears stable.^{5,22} By the ninth decade, the olfactory threshold increases by about 50%, contributing to poor smell recognition.^{5,10,23}

Despite early data to the contrary, the physiologic function of the esophagus in otherwise healthy individuals is well preserved with increasing age, with the exception of very old patients.^{24,25} Studies from the early 1960s introduced the concept of the “presbyesophagus” based on cineradiographic and manometric data,^{26,27} but the term has been abandoned.²⁸ A more recent study that excluded patients with diabetes or neuropathy found no increase in dysmotility in elderly men.²⁹ Investigators have also found that minor alterations may occur in some octogenarians, including decreased pressure and delayed relaxation of the upper esophageal sphincter and reduction in the amplitude of esophageal contraction.^{30,31} Furthermore, a recent study has shown age-related changes of increased stiffness and reduced primary and secondary peristalsis in the human esophagus that is associated with a deterioration of esophageal function beginning after the age of 40.²⁷ In addition, in a study comparing esophageal manometry and scintigraphic examinations of gastroesophageal reflux in groups of healthy volunteers ranging from 20 to 80 years of age, it was determined that while the number of reflux episodes per volunteer was similar in the various age groups, the duration of reflux episodes was longer in older volunteers. The older participants had impaired clearance of refluxed materials due to a high incidence of defective esophageal peristalsis.³³ Similarly, in another study, age was shown to correlate inversely with LES pressure and length, UES pressure and length, and peristaltic wave amplitude and velocity suggesting that normal esophageal motility deteriorates with advancing age.³⁴ Together, the above findings may help explain the high prevalence of reflux symptoms in the elderly.

Most studies on gastric histology have found evidence of an increased prevalence of atrophic gastritis in people over 60.^{35,36} Consequently, it has been suggested that aging results in an overall decline in gastric acid output.^{24,37,38} However, more recent data have demonstrated that gastric atrophy and hypochlorhydria are not normal processes of aging. Rather, *Helicobacter pylori* infestation, which is common in the elderly, not advancing age itself, appears to be the more likely cause of these histologic and acid secretory changes.^{35,39–43} The literature remains conflicted over the issue of whether aging alone, rather than factors such as increased *H. pylori* infestation and decreased smoking leads to altered pepsin secretion.^{6,41,44–45} Intrinsic factor secretion is usually maintained into advanced age and is retained longer in the setting of gastric atrophy than is acid or pepsin secretion.^{46,47} Gastric prostaglandin synthesis, bicarbonate, and nonparietal fluid secretion may diminish, making the elderly more prone to nonsteroidal anti-inflammatory drug (NSAID)-induced mucosal damage.^{5,6,10} Finally, most (but not all) studies have shown that gastric emptying of solids remains intact in the elderly, although liquid emptying is prolonged.^{48–53}

Small bowel histology^{54–56} and transit time^{10,52,57–59} do not appear to change with age in humans, although increased epithelial proliferation in response to cellular injury has been found in a rodent model.⁶⁰ Splanchnic blood flow is reduced in the elderly population.⁶ Small bowel absorptive capacity for most nutrients remains intact, but there are some exceptions especially those due to effects of disease (e.g., chronic gastritis and bacterial overgrowth) and medications on micronutrient absorption.¹⁰ No change with aging was found in duodenal brush border membrane enzyme activity of glucose transport.⁶¹ D-xylose absorption testing remains normal after correction for renal impairment, except perhaps in octogenarians.^{62,63} Jejunal lactase activity decreases with age, whereas that of other disaccharides remains relatively stable, declining only during the seventh decade.⁶⁴ Protein digestion and assimilation,^{24,65} and fat absorption remain normal with aging, although the latter has a more limited adaptive reserve capacity.^{67–70} Absorption of fat-soluble vitamin A is increased in the elderly population,^{10,46,71} while vitamin D absorption may be impaired^{46,66,72,73} and a reduction in vitamin D receptor concentration and responsiveness occurs.^{5,18,66} Absorption of the water-soluble vitamins B₁ (thiamine),⁷⁴ B₁₂ (cyanocobalamin),^{67,69,75} and C (ascorbic acid) remains normal, whereas disparate data exist on folate absorption with aging.^{77,78} Iron absorption is maintained in the healthy elderly who are not hypochlorhydric,^{79,80} but absorption of zinc^{46,81} and calcium^{46,82–84} declines with age.

Several histologic changes have been demonstrated in the colon, including increased collagen deposition,⁶ atrophy of the muscularis propria with an increase in the amount of fibrosis and elastin,^{24,85} and an increase in proliferating cells especially at the superficial portions of the crypts.^{60,86} Some studies have found that colonic transit time increases with aging to varying degrees,^{70,87,89} perhaps due to the increase with age in the number of abnormally appearing myenteric ganglia in the human colon.⁸⁸ Other studies have not shown any change.^{90,91} Current thinking holds that colonic motility and the colon's response to feeding are largely unaffected by healthy aging. Prolonged transit time in older people with constipation is due to factors associated with aging (e.g., comorbidity, immobilization, drugs) rather than aging per se.⁹²

Anorectal physiologic changes have been well-documented. Aging is associated with decreased resting anal sphincter pressure in both sexes and decreased maximal sphincter pressure in women.^{93,94,95} This may be due in part to age-related changes in muscle mass and contractility and in part to pudendal nerve damage associated with perineal descent in elderly women.^{95,96} The closing pressure (i.e., the difference between the maximum resting anal pressure and the rectal pressure) also falls in elderly women.⁹⁷ Maximum squeeze pressure declines with age, particularly in postmenopausal women,⁸ as does rectal wall elasticity.^{98,99} An age-dependant increase in rectal pressure threshold producing an initial sensation of rectal filling has also been demonstrated.¹⁰⁰ Defecation dynamic studies in older women show a significant failure of rectal evacuation because of insufficient opening of the rectoanal angle and an increased degree of perineal descent compared with younger women.^{92,101} Histologic¹⁰² and endosonographic¹⁰³ studies on anorectal structure revealed that the internal anal sphincter develops

fibro-fatty degeneration and increased thickness, respectively, with aging.

The pancreas undergoes minor histologic changes with aging.^{24,104,105} There also appears to be a steady increase in the caliber of the main pancreatic duct, with other branches showing areas of focal dilatation or stenosis without any apparent disease or functional age-related changes.^{104,106} In fact, 69% of patients older than 70 years of age without pancreatic pathology have a "dilated" duct when criteria developed for younger patients are applied.¹⁰⁷ High echogenicity of the pancreas is a normal finding on ultrasonography.¹⁰⁸ Aging reduces exocrine pancreatic flow rate and secretion of bicarbonate and enzymes, and the rate falls significantly with repeated stimulation.^{8,104,105,109,110} However, other studies have shown a lack of reduced pancreatic secretions with age, independent of disease and the effect of drugs.¹¹⁰

Anatomical studies on the liver reveal an age-related decrease in weight, both absolute and relative to body weight, and in the number and size of hepatocytes.^{111–112} Pseudocapillarization of the hepatic sinusoid (morphologic changes such as defenestration and thickening of the liver sinusoidal endothelial cell, increased numbers of fat engorged nonactivated stellate cells), lipofuscin accumulation, bile duct proliferation, fibrosis, and nonspecific reactive hepatitis are histologic changes more common in the elderly population.^{112,113,114} The major functional changes in older patients are reduction in hepatic blood flow,^{110,114} altered clearance of certain drugs, and delayed hepatic regeneration after injury.^{113–117} The altered drug clearance is due to age-related reductions in phase I reactions (e.g., oxidation, hydrolysis, reduction), first pass hepatic metabolism, and serum albumin binding capacity. Phase II reactions (e.g., glucuronidation, sulfation), however, remain unaffected by aging.^{111,112,115,116} There are no age-specific alterations in conventional liver blood tests.¹¹⁷

Although an early cholecystographic study found that gallbladder emptying remained stable with increasing age,^{118,119} more recent data showed that gallbladder contraction in the elderly person may be less responsive to CCK.^{119,120} Increases in the proportions of the phospholipid and cholesterol components of bile raise the lithogenicity index,^{121,122} leading to increased occurrence of gallstones in the aged.²⁴ Cholelithiasis is particularly common in elderly patients who have undergone an emergency cholecystectomy, the incidence of bile duct stones approached 50%.¹²³ Even in the absence of bile duct stones or other pathology, older patients generally have larger common bile duct diameters than do younger patients.¹²⁴

ALTERED MANIFESTATION OF ADULT GASTROINTESTINAL DISEASES

Although there are certain disorders that occur almost exclusively in the elderly population, the majority of diseases afflicting older people are those that affect younger adults as well. However, these illnesses may have atypical features that must be recognized by clinicians and represent a formidable challenge. In elderly people with an "acute abdomen," the initial diagnostic impression has been found to be incorrect in up to two thirds of patients,¹²⁵ and the mortality in octogenarians is 70 times that in young adults.¹²⁶

Acute abdominal pain appears to mute with age.^{47,127} Theories explaining this phenomenon include increased endogenous opiate secretion, a decline in nerve conduction, and mental depression.¹²⁸ Pain localization is often atypical in elderly patients. For example, in a study on acute appendicitis, 21% of patients over 60 years of age have atypical pain distribution, while this occurred in only 3% of patients under 50 years of age.¹²⁹

The causes of acute abdominal pain differ as well. Acute cholecystitis, rather than nonspecific abdominal pain or acute appendicitis, was found to be the most common cause in one large survey.^{126,127} In this series, 10% of patients over 70 years of age were found to have a vascular cause for their pain, such as mesenteric ischemia, embolus, or infarction. Furthermore, retrospective studies have shown that in elderly patients with acute cholecystitis, more than 60% of elderly patients did not have the typical back or flank pain and 5% had no pain at all. In addition, 40% denied nausea, more than 50% were afebrile, and 41% had a normal white count. Overall, 13% of elderly patients had no fever, leukocytosis, or abnormal liver function tests.¹²⁷ A multicenter review found that 25% of emergency patients over the age of 70 had cancer (usually colorectal in Europe and North America, and hepatocellular in tropical regions)¹²⁶ as the cause of pain, whereas patients below age 50 had malignancy as the explanation in fewer than 1% of cases.¹³⁰

Acute appendicitis may have few overt abdominal signs^{127,131,129} and may therefore progress more frequently to gangrene and perforation.¹³² Other intraabdominal inflammatory conditions, such as diverticulitis, may have rather nonspecific symptoms including anorexia, altered mental status, low-grade or absence of fever, relatively little tenderness, and late-stage complications (e.g., hepatic abscess). Even perforation of a viscus may lack the typical dramatic manifestations.^{128,136} Possible explanations for the paucity of tenderness in some cases include altered sensory perception, use of psychotropic drugs, and absence of chemical peritonitis if the patient is hypochlorhydric.⁴⁷ The site of perforation also differs with age. Colonic perforation is more common than perforated peptic ulcer disease or appendicitis, the two most common causes for generalized peritonitis in younger patients.¹²⁶

Studies vary regarding whether or not there is a higher prevalence of gastroesophageal reflux disease (GERD) in the elderly population,^{134,137,139,140} but several studies suggest that the frequency of GERD complications is significantly higher in older people.^{134,137,138} Severe esophagitis is much more common in patients beyond the age of 65 than in young people.^{138,142} Esophageal sensitivity seems to decrease with age,¹⁴¹ so very severe esophagitis may be associated with a relative paucity of symptoms. In fact one study showed that greater than 75% do not experience acid regurgitation as an initial symptom.¹³⁴ Therefore manifestations of GERD are more likely to be late-stage complications, such as bleeding from hemorrhagic esophagitis,¹⁴² dysphagia from a peptic stricture, or adenocarcinoma in the setting of Barrett's esophagus. GERD-induced chest pain may mimic or occur concomitantly with cardiac disease; thus reflux must be excluded in any elderly patient with all but very typical angina.²⁵ Aspiration from occult GERD should be considered in elderly patients with recurrent pneumonia or exacerbations of underlying

chronic obstructive pulmonary disease.²⁵ Early endoscopy is indicated in all elderly patients with GERD, regardless of symptom severity.^{134,137} The medical and surgical treatment of GERD in the elderly follows the same principles as for young patients.¹³⁷ Proton pump inhibitors as a class are considered first-line treatment for GERD and erosive esophagitis in the elderly,^{134,143} although the elderly may require a greater degree of acid suppression than young patients to heal their esophagitis.¹⁴⁰ And with the advent of newer proton pump inhibitors, studies have shown good tolerability even for long-term therapy due to minimal interactions with other drugs because of a lower affinity for cytochrome P450.¹³³

Gastroduodenal ulcer disease has a several-fold greater incidence, hospitalization rate, and mortality in the elderly.^{144–146} Up to 90% of ulcer-related mortality in the United States occurs in patients over 65.¹⁴⁶ This is due to an increase in injurious agents (e.g., *H. pylori* and nonsteroidal antiinflammatory drugs [NSAIDs], two factors which do not seem to act synergistically)^{147,153} and to impaired defense mechanisms (e.g., lower levels of mucosal prostaglandins).^{10,148} There may be a paucity or distortion of classic burning epigastric pain, temporal features related to food intake, and typical patterns of radiation.⁴⁷ Pain was absent in one third of elderly hospitalized patients with peptic ulcer disease.¹⁴⁹ As a result, elderly patients more frequently develop complications such as bleeding or perforation. Giant benign ulcers of the elderly can mimic malignancy by presenting with weight loss, anorexia, hypoalbuminemia, and anemia. Despite the increased morbidity and mortality of upper GI bleeding in the elderly, endoscopic and clinical criteria have been reported that would allow for successful outpatient management.^{150–153}

The manifestations of celiac sprue differ considerably in the elderly since features are generally more subtle than in young patients.^{47,157} Only one quarter of newly diagnosed elderly patients with celiac disease have primarily diarrhea and weight loss.¹⁵⁴ Vague symptoms, including dyspepsia or an isolated folate or iron deficiency, may be the patient's sole manifestation.^{157,158} In one study, the mean delay to diagnosis in the elderly aged 65 years and older was 17 years.¹⁵⁹ Severe osteopenia and osteomalacia¹⁵⁷ and a bleeding diathesis due to hypoprothrombinemia are more common in the elderly than in the young.⁴⁷ Small bowel lymphoma may be particularly common when celiac disease occurs in the elderly person.^{155,159} Therefore elderly patients with persistent symptoms including weight loss, pain, and bleeding—despite strict adherence to a gluten-free diet—require careful evaluation to exclude GI malignancy.¹⁵⁶

Constipation is perceived by elderly patients to be straining during defecation rather than decreased bowel frequency,^{160–162} and it may be manifested in unusual ways. Excessive defecatory straining in patients with underlying cerebrovascular disease or impaired baroreceptor reflexes can present as syncope or a transient ischemic attack. When unrelieved constipation progresses to fecal impaction, an overflow "paradoxical" diarrhea may occur, even in patients with relatively normal anal sphincter pressure. If the clinician does not recognize this and prescribes the standard antidiarrheal therapy, the underlying impaction will only worsen and potentially lead to other serious complications, such as stercoral ulcers and bleeding.^{161,162}

Crohn's disease of new onset in elderly people has been commonly reported to be limited to the colon more often than it is in young patients.¹⁶⁴ The colitis is more often left-sided in the elderly, whereas proximal colonic involvement is more common in the young.^{165,166} Older patients are less likely to have close relatives affected by Crohn's disease and to have abdominal pain as a presenting symptom.¹⁶⁷ Crohn's disease in the elderly group develops more rapidly and is characterized by a shorter time interval between onset of symptoms and first resection.¹⁶⁷ Elderly patients with Crohn's disease may suffer fewer relapses,⁴⁷ and their postoperative recurrence rate is lower than, or equal to, that of young people.¹⁶⁴ However, in older patients who do have postoperative recurrence, it occurs more rapidly than in younger patients.¹⁶⁷ Whereas those few young Crohn's disease patients who die do so of their disease, death in older patients is usually due to unrelated causes.¹⁶⁴ Older patients are more prone to steroid-induced osteoporosis,¹⁵⁶ bisphosphonates prevent and effectively treat bone loss in these patients¹⁶⁸ and their use must be strongly considered in this setting.

The manifestations of ulcerative colitis are generally the same in the young and the old, including extraintestinal manifestations.¹⁶⁶ In the elderly person, proctosigmoiditis is more common, whereas pancolitis and the need for surgery are less common.

Therapy for inflammatory bowel disease in the elderly can follow the same stepwise regimen as in the younger population. However, a clear distinction must be made between the "fit" elderly and the "frail" elderly. Studies have shown that the "fit" elderly can tolerate therapeutics similar to the younger generation, taking into account the natural decline in age-related drug metabolism with minimal additional risk or morbidity.²⁰⁴

The most common manifestations of gallstone disease in the elderly population are acute cholecystitis and cholangitis.⁴⁷ In fact, biliary tract disease is the most common indication for surgical intervention in patients having acute abdominal pain over the age of 55 years.¹²⁷ Cholecystitis in the elderly person may have nonspecific symptoms, including vague mental and physical disability.^{127,169,170} Pain may be muted¹²⁷ or absent even in the presence of gallbladder empyema, leading to a delay in hospitalization.¹⁷¹ Typical features of cholangitis may be absent. Therefore blood cultures are critical to exclude bacteremia as the sole evidence of an infected biliary tract, which can result in greater mortality in the elderly.^{172,173} Elderly patients who require emergency cholecystectomy have a higher mortality rate than younger patients, but can do well with elective operations aside from longer operative times and postoperative hospital stays.¹⁷⁴ Thus surgery should not be denied to the healthy elderly patient with recurrent biliary colic based on age alone.^{123,175} Minimally invasive procedures such as endoscopic retrograde cholangiopancreatography and laparoscopic cholecystectomy should be used whenever possible.¹²³

The clinical course of liver disease in the elderly is usually similar to that in the young, although complications are tolerated less well.^{47,176} Chronic hepatitis C, along with alcoholic liver disease, is emerging as the most common cause of chronic parenchymal liver disease in the elderly population.^{117,178} Viral hepatitis more commonly has a prolonged and cholestatic picture in the elderly, although data are equivocal on whether older people are more or less

likely to suffer severe or fulminant hepatitis.¹¹² Although the risk of death from fulminant liver failure from acute hepatitis A infection appears to increase with age,¹⁷⁸ acute hepatitis B in elderly patients is usually a mild, subclinical disease and the risk of fulminant disease is not increased.¹⁷⁷ However, a higher risk for progressing to chronic infection exists for those who acquire the disease after 65 years of age.¹⁷⁸ Advanced age at the onset of infection with hepatitis C is associated with an increased mortality rate.¹⁷⁷ This is related to a more rapid rate of fibrosis, the cause of which is unknown but presumed to be related to the decline in immune function with age.¹⁷⁸ When fulminant hepatic failure develops from any cause, advanced age is an adverse prognostic variable.¹¹⁷ Certain conditions, including alcoholic liver disease, hemochromatosis, primary biliary cirrhosis, and hepatocellular carcinoma, are often seen in more advanced stages when they first present in older patients.¹¹²

Nonalcoholic fatty liver (NAFLD) is the most common liver disorder in the United States and worldwide²⁰⁴ and is seen with increasing prevalence in the elderly.²⁰⁵ However, recent studies have shown a lack of association with the metabolic syndrome, a clear distinction from the disease in adulthood.²⁰⁵ In addition, the natural progression of NAFLD with associated liver complications is typically noted between the sixth and eighth decades of life.²⁰⁶ Therefore the diagnosis of cryptogenic cirrhosis in the elderly may be directly related to the ever rising epidemic of fatty liver in adulthood.

GASTROINTESTINAL PROBLEMS UNIQUE TO THE ELDERLY POPULATION

Certain gastrointestinal symptoms and diseases occur primarily, or even exclusively, in the elderly population. In the esophagus, a posterior hypopharyngeal (Zenker's) diverticulum may form as a result of reduced muscle compliance of the upper esophageal sphincter.^{179,180} The most common presentation is dysphagia; however, serious complications include aspiration and malnutrition. Neurologic disorders, particularly cerebrovascular insult (e.g., small basal ganglia infarcts)¹⁰ and Parkinson's disease, account for 80% of cases of oropharyngeal dysphagia in elderly people.¹⁸¹ Dysphagia aortica is a syndrome in which symptoms are caused by extrinsic compression of the esophagus by a large thoracic aneurysm or a rigid atherosclerotic aorta.³¹ Although cervical osteophytes are common in the elderly population, they are thought to be a very rare cause of dysphagia.³¹

Stomach disorders generally confined to elderly people include atrophic gastritis, with or without pernicious anemia. As mentioned previously, prolonged *H. pylori* infection rather than aging alone may be responsible for this condition. A Dieulafoy's lesion, resulting from a nontapering ectatic submucosal artery, may be an obscure cause of upper GI bleeding in patients of all ages but is particularly frequent in the elderly population.^{182,183}

The prevalence of small bowel diverticulosis increases greatly in older people.¹⁸⁵ The condition may be limited to a single large duodenal diverticulum or may be characterized by numerous diverticula throughout the jejunum. Although most cases are completely asymptomatic, some lead to perforation, hemorrhage, or bacterial overgrowth-induced malabsorption.^{47,185,186}

Chronic mesenteric ischemia, manifested by intestinal angina, is a very rare form of mesenteric vascular disease seen in elderly patients with atherosclerosis.^{187,188} In fact, mesenteric artery stenosis is found in 17.5% of elderly patients aged greater than 70 years.¹⁸⁷ Aortoenteric fistula, an uncommon cause of life-threatening GI hemorrhage, occurs in elderly patients with prior graft placement for an abdominal aortic aneurysm (AAA) or, rarely, with an untreated AAA. It can also occur in patients who have undergone aortoiliac bypass surgery (0.5%) and in patients with native anatomy and after enteral stent placement.¹⁸⁴

NSAID-induced enteropathy, characterized by ulceration, leading to acute or occult bleeding, ileal stenosis, strictures, protein loss, or iron deficiency, has been increasingly recognized.¹⁵⁶

Age is a strong risk factor for colon polyps and cancer. Guidelines that advise colorectal screening examinations beginning at age 50 in average-risk patients and at age 40 for certain high-risk patients do not provide upper age constraints for colorectal screening. Some experts have suggested an age cutoff at 80 years for screening¹⁸⁹ and 85 years for surveillance for patients who have had only small tubular adenomas.¹⁹⁰ Since these ages are somewhat arbitrary, colorectal screening and surveillance in the elderly group must be individualized based on comorbidity and life expectancy.^{191,192} Colonoscopic polypectomy, rather than surgery, has been advocated for the treatment of large polyps in healthy elderly patients up to 90 years old in whom life expectancy is at least 5 years.¹⁸⁹

Several other colonic disorders are seen far more commonly in older patients than in younger patients. These include colonic diverticulosis, a condition found on post-mortem examination in more than 50% of people over the age of 70.¹⁹⁴ In fact, a recent study has estimated its prevalence to be 65% in elderly patients greater than 65 years of age.¹⁹³ Also common is segmental colitis associated with sigmoid diverticulosis,^{195,196} sigmoid volvulus, vascular ectasia in the cecum,¹⁹⁷ stercoral ulcer in the setting of fecal impaction; fecal incontinence,^{160,163,198,200} the second leading cause of institutionalization among the elderly;^{96,200} and *Clostridium difficile* infection, a frequent cause of diarrhea in older people,^{196,199} and the most common cause of nosocomial infectious diarrhea in the nursing home setting.²⁰¹

The majority of elderly patients with jaundice have biliary tract obstruction as the cause, rather than hepatocellular disease. Malignancy is more common than choledocholithiasis as a cause of obstruction. Since an elderly person with malignant obstructive jaundice rarely survives more than 4 months, endoscopic rather than surgical biliary decompression is appropriate.¹²³ In this setting, endoscopic biliary stenting for palliation has been advocated to restore a sense of well-being, to avoid early liver failure and encephalopathy, and to improve the patient's nutritional and immunologic status.^{123,202} However, with the advent of improved surgical techniques and postoperative mortality, surgery has expanded to a greater number of patients during the past decade and has found increased use in patients over 70 years old.²⁰² When acute hepatitis occurs, one third of cases

are commonly¹⁷⁸ drug induced and not viral as in young people.¹¹² Pyogenic liver abscesses primarily affect elderly patients, and should be considered in the differential diagnosis of fever or bacteremia of unclear cause.¹⁷⁷

SUMMARY

The gastrointestinal tract generally maintains normal physiologic functioning in the elderly population. Most new GI symptoms in otherwise healthy older patients are due to pathology rather than to the aging process alone. These patients merit attentive and expeditious evaluation and management since their ability to tolerate illness is lower than that of younger patients.

KEY POINTS

Evaluation and Treatment of GI Disorders

- Normal physiologic changes in the aged gastrointestinal tract are few, so clinicians must seek out and actively treat GI disorders (e.g., oropharyngeal dysphagia, malabsorption, abnormal liver enzymes) and not ascribe these signs and symptoms to the aging process.
- Elderly patients have diminished reserve capacity to accommodate illness and should be thoughtfully evaluated and treated early in the course of disease to prevent irreversible deterioration.
- Goals of treatment must be realistic and individualized, with an emphasis on returning the patient to a functional lifestyle.
- Comorbid conditions and concomitant medications have a dramatic effect on the presentation and prognosis of GI disease in elderly people.
- To improve compliance, clinicians must avoid prescribing medications that are expensive and/or are taken frequently throughout the day if alternatives are available because elderly patients may be on a fixed income, subject to "polypharmacy," or have memory impairment.
- Clinicians should avoid prescribing drugs more likely to cause adverse effects (e.g., isoniazid, corticosteroids, opiates, mineral oil, NSAIDs, anticholinergics) if reasonable alternatives are available, and avoid overprescribing tranquilizers and antidepressants for symptoms thought to be due to somatization.
- Although irritable bowel syndrome of new onset may occur in the elderly, 90% of cases first appear before the age of 50. Therefore this diagnosis should be rendered only after thorough evaluation to exclude other diseases, including malignancies or ischemia.
- Endoscopy and abdominal surgery can be performed safely in the elderly. Morbidity and mortality are related to the degree of concomitant disease and the emergent or elective nature of the procedure. An unnecessary delay in surgery is often lethal.
- Chronologic age need not be an absolute contraindication to aggressive therapeutic measures, such as chemotherapy or organ transplantation, as the tolerance of these interventions correlates more with the overall physiologic condition.

INTRODUCTION

Although traditional classification considers the upper and lower urinary tracts as part of one system, each serves a distinct function. We are greatly indebted to Drs. Jassal and Oreopoulos, authors of this chapter (Aging of the Urinary Tract) in the previous edition, for their detailed discussion of renal aging. In this edition, both upper and lower urinary tract components will be considered, emphasizing the known effects of aging on each system. Nevertheless, a number of potentially pertinent topics will not be discussed in this chapter. For example, age-related changes in renal handling of water and electrolytes are addressed in Chapter 85, whereas diseases which commonly affect the aged kidney, prostate, and gynecologic structures are discussed in Chapters 84, 86, and 87, respectively. Of course, given the multifactorial systemic complexity inherent to aging and to common geriatric syndromes (Chapter 10),¹ the discussion will need to cross traditional organ-based boundaries. Therefore we will also discuss the ability of age-related declines in renal function to influence key geriatric measures, such as cognitive function and mobility performance. Conversely, given growing evidence that oxidative stress, inflammation, and nutrition can influence aging- and disease-related processes across many different tissues, the ability of these systemic factors to modify urinary tract aging will also be considered. Finally, the contribution of lower and upper urinary tract dysfunction to urinary incontinence, a major geriatric syndrome, is discussed in Chapter 109.

UPPER URINARY TRACT: KIDNEYS AND URETERS

Overview

Declines in renal function represent one of the best documented and most dramatic physiologic alterations in human aging. In spite of great progress, important issues remain. For example, it has been difficult to explain why renal aging can be so variable between seemingly "normal" individuals and to establish which of these changes may potentially be reversible. Nevertheless, recent developments and continuing research in this area offer unique opportunities for improving the lives of older adults.²⁻⁵

Glomerular filtration rate

Age-related declines in glomerular filtration rate (GFR) are well established; yet contrary to general belief, GFR does not inevitably decrease with age. Among Baltimore Longitudinal Study of Aging participants, mean GFR declined approximately 8.0 mL/min per 1.73 m²/decade from the middle of the fourth decade of life.⁶ However, these decrements were not universal, with approximately one third of these subjects showing no significant decrease in GFR over time.⁶ This high degree of interindividual variability among relatively healthy older adults has raised the hope that age-related declines in GFR may not be inevitable and could ultimately be preventable even in the absence of an overt disease process. At the

same time, clinicians wishing to prescribe renally excreted medications to healthy older adults clearly require reliable tools to accurately estimate GFR.

The decrease in GFR with age is generally not accompanied by elevations in serum creatinine⁶ since age-related declines in muscle mass tend to parallel those observed for GFR, causing overall creatinine production to also fall with age. Thus serum creatinine levels generally overestimate GFR with age, and in women and underweight individuals serum creatinine is most insensitive to impaired kidney function.⁷ Although many formulas have been devised for estimating creatinine clearance based on normative data,^{8,9} their reliability in predicting individual renal function is poor.^{10,11} In the frail and severely ill patients on multiple medications—where the need for accurate estimation is greatest—the reliability of such estimates may be the most questionable. In consequence, timed short duration urine collections for creatinine clearance measurement are generally recommended.^{10,12} In contrast to the poor predictive ability of low creatinine, elevations in serum creatinine above 132 mmol/L (1.5 mg/dL) reflect declines in GFR greater than what would be typically expected with normal aging, indicating the presence of likely underlying pathology. Ultimately, even creatinine clearance has limitations and may underestimate GFR.¹³ Cystatin C, a measure of kidney function that is independent of muscle mass, has been advocated as an improved marker of reduced GFR in the elderly with creatinine levels within the normal range.¹⁴ Although FDA-approved kits for its measurement have been available since 2001 and in spite of its potential attraction in the management of frail older adults, the precise role of cystatin C measurements in clinical decision-making remains to be defined.

Renal blood flow

On average, aging is associated with a progressive decrease in renal plasma flow.^{15,16} Losses of 10% per decade have been described, with typical values declining from 600 mL/min in a young adult to 300 mL/min at 80 years of age.^{15,16} Perfusion of the renal medulla is maintained in the face of lower blood flow to the cortex, which can be observed as patchy cortical defects on renal scans obtained in healthy older adults. Regional renal flow and GFR are determined by a balance between the vascular tone involving afferent and efferent renal blood supply. Generally, renal vasoconstriction increases in old age, whereas the capacity of the vascular bed to dilate is decreased. Responsiveness to vasodilators (e.g., nitric oxide, prostacyclin) appears to be attenuated, whereas responsiveness to vasoconstrictors (e.g., angiotensin II) is enhanced.⁵ Basal renin and angiotensin II are significantly lower in older adults, whereas the ability of various different stimuli to activate the renin-angiotensin system is blunted.

Tubular function

The ability of the tubules to excrete and reabsorb specific solutes plays a crucial role in maintaining normal fluid and electrolyte balance. The impact of aging and specific disease

processes on the ability of tubules to handle specific solutes is discussed in another chapter (Chapter 85). Nevertheless, some overarching principles are worthy of note. First, overall tubular function appears to decline with aging. Second, the ability to handle water, sodium, potassium, and other electrolytes is generally impaired with aging. Third, such physiologic declines do not generally affect the ability of older adults to maintain normal fluid and electrolyte balance under basal conditions. Fourth, older adults are less able to maintain normal homeostasis when exposed to specific fluid and electrolyte challenges.^{2,5,17}

For example, ability to both conserve and excrete sodium is impaired, with reduced salt resorption in the ascending loop of Henle, reduced serum aldosterone secretion, and a relative resistance to both aldosterone and angiotensin II.^{2,5} As a result, older adults take longer to reduce their sodium excretion in response to a salt-restricted diet.^{2,5} Conversely, older adults take longer to excrete a sodium load.^{2,5} Qualitatively similar changes have been described as regards tubular capacity to adjust to changes in water.

Structural changes

As with other organs, there are both differences between individuals—some have more evident aging changes than others—and within individual kidneys (i.e., different parts of the kidney are affected differently by aging). In general, the aged kidney is granular in appearance, with modest declines in parenchymal mass.^{2,5} The most impressive changes involve a reduction in both the number and size of nephrons in the renal cortex, with a relative sparing of the medullary regions.^{2,5} Loss of parenchymal mass leads to a widening of interstitial spaces between the tubules and an increase in interstitial connective tissue. Numbers of visible glomeruli in aged kidneys decline in parallel with change in weight, with the percentage of glomeruli that are sclerotic increasing.^{2,5} Sclerosis is associated with lost lobulation of the glomerular tuft, increased mesangial cells, and decreased epithelial cells, resulting in a smaller effective filtering surface. In response, remaining nonsclerotic glomeruli compensate by enlarging and hyperfiltering.

Even in the absence of hypertension and other relevant diseases, important changes of the intrarenal vasculature can be observed in old age.^{2,5} Larger renal vessels may show sclerotic changes, whereas smaller vessels generally are spared. Nevertheless, arteriolar-glomerular units demonstrate distinctive changes in old age.^{2,5,18} Cortical changes are more profound, with hyalinization and collapse of glomerular tufts, luminal obliteration within preglomerular arterioles and decreased blood flow. Structural changes within the medulla are less pronounced, whereas juxtamedullary regions demonstrate evidence of anatomic continuity and functional shunting between afferent and efferent arterioles.

Mechanistic considerations

The hyperfiltration theory suggests that a loss of glomeruli results in increased capillary blood flow through the remaining glomeruli and a correspondingly high intracapillary pressure.^{2,5} Such age-related increases in intracapillary pressure (or shear stress) can also result in local endothelial cell damage and resultant glomerular injury, contributing to a progressive glomerulosclerosis.^{2,5,19} Cytokines and other vasoactive humoral factors have been implicated in this type

of pressure-mediated renal damage.^{2,5,20} Also in support of the hyperfiltration theory, both restricted protein intake²¹ and those antihypertensives that reduce single nephron GFR (e.g., ACE inhibitors and angiotensin II blockers)²¹ reduce glomerular capillary pressure, attenuate glomerular injury, and prevent measurable declines in renal function.

Other factors and mechanisms contribute to age-related declines in renal function. For example, individuals born with a reduced nephron mass could be more vulnerable to all categories of renal injury, including that associated with aging. In fact, a growing body of research has linked renal aging to the damaging effects of normal metabolism through the accumulation of toxins, such as reactive oxygen species (ROS), advanced glycosylation end products (AGE), and advanced lipoxidation end products (ALE).^{2,3,5,22,23} This "toxin-mediated" theory has many attractions. First, these toxins accumulate with aging and can induce structural and functional changes. Second, they provide vital linkages between efforts to understand aging at the level of a single organ to traditional gerontologic research into longevity (Chapter 4). Third, nutritional and eventual pharmacologic interventions may allow individuals to decrease exposure to such toxins and to ultimately prevent or delay renal aging. Fourth, such research has permitted the development of a pathophysiologic framework within which multiple different risk factors including underlying genetic predisposition, renal progenitor cell behavior,²⁴ gonadal hormone levels,²⁵ diet,²² smoking,²⁶ and multiple subclinical processes can all influence how renal aging manifests in individuals.^{2,5,23}

A system-based perspective

Renal aging cannot be viewed in isolation from aging at the systemic level. Not only are most individuals with chronic kidney disease (CKD) elderly, but these patients are frail and at high risk of being disabled.⁴ Individuals with advanced CKD have an especially high risk of developing cardiovascular disease,²⁷ cognitive declines,^{27–30} sarcopenia,^{31–33} and poor physical performance.^{27,34} It remains to be seen to what extent milder declines in renal function, more consistent with normal aging, may contribute to altered body composition and physiologic performance seen in generally healthy older adults. As discussed, creatinine-based estimates of GFR depend on skeletal muscle mass and tend to overestimate GFR in older adults. Thus it is interesting that even mild declines in GFR as measured using cystatin C were associated with poorer physical function, whereas creatinine-based GFR estimates demonstrated a relationship only when less than 60 mL/min/1.73 m².³⁵ Ultimately the development of an approach that places renal aging in a systems-based context where key functional issues are also considered may offer some of the most exciting opportunities for developing interventions that will help maintain function and independence in late life.

LOWER URINARY TRACT: BLADDER AND OUTLET

Overview

The function of the lower urinary tract (LUT) is to isolate the kidneys from the exterior environment, thus allowing urine storage and periodic evacuation. The anatomic arrangement of the non-refluxing ureterovesical junction, the fluid-tight

urethral sphincteric mechanism, and the interposed chamber (the bladder) create an effective barrier to the retrograde passage of infectious agents into the kidneys and thence into the bloodstream. Presumably, as the result of evolutionary pressures, the bladder and its outlet normally function as a urine storage structure sufficiently capacious to accept several hours' volume of renal output, whereas an efficient evacuation mechanism under voluntary permissive control can be quickly and voluntarily activated and then returned to storage status.

The requirements for proper function of this system include normal sensory transduction of normal physiologic bladder filling; central transmission and subconscious processing; appropriate conscious recognition and processing; coordination of sphincteric relaxation and bladder pressurization via detrusor contraction; normal biomechanical function of the bladder and its outflow, and intact urethral/bladder guarding and voiding reflexes. In addition to the multiplicity of potential age-associated pathologies, which may disturb this complex process, biomechanical and functional changes as a result of the aging process per se also alter the storage and evacuation function of the LUT (Table 18-1). This section will discuss common LUT symptoms and how these may relate to changes due to "normal" aging versus pathologic aging.

Lower urinary tract symptoms are broadly categorized into irritability (overactive bladder; frequency/urgency/nocturia), obstructive/retentive (hesitancy, abnormal stream, incomplete emptying), and incontinence. The prevalence of all such symptoms increases with age and is population-dependent. The NOBLE study reported data on 5204 randomly selected participants. Overactive bladder symptoms were experienced by 5% to 10% of people under age 35, increasing to 30% to 35% over age 75, with no gender differences.³⁶ Overactive bladder symptoms including incontinence were experienced more commonly and earlier in

life in women than in men, with 19% of women and 8% to 10% of men over age 65 reporting some degree of urinary incontinence. Similarly, in 550 symptomatic patients, lower urinary tract symptoms increased with age in both women and men.³⁷ The prevalence of moderate to severe symptoms roughly doubled between age 40 and 49 and over 80.³⁷ A urodynamic study of continent elderly people found that 63% were symptom-free, 52% were both symptom-free and free of any potential confounding disease or drug, and 18% were also free of any urodynamic abnormality.³⁸ Detrusor overactivity unrelated to identifiable disease was observed in 53%, with no correlation with either gender or age.³⁸ Bladder contractility decreased with age, as defined by postvoid residual volume after a strain-free void.³⁸ Finally, a urodynamic study of incontinent institutionalized elderly patients reported a prevalence of detrusor overactivity of 61%,³⁹ with a similar proportion (59%) showing detrusor underactivity.³⁹ In the same study, 92% of the nondemented individuals, but only 65% of the demented subjects, reported warning sensations.³⁹

Physiologic assessment

Impaired detrusor and sphincteric function are common in old age, consistent with lower urinary tract symptoms being more common in older adults. However, the relative contributions of aging have yet to be disentangled from those of the menopause, pelvic organ prolapse, bladder outlet obstruction, and comorbidities (obesity, cardiovascular insufficiency, dementia, diabetic and other neuropathies).

The impact of prostatic hypertrophy (BPH) in men on lower urinary tract function is discussed elsewhere (Chapter 86). In women, pelvic organ prolapse may bear both direct and indirect relationships to lower urinary tract dysfunction.⁴⁰ About 40% of women with LUT symptoms have vaginal prolapse, and vice versa. Lower urinary tract symptoms correlate moderately well with the severity of vaginal prolapse.⁴¹ Anterior and posterior vaginal prolapse to levels above the introitus may be associated with irritative and incontinence symptoms, and anterior and apical vaginal prolapse beyond the introitus may produce bladder outlet obstruction. Significantly, sphincteric incompetence may be masked by significant anterior prolapse; we await reliable methods to assess sphincteric competence in such patients.

The impact of estrogen loss with menopause and aging on lower urinary tract function is not well characterized. In mature rodents, oophorectomy results in decreases in detrusor smooth muscle, axonal degeneration, and EM findings of sarcolemmal dense band patterns with diminished caveolar numbers, suggesting impaired contractile properties as a result of de-estrogenization.^{42,43} In a study of symptomatic premenopausal and postmenopausal women, a lower mean maximum detrusor pressure was observed during voiding in postmenopausal women, suggesting that menopause may influence LUT function either by impaired detrusor function or reduced outlet resistance.⁴⁴ The clinical impact of estrogen replacement on symptoms of bladder overactivity and incontinence are contradictory and incomplete.

Recent physiologic studies have associated aging with an increased volume at first desire to void, diminished capacity, decreased voiding volumes and flow rates, impaired detrusor contractility, increasing prevalence of detrusor overactivity,

Table 18-1. Potential and Common Influences on LUT Function in the Elderly

<p>"Normal" Aging</p> <ul style="list-style-type: none"> • Afferent/thresholding changes • Diminished neuromuscular detrusor function • Altered outflow tract characteristics • Increased nocturnal urine production <p>Pathologic Internal Dysfunctions</p> <ul style="list-style-type: none"> • Afferent dysfunction: neural tissue damage (i.e., childbearing, biomechanical changes [injury, disease], surgery, chronic obstruction, diabetes) • Efferent dysfunction: chronic obstruction, tissue damage (neurologic, myopathy), etc. • Control/reflex dysfunction: disc or cord disease, CNS disease • Defects of volition due to dementia, CVA, etc. <p>External Factors</p> <ul style="list-style-type: none"> • Fecal impaction and sensorimotor reflex suppression secondary to colorectal distention • Medications: decreased urethral resistance (α-blockers, neuroleptics, benzodiazepines), increased bladder pressure (bethanechol, cisapride), increased urine production (diuretics), efferent/motor impairment (anticholinergics, antiparkinsonism agents, β-blockers, disopyramide); indirect effects (cough—ACE inhibitors, mental status changes—psychotropics). • Environmental inadequacies

and impaired sphincteric function.^{38,45–50} Even so, methodological problems prevent firm conclusions. Studies typically use selected populations, most are studies of symptomatic patients and such important physiologic factors as estrogenization status and pelvic floor support and function status, and bladder outlet patency assessments are not reported. Furthermore, cystometric interdependencies are inconsistently considered; for example, flow rates are dependent upon voided volumes. If voided volumes are diminished, flow rates can be expected to be lower. In the absence of bladder outlet obstruction, volume-corrected flow rates do not deteriorate with age.^{50–52}

Bladder function and structure

Distinct morphologic changes of the detrusor relating to aging have been described. A decrease in detrusor muscle to collagen ratio⁵³ and nerve density in the detrusor⁵⁴ accompanies aging, although quantitative assessment in a rat model demonstrated no diminution in nerve density at the bladder neck in aged versus mature rats.⁵⁵ Classic associations of electron microscopy with urodynamic findings in an aged population were reported by Elbadawi et al.^{56–59} Aging with normal urodynamic performance is associated with the so-called “dense band” pattern, in which the sarcolemma is dominated by dense bands with depleted caveolae and slight widening between muscle cells.⁵⁷ Impaired detrusor contractility is associated with widespread degeneration of muscle cells and axons, with sarcoplasmic vacuolation, sequestration/blebbing, cell shriveling and fragmentation, and presence of cellular debris in the intercellular spaces.^{57,60,61}

Specific changes in the neuropharmacology of detrusor function have also been attributed to aging. The detrusor normally contracts in response to M3 muscarinic receptor activation via pelvic nerve efferent release of acetylcholine (M2 receptors are also present, but their precise role is not known).⁶¹ M3 receptor numbers decrease with age⁶² and M3-stimulated activity is diminished, although the clinical importance of decreased contractile sensitivity is unclear.⁶³ Against the decline in M3 responsiveness, other factors appear to become more important, including purinergic transmission,^{64–66,67} nonneuronal urothelial acetylcholine release⁶⁴ and an increased contractile response to norepinephrine.⁶⁸ These findings suggest that receptor-mediated sensory and motor responses in addition to inherent muscular changes are important in the alterations of detrusor function with aging.^{64,69}

Demonstrable detrusor motor dysfunction is associated with aging. The bladder may not contract well enough to ensure adequate emptying, or it may contract inappropriately. In both cases, irritative and obstructive symptoms can result, with varying degrees of urinary incontinence. Detrusor underactivity and overactivity can coexist; patients with both problems tend to be older than those with only detrusor overactivity or impaired contractility, suggesting these may reflect distinct, but related processes.

The ability of the bladder to create expulsive pressure against a relaxed outlet over a time sufficient to empty the bladder requires normal detrusor muscular function, conceptualized as detrusor contractility. Detrusor underactivity (i.e., the inability to generate sufficient bladder pressure over time to ensure normal emptying) is a common problem in

elderly patients with LUTS such as urinary retention, poor urinary stream, and/or incontinence.^{39,61} Neither detrusor contractility nor detrusor underactivity has an accepted cystometric definition; detrusor underactivity probably represents the clinical result of the physiologic entity of impaired detrusor muscle contractility. Although several studies have concluded detrusor contractility diminishes with age, their assessment of “contractility” is confounded by lack of pressure/flow assessment and population selection.^{45,70} Furthermore, the use of “stop-test” to assess isovolumetric detrusor contractility has been inconclusive,^{51,52} possibly due to the variable effects of methodologic perturbations of bladder outlet function. Total detrusor effort does not change with age; however, aging is associated with failure of contraction initiation and slowed contraction velocities.⁷¹ Maximum detrusor pressure and detrusor pressure at maximum flow are not a function of age in symptomatic unobstructed, unoperated men and women over age 40, although unadjusted flow rates decrease and PVR volumes increase with age.⁴⁷ Maximum detrusor pressures associated with detrusor overactivity decrease with age,⁷² suggesting larger absolute but decreased functional bladder capacity and diminished voiding efficiency. Maximal detrusor pressure responses occur at greater bladder volumes in aged animals than in mature animals.⁷³ The finding of greater contractility (by stop-test) in aged patients with detrusor overactivity at lower bladder volumes as compared with patients without detrusor overactivity⁵² suggests that maximal contractility is preserved, and that functional deficits (evidenced as detrusor underactivity) are due to an inability to maintain a contractile state.

Animal studies provide evidence that age-related decrements in voiding efficiency are not a result of maximal pressure generating capabilities but rather the ability to maintain adequate pressurization. The maximal contractile response to acetylcholine increases with age in *ex vivo* rat bladder studies.⁷⁴ In a cystometric study of young, adult, and aged female rats, bladder compliance decreased with age, and the threshold bladder pressure for voiding contractions increased, suggesting altered afferent function affecting the micturition reflex. However, maximal voiding bladder pressures, bladder capacity, and voiding efficiency did not differ among groups. This study also reported more nonvoiding contractions, impaired compliance, increased bladder capacity, and diminished voiding efficiency in obstructed animals relative to their unobstructed counterparts. Of interest is that only the young animals were able to compensate for outlet obstruction with an increased voiding bladder pressure.⁷⁵ Similarly, other animal models have demonstrated an impaired ability of the aged detrusor to accommodate obstructive, ischemic, and fatigue stresses.^{76–78} Thus, contractile deficiencies in the aged may include failure to accommodate altered bladder outlet, vascular, and sensory changes associated with aging, rather than only an inherent contractile failure of the muscle.

No changes in flow rates were observed over 27 months in asymptomatic postmenopausal women in a longitudinal study.⁵⁰ If impaired contractility is associated with aging, it develops over a relatively long period. Of interest is that in this same study, postmenopausal women with detrusor overactivity had impaired voiding function, which deteriorated over the same time period, suggesting that LUT dysfunction

associated with aging is multidimensional and more rapidly progressive once initiated. This may be interpreted as age-related deterioration of multiple overlapping functions, with an eventual systemic decompensation at some threshold level.

Overactive bladder (irritative) symptoms such as urinary frequency, nocturia, urgency, and urge incontinence are more prevalent with age, and may be the result of abnormal sensory and/or motor activity. Detrusor overactivity (DO) is the undesired contraction of the detrusor, with or without urine loss. As a description of a urodynamic finding, the term replaces older and less accurate terms such as detrusor hyperreflexia and detrusor instability.⁷⁹ At very low levels it may be asymptomatic; no urodynamic standard for clinical significance exists, and studies reporting the incidence of DO have used differing urodynamic definitions. Detrusor overactivity is found in about one-half of elderly patients with irritative symptoms.⁸⁰ Most, if not all, elderly patients with urge incontinence have detectable detrusor overactivity.^{52,80} A particularly vexing problem is the combination of DO with impaired contractility, historically referred to as DHIC (detrusor hyperreflexia with impaired contractility). Although the concept of an inefficient detrusor coupled with motor overactivity analogous to a fibrillatory heart is not difficult, the problems of defining DO and impaired contractility complicate a precise physiologic definition of DHIC. It is associated with more complex symptomatology, and is estimated to be the underlying problem in one third of incontinent institutionalized elderly.⁴⁵ In community-dwelling symptomatic elderly patients using conservative urodynamic definitions, detrusor underactivity was found in 48% of men and 12% of women. Among people with detrusor underactivity, two thirds of men and one half of women also had detrusor overactivity.⁸¹ Coexisting neurologic disease is common in DHIC patients; 28% were found to have ALS, parkinsonian syndrome in 18%, MSA in 18%, and Alzheimer dementia in 13%.⁸²

Several lines of research have suggested age-related changes in the afferent limb of the micturition reflex play important roles in the clinical changes observed with aging LUT function. Aged animals void less often, but with higher volumes, and demonstrate a greater pressure threshold for voiding, but no difference in maximal pressure,⁸³ suggesting a primary impact of aging on LUT sensory activity. Animal and human studies suggest that the decreased afferent signal results in larger bladder volumes. These diminished sensations can result in delayed sensations of bladder filling, diminished "warning time" between the first urge to urinate and urgency with leakage,⁸⁴ and impaired bladder emptying. The resultant decreased functional capacity may then aggravate symptoms of urinary frequency/urgency/urge incontinence by perpetuation of bladder volumes in the narrow functional zone between first urge to urinary and leakage.

Outlet function and structure

The urinary sphincter is under semivoluntary control. The concept of an internal and external sphincter is not anatomically precise. Rather, the sphincteric mechanism is more accurately divided into factors intrinsic and extrinsic to the urethra itself.⁸⁵ Intrinsic factors result in resting closure of the lumen, and include mucosal adherence and

biomechanical properties relating to flow of fluid through a compliant tube. In addition to the inherent physical properties of urethral dimensions and connective tissue performance, urethral dynamics are actively modified by urethral smooth muscle, under autonomic influence. The extrinsic mechanisms are primarily responsible for the ability to voluntarily and/or reflexively increase urethral resistance to flow in response to sudden increases in bladder pressure, generated by coughing, laughing, etc. (so-called stress incontinence) or detrusor contraction as a result of detrusor contraction or overfilling. The extrinsic mechanisms are composed of the paraurethral connective tissues and their direct and indirect connections via striated muscle to the bony pelvis.

Age-related sarcopenia and changes in connective tissue composition result directly in changes in sphincteric efficiency and probably impact urine storage and voiding efficiency. Smooth and striated muscle thickness and fiber density in the bladder neck and urethra have been found to be diminished in older women relative to young women.⁸⁶⁻⁸⁸ Striated muscle changes are circumferentially uniform, although the decrease in smooth muscle is most pronounced on the dorsal/vaginal aspect of the urethra.⁸⁸ These changes presumably result in alterations of urethra sphincter function, as suggested by the finding of lower detrusor pressures at the opening and closing of the urethra in older women.^{55,89} Although the validity of urethral closure pressure (UCP) as a measure of sphincteric competency is debatable, it negatively correlates with age.⁷² Although a decrease in urethral resistance may impair sphincteric efficiency, it may ameliorate potential obstructive/retentive problems resulting from impaired contractility; *ex vivo* animal studies have demonstrated that aged bladders are unable to maintain effective detrusor contractions against an increased outlet resistance.⁹⁰

KEY POINTS

Aging of the Urinary Tract

- Average declines in renal function hide considerable variability, including an impressive proportion of people in whom age appears to have only a small influence on renal function.
- Although elderly people with chronic kidney disease are more likely to be frail, whether frailty itself is specifically associated with incident renal impairment is not clear. Aspects of the frailty state (e.g., sarcopenia) are associated with aspects of age-related urinary tract dysfunction (e.g., detrusor hypoactivity).
- In the upper urinary tract, several changes are seen with age that reduce glomerular filtration; serum creatinine is a poor estimate of actual GFR with age and with frailty.
- In the lower urinary tract, symptoms alone are generally inadequate to establish a diagnosis. Bladder irritative symptoms (frequency, nocturia, urgency) can result from detrusor overactivity (inappropriate contraction), underactivity (poor emptying performance), or sensory dysfunction. Incontinence and obstructive symptoms may result from detrusor and/or outlet dysfunctions.
- A challenge for rational therapy is that both detrusor underactivity and overactivity can exist in the same patient.
- In general, changes in bladder sensorimotor capabilities result in altered storage and voiding functions. Bladder volumes may increase in combination with less efficient sensation, resulting in less warning before an overwhelming urge to void.

As explained earlier, diminished urethral afferent activity related to aging may have a role in impaired voiding function. Conversely, urethral afferent activity may also impair successful urine storage and thus be an important contributor to age-related overactive bladder symptoms, including frank detrusor overactivity and urge incontinence. Urethral closure pressures negatively correlate with age, and are positively associated with detrusor overactivity in humans,⁷² suggesting a role for inappropriate activation of prevoiding urethral-detrusor reflexes because of impaired sphincteric function in the age-related prevalence of detrusor overactivity.

A system-based perspective

Aging is associated with an increased prevalence of bothersome lower urinary tract symptoms and demonstrable alterations of function. Changes in tissue properties and

sensorimotor function demonstrate complex interactions, producing functional changes which do not correlate well with symptoms. These alterations are complicated by other age-related physiologic changes and comorbidities. The determinants of urine storage and voiding functions include renal output, lower urinary tract biomechanical and sensorimotor function, central processing abilities, and mobility. Degradation of the ability to normally store and appropriately evacuate urine thus has many contributors, both external and inherent to the lower urinary tract.

The musculoskeletal system serves three primary functions: (1) it enables an efficient means of limb movement; (2) it acts as an endoskeleton, providing overall mechanical support and protection to soft tissues; and (3) it serves as a reservoir of mineral for calcium homeostasis. In the elderly population, the first two of these functions frequently become compromised; musculoskeletal problems are the major cause of pain and physical disability in people over the age of 65 years¹ and fracture incidence rises steeply with age² (Fig. 19-1). Several factors contribute to the age-related decline in musculoskeletal function:

1. Aging effects on components of the musculoskeletal system (i.e., articular cartilage, the skeleton, and soft tissues), contribute toward the increasing incidence of osteoporosis and osteoarthritis (OA), the reduced range of joint movement, and the stiffness and difficulty in initiating movement.
2. There is the age-related rise in the prevalence of common musculoskeletal disorders that begin in young adulthood or in middle age, and cause increasing pain and disability without shortening life span (e.g., seronegative spondylarthritides, musculoskeletal trauma).
3. There is a high incidence of certain musculoskeletal disorders in the elderly, such as polymyalgia rheumatica, Paget's disease of bone and crystal-related arthropathies.

A number of interrelated hypotheses have been advanced to explain the high prevalence of bone, muscle, and joint problems in older humans³⁻⁶:

1. The long life span results in increasing accumulation of mechanical damage to the musculoskeletal system.
2. There is a lack of genetic investment in the repair of age-related tissue damage that develops in the post-reproductive phase of life.
3. The musculoskeletal system in humans has not adapted fully to the upright posture and prehensile grip because of lack of evolutionary pressure to do so, with the result that many of our bones and joints are inappropriately shaped and "underdesigned" to be able to cope with the stresses applied.
4. By virtue of their sedentary lifestyle, modern humans tend to be exposed to less mechanical stress than their ancestors. Because musculoskeletal strength is governed by the mechanical inputs to which that individual is exposed, this may result in a weaker musculoskeletal system, which is not well adapted for episodes of sudden major stress.

Several different mechanisms are involved in musculoskeletal tissue aging,⁷ including:

- Reduced synthetic capacity of differentiated cells such as osteoblasts and chondrocytes, with a consequent loss of ability to maintain matrix integrity

- A decline in the mesenchymal stem cell populations
- Posttranslational modification of structural proteins, such as collagen and elastin
- The accumulation of degraded molecules, such as proteoglycan fragments, in musculoskeletal tissue matrices
- Decreased circulating and local levels of trophic hormones, growth factors, and cytokines, such as insulin-like growth factor-1 (IGF-1), involved in maintaining tissue integrity; or an altered ability of the cells to respond to them
- A decreased capacity for wound healing and tissue repair, which may be the result of some or all of the mechanisms described above
- Alterations in the loading patterns of tissue, or the tissue's response to loading

The major tissues that have received the most attention and which are pivotal to the integrity of the system are articular cartilage, the skeleton, and soft tissues. Age-related changes in these structures are now described in more detail.

ARTICULAR CARTILAGE

The structure of a mammalian synovial joint is summarized in Figure 19-2. Much of its function derives from the properties of articular cartilage, which cushions the subchondral bone and provides a low-friction surface necessary for free movement. Articular cartilage contains very few cells, is aneural and avascular, and yet its integrity is maintained throughout a lifetime of biomechanical stress. With increasing age, the cartilage surface often starts to break down, leading to OA. This is associated with changes in other tissues of the joint (Fig. 19-3). However, OA is not an inevitable consequence of aging; instead, aging adds to the risk of OA. With age, articular cartilage thins and changes color from a glistening white to a dull yellow. In addition, the mechanical features of the tissue change. There is a decrease in tensile stiffness, fatigue resistance, and strength, but no significant change in the compressive properties. These changes are partly caused by the decrease in water content that accompanies aging. The morphology and function of the cells (chondrocytes) and nature of the two main matrix components, aggrecan (aggregating proteoglycans) and type II collagen, also change with age. The density of cells in the tissue changes little, but their morphology alters with an increase in intracytoplasmic filaments and they change their secretion of matrix components, producing more variable proteoglycans. Aging is also associated with alterations in the response by chondrocytes to anabolic and catabolic stimuli, such as IGF-1 and interleukin-1. For example, immature cartilage degrades more readily when stimulated with interleukin-1. Generally with age, repeated cell divisions lead to progressive telomere shortening and replicative senescence. However, connective tissue cells and their stem cells may be less susceptible given their relatively slow turnover rates.⁸ Stress-induced premature senescence (SIPS) has been proposed as

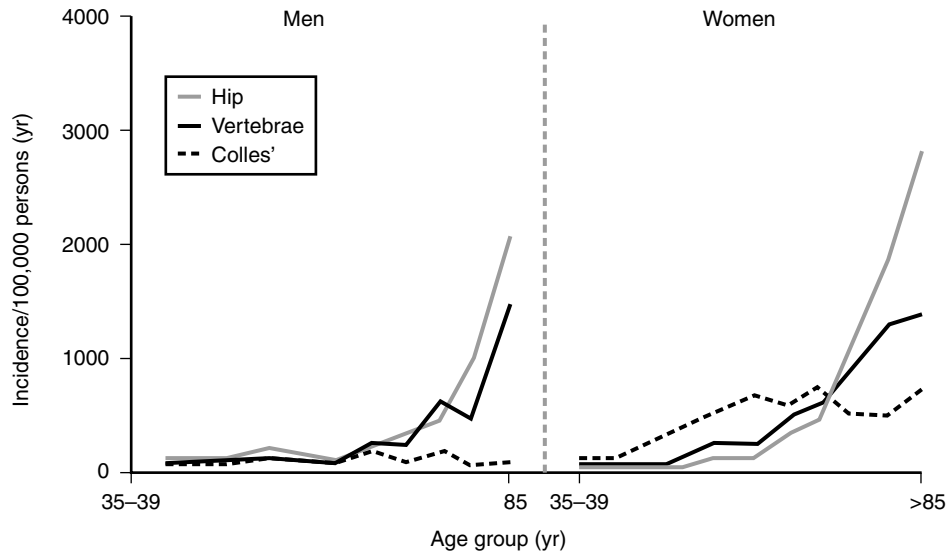

Figure 19-1. Age-specific incidence rates for hip, vertebral, and distal forearm (Colles') fracture in Rochester, Minn., men and women. (Adapted from Cooper C, Melton LJ. Epidemiology of osteoporosis. *Trends Endocrinol Metab* 1992;3:224-9).

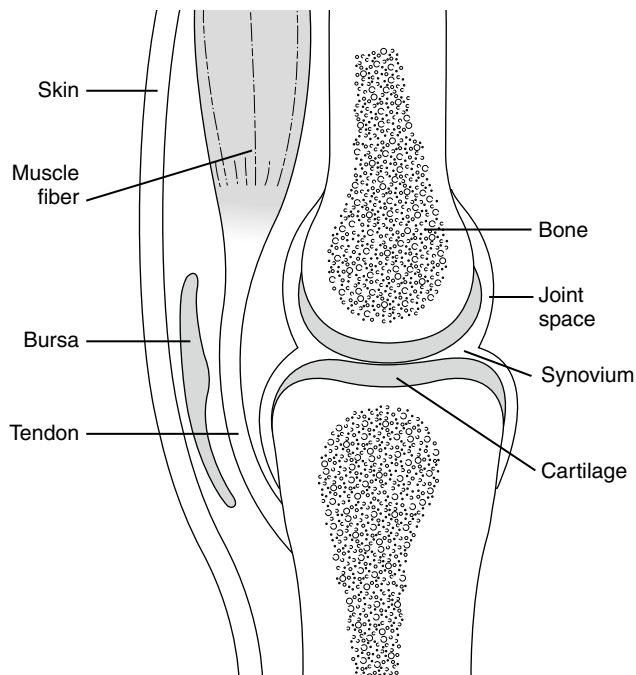

Figure 19-2. The synovial joint. The histologic appearances of the main tissues are highlighted. (Courtesy Drs J. H. Klippel and P. A. Dieppe.)

an alternative explanation to replicative senescence; insults such as mechanical loading, interleukin-1, and caveolin-1 lead to increasing expression of senescence biomarkers.^{9,10}

Depletion of cartilage proteoglycan is one of the earliest signs of articular cartilage loss in OA. Proteoglycans consist of a protein core and two major glycosaminoglycan (GAG) side chains: chondroitin sulfate (CS) and keratan sulfate (KS). The CS is the predominant GAG chain in human articular cartilage. It is made up of oligosaccharide (sugar) chains containing a basic disaccharide repeat of two sugar

molecules (*N*-acetylgalactosamine and glucuronic acid). These sugar molecules carry a sulfate group on either the sixth (C6) or fourth (C4) carbon atom of the sugar ring. Such sulfation patterns are often called C6 and C4 sulfation and show marked changes with aging and in OA.^{11,12} More than 90% of the CS in adult human articular cartilage is C6, which is thought to interact with collagen and other extracellular matrix macromolecules and help maintain the integrity of the cartilage.¹¹ C4 accounts for less than 10% of the adult cartilage and is thought to be a characteristic of immature cartilage. In OA cartilage, there is an increase in C4 and decrease in C6. Changes in the C6:C4 ratio of the articular cartilage with aging and in OA may make the cartilage more susceptible to cytokine-mediated damage.¹²

The main proteoglycan, aggrecan, binds with hyaluronan to form massive, hydrophilic aggregates that expand the collagen framework of the tissue to provide it with its compressive and tensile strength. With age there is reduced proteoglycan aggregation, with smaller proteoglycans being synthesized with an increase in KS and reduced CS content, and increased aggrecanase production leading to aggrecan degradation. Synthesis of KS requires less oxygen than CS, thus the KS-CS balance has recently prompted research interest into changing oxygen tension patterns within connective tissues as a result of ischemia.^{13,14}

Collagen also changes, with some increase in fiber diameter and an increase in cross-linking. This fiber cross-linking may be enzymic or nonenzymic, involving lysyl hydroxylase or not, respectively. In young growing skeletons, collagen turnover is high and enzymic divalent and trivalent cross-links stabilize the collagen fibers, with almost complete hydroxylation of telopeptide lysines. With age lysyl hydroxylase activity wanes, causing incomplete hydroxylation of telopeptide lysines, that is, until maturation is complete, after which enzymic cross-linking remains constant. However, collagen fiber cross-linking does increase with age because of nonenzymic reactions between glucose and lysine, forming glucosyl lysine and related molecules. Subsequent oxidative and nonoxidative reactions produce stable end products

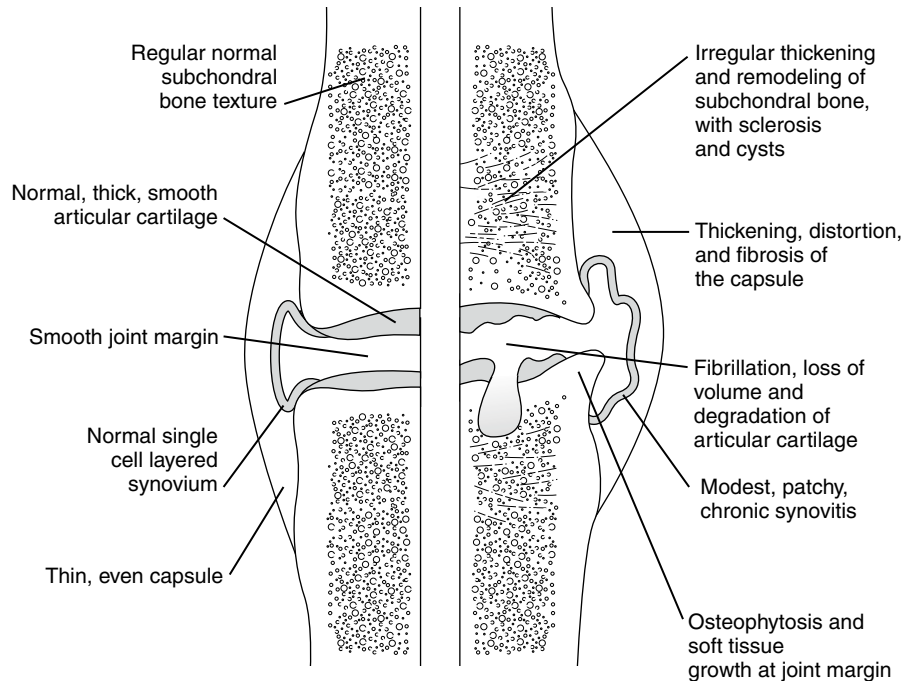

Figure 19-3. Normal versus osteoarthritic synovial joint. (Courtesy Drs J. H. Klippel and P. A. Dieppe.)

known as advanced glycation end products (AGEs), some of which can act as collagen cross-links producing fibers too stiff for optimal function.^{15,16} Hyperglycemia and oxidative stress increase AGE production and dietary AGE intake may also be important.^{17,18} Elastin, which conveys extensibility and elastic recoil in some ligaments, is also stabilized by cross-linking, and AGE production can also prompt age-related stiffening.¹⁹

Changes in calcified cartilage, the layer separating articular cartilage from subchondral bone, are felt to be important in the pathogenesis of OA; however, the underlying mechanisms remain unclear.²⁰ Estrogen receptors have been identified in articular chondrocytes with estrogens influencing cellular homeostasis.²¹ The chondroprotective properties of estrogen are lost following menopause. A history of hormone replacement therapy has been associated with a reduced prevalence of OA.²² In men, testosterone levels have been positively associated with cartilage volume.²³

Cell death in cartilage

There has been much research interest into apoptosis, a normal physiologic process involved in the removal of potential carcinogenic and damaged cells. The process is also involved in development; for example, during endochondral ossification of the hyaline cartilage, cells (chondrocytes) die by apoptosis.²⁴ An age-related decrease in articular cartilage cellularity has been associated with cartilage fibrillation, thinning, and an increased prevalence of OA in elderly people.^{25,26} Now chondrocyte apoptosis appears to be a crucial event in cartilage aging and the pathogenesis of OA. Cartilage matrix degradation by apoptotic bodies, abnormal loading, changes in nitric oxide synthesis, altered cytokine regulation, impaired mitochondrial functioning, and downregulation of the *Bcl-2* gene have all been implicated in the control

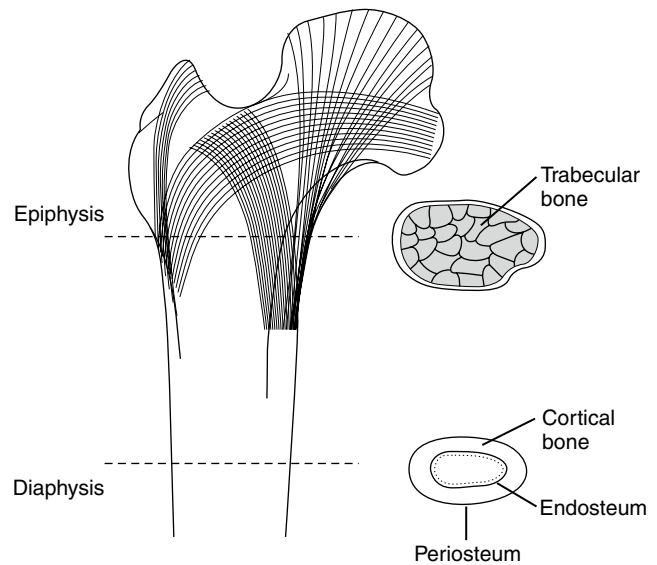

Figure 19-4. The macroscopic organization of bone. (Courtesy Drs J. H. Klippel and P. A. Dieppe.)

of chondrocyte apoptosis in animals.²⁷ How these all relate to human aging remains an area of interest.

THE SKELETON

Weight-bearing bones consist of an outer shell of cortical bone; an arrangement designed for maximum strength. In addition, certain sites, such as vertebrae and metaphyses, contain an inner meshwork of trabecular bone to act as an internal scaffold (Figure 19-4). Microscopically, the skeleton is made up of interconnecting fibrils of type I collagen,

which provide tensile strength. Hydroxyapatite crystals, which are made up of calcium and phosphate, are deposited in holes within the collagen fibrils, giving bone its rigidity. Adult bone continuously undergoes self-renewal. This process, known as bone remodeling, occurs at discrete sites

Figure 19-5. The bone remodeling sequence. This commences with osteoclastic bone resorption, following which a cement line is laid down (reversal phase). Osteoblasts then fill up the resorption cavity with osteoid, which subsequently mineralizes—the bone surface finally being covered by lining cells and a thin layer of osteoid.

throughout the skeleton called bone remodeling units. Bone remodeling involves the coordinated activity of those cells responsible for bone formation and resorption (i.e., osteoblasts and osteoclasts, respectively) in a continuous cycle aimed at replacing microdamage and at adapting bone density and shape to the patterns of forces it endures (Figure 19-5). Osteoclasts differentiate from hematopoietic precursors shared with macrophages, whereas osteoblasts, which produce osteoid and promote mineralization, arise from mesenchymal precursors that also give rise to fibroblasts, stromal cells, and adipocytes. Osteoblasts produce macrophage colony stimulating factor (M-CSF) and membrane-bound receptor activator of nuclear factor-kappa B ligand (RANKL), factors crucial for osteoclastogenesis.²⁸ RANKL, by binding to the osteoclast's RANK receptor, stimulates osteoclast differentiation, averting cell death. This process is regulated by osteoblasts that produce osteoprotegerin, a decoy receptor.²⁹ Multiple factors influence the RANK-RANKL interaction, PTH, vitamin D, cytokines, interleukins, prostaglandins, estrogen, mechanical forces, transforming growth factor β and thiazolidinedione PPAR γ ligands commonly used in the treatment of type 2 diabetes mellitus, to name but a few, and work is underway to better understand these processes.

Structural changes in the skeleton

Once middle age is reached, the total amount of calcium in the skeleton (i.e., bone mass) starts to decline—a process that is accelerated during the first few years following menopause in women.³⁰ This is associated with changes in skeletal structure by which the skeleton becomes weaker and more prone to sustaining fractures. Where these alterations affect trabecular bone, individual trabeculae undergo thinning followed by perforation and ultimately removal, leading to disruption of the trabecular network (Fig. 19-6). The bony cortex also becomes considerably weaker during aging, through a combination of thinning as a result of expansion of the inner medullary cavity and an increase in size, number, and clustering of Haversian canals. Along with deterioration in skeletal architecture, the material strength of bone may also decline significantly with age; microfractures are thought to accumulate within bone tissue with increasing

Figure 19-6. Changes in trabecular structure associated with osteoporosis. Scanning electron micrographs of lumbar vertebrae (magnification $\times 20$) obtained from: (A) a 31-year-old male; (B) an 89-year-old female. Note the loss of bone tissue associated with thinning and removal of trabecular plates. (Kindly supplied by Professor A. Boyle, Department of Anatomy and Developmental Biology, University College, London.)

age, representing the accumulation of fatigue damage.³¹ In addition, adverse biochemical changes may occur, such as a decline in cross-linking efficiency, required for stabilizing collagen fibrils.³²

Changes in skeletal metabolism

Bone loss in the elderly population is largely a result of excess osteoclast activity,³³ which causes both an expansion in the total number of remodeling sites and an increase in the amount of bone resorbed per individual site, resulting in a bone remodeling imbalance. The rise in osteoclast activity in older women partly reflects the decline in ovarian hormone production following menopause because estrogens exert an important restraining influence on bone resorption by limiting RANKL production and promoting osteoclast apoptosis while also exerting antiapoptotic effects on osteoblasts.³⁴ The age-related decline in bone density had been felt to be due to falling estrogen levels in women and testosterone levels in men. However, more recently estrogens have emerged as the dominant sex steroid, regulating male bone loss later in life, and, in combination with testosterone, acquisition of peak bone mass early in life.³⁵ Strong positive correlations between serum estradiol, particularly bioavailable estradiol, levels and bone mineral density (BMD) have been observed, whereas correlations between testosterone and BMD have been weak or lacking.^{36,37}

In addition, osteoclast activity may be elevated in the elderly population as a consequence of vitamin D deficiency, which is widespread among elderly people.³⁸ Dietary vitamin D insufficiency combined with reduced sunlight exposure and a reduced capacity to synthesize vitamin D in aging skin, lead to mild secondary hyperparathyroidism.^{39–41} These effects of vitamin D insufficiency on bone metabolism are aggravated by an age-related decline in efficiency of gastrointestinal calcium absorption and an age-related decline in efficiency of renal 1α hydroxylation of vitamin D. Low vitamin D levels influence mesenchymal stem cell differentiation toward greater adipogenesis at the expense of osteoblastogenesis.⁴² Despite subclinical evidence of osteomalacia, many of these patients present in the same way as osteoporosis, for example, with fractures of the femoral neck. Furthermore, an increased tendency toward bone marrow adipogenesis, to the detriment of osteoblast production, with consequent accumulation of bone marrow fat rather than trabecular bone, has been observed independent of estrogens.^{42,43} Furthermore the peroxisome proliferator-activated receptor (PPAR) induced in humans treated for diabetes mellitus with thiazolidines, has through its effects on adipogenesis been implicated in the development of osteoporosis.⁴⁴ PPAR, together with the Wnt signaling pathway, are currently of interest as potential therapeutic targets for osteoporosis.

An age-related reduction in the bioavailability of other important regulatory factors such as IGF-1 have also been described. Aging leads to a gradual decline in circulating growth hormone (GH) and IGF-1, with consequent declines in bone density, lean body mass, and skin thickness; the so-called "somatopause."⁴⁵ Reductions in these trophic factors encourage local expression of molecules (e.g., TNF- α and interleukins), which increase osteoclast and decrease osteoblast activity and downgrade the differentiation potential of bone marrow stem cells.²⁸ Therapeutic GH has been shown to increase bone mineral density in GH-deficient

osteoporotic patients.⁴⁶ Immobilization is recognized to cause bone loss whereas physical activity can help attenuate rates of age-related bone loss. Reductions in physical activity often accompany aging, thereby reducing the quality and quantity of mechanical inputs to the skeleton, which are important in maintaining osteoblast activity. Use of whole-body vibration exercise has been shown to increase femoral neck BMD and balance.⁴⁷ Cellular sensing of normal and abnormal mechanical loads and the consequent alterations in cell biology is known as mechanotransduction, a mechanism designed to maintain normal tissue homeostasis⁴⁸ and poorly understood in elderly human tissue.

SOFT TISSUES

Age-related changes occur in other bone- and joint-related tissues, largely as a result of reduced synthesis and posttranslational modification of collagen, which leads to reduced ligament elasticity. For example, the tensile strength of tendons and ligament-bone complexes declines with age and integrity of joint capsules may be lost. This may result in disorders such as dysfunction of the rotator cuff of the shoulder, which may be associated with communications between the shoulder joint and subacromial bursa. In addition, there is a gradual loss of connective tissue resistance to calcium crystal formation in the elderly population, leading to an increase in the incidence of crystal-related arthropathies. Functional impairment in soft tissues may also adversely affect biomechanics of the joint, which may be an important initiating factor in the development of OA. For example, age-related changes have been described in the metabolism and composition of the extracellular matrix in the meniscus,⁴⁹ which may contribute to the development of knee OA.

Back and neck pain and stiffness are common complaints in the elderly population, which are likely to reflect age-related changes in intervertebral discs. The latter consist of an outer fibrous ring called annulus fibrosus and an internal gelatinous (semifluid) structure called nucleus pulposus. As people get older, the diameter of the nucleus pulposus and the hydrostatic pressure within this region decreases, resulting in increased compressive stress within the annulus.⁵⁰ Thus with age the intervertebral disc becomes more compressed, causing a decrease in the intervertebral space and therefore an overall decrease in height of the individual. The extracellular matrix of the disc contains a network of collagen fibers (both type I and type II) that are responsible for the tensile strength, and aggregating proteoglycans that help the disc to resist compressive forces. Age-related changes in the distribution and concentrations of these macromolecules can also significantly alter the mechanical properties of the disc. In many ways, extracellular matrix metabolism is rather similar to articular cartilage; for example, with age there is increased degradation and reduced synthesis of type II collagen, and the glycosaminoglycan and collagen contents are decreased.⁵¹

Sarcopenia is the slow and progressive age-related loss of skeletal muscle, resulting in reduced muscle power and function. The consequences of increased falls and hence increased fracture risk with associated loss of independence can be devastating. Sarcopenia is predominantly due to a decline in muscle fiber number, although atrophy of fibers, especially type II fibers, also occurs. Sarcopenia has been

associated with declining levels of anabolic factors: estrogen and vitamin D levels in women, testosterone and physical performance in men, in addition to waning GH and IGF-1 levels. Furthermore, increased levels of catabolic cytokines have also been implicated—interleukin-6, particularly in older women, and TNF- α , particularly affecting muscle mass in men.^{52–54} Denervation resulting in motor unit reduction may also be important.

CONSEQUENCES OF BONE AND JOINT AGING

Musculoskeletal problems cause a huge burden of pain and physical disability in older people. The most important functional impairments include the marked loss of muscle strength, reduced range of movements of the spine and peripheral joints, and loss of joint proprioception contributing to problems of balance. In addition, spinal osteoporosis causes progressive kyphotic deformity and height loss, which in some individuals may be relatively asymptomatic. The key symptoms include pain and stiffness. Although pain thresholds may increase, there is also a very high prevalence of musculoskeletal pain. For example, some 25% of those individuals over the age of 55 years complain of current knee pain. Stiffness and difficulty in initiating movement are almost universal in those over the age of 70 years.

Changes in the bone and soft tissues make the whole system more susceptible to trauma. Periarticular pain syndromes and spinal disorders related to minor trauma are common, but by far the most important consequence is the high incidence of fractures. These partly reflect the age-related increase in skeletal fragility that characterizes osteoporosis, and partly the age-related increase in falls, which is multifactorial (see Chapter ***). Osteoporosis predisposes to an increased risk of fracture at all skeletal sites other than flat bones such as the skull, although fractures of the vertebrae, distal radius, and hip are by far the most common (see Fig. 19-1). The relative increase in hip fractures in the very elderly may also be related to changes in the pattern of falling since older subjects, with slower motor function, may be less likely to fall onto an outstretched arm.

The extent of the disability related to musculoskeletal changes is well described in community-based epidemiologic studies. Problems with reaching and with locomotion

are particularly frequent, the latter contributing extensively to the isolation of elderly people. In addition, it is well recognized that in those who sustain a hip fracture the majority fail to regain their previous level of functioning, and there is also an appreciable excess mortality; 10% dying in hospital within the first month, with overall around a third dying within a year.⁵⁵

THE FUTURE

An aging population, with a rising age-specific incidence of fracture, has serious implications for our projected fracture rates. Fragility fractures are expensive, both in terms of direct medical costs, but also through the costs of their social sequelae. Furthermore, globally the prevalence of obesity is rising at an alarming rate. The cumulative physical consequences of a life of repetitive excessive skeletal loading is likely to manifest in substantially greater morbidity in the elderly in the years to come. Although present treatments for osteoporosis mostly focus on suppressing bone resorption, future treatments are likely to be anabolic, following on from the identification and understanding of the genes and the gene products responsible for the regulation of bone mass.

KEY POINTS

Bone and Joint Aging

- Musculoskeletal problems cause a huge burden in elderly people through a combination of pain and functional impairment.
- These problems result partly from the increased incidence of common musculoskeletal disorders in the elderly, such as rheumatoid arthritis and polymyalgia rheumatica.
- The high burden of musculoskeletal disease in elderly people also reflects the impact of the aging process on tissues which make up the musculoskeletal system, such as articular cartilage and bone.
- There have been considerable advances in recent years in the understanding of the cellular and molecular mechanisms that underlie these age-related changes.

Aging and the Endocrine System

Harvinder S. Chahal
William M. Drake

INTRODUCTION

As individuals age, complex endocrine changes occur, resulting in a decline of endocrine function involving the responsiveness of tissues and reduced hormone secretion from peripheral glands. This is associated with modifications in the central mechanisms controlling the temporal organization of hormonal release with a dampening of circadian hormonal and nonhormonal rhythms. The effects of aging can occur in any endocrine gland and many endocrine functions are so intertwined that reductions in function can adversely affect other glands. Changes in many endocrine systems occur with healthy aging, including the growth hormone/insulin-like growth factor-1 axis (somatopause), estrogen (menopause), testosterone (andropause), dehydroepiandrosterone and its sulfate (adrenopause), the hypothalamic-pituitary-cortisol axis and the hypothalamic-pituitary-thyroid axis. This chapter will delineate some aspects of the interplay between the aging process and endocrine function regulation and explores the age-related changes in hormone metabolism and production, with their associated clinical consequences. However, in evaluating the changes that occur in endocrine glands it is important to distinguish between the real aging effects on endocrine mechanisms from any confounding factors due to the higher prevalence of age-related illness.

Growth hormone/insulin-like growth factor-1 axis

Growth hormone (GH) has both an anabolic and lipolytic effect and its action on peripheral tissues is partly mediated by circulating (hepatic generated) or paracrine insulin-like growth factor-1 (IGF-1).¹ Throughout life the secretion of GH undergoes marked changes. Before puberty, GH secretion is relatively low, but during sexual maturation and adolescence, GH output increases, resulting in accelerated somatic growth.² However, with aging there is reduced GH secretion with a decline in both serum GH and IGF-1 levels.¹ There is a greater than 50% reduction in healthy older adults' GH production and IGF-1 concentrations³ and this progressive decline has been termed *somatopause*. This decrease in GH secretion is known to cause a reduction of protein synthesis, a decrease in lean body mass and bone mass, and a decline of immune function.¹

The exact neuroendocrine mechanism of somatopause remains unclear. Early studies suggested the occurrence of senescent changes in the pituitary,^{4,5} but this has not been supported by several observations showing that there is no decrease in pituitary somatotroph cell numbers⁶ or that neither exogenous growth hormone-releasing hormone (GHRH)^{7,8} nor GH-releasing peptide analogues⁹ can rejuvenate GH output and plasma IGF-1 levels in older subjects. Consequently, research has focused on the hypothalamic regulation of GH secretion whereby an age-dependent decrease in hypothalamic GHRH output contributes to the GH decline with aging.¹⁰ Low physical fitness and higher adiposity seen

in older individuals also contribute to decreased GH secretion,¹¹ although the underlying mechanism is uncertain. The low IGF-1 levels seen with aging are not due to hepatic responsiveness to the hormone because serum IGF-1 levels increase in both young and old men after exogenous administration of either GH or GHRH.¹

The suggestion that older individuals have genuine GH deficiency that would benefit from GH treatment has arisen from the observation that nonelderly GH-deficient adults have changes in body composition similar to the aging phenotype, which are improved by long-term recombinant human GH therapy.¹² There is much uncertainty regarding the overall balance of benefits versus risks of GH replacement in older individuals.¹³ In 1990, a study showed 6 months of treatment with recombinant GH in 12 healthy 61- to 81-year-old men with serum IGF-1 concentrations below those of healthy younger men resulted in a 9% increase in lean body mass and a 15% decrease in adipose tissue mass.¹⁴ However, the weekly dose of GH was approximately twice as high as the dose used in nonelderly GH-deficient adults, the study was not double-blinded, and no assessment was made regarding muscle strength, exercise endurance, or quality of life.¹⁵ A double-blind placebo-controlled study in healthy women ($n = 57$) and men ($n = 74$) aged 65 to 88 years found that GH with or without sex steroids increased lean body mass and decreased fat mass.¹⁶ However, no change in muscle strength or maximal oxygen uptake during exercise was observed. These findings mirrored a previous randomized, controlled, double-blind trial in 1998 in which 6 months of physiologic GH doses administered to 52 healthy men aged older than 69 years with low baseline IGF-1 levels resulted in body composition improvement, but no functional ability change.¹⁷ A further study was performed on 18 healthy men aged 65 to 82 years who initially underwent progressive weight training for 14 weeks to invoke a trained state and then were randomized to receive GH or placebo while continuing a further 10 weeks of strength training.¹⁸ This study suggested that in older men GH supplementation does not augment the response to strength training.

The age-related testosterone decline in men may also contribute to the observed reduction in GH secretion. Nonpharmacologic doses of combined GH and testosterone in older men result in improvement in selected aspects of physical performance and increased muscle IGF-1 gene expression without measurably changing body composition or muscle strength.¹⁹ In two more recent studies, coadministration of low dose GH with testosterone resulted in beneficial changes in midthigh muscle, aerobic capacity,²⁰ and whole-body protein turnover and synthesis.²¹

The original enthusiasm for the use of GH replacement in aging individuals has been severely dampened by the known adverse side effects, including arthralgia, carpal tunnel syndrome, edema, and hyperglycemia. There is also concern regarding the association of cancer and the GH-IGF-1 axis

in the normal population.^{15,16} GH replacement studies in aging individuals have been for a maximum of 12 months, so long-term safety data have not been published. In a recent systematic review of the GH trials, it was concluded that the increased rates of side effects of GH replacement outweighed the small beneficial effects on body composition in healthy older individuals.²² Long-term studies are needed to determine the efficacy and safety of GH treatment in older adults who are not GH deficient. The beneficial effects of GH secretagogues in the elderly also need to be investigated.

Menopause

From the age of 40 ovulation frequency decreases and in most women reproductive ovarian function ceases within the next 15 years, resulting in menopause.²³ Ovarian follicles function less well during this period, with serum estradiol concentrations being lower and follicle-stimulating hormone (FSH) concentrations higher than in younger women, whereas luteinizing hormone (LH) is unchanged.²⁴ Follicular activity eventually ceases, estrogen concentrations fall to postmenopausal values, and both FSH and LH levels rise above premenopausal concentrations.²³ The changes in the hypothalamic-pituitary-gonadal axis result in an increased risk of cardiovascular events, rapid loss of skeletal mass, vasomotor instability, psychological symptoms, and atrophy of estrogen responsive tissue.

During the postmenopausal period, serum concentrations of atherogenic lipids deteriorate, with an increase in low-density lipoprotein and total cholesterol and a reduction in high-density lipoprotein, leading to a greater risk of cardiovascular disease.²⁵ These biochemical markers are favorably altered by hormone replacement therapy, but there is no improvement in cardiovascular disease outcome.^{26,27}

There is rapid bone loss at the time of menopause as a result of estrogen withdrawal, which takes place on the background of age-related bone loss that begins from the fourth decade of life. A modest rise in serum ionized calcium occurs without any change in parathyroid hormone (PTH) levels, suggesting a possible change in the PTH set-point. There is also a decline in the estrogen-dependent components of intestinal calcium absorption and renal tubular calcium reabsorption. The associated high bone resorption with normal PTH also suggests an increased sensitivity of bone to PTH. There is no change in serum 1,25-vitamin D.²⁸ Estrogen replacement maintains bone mass and reduces fracture risk during the immediate menopausal period, when the rate of bone loss is greatest.²⁹ In postmenopausal women bone mass has also been maintained with bisphosphonates, which act by inhibiting bone resorption more than formation,³⁰ and raloxifene treatment, which is a selective estrogen receptor modulator acting selectively on bone and lipid profiles.³¹

Vasomotor symptoms originate in the hypothalamus with a resetting of the thermoregulatory system²³ and the hot flush is preceded by an LH surge.²⁵ Decreased estrogen levels reduce serotonin levels, resulting in hypothalamic 5-HT_{2A} receptor upregulation, which leads to a change in the set-point temperature resulting in hot flushes.³² However, the full mechanism is incompletely understood. These episodes are reduced with hormone replacement, but not entirely eliminated.³³ Cognitive disturbances are reported during menopause, which appear to be related to changes in estrogen levels; however, studies have shown inconsistent

results regarding the effect of estrogen replacement on cognitive function in postmenopausal women.³⁴ The decline in estrogen levels in postmenopausal women results in vaginal mucosa atrophy, dysuria, urinary frequency, and incontinence. Local or systemic estrogen replacement therapy may improve these symptoms.³⁵ Loss of libido in postmenopausal women occurs partly due to a decline in both estrogen and testosterone levels because ovarian function ceases.³⁶

The Women's Health Initiative (WHI) study has caused considerable debate regarding the risk benefit of hormone replacement therapy. The combined estrogen and progestin arm of the study was terminated early because women on combined hormonal therapy had an excess risk of breast cancer.²⁶ At the time the trial was stopped, the estrogen plus progestin group had significantly increased risks of coronary heart disease, stroke, and pulmonary embolism, whereas the risks of colorectal cancer and hip fracture were decreased and mortality risk was not significantly different.³⁷ In the postintervention follow-up period of 2.4 years, the increased risk of cardiovascular events and decreased fracture risk both disappeared. The group of patients that were initially randomized to combined hormonal therapy were more likely to develop breast cancer, and had a significantly greater risk of all malignancies.

The unopposed estrogen arm of the WHI study showed similar results to the combined treatment arm with regards to heart disease, stroke, and thromboembolic events. There was a trend toward a decrease in breast cancer incidence.³⁸ Further analysis from WHI showed that estrogen therapy alone or in combination with progestin treatment, increased the risk of both mild cognitive impairment and dementia.³⁹ Another trial of estrogen plus progestin in postmenopausal women with established coronary disease did not demonstrate beneficial effects of hormone replacement therapy for the secondary prevention of heart disease.²⁷ Careful explanation is needed for patients to understand that hormone replacement therapy may carry a modestly increased risk of ischemic stroke, coronary events, venous thrombosis, and possibly breast cancer. In order to minimize these hazards, hormone replacement therapy should be considered only for severe menopausal symptoms and for the shortest possible time in women who are fully informed of these risks.⁴⁰ For a more comprehensive review regarding the management and treatment of menopause, the reader is directed to a recent review article by Nelson.⁴¹

Andropause

For many years there was much debate regarding whether serum total testosterone levels were truly lower in healthy older men, or whether this decline was a result of confounding effects from chronic illness and medications. However, cross-sectional and longitudinal studies have shown a gradual, but progressive age-dependent decline in testosterone levels in healthy men, which has been termed *andropause*.^{42,43} This is more noted for free testosterone than for total testosterone because there is an age-associated increase of sex hormone binding globulin levels.⁴⁴ Unlike the sharp decline in estrogen production at menopause, the age-related decline in testosterone level is more variable, with unclear clinical consequences.⁴⁵

In elderly men the reduction in serum testosterone levels is mainly due to decreased production rates,⁴⁶ which occur

at all levels of the hypothalamic-pituitary-testicular axis.⁴⁷ Both serum LH and FSH levels show an age-related increase in longitudinal studies, but the age-related decline in testosterone levels is not often reciprocated with changes in serum LH concentrations.⁴⁸ This is most likely due to the age-related impairment of gonadotrophin-releasing hormone secretion and alterations in gonadal steroid feedback mechanisms.⁴⁹ Aging decreases the testosterone response to LH and human chorionic gonadotrophin,⁵⁰ and the circadian rhythm of plasma testosterone secretion—with higher levels in the morning than in the evening—is generally blunted in older men.⁵¹

The typical phenotype associated with declining testosterone levels in aging men includes increased fat mass, loss of muscle and bone mass, fatigue, depression, anemia, poor libido, erectile deficiency,⁴² insulin resistance,⁵² and higher cardiovascular risk.⁵³ These clinical features are similar to changes associated with testosterone deficiency in young men, so the syndrome of androgen deficiency of the aging male (ADAM) has been described. However, this phenotype may also occur in older men with normal androgen levels and so the ADAM syndrome has not been universally accepted.⁵⁴

Several clinical studies have been performed to determine whether testosterone supplementation may benefit aging individuals. Despite several trials examining various parameters, including body composition, muscle strength, bone density, metabolism, and lipid profile, there is still no consensus as to whether androgen treatment may be beneficial in older men.⁵⁵ Data from large clinical trials in elderly males is lacking and the short-term and long-term benefits of testosterone replacement therapy need to be critically evaluated.⁵⁶

Dehydroepiandrosterone

Even though dehydroepiandrosterone (DHEA) and its sulfate-bound form (DHEAS) are the most abundant steroid hormones, their full physiologic functions are still unknown. DHEA(S) is an abundant circulating adrenal androgen, but may have cardioprotective, antidiabetic, antiobesity, and immunoenhancing properties.⁵⁷ Much debate has focused on the antiaging effects of DHEA and its potential use as the “hormone of youth.”⁵⁸ The major age-related change in the human adrenal cortex is a striking decrease in the biosynthesis of DHEA(S).^{59–61} Serum DHEA levels decline rapidly and markedly after the age of 25,⁶⁰ with 80-year-old patients having DHEA levels 10% to 20% of those of younger counterparts.⁶² However, the physiologic consequence of this decline is incompletely understood. Many speculate that administration of DHEA may reverse the aging effects, and there is widespread commercial availability of DHEA outside the regular pharmaceutical networks, without adequate scientific evidence.⁶³ Cross-sectional studies describe an association between the decline in DHEAS levels and cardiovascular disease, breast cancer, low bone mineral density, depressed mood, type 2 diabetes, and Alzheimer’s disease, but this may be due to the actual aging process rather than being causally related.⁶⁴

There is a noted sexual dimorphism in adrenal hormone regulation with healthy aging. In older women lower DHEA(S) and higher cortisol levels are seen compared with older men. This is in contrast to cortisol levels in men and

women, which show a progressive, parallel increase with aging. The consequence of sexual dimorphism in adrenal hormones may have implications for age-related changes in cardiovascular disease, brain function, and bone metabolism.⁶⁵

The largest study to date assessing the effect of oral DHEA in otherwise healthy older individuals was a double-blind randomized parallel study of 140 men and 140 women aged 60 to 79 years, who were given daily 50 mg doses of DHEA or a placebo.⁶⁶ No improvement in well-being or cognition was found. Other trials have failed to demonstrate any benefit of DHEA on well-being, mood, cognition, or activities of daily living,^{67–69} suggesting that the decline in serum DHEA levels with aging does not have deleterious effects on well-being, cognition, and sexuality.⁶³

In summary, there is no clear clinical consequence of the age-related decrease in serum concentration of DHEA and there are no clear benefits of DHEA replacement in older individuals.^{63,70}

Hypothalmo-pituitary-adrenal axis

The hypothalamo-pituitary-adrenal (HPA) axis has an important role in the life-sustaining homeostatic and allostatic adjustments to internal and external stressors. This stress adaptive axis is a dynamic feedback network with circadian rhythmicity and pulsatile neurohormone secretion.⁷¹ However, how this axis changes with aging is incompletely understood. There are variable age-related changes in the effects of ACTH on cortisol secretion or cortisol on ACTH secretion,⁷² with no deficiency of adrenal production of corticosteroids.⁷³ Healthy aging disrupts the neuroendocrine mechanisms coordinating within axis pulsatility and 24-hour rhythmic cortisol release and alters the interaxis mechanisms that link LH and cortisol release. Serum cortisol secretion may vary more within a 24-hour period in older subjects, as compared with younger subjects.⁷¹ There is a 20% to 50% increase in 24-hour mean cortisol levels between 20 and 80 years of age,⁵⁹ the evening nadir in serum cortisol concentrations may be higher and earlier in older subjects,^{59,74} and there is no age-related change in corticosteroid binding globulin levels.⁶⁵ The inhibition of ACTH and cortisol secretion with dexamethasone is similar to that seen in younger individuals,⁷² but may be slower in onset.⁷⁵ In older women, serum cortisol concentrations increase more with exogenous ACTH.⁷² Older men have similar rises in serum concentrations as younger men and the cortisol response to stress is prolonged in older individuals.⁷¹ There are gender-specific, age-related alterations of the HPA axis. With healthy aging there is an increase in the cortisol response to CRH challenge and diminished hypothalamic-pituitary sensitivity to glucocorticoid feedback inhibition, which is more profound in older women than older men.⁶⁵

These age-related changes of the HPA axis could be of physiologic importance with chronic cortisol excess being implicated in hippocampal atrophy and cognitive impairments during aging. Cortisol circadian amplitude and phase changes may be relevant in the cause of sleep disorders in the elderly.⁵⁹ Additionally in older females, increasing levels of HPA-axis activity, as measured by urinary free cortisol excretion, are associated with declines in memory performance.⁷⁶ In healthy older men, cortisol levels are inversely related to both bone mineral density and the rate of bone loss, suggesting that bone density and the rate of involutional

bone loss in healthy individuals might also be regulated by the HPA axis.⁷⁷ Furthermore in both men and women, cortisol levels are strongly associated with the risk of clinical fractures.⁷⁸ Lastly there is an association between 24-hour cortisol production rate and increased body fat in older men. Thus the increase in HPA-axis activity may play a role in the alterations in body composition and central fat distribution that are seen in aging.⁷⁹

Hypothalamo-pituitary-thyroid axis

With aging there are a significant number of complex physiologic alterations. However, it is important to note that these direct age-related changes need to be distinguished from indirect alterations caused by simultaneous thyroidal or nonthyroidal illness, or other physiologic or pathophysiologic states whose incidence increases with age. Thyroid function tests in the elderly are difficult to interpret because several changes formerly believed to be a direct result of the aging process have subsequently been shown to be due to the increased prevalence of subclinical thyroid disease and/or the result of nonthyroidal illness.⁸⁰ With age, thyroid hormone clearance decreases, but there is also a decline in thyroid hormone secretion, resulting in unchanged total and free serum thyroxine (T_4) concentrations.⁸¹ In contrast serum total and free triiodothyronine (T_3) concentrations are decreased with aging, most likely due to reduced peripheral conversion of T_4 to T_3 as a direct effect either of nonthyroidal illness or of aging itself.⁸⁰

Apparently older euthyroid patients may have reduced serum thyroid-stimulating hormone (TSH) concentrations,^{82,83} but this is usually a pathologic finding indicating either exogenous or endogenous thyrotoxicosis.⁸⁴ However, in elderly patients without clinical or subclinical hyperthyroidism, slightly decreased serum TSH may be seen.^{83,85} An age-dependent reduction of daily TSH secretion rate has been reported,⁸⁶ the cause of which is unknown. It may be due to supersensitivity of thyrotrophs to the negative feedback from T_4 , but other theories such as reduced hypothalamic thyroid-releasing hormone secretion have not been excluded.⁸⁰ The amplitude of the nocturnal pulses of TSH secretion, which results in the majority of 24-hour TSH secretion, is lower in older subjects,⁸⁷ leading to decreased T_4 secretion in response to the decrease in T_4 clearance.⁸¹

Thyroidal disease prevalence increases with age, with all types of thyroid disease being found, but the clinical manifestations are different from those in younger patients. In older individuals there is a higher prevalence of autoimmune hypothyroidism. Hyperthyroidism is mainly characterized by cardiovascular symptoms and is frequently due to toxic nodular goiters; differentiated thyroid carcinoma is more aggressive.⁸⁸

Aging is also associated with the appearance of thyroid autoantibodies, but the biologic and clinical significance of this finding is unknown. Thyroid autoantibodies are rare in healthy centenarians and in other highly selected aged populations, although they are observed in unselected or hospitalized elderly patients, suggesting that the appearance of these autoantibodies is due to age-associated disease rather than a consequence of the aging process itself.⁸⁹ However, even though physiologic changes are seen in the hypothalamo-pituitary-thyroid axis, their contribution to the pathogenesis of age-associated diseases, such as atherosclerosis, coronary heart disease, and neurologic disorders, still needs to be determined.⁸⁰

CONCLUSION

Each endocrine system undergoes complex changes with aging, many of which occur independently from confounding factors because of the higher prevalence of age-related illnesses. These changes ultimately cause a decline in the peripheral levels of estrogen and testosterone, with an increase in luteinizing hormone, follicle-stimulating hormone, and sex hormone binding globulin. There is additionally a decline in serum concentrations of growth hormone, insulin-like growth factor-1, and dehydroepiandrosterone and its sulfate-bound form. The endocrine functions that are essential to life, such as adrenal and thyroid functions, show an overall minimal change in basal levels with aging even though there are complex changes that do occur within the hypothalamo-pituitary-adrenal/thyroid axis. The clinical significance of these deficiencies is variable and is still being evaluated. Menopause causes a series of changes in bone metabolism, lipid metabolism, vasomotor symptoms, and possibly cognition. Similarly, gonadal function decline in men is associated with loss of muscle and bone mass, increased fat mass, insulin resistance, higher cardiovascular disease risk, poor libido, erectile dysfunction, fatigue, depression, and anemia. Declines in the GH-IGF-1 axis result in reduced protein synthesis, decreased lean body and bone mass, and a decline of immune functions. The clinical significance of adrenal hormone changes is variable.

There have been many studies trying to reverse the endocrine effects seen in aging by restoring the serum hormonal levels of older individuals back into younger ranges. However, whether these therapies have true clinical benefit is still unclear. The "magic pill" to reverse the process of aging has still not been discovered and the quest for a "hormone of youth" continues.

HEMATOPOIESIS

The production of blood

Normal blood cell development is reviewed with emphasis on recent developments and controversies related to blood cell development, function, and aging. In that blood and bone marrow have always been among the most accessible tissues for experimental study, any review of aging and the blood will contain historical insights into underlying mechanisms of cellular, immunologic, and genetic changes associated with aging. With recent advances, we can now add additional epigenetic, stem cell, molecular, and cellular insights.

SITES OF BLOOD CELL DEVELOPMENT, BONE MARROW, AND STROMA

Healthy individuals produce billions of red and white blood cells every hour of every day under normal conditions. With infection, bleeding, or other stresses, production is increased in response to complex physiologic mechanisms. The entire process of hematopoiesis begins with a limited number of hematopoietic stem cells (HSCs),¹ which serve as the reservoir for the progenitors that fuel mature blood cell production, while maintaining the stem cell compartment. The sites of hematopoiesis change with mammalian development.² During the first 6 to 8 weeks of human embryonic life, the yolk sac is the site of hematopoiesis, followed by a fetal liver stage. With further organismal development, the bone marrow becomes and remains the major site of hematopoiesis, outside of pathologic disorders such as thalassemia and myeloproliferative disorders (MPD), in which extramedullary hematopoiesis in spleen, liver, and elsewhere may occur. Elegant studies in mice have tracked the developmental migration of HSCs through these various tissues and identified the earliest site of origin of definitive HSC in the embryo proper as the aorta gonad mesonephros (AGM) region.³

The bone marrow is a specialized microenvironment. At birth the bone marrow is a fully hematopoietically active tissue, but with aging there is replacement of active hematopoietic tissue with inactive adipose tissue. An approximately 1% per year involution is a rough standard used to assess clinical bone marrow biopsy cellularity in different age individuals.⁴ Bone marrow stroma includes a diverse cellular mix of fibroblasts, macrophages, mast cells, reticular cells, endothelial cells, osteoid, and adipocytes. Conventional histologic and immunohistologic analysis has identified a generally orderly arrangement of developing cells in the bone marrow, including the presence of early granulocytic cells along the bony trabecular margins, and erythroid islands, megakaryocytes, and occasional lymphoid nodules positioned in the intertrabecular spaces. Examples of special cellular relationships include erythroid islands with a central macrophage that facilitates red cell enucleation,⁵ and megakaryocyte localization near draining venules to facilitate platelet release into the bloodstream.⁶ Age-related histologic findings include marrow necrosis and fibrosis, loss of bone substance, increase in bone marrow iron stores, expansion of adipose tissue, and

accumulation of benign lymphoid aggregates.⁷ Although analysis of individual cytokines, cellular compositions, and supportive stromal functions can be measured to decrease with aging, the underlying mechanisms responsible for these changes are poorly understood.

Recent technological advances have helped to identify a specialized component of the bone marrow microenvironment, the "niche." This three-dimensional functional hematopoietic unit has specialized anatomic relationships between bone, blood vessels, and differentiating hematopoietic cells. As such, the HSC niche functions as an anatomically confined regulatory environment governing HSC numbers and fate.⁸ An example of a molecular interaction facilitating specialized function in the niche is the tyrosine kinase containing receptor (Tie2) on HSCs, and the interacting ligand (Ang-1) produced by surrounding stroma to enhance the ability of HSCs to become quiescent and increase local adhesion to bone.⁹ This interaction is thought to protect HSCs from stresses that suppress hematopoiesis.

Niche anatomic relationships include vascular endothelium and perivascular cells, sympathetic nervous system components, and osteoclasts. Osteoblasts and CXC chemokine ligand 12 expressing reticular cells have been identified as important regulatory components. Wnt family members, Ang-1/Tie-2, calcium-sensing receptor signaling, osteopontin, and other extracellular matrix components have also been implicated.⁸ Two spatially and likely functionally distinct bone marrow microenvironment/niches have been proposed.^{10,11} The endosteal HSC niche contains osteoblasts as the main supportive cell type. The vascular niche has HSCs associated with the sinusoidal endothelium in the bone marrow and spleen.¹² These environments serve as sites for local cytokine production. Factors implicated in HSC function include the Notch ligands—Delta and Jagged—involved in the generation, antidifferentiation, and expansion of HSCs.¹³ Wnt signaling is involved in HSC generation and expansion and maintenance of HSCs in a quiescent state.¹⁴ Bone morphogenic proteins (BMP) and transforming growth factor- β regulate HSC activity,¹⁵ and BMP appears to regulate the size of the endosteal niche.¹⁶ Many other soluble factors are also currently under investigation, including fibroblast growth factors, angiopoietin-like proteins, insulin-like growth factor 2, and others.¹⁷

In addition to maintenance of normal steady-state hematopoiesis, the microenvironmental niche appears to be involved in disease pathogenesis. Perturbations of the niche as a cause of hematologic disease are supported by the observation of Walkley et al, where mice null for the retinoic acid γ -receptor (RAR- γ -/-) develop a MPD dependent not on the HSCs of the null mice, but rather on the microenvironment.¹⁸ Similarly, inactivation of the retinoblastoma gene in a murine model resulted in a profound myeloproliferative disorder as a consequence of impaired RB-dependent interaction between myeloid-derived cells and the microenvironment.¹⁹ The human MPD primary myelofibrosis, long known as a disorder of abnormal marrow fibrosis leading to "wandering

stem cells²⁰ has been proposed to be a clonal disorder of stem cell niche deregulation and abnormal stroma.²¹ Donor cell leukemia (DCL), a rare complication of bone marrow transplantation, has been potentially linked to niche damage from inflammation triggered by the primary underlying malignancy, or active chemotherapeutic and radiation conditioning, or transplant-related immune modulatory treatments—all leading to extrinsic leukemic influences on donor HSCs.²²

Besides serving as a primary site of hematopoiesis, recent studies have identified the bone marrow as a potential source of cells for nonhematopoietic wound healing or regeneration. The precise nature of the source of the donor cells from the bone marrow remains controversial and the subject of much investigation. Examples of possible bone marrow-derived tissue contributors include mesenchymal stem or stromal cells,^{23,24} and fibrocytes.²⁵ The heart,²⁶ cornea,²⁷ and liver²⁸ are among many tissues that are being examined as potential target organs for bone marrow–derived regenerating tissue grafts.

HEMATOPOIETIC STEM CELLS

The stem cell model of hematopoiesis starts with the totipotent HSC that has the capacity for self-renewal to prevent exhaustion of the HSC compartment, and the asymmetric proliferation and differentiation to produce large numbers of lineage-restricted hematopoietic cells daily, and the ability to reconstitute hematopoiesis in a lethally irradiated host.¹ Although intrinsic and extrinsic control of the early developmental steps from self-renewing HSC and cells committed to differentiation are poorly understood, these represent an excellent general model system to define basic mechanisms of mammalian cell development and differentiation. The ability of transferred HSCs to reconstitute hematopoiesis provides the clinical basis for bone marrow transplantation. The earliest description of HSCs was based on studies showing murine bone marrow transplanted into lethally irradiated mice, rescuing the recipient by reconstituting donor hematopoiesis.²⁹ Remarkably, intravenous injection is possible because the HSCs are able to home to the bone marrow, and identify and interact with the niche. The biology and physiology of the HSC is enormously complex and is the subject of many reviews^{1,2,30} that include descriptions of the characterization and developmental origins of HSCs, enumeration and cellular sources, regulation of cell fate decisions, and clinical implications for bone marrow transplantation. Several areas of stem cell biology particularly relevant to aging stem cells are discussed later in this chapter.

TELOMERES AND SENESCENCE

Normal somatic cells appear to have a finite number of cell divisions available to them. In 1961 Hayflick and Moorhead described experiments that established this concept.³¹ After completing this limiting number of cell divisions, a resting phase or senescence is entered. These postmitotic cells do not immediately die, but may survive for several years with normal function but with biochemical changes. Cellular senescence has long been used as a cellular model for understanding mechanisms underlying the aging process. Compelling evidence obtained in recent years demonstrates that DNA damage is a common mediator for both replicative senescence, which is triggered by telomere shortening, and

premature cellular senescence induced by various stressors, such as oncogenic stress and oxidative stress.³² Extensive observations suggest that DNA damage accumulates with age and that this may be due to an increase in production of reactive oxygen species (ROS) and a decline in DNA repair capacity with age. Mutation or disrupted expression of genes that increase DNA damage often results in premature aging. In contrast, interventions that enhance resistance to oxidative stress and attenuate DNA damage contribute toward longevity. There is significant evidence that deregulated accumulation of ROS in HSCs leads to abnormal hematopoiesis.^{33,34} The precise levels of contribution of ROS production, oxidative damage, DNA repair machinery abnormalities, genomic instability, and other triggers of senescence to the aging process and age-related HSC dysfunction remain to be determined.

Telomeres and telomerase have been specifically investigated as potential components of age-related bone marrow failure and hematopoietic cell function. Human diseases characterized by mutation in the telomerase apparatus and associated with telomerase dysfunction have provided unique insights into tissue aging.³⁵ There are at least three human diseases that are associated with germ-line mutations of the genes encoding the two essential components of telomerase, TERT and TERC. Heterozygous mutations of these genes have been described for patients with dyskeratosis congenita, bone marrow failure, and idiopathic pulmonary fibrosis. The spectrum of mutations in TERT and TERC varies for these diseases and appears at least in part to explain the clinical differences observed. Environmental insults and genetic modifiers that accelerate telomere shortening and increase cell turnover may exaggerate the effects of telomerase haploinsufficiency, contributing to the variability of age of onset and tissue-specific organ pathology.

Warren et al, 2008, reviewed the general lack of direct evidence for progressive depletion of the HSC pool based on telomere shortening, however.³⁶ Serial bone marrow transplantation experiments in mice suggest that although the replicative potential of HSCs is finite, there is little evidence that replicative senescence causes depletion of the stem cell pool during the normal life span of either mouse or man. In fact extensive evidence suggests that HSC numbers substantially increase with advancing age in mice.³⁷ The expansion of the HSC pool is a cell-autonomous property as HSCs from aged donors exhibit a greater capacity than young controls upon transplantation into young recipients.³⁸ Although there is an increase in the number of HSCs with age, they have functional deficiencies, including altered homing and mobilization properties^{39,40} and decreased competitive repopulation abilities.³⁷ Remarkably, a skewing of lineage potential from lymphopoiesis to myelopoiesis has been observed with age.³⁰ There are reduced lymphoid progenitors in old mice and maintained to increased myeloid progenitors. These HSC findings may explain some of the features of age-related immune cell senescence and an increase in the myelogenous hematological malignancy incidence noted with aging.

EPIGENETICS

Epigenetic marks represent DNA modifications of genomic DNA or associated proteins, other than the DNA sequence itself, that are heritable through cell division. These include

DNA methylation, a covalent modification of cytosine; histone modifications affecting the nucleosomes around which the DNA is coiled; and alterations in nucleosomal packing or higher-order folding of chromatin. Acquired epigenetic changes are common in human malignancy.⁴¹ Epigenetic changes have been associated with the loss of responsiveness to stress that accompanies aging.⁴² The intersection of cancer risk, which increases with age and is associated with epigenetic changes, with the normal aging process is an open question. A recent direct examination of longitudinal changes in global DNA methylation in the same individuals over time has provided insight into this problem.⁴³ Methylation was serially tested in two separate cohorts of individuals 11 or 16 years apart on average. Significant methylation change over time was identified. Also, familial clustering of methylation change was observed, suggesting that methylation maintenance may be under genetic control. There is growing evidence for significant epigenetic regulation of HSC function and behavior.

HSCs are defined by their self-renewal capacity and undifferentiated state. The mechanisms that control these are poorly understood. *In vivo*, *in vitro*, and gene expression profiling studies have revealed extensive heterogeneity in the phenotypes and properties of HSCs. Analysis of single HSC in long-term transplantation assays and genetic differences in HSC behavior in different strains of inbred mice demonstrate that many HSC behaviors are fixed intrinsically through genetic or epigenetic mechanisms.^{30,44} A striking example of epigenetically fixed heterogeneity among HSCs is found in myeloid-biased HSCs. These HSCs make typical levels of myeloid cells but generate too few lymphocytes. The diminished lymphoid progeny have impaired response to IL-7.⁴⁵ Using highly purified HSCs from young and aged mice, Chambers et al also identified functional deficits but also an increase in stem cell number with advancing age.⁴⁶ Gene expression analysis identified approximately 1500 of more than 14,000 genes that were age-induced and 1600 that were age-repressed. Genes associated with the stress response, inflammation, and protein aggregation dominated the upregulated expression profile, whereas the downregulated profile was marked by genes involved in the chromatin remodeling and the preservation of genomic integrity. Many chromosomal regions showed coordinate loss of transcriptional regulation; an overall increase in transcriptional activity with age and inappropriate expression of genes normally regulated by epigenetic mechanisms was observed.

Application of chromatin-modifying/epigenetic drugs to normal HSC cultures with cytokines results in the preservation of marrow-repopulating activity and activation of several genes and their products implicated in HSC self-renewal compared with cells exposed to cytokines alone, which lost their marrow-repopulating activity.⁴⁷ Previous attempts to expand HSCs resulted in HSC differentiation and stem cell exhaustion or, at best, asymmetric cell divisions and maintenance of the same numbers of HSCs. These observations suggest chromatin modifying agents may allow symmetric division of HSCs and expansion of potential therapeutic grafts, with preservation of stem cell function. The demethylating agents 5-aza-2'-deoxycytidine (decitabine, DAC) and 5-azacytidine (AZA) at low doses induce hematologic and cytogenetic remission in a subset of patients with myelodysplastic syndrome (MDS). The effects on platelet counts

can be remarkable and response is correlated with increased survival.⁴⁸ Molecular analysis of patients with an informative clonal marker and a neutrophil response indicates that restoration of normal nonclonal hematopoiesis may be the predominant effect of DAC.⁴⁹ Further evaluation of the mechanisms that chromatin modifying agents alter normal and malignant hematopoiesis will be necessary to fully exploit these early observations.

PROGENITOR COMPARTMENT

Lineage-restricted progenitor cells derived from HSCs allow amplification of numbers and differentiation into separate lineage effector cells. Ultimately, more than 10 different mature cell types are derived from the HSC through these progenitors. Within a pathway, there are early and late progenitors, which differ in the number of potential proliferative cell divisions. Identification and study of progenitors has been greatly facilitated through the development of culture systems, including the identification of growth factors necessary to prevent apoptosis, an important default regulatory pathway in many if not all hematopoietic lineages. The regulation of hematopoietic cell lineage commitment remains controversial. As intrinsic determinants of cellular phenotype, transcription factors represent major components of the underlying process.^{2,50}

The successful isolation of the common lymphoid progenitor (CLP), which can generate all lymphoid types but not any myeloid cells, and its counterpart—the common myeloid progenitor (CMP), which can be the source of all myeloid-cell types—provides important insights into developmental cellular pathways, suggesting that the myeloid and lymphoid developmental programs operate independently downstream of HSCs. Recent studies suggest that even these pathways, however, are much more complicated.^{51,52} Key concepts related to underlying basic mechanisms responsible for progenitor cell development include the roles of qualitative and quantitative variations of transcription factor abundance, including transcription factor complexes, and even order of expression.⁵³ Some factors are dominant for specific lineages. Graded reduction of *C/EBP α* transcription factor in granulocyte monocyte progenitors (GMPs) results in a mast-cell production frequency inversely proportional to the abundance of the *C/EBP α* transcription factor.⁵³ Taking advantage of a PU.1-null mouse model, DeKoter and Singh⁵⁴ showed that high-level PU.1 expression is associated with macrophage differentiation, whereas low-level expression promotes B-cell formation. Lineage diversification also involves interplay of antagonistic competing lineage determining transcriptional programs. Continuing the PU.1 macrophage example, further investigation of PU.1 regulation of macrophage differentiation from upstream macrophage/granulocyte progenitors led to the discovery of a circuit of counter antagonistic repressors, *Egr-1/2/Nab-2* and *Gfi1*.⁵⁵ Previous work had revealed the antagonism of PU.1 and *GATA-1* in erythroid vs. myeloid lineage determination.^{56,57}

Based on the importance of transcriptional control mechanisms on hematopoietic regulation, it has been proposed that cumulative somatic mutations in transcription factors might contribute to the aging process by disrupting the transcriptional networks that regulate cell structure and function. This hypothesis was termed “transcriptional instability”; but

experimental investigation has not supported this hypothesis to date.⁵⁸ Using a more evolutionarily distant model system, Budovskaya et al⁵⁹ did find an association between global aging in the nematode *Caenorhabditis elegans* and expression differences in three GATA transcription factors: ELT-3, ELT-5, and ELT-6. In old age, ELT-5 and ELT-6 expression increases and ELT-3 decreases, resulting in changes in a multitude of genes with GATA regulatory sites. These results suggest that aging in worms is caused by a drift in a GATA transcriptional regulatory network rather than accumulation of cellular damage. Interestingly, mammalian GATA binding transcription factors, particularly GATA-1, GATA-2, and GATA-3, have many critical roles in hematopoiesis from HSC, T cell, and myeloid effector cell biology.²

CIRCULATING BLOOD CELLS

Circulating blood cells represent the third class of hematopoietic cells in Metcalf's original classification of hematopoiesis.⁶⁰ The cellular components of circulating blood cells includes granulocytes, monocytes, eosinophils, basophils, erythroid cells, and lymphocytes. As critical physiologic cellular effectors, age-related changes in number and/or function have been proposed to contribute to the frailty that develops in some aging individuals.

GRANULOCYTES

Granulocytes, including neutrophils, eosinophils, and basophils, are components of the innate immune response to bacterial, fungal, and protozoal infections. It is well known that the immune response decreases during aging, leading to a higher susceptibility to infections, cancers, and autoimmune disorders. One of the most important cellular components of the innate immune response is neutrophils. Polymorphonuclear neutrophils (PMNs) are the first cells to be recruited to the site of inflammation. They have a short life span and die by apoptosis. However, their life span and functional activities can be extended in vitro by a number of proinflammatory cytokines, including the granulocyte-macrophage colony stimulating factor (GM-CSF). It has been shown that the functions and the rescue from apoptosis of PMNs tends to diminish with aging. With aging there is an alteration of other receptor-driven functions of human neutrophils as well, such as superoxide anion production and chemotaxis. Observations of molecular defects in neutrophil receptor mediated signaling⁶¹⁻⁶³ taken together describe an acquired defect in innate immunity with aging that at least in part might partially explain the higher incidence of sepsis-related deaths in the elderly population and may impact on frailty. Clinical studies investigating whether hematopoietic growth factors at pharmacologic doses (including G-CSF and GM-CSF) improve outcome in older adults with cancer have demonstrated some success.⁶⁴

EOSINOPHILS, BASOPHILS, AND MAST CELLS

Eosinophils function in host defense, allergic reactions, and other inflammatory responses, tissue injury, and fibrosis. Age-related changes in eosinophil function have been identified by Mathur et al.⁶⁵ The role of abnormal peripheral

blood eosinophil "effector" functions in the pathophysiology of clinical entities such as asthma in the elderly remains to be determined. Basophils are the least common of the human granulocytes and are implicated in immediate hypersensitivity reactions, such as asthma, urticaria, allergic rhinitis, and anaphylaxis. Basophils and mast cells are effectors of immediate allergic reaction via their high-affinity receptors for IgE. Mast cells are derived from bone marrow hematopoietic progenitors in the bone marrow, although they only transiently circulate in blood enroute to tissue sites. Like other hematopoietic lineages, transcriptional networks responsible for mast cell lineage commitment and differentiation are areas of active investigation.⁶⁶ Nguyen et al⁶⁷ have identified age-induced reprogramming of mast cell degranulation and Sparrow et al identified inflammatory airway mechanisms involving basophils in older men, which may participate in inflammatory responses including asthma in the elderly patient.⁶⁸

MONOCYTES AND MACROPHAGES

Monocytes and macrophages are closely related developmentally to neutrophils. Circulating monocytes give rise to a variety of tissue-resident macrophages throughout the body and specialized cells, such as osteoclasts and dendritic cells (DCs). Monocytes originate in the bone marrow from a common myeloid progenitor that is shared with neutrophils and are released into the peripheral blood where they circulate for several days before entering the tissues and replenishing tissue macrophage populations.⁶⁹ Circulating monocytes represent approximately 5% to 10% of human peripheral blood leukocytes in nonpathologic situations. Significant heterogeneity exists in the monocyte/macrophage phenotype, which has been investigated functionally, morphologically, through cell surface markers, and more recently through genetically altered mouse models.^{70,71} For example, KLF4^{-/-} mice were identified as having a lack of inflammatory monocytes,⁷² producing fewer monocytic cells, and having increased granulocytic cells in clonogenic assays.⁷³ The many functional roles of monocyte, macrophage, dendritic, and osteoclast cells in maintenance of tissue homeostasis through clearance of senescent cells; remodeling and repair of tissues after inflammation; antigen presentation; and other immune function through production of inflammatory cytokines are only partially understood. Some tumors even recruit infiltrating monocytes for nefarious purposes such as enhancing tumor angiogenesis.⁷⁴ Similar to age-related changes in neutrophil signaling pathways impeding the immune response described earlier, monocyte macrophage signaling including Toll-like receptors has also been reported to be altered.⁷⁵

RED CELLS

Erythrocytes transport hemoglobin, the major oxygen carrying pigment, and thus provide tissue gas exchange. Hormones that change with age, hypoxia, sex, and other poorly understood factors influence red cell numbers in mammals. The erythroid lineage was among the first of the hematopoietic lineages where tissue specific hematopoietic transcription factors were first cloned and then ablated in mice to identify their roles in hematopoiesis.² Recent discoveries

place the erythroid and megakaryocyte lineages again at the forefronts of new developmental pathways. MicroRNAs (miRNAs) are a novel class of small, regulatory RNA molecules that play evolutionarily conserved roles in cellular function and development, and mediate target gene repression through 3' untranslated region (UTR) interactions.⁷⁶ First implicated and confirmed to regulate lymphopoiesis in hematopoietic cells,⁷⁷ specific miRNAs have also been implicated as necessary for normal erythroid and megakaryocyte development.^{78,79} The precise target genes and mechanisms remain under intense evaluation. Abnormal miRNA expression has been implicated in leukemia and lymphomas and mechanistic studies support a role for miRNAs in the pathogenesis of these disorders.⁸⁰

Age-related changes in red cell numbers is unfortunately not an infrequent finding in aging adults. Anemia for all adult age ranges is one of the most frequent diagnoses on the medicine wards. Mechanisms explored to explain the anemia in the older adult include the identification of excessive circulating inflammatory cytokines such as IL-6, which may negatively impact on hematopoiesis through multiple mechanisms, including antagonizing function or impairing erythropoietin production.⁸¹ Epidemiologic studies report that a third of the cases of anemia in older persons are unexplained, however. The diagnosis and treatment of anemia in older adults is more comprehensively reviewed in other chapters.

LYMPHOID DEVELOPMENT

Like myelopoiesis, lymphoid development has intrinsic and extrinsic controls and requires specific environmental interactions.^{82,83} Understanding these developmental stages is critical to understanding normal and abnormal immunity and lymphogenesis. The peripheral immune system develops from stem cells originating in the bone marrow. Lymphoid progenitors migrate from the bone marrow (including B and T cells) to specialized peripheral sites, including the thymus, spleen, Peyer's patches, Waldeyer's ring, and lymph nodes to undergo further maturation, differentiation, and acquire self/non-self "training." Upon identification of a danger signal or foreign invader, innate immune cells respond by destroying infected cells (NK cells) and releasing cytokines and chemokines to recruit additional immune cells to fight the invader or infection and alter the host environment (inflammation). This innate immune response is often followed by an adaptive (antigen-specific) immune response with the recruitment of effector B and T lymphocytes. Following effective clearance of the invading pathogen, the host immune response must return to the quiescent state to prevent damage from an excessive immune response. A specialized subset of T cells recently described, called regulatory T cells (Treg), participate in this process.⁸⁴

AGING AND T CELLS

T cells become specialized in the thymus to provide adaptive cellular immunity via CD8 cytotoxic T cells, and play important roles in B cell-mediated humoral immunity through helper functions. T cells have been identified as highly susceptible to age-related changes. A number of factors have been linked to the decline in T-cell function with

age; however, it appears that age-induced thymic atrophy and decreased output of naïve T cells is a critical factor.⁸⁵ Changes in the composition of the bone marrow stroma with age and decreased nurturing of hematopoietic precursors contribute to decreased T-cell production with aging. Secretion of IL-7, an essential T-lineage survival cytokine, is decreased in aged bone marrow.⁸⁶ The precise nature and identity of the bone marrow-derived, earliest committed T cells remains controversial, which complicates quantitation with age. Early T-lineage progenitors (ETPs), which give rise to T cells, are generated in the bone marrow. Thymocyte progenitor cells then enter the thymus and begin their differentiation and education process with changes in surface marker expression, rearrangement of their T-cell receptor, and positive and negative cellular selection. The overall process of T-cell maturation and education is modulated by cytokines, hormones, epithelial cells, macrophages, dendritic cells, and fibroblasts in the thymic stroma. Increasing understanding of the thymic epithelial-hematopoietic cell interactions includes identification of Notch pathway receptors and ligands required for T-cell development.⁸⁷ As an individual ages, the thymus involutes and the output of T cells falls significantly.^{88–89} By 70 years of age, the thymic epithelial space shrinks to less than 10%

KEY POINTS

Aging and the Blood

- Considerable progress is being achieved in identifying gene regulatory networks that direct hematopoietic cell fate. Harnessing this information may lead to more effective hematopoietic cell therapies.
- We are only beginning to appreciate the impact of regulatory RNAs including microRNAs (miRNAs) on normal and malignant hematopoietic development and function. Current examples include regulation of hematopoietic stem cell (HSC) and progenitor cell function, immune cell differentiation, response to infection, and development of immunologic disease and malignancy.
- Studies of the aging HSC are providing increased understanding and molecular insights into cellular senescence, aging, and the age-associated increase in malignancy and patterns of leukemia susceptibility.
- With increased understanding of the HSC niche we can anticipate improved approaches to HSC therapy, age-related disorders of lymphopoiesis and hematopoiesis, and the development of treatments for niche-derived diseases.
- Further characterization of leukemic stem cells will lead to more effective therapies for these typically poor prognosis disorders in adults, including novel therapies directed against the leukemic stem cell, not the bulk tumor.
- Identification and characterization of regulatory T cells (Tregs) are providing new insights into autoimmune and malignant immune disorders and may provide a cellular target for new therapies for these conditions.
- Continued study of acquired abnormalities in signaling and other underlying mechanisms of effector cell dysfunction with aging may provide insight and new effective therapies associated with hematopoietic contributions to frailty.
- The bone marrow continues to be evaluated as a source of alternative cellular regenerative therapies. Better understanding of stem cell biology and lineage plasticity are required to advance this burgeoning field.

of the total tissue. New techniques to monitor newly produced (naïve) recent thymic emigrants (RTEs) have provided powerful molecular tools to evaluate the attenuation of thymopoiesis with aging.⁹⁰ CD4:CD8 recent thymic emigrant numbers diminish with age, and RTE maturation and activation is suboptimal in aged mice. These and other observations⁹¹ provide promise that therapeutic regeneration of functional thymic epithelial space in aging individuals could potentially reverse some of the age-related T-cell deficits.

With aging, the decrease in naïve T cells is accompanied by an increase in memory T cells in the periphery. Impaired T-cell contributions to humoral immunity are numerous including decreased IL-2 production,^{92,93} germinal center defects,⁹⁴ reduced activation, differentiation, and cytokine production.^{92,93} Impaired CD8 cytotoxic effector T-cell function is also diminished when influenza responses in murine models or humans are assayed.⁹⁵ These and other studies^{96,97} provide some of the mechanisms that might explain disease-related immune system senescence effects associated with aging. Much recent work on the regulation of the immune system has focused on regulatory T cells (Tregs), CD4⁺/CD25⁺/Foxp3⁺ regulatory T cells that play a key role in controlling the host immune response to prevent excessive immune response and damage.^{84,98,99} Quantitation and functional evaluation of these cells in disease and aging is under active investigation.¹⁰⁰

AGING AND B CELLS

B-lymphocyte development begins in the fetal liver and bone marrow in defined stages characterized by the status of immunoglobulin gene rearrangement in cells expressing combinations of specific cell surface antigens.⁸³ The production of B lymphocytes begins to decline steadily in adult life and is severely compromised in the elderly.^{101,102}

In addition to reduced production of B-lineage cells in aged mice and man, studies have shown that the numbers of all B-cell progenitors, including ELP, CLP, pre-pro-B, and

pro-B cells, are reduced in old bone marrow.¹⁰³ The decline in B-cell production is not restricted to very old mice.¹⁰⁴ Gene profiling of young and old HSC³⁰ suggests that age-related defects in the hematopoietic system appear to be different between lymphoid and myeloid lineages. The expression of lymphoid-specific gene sets was significantly reduced in old HSCs, whereas genes directing myeloid development were upregulated. Numerous biochemical and differentiation defects have also been identified in later developmental stages of B-cell production. Compromised CLP to pre-pro-B, and Pro-B to pre-B cell differentiation and proliferation and impaired responses to lymphopoietic cytokines IL-7 and TSLP all represent defects that may contribute to the reduced numbers of B-cell progenitors in the bone marrow of older mice.¹⁰³ Murine transplant studies that showed rescue of aged B-lineage progenitors transplanted into young but not old environments¹⁰⁵ are additional evidence for stromal contributions to B-cell, age-related senescence.

The translational impact of these elegant murine studies remains to be integrated with other immune defects identified in aging individuals and correlated with clinical outcomes and potential interventions. One recent approach to autoimmune diseases refractory to conventional treatments includes "rebooting the immune system." High-dose cyclophosphamide (HiCy) chemotherapy has been administered to patients with systemic lupus erythematosus, autoimmune hemolytic anemia, myasthenia gravis, multiple sclerosis, and other autoimmune disorders with the goal of largely eliminating the mature immune system while leaving the hematopoietic precursors intact.^{106–108} These HiCy treatments have been effective, even in highly refractory patients, but are not always durable, indicating that continued immunosuppression or additional approaches (rebooting and retraining) may be necessary for cure.¹⁰⁹

INTRODUCTION

The skin performs many vital functions including homeostatic regulation; prevention of percutaneous loss of fluid, electrolytes, and proteins; thermoregulation; sensory perception; and immune surveillance. In addition, skin forms the most visible indicator of age, the features of which are now widely considered cosmetically unacceptable. Through the effects of aging, skin becomes dry and itchy,¹ and more susceptible to infection,² immunologic disorders,³ vascular complications and increased risk of cutaneous malignancy. In fact most people over the age of 65 have at least one skin disorder, and many have two or more.⁴ The skin is subject to intrinsic (chronologic) aging, which is under genetic and hormonal influence, and to extrinsic aging, which is caused by environmental factors, principally UV radiation (UVR) and also smoking. UVR-induced aging is known as photoaging. The skin is particularly vulnerable to the effects of external insults and the appearance of the skin differs greatly between covered (e.g., buttocks) and sun-exposed (e.g., face, forearm) sites. There are distinct morphologic and histologic features differentiating intrinsic and extrinsic aging of the skin; however, there is also evidence that these two processes have some overlapping biologic, biochemical, and molecular mechanisms.⁵ The overall result is loss of elasticity and tensile strength with wrinkle formation, increased fragility, and impaired wound healing. The skin is equipped with multiple inherent mechanisms that protect against the harmful processes that induce aging, however, the efficacy of these mechanisms decreases significantly over time.

INTRINSIC AGING

Intrinsic aging, although genetically predetermined, varies between populations and different sites on the same individual. The process of intrinsic aging falls into two categories: one that is engendered within the tissue itself and one which is caused by the influence of aging in other organs, for example, age-related hormonal changes. The former is largely controlled by progressive telomere shortening, compounded by low-grade oxidative damage to telomeres and other cellular constituents.⁶ A study looking at normal human epidermis established that progressive telomere shortening associated with aging is characterized by tissue-specific loss rates.⁷ Clinically, intrinsically aged skin is dry, lax, and finely wrinkled.⁸

EXTRINSIC AGING

Photoaging

Exposed sites, in particular the face, anterior chest, and extensor surfaces of the arms, display the hallmarks of extrinsically aged skin resulting from the cumulative effects of life-long UVR. It has been stated that photodamage accounts for up to 90% of age-associated cosmetic problems⁹ and it is mostly preventable. Ultraviolet B (UVB, 280 to 320 nm) only penetrates as far as the epidermis and is responsible for sunburn, tanning, and photocarcinogenesis.¹⁰

UVB is the major cause for direct DNA damage and induces inflammation and immunosuppression.¹¹ The effects of ultraviolet A (UVA, 320 to 400 nm), although less well understood, are thought to play a larger role than that of UVB in photoaging given UVAs far greater abundance in sunlight, far greater day-long and year-round average irradiance, and greater average depth of penetration into the dermis.¹¹ In pale-skinned individuals, the first signs of extrinsic aging on exposed sites are apparent by the age of 15 years,¹² whereas on nonexposed sites they are not apparent until age 30.¹³ The pursuit of a tan remains a high priority in Western culture, resulting in ever-rising rates of skin cancer and prematurely aged skin. Clinically, photo-aged skin is characterized by deep wrinkles, laxity, roughness, a sallow or yellow color, increased fragility, purpura formation, pigmentary changes, telangiectasia, impaired wound healing, and benign and malignant growths. The mechanisms through which UVR induces accelerated aging are discussed later in the chapter.

Smoking

Smoking is an independent risk factor for premature facial wrinkling after controlling for sun exposure, age, sex, and skin pigmentation.¹⁴ The relative risk of moderate-to-severe wrinkling for current smokers was found to be 2.3 for men and 3.1 for women.¹⁵ There is a clear dose-response relationship, with facial wrinkling increasing in individuals who smoke for longer and also with increasing numbers of cigarettes per day.¹⁴ Some studies have reported that women are more susceptible to the wrinkling effects of smoking.¹⁵ When smoking and excessive sun exposure combine, the effect on wrinkling multiplies. The risk of developing wrinkles increases to 11.4 times that in a normal age-controlled population.¹⁶ The exact mechanism for the aging effects of smoking is poorly understood. The effects may be topical due to the drying or irritating effect of cigarette smoke on the skin, or systemic with induction of matrixmetalloproteinase-1 (MMP-1),¹⁷ or through affecting cutaneous microvasculature, which is constricted by acute and long-term smoking.¹⁸

Skin type

Pigmentation of the skin is protective against the cumulative effects of photoaging; those with skin type VI (black) showing little difference between exposed and unexposed sites.¹⁹ In addition, the difference in skin cancer rates between Whites and African Americans indicates that pigmentation provides a 500-fold level of protection from UV radiation.²⁰ The appearance of photodamaged skin differs for those with skin types I and II (red hair/freckles/burns easily) and those with skin types III and IV (darker skin, tans easily). The former tend to show atrophic skin changes, with fewer wrinkles and sometimes focal depigmentation (guttate hypomelanosis) and dysplastic changes, such as actinic keratoses and epidermal malignancies. In contrast, those with III/IV skin develop hypertrophic responses, such as deep wrinkling, coarseness, a leather-like appearance, and lentigines.¹¹ Basal cell carcinoma and squamous cell carcinoma occur almost exclusively on sun-exposed skin of light-skinned people.

Wrinkling in Asian skin has been documented to occur later and with less severity than in Whites.¹³

EPIDERMIS

The epidermis is composed of an outer nonviable layer called the stratum corneum, and the bulk of epidermis consists primarily of keratinocytes, with smaller populations of Langerhans cells and melanocytes.

The stratum corneum is the body's principal barrier to the environment and also plays a major role in determining the level of cutaneous hydration. Its structure is often compared to the "bricks and mortar" model consisting of protein-rich corneocytes, which are embedded in a matrix of ceramides, cholesterol, and fatty acids.²¹ These lipids form multilamellar sheets amid the intercellular spaces of the stratum corneum and are critical to its mechanical and cohesive properties, enabling it to function as an effective water barrier.²² There is general agreement that the thickness of the stratum corneum does not change with age²³ and that barrier function does not alter significantly. However, certain features of aging skin do indicate an abnormal skin barrier, namely the extreme skin dryness (xerosis) and increased susceptibility to irritant dermatitis that accompanies old age. Furthermore there is evidence of altered permeability to chemical substances²⁴ and reduced transepidermal water flux in aged skin.²¹ It seems that baseline skin barrier function is relatively unaffected by age.²³ However, if the skin is subjected to sequential tape stripping, the barrier function in aged skin (>80 years) is much more readily disrupted than in young skin (20 to 30 years).²³ In addition, the same study found that after tape stripping, barrier recovery was greatly disturbed in the older age group. The reason for this abnormality is not entirely understood; however, it appears that there is a global reduction in stratum corneum lipids, which affects the "mortar" that binds the corneocytes. More recently studies have confirmed that in moderately aged (50 to 80 years) individuals, abnormal stratum corneum acidification results in delayed lipid processing, delayed permeability barrier recovery, and abnormal stratum corneum integrity.²⁵ Not only does the rise in stratum corneum pH interfere with lipid production, it also accelerates the degradation of intercorneocyte connections, the corneodesmosomes.²⁶ The abnormal acidification is linked to decreased membrane Na⁺/H⁺ transport protein.²⁵ In addition, with age, stratum corneum turnover time lengthens with protracted replacement.²⁷

Studies of epidermal thickness disagree, and no conclusion can yet be drawn on any change with age.²⁰ It appears that the epidermis thins with age at some body sites, such as the upper inner arm^{28,29} and back of the upper arm,³⁰ but remains constant at others, such as the buttock, dorsal forearm, and shoulder.³¹ This variation is clearly not accounted for by sun or environmental exposure alone.²⁰ Differences in study method, population, and body site likely account for these greatly different results. One author suggests that although epidermal thickness remains constant with advancing age, variability in epidermal thickness and keratinocyte size increases.⁸

The most consistent change found in aged skin is flattening of the dermoepidermal junction at sites that were highly corrugated in youth.³² The flattening creates a thinner looking epidermis primarily because of retraction of the rete ridges.²⁰ With this reduced interdigitation between layers, there is less resistance to shearing forces.¹³ There is also a reduced surface

area over which the epidermis communicates with the dermis, accompanied by a reduced supply of nutrients and oxygen.³³

There is general agreement that epidermal cell turnover halves between the third and seventh decades of life.^{34,35} This is consistent with the observation that wound healing capacity deteriorates in old age.³⁶

Keratinocytes

With age there is increasing atypia of the basal layer keratinocytes.²⁹ Involucrin, a differentiation marker normally expressed by irreversibly differentiated keratinocytes in the stratum corneum, has been found to have increased expression in sun-damaged skin.³⁷ This is consistent with the fact that keratinocyte differentiation is impaired by UVR. In addition, in basal epidermal cells there is downregulation of certain β_1 -integrins,³⁷ which are markers of keratinocyte differentiation and adhesion to the extracellular matrix, suggesting that proliferation and adhesion of keratinocytes in photodamaged aged skin are significantly abnormal.

Melanocytes

With age there is a reduction in the number of melanocytes of between 8% and 20% per decade. This is manifest as a reduction in melanocytic nevi in older patients.³⁸ There is an associated loss of melanin in the skin, which means less protection against the harmful effects of UV radiation. Consequently, the elderly are more susceptible to skin cancers and sun protection remains very important for this group, despite the fact that the majority of an individual's harmful sun exposure occurs in the first 2 decades of life.³⁹

DERMIS

The dermis consists predominantly of connective tissue, and contains blood vessels, nerves, and the adnexal structures including sweat glands and sebaceous glands. Its main role is to provide a tough and flexible layer that supports the epidermis and binds to the subcutis, the fatty layer deep to the dermis. Dermal connective tissue contains collagen and elastin. Collagen fibers comprise the biggest volume of the skin and give the skin its tensile strength, whereas elastin fibers contribute to elasticity and resilience.³³

As with the epidermis, studies reveal conflicting results, with some showing thinning with age and others no change.²⁰ It has been suggested that the initial effect of photodamage in young skin is thickening through solar elastosis; in contrast in the elderly more severe damage results in notable thinning.⁴⁰ However, despite extensive data, it is extremely difficult to define the effects of aging on skin thickness, partly because of individual and regional variations between different studies.²⁰

It is generally accepted that changes in the dermis are responsible for wrinkling; however, the mechanism is not entirely understood.³² There is general atrophy of the extracellular matrix, accompanied by a decrease in cellularity, especially of the fibroblasts, which also have reduced synthetic ability.^{41,42} There are more abnormalities of collagen and elastic fibers in sun-exposed sites.^{43,44}

Collagen

Collagen is the most abundant protein found in humans, and as the primary structural component of the dermis is responsible for conferring strength and support to human

skin. Alterations in collagen play an integral role in the aging process.³⁹

In the dermis of young adults, collagen bundles are well organized; they are arranged in such a way that allows for extension, with return to their resting state facilitated by the interwoven elastic fibers.³² In aging there is an increase in density of collagen bundles⁴⁵ and they lose their extensible configuration, becoming fragmented, disorganized, and less soluble.^{46,47}

Both UVR and the intrinsic aging process, mainly through the production of reactive oxygen species (ROS), result in upregulation of the collagen degrading enzymes matrix metalloproteinases.⁴⁸ In addition, there is a decrease in collagen synthesis⁴⁹ and thus a shift in the balance between synthesis and degradation occurs.⁸ Different collagens in the skin have different functions and they are all affected differently by the aging process. In young skin collagen I comprises 80% of dermal collagen and type III makes up 15%; however, with age there is a decrease in collagen I with a resultant increase in the ratio of type III to type I collagen.^{47,50} There are also changes to levels of collagen IV and VII. Collagen IV, an integral part of the dermoepidermal junction, provides a structural framework for other molecules and plays a key role in maintaining mechanical stability³⁹ and collagen VII is critical for basement membrane binding to the underlying papillary dermis.³⁹ There are significantly lower levels of both collagen IV and collagen VII at the base of wrinkles and it is speculated that loss of these collagens contributes to wrinkle formation.⁵¹

Elastin

Elastin exhibits numerous age-related changes, including slow degradation^{52,53} and accumulation of damage in existing elastin with intrinsic aging,⁵² increased synthesis of apparently abnormal elastin in photo-exposed areas,⁵⁴ and abnormal localization of elastin in the upper dermis of photodamaged skin.²¹

Histologically, one of the most striking features of photodamaged skin is the change in elastotic material. On hematoxylin and eosin staining, there is an area of amorphous blue staining in the superficial to mid-dermis, and is referred to as "solar elastosis." This represents a tangled mass of degraded elastic fibers accompanied by amorphous material composed of disorganized tropoelastin and fibrillin in the upper dermis.¹¹ Even in sun-protected sites, most elastin fibers appear abnormal after the age of 70 years.^{44,55} This abnormal elastotic material provides neither elasticity nor resilience to the skin.

Glycosaminoglycans and water content

Glycosaminoglycans (GAGs) along with collagen and elastin are major constituents of the skin, and include hyaluronic acid, dermatan sulfate, and chondroitin sulfate.³⁹ The key role of these molecules is to bind water, and their presence enables the skin to remain plump, soft, and hydrated.³⁹ In photoaged skin the level of GAGs increases^{56,57}; however, these molecules are unable to exert their hydrating effect as they are deposited on elastotic material rather than scattered diffusely in the dermis, as in young or photoprotected skin.⁵⁷

Young skin is well hydrated as most of the water is bound to proteins.⁵⁸ Water molecules that are not bound

to proteins bind to each other and form what is known as tetrahedron or bulk water.⁵⁸ In intrinsically aged skin, water structure and binding does not appear to be altered significantly.⁵⁶ In photoaged skin there is an increase in total water content⁵⁶; however, as proteins are more hydrophobic⁵⁹ and folded^{56,58} than those in sun-protected skin, and GAGs are deposited on elastotic material, water binds to itself rather than to these molecules, and so is present mostly in the tetrahedron form.⁵⁶ In addition, tetrahedron water does not offer the same level of hydration and turgor as the bound form of water, thus contributing to the dry xerotic appearance of photoaged skin.²¹

Dermal vasculature

Although not all studies are in agreement, it appears that increased age may be associated with decreased cutaneous perfusion, especially in photo-exposed areas.²⁰ One study has demonstrated a 35% reduction in venous cross-sectional area in aged skin as opposed to young skin.⁶⁰ This reduction in vascularity is particularly noticeable in the papillary dermis (superficial dermis), where there is loss of the vertical capillary loops. Reduced vascularity results in skin pallor, depleted nutrient exchange, and disturbed thermoregulation.³⁹ There is some evidence that the vasoconstrictive or vasodilatory responses to cold and heat, respectively, are delayed in the elderly, further diminishing thermoregulatory responses.²⁰ In addition, dermal vasculature in mildly photodamaged skin displays venule wall thickening. However, in severely photodamaged skin the walls are thinned and become dilated, manifesting clinically as telangiectasia.¹¹

SWEAT GLANDS

Eccrine sweat glands

There is a reduction in the number of eccrine sweat glands⁶¹ and output per gland⁶² with increasing age, which also impacts on thermoregulation. There is an equally reduced response to the effects of epinephrine in men and women in old age; however, there is a far greater decrease in response to acetylcholine in men than in women in old age. This suggests that the effects of cholinergic sweating are indirectly affected by hormones.⁶² Further evidence for this is provided by the observation that the maximum rate of cholinergic sweating is far greater in adult males than in adult females or juveniles, and is probably therefore androgen-dependent.⁶³

Apocrine sweat glands

Apocrine gland activity is diminished, probably as a consequence of declining testosterone levels, leading to a reduction in both pheromone secretion and consequent body odor.⁶⁴

SEBACEOUS GLANDS

Age does not alter the number of sebaceous glands, although they become hyperplastic and larger,⁶⁵ particularly in photoaged skin and may present as giant comedones. Despite this increase in size, there is a 50% reduction in sebum production,⁶⁶ which contributes to xerosis of aged skin. Some investigators believe that this is due to decreased levels of testosterone,⁶⁷ although this does not explain the hyperplasia. In addition, the constituency of

aged sebum is altered, in that it contains less free cholesterol and more squalene.⁶⁸

Nails

Nail growth increases until about the age of 25 years, thereafter it starts to decrease.³² Until the age of 70, nail growth is greater in men than women, after which the situation appears to be reversed.⁶⁹ Nails become more brittle in the elderly and develop beaded ridging. This brittleness may be caused by a reduction in lipophilic sterols and free fatty acids.⁷⁰

Hair

Changes in hair color and density are very visible indicators of age and are the target of endless manipulation to maintain a youthful appearance. It is estimated that by the age of 50, approximately 50% of people are 50% gray, irrespective of hair color and sex.⁷¹ Hair graying appears to be a consequence of an overall and specific depletion of hair bulb and outer root sheath melanocytes, as melanocytes are still detected in sebaceous glands and the surrounding interfollicular epidermis.⁷² The mechanism for this steady depletion remains uncertain.

With age there are changes in hair follicle density, hair shaft diameter, and rate of hair growth. These changes are brought about through a variety of mechanisms and vary greatly according to site. Chest, axillary, and pubic hair all decrease in density with age; however, in men there is often increased hair growth in the eyebrows, around the external auditory meati, and in nostrils.³² In elderly women there is conversion of vellus to terminal hairs on the chin and moustache.

Aside from intrinsic aging, a principal influence on hair with age is androgenetic alopecia. This is a genetically predetermined condition that results in patterned scalp hair loss and arises due to increased sensitivity of hair follicles to the effects of dihydrotestosterone, produced by breakdown of free testosterone by the enzyme 5 α -reductase.⁷³ It affects at least 50% of men by the age of 50 years and 50% of women by the age of 60 years.⁷⁴ Hairs in the affected area become finer and less pigmented until they resemble vellus hairs.⁷⁴

Immune function

The density of Langerhans cells in the skin decreases greatly in the elderly even in sun-protected sites.^{75,76} Not only is there a reduction in the number of Langerhans cells, but they have reduced ability to migrate from the epidermis in response to tumor necrosis factor- α .⁷⁷ Similarly, T cells are reduced in number and become less responsive to specific antigens.^{27,78} Aging skin also appears to have a reduced ability to produce certain cytokines such as interleukin-2,⁷⁹ whereas there is an increase in other cytokines such as interleukin-4.⁷⁹ The consequence of these changes is a reduced intensity to delayed hypersensitivity reactions³ and increased susceptibility to photocarcinogenesis and chronic skin infections.³⁴

Nerves and sensation

There is a decrease in sensory perception and an increase in pain threshold with age.⁸⁰ It has been demonstrated that there is loss of Meissner's corpuscles in the little finger, from

over 30/mm² in young adults to approximately 12/mm² by the age of 70 years.⁸¹

Subcutaneous tissue

There are age-dependent changes in subcutaneous fat distribution. There is loss of fat from the face, dorsal aspects of the hands and the shins, with gains in subcutaneous fat in other areas, particularly the waist in women and abdomen in men.³⁸

Women

Reduced estrogen levels in postmenopausal women contribute to wrinkling, dryness, atrophy, laxity, poor wound healing, and vulvar atrophy.⁸² Studies suggest that loss of collagen is more closely related to postmenopausal age than chronological age, and thus reflects hormonal effects.^{83,84} Estrogen therapy appears to prevent collagen loss in women with higher baseline levels of collagen, and stimulates synthesis of collagen in those that have lower initial collagen levels.^{85,86} Studies have also supported a relationship between estrogen deprivation and degenerative changes of dermal elastic tissue.⁸⁷ However, it remains uncertain whether there are beneficial effects of estrogen therapy on skin elasticity.⁸⁸ There is some evidence that hormone replacement therapy (HRT) improves skin dryness⁸⁹ and wound healing,⁹⁰ and increases skin surface lipids.^{91,92}

Mechanism

The production of reactive oxygen species (ROS) or free radicals, through UVR, smoking, pollution, and normal endogenous metabolic processes, is thought to contribute to the process of aging in the skin. ROS induces gene expression pathways that result in increased degradation of collagen and accumulation of elastin.⁹³ ROS not only directly destroys interstitial collagen, but also inactivates tissue inhibitors of matrix-metalloproteases and induces the synthesis and activation of matrix degrading metalloproteases.⁹³

Hormones have also been shown to play a role. Postmenopausal hormone changes are responsible for a rapid worsening of skin structure and functions, which can be at least partially repaired by HRT or local estrogen treatment.^{84,94}

Mitochondrial DNA (mtDNA), due to repeated constitutional oxidative stress, incurs regular DNA damage and in particular deletion of a specific length of DNA, which is known as the "common deletion." This deletion is 10 times more common in photodamaged than in sun-protected skin. It results in decreased mitochondrial function and further accumulation of ROS, with additional damage to the cell's ability to generate energy. The extent of mtDNA damage in photodamaged skin does not correlate with the chronological age of the person, but rather with photodamage severity (reviewed by Yaar and Gilchrist¹¹).

UVR can accelerate telomere shortening, which occurs ordinarily with every cell division. This results in the activation of DNA damage response proteins such as p53, the tumor suppressor protein, thereby inducing proliferative senescence or apoptosis, depending on the cell type.^{6,95}

Treatment and prevention

Sun avoidance and sunscreen use is central to preventing age-related skin changes. Aside from this there are a number of products of proven and still controversial efficacy.

Topical retinoids can cause a significant improvement in skin surface roughness, fine and coarse wrinkling, mottled pigmentation, and sallowness.⁹⁶ Histologically, there is reduction and redistribution of epidermal melanin, increased papillary dermal collagen deposition, and increased vascularity of the papillary dermis. Tretinoin treatment not only improves photodamage, but also reverses histologic changes associated with intrinsic aging.^{97,98} These effects are thought to be mediated via the nuclear retinoic acid receptors (RARs). Retinoids not only improve the cosmetic appearance of aging, but also help prevent skin cancer.¹¹

There are also many novel therapies undergoing investigation. For instance, the delivery of enzymes that assist in DNA repair, antioxidants such as the polyphenols, flavinoids, alpha-hydroxy acids, and many others. Dietary lipids appear to play a role in skin aging. There is evidence that a low-fat diet provides some protection against the development of actinic keratoses⁹⁹; however, certain dietary fats appear to be protective against UV-induced damage.¹¹ Future treatments include inducing cutaneous pigmentation, thus protecting the skin from UVR damage, and various approaches to this are in development.¹¹ Nonmedical therapies include laser treatment, injectable fillers, botulinum toxin, and of course surgery.

CONCLUSION

Skin is subject to a complex blend of intrinsic and extrinsic aging processes and is particularly vulnerable to environmental insults, namely UVR. Although there are numerous

defense mechanisms to protect the skin from damage, the efficacy of these diminish over time, resulting in the clinical features associated with aging and the development of skin cancers. Sun protection is the key to prevention and novel therapies are also emerging.

KEY POINTS

Aging and the Skin

- Aging of the skin is affected by intrinsic and extrinsic factors.
- UV radiation is responsible for most of the visible signs of aging and is known as photoaging.
- Photoaging is seen on sun-exposed sites, such as the face and forearms.
- Photoaging results in increased degradation of collagen and increased deposition of abnormal elastin in the dermis.
- Intrinsic aging is associated with fine wrinkling, xerosis (dryness), and skin laxity. Extrinsic aging is associated with coarse wrinkles, xerosis, mottled dyspigmentation, skin laxity, roughness, and the development of malignant neoplasms.
- The mechanisms for aging skin include the actions of ROS, mtDNA mutations, and telomere shortening.
- Hormonal changes, particularly in women, are important for skin aging.
- The key to treatment is prevention through sun protection, but other novel therapies are emerging.

Each day worldwide, elderly people consume millions of doses of medications. This remarkable amount of medication use benefits many elderly people greatly by preventing and treating disease, preserving functional status, prolonging life, and improving or maintaining good quality of life. However, this level of medication exposure may also harm elderly people via adverse drug reactions and is associated with problems such as drug interactions. The harmful and beneficial responses of elderly individuals to drugs are partially dependent upon age-related physiologic changes that influence how the body handles a given drug (i.e., pharmacokinetics) and what a drug does to the body (i.e., pharmacodynamics). To obtain the desired therapeutic response and prevent drug-related problems, it is also useful to have an understanding of drug use patterns in the elderly. Therefore, this chapter first examines the epidemiology of drug use in elderly populations around the world, followed by age-related alterations in drug pharmacokinetics and pharmacodynamics, and finally drug interactions.

EPIDEMIOLOGY OF DRUG USE

In general, the number of medications (prescription and nonprescription) used by older individuals is greater than the number used by younger persons.¹ The number and type of medications used by elders are based in part on living situations and access to medications, as detailed later.

In the community

More than 75% of community-dwelling elderly people use one or more medications, with percentages varying by country: Sweden (93%), Netherlands (90%), United States (88%), Italy (93%), Canada (75%), and Ireland (75%).²⁻⁷ The average number of medications being used at a given time is higher for U.S. elders compared with elders elsewhere. The U.S. average ranges between 3 and 8, whereas the average in Sweden is 4.2, the average in Taiwan is 4.7, and the average in Italy is 3.5.^{2,4,5,8-10} The most common types of medications are cardiovascular, gastrointestinal, central nervous system, analgesic, and vitamin agents.^{1,2,5,6,10-13} The most common factor associated with medication use is gender, with females using more medications than males.^{1,5,12-16} Increasing age has also been associated with increased medication use in the United States, Canada, and the United Kingdom.^{11,12,14,16} In the United States, race has been associated with differences in medication use, with African Americans and Hispanic Americans demonstrating less use than whites.^{9,17}

In hospitals

Medication use by elderly people at the time of hospital discharge is slightly higher than that of community-dwelling elders; it ranges, on average, from about 3 white medications in Germany to 5 in the United States, Australia, and the Netherlands.¹⁸⁻²¹ There is a paucity of information with regard to the types of medications used by elders in this setting. However, in small studies conducted in the Netherlands,

the United States, and Australia, the most common types of medications are cardiovascular, gastrointestinal, central nervous system, and analgesic agents, with noticeably frequent use of antimicrobials and laxatives.¹⁸⁻²⁰ There are conflicting studies regarding whether sex, increasing age, and the number of medical conditions are factors enhancing medication use in this setting.^{1,7,18-21}

In long-term care facilities

The level of medication use by elderly people in long-term care facilities (LTCFs) is generally higher than that of elders living at home.²² For example, more than 75% of U.S. LTCF residents receive four or more medications compared with 51% of Italian residents, 41% of Japanese residents, and 27% of Irish residents.^{7,8,23} There is also disparity worldwide in the percentages of LTCF residents taking large numbers of medications. In the United States and Iceland, 33% of LTCF residents take 7 to 10 medications, whereas only 5% of residents exhibit this degree of use in Denmark, Italy, Japan, and Sweden.²³ The average number of routinely scheduled medications in most LTCF populations ranges from 4 to 5, except in the United States and Sweden where the average is 6 to 7.^{2,7,8,22,24-26}

The most common types of medications used are cardiovascular, central nervous system, laxative, and analgesic agents.^{7,8,27} Overuse of certain centrally active medications, namely psychotropics, can be a particular problem in the LTCF setting.²⁸ Factors that have been associated with increased psychotropic use include dementia or mental illness and lack of drug monitoring.²⁹ Before 1987, there was a higher rate of usage of these agents in U.S. LTCFs.²⁸ Federal legislation was then enacted that defined clear indications for appropriate prescribing of these agents and mandated close monitoring of them (Omnibus Budget Reconciliation Act or OBRA 1987), resulting in a dramatic reduction in use.²⁹ Psychotropic medication usage rates are much higher in LTCFs in countries where there is no such monitoring.²⁹

Access to medications

Universal public health insurance programs for elderly people in Australia, Sweden, Canada, France, Germany, Japan, New Zealand, and the United Kingdom provide some level of drug benefit coverage, with the drug benefits differing in the amount of cost sharing, the maximum amount of coverage, and the specific pharmaceuticals covered.³⁰ The U.S. health insurance program for the elderly, Medicare, began coverage of outpatient drugs in 2006 via Medicare Part D. Although characterized by substantial copayments and an absence of coverage over a small but fixed drug cost range (the so-called "doughnut hole"), U.S. elders are now protected from catastrophic out-of-pocket costs for outpatient drugs. This in turn has improved adherence and reduced the need for elders to forgo necessities to purchase medications.³¹⁻³³ Additionally, in developing countries, the supply of medications may be inadequate or too expensive for elders to purchase.³⁴

ALTERED PHARMACOKINETICS

Table 23-1 illustrates an overview of age-related changes in drug pharmacokinetics.^{35,36} The text herein details these changes in drug absorption, distribution, metabolism, and elimination.

Absorption

Numerous changes occur in the physiology of the gastrointestinal tract as a function of advancing age that might be expected to affect the absorption of drugs administered orally.³⁷ Gastric pH rises owing to the development of atrophic gastritis (as well as the use of acid-suppressive medications to treat age-related GI disorders, such as peptic ulcer and gastroesophageal reflux). Gastric emptying is somewhat delayed and decreases are seen in intestinal blood flow (30% to 40% from age 20 to 70 years), intestinal motility, and number of functional absorptive cells.

Most drugs administered orally are absorbed via the process of passive diffusion, a process minimally affected by aging. A few agents require active transport for GI absorption and their bioavailability may be reduced as a function of aging (e.g., calcium in the setting of hypochlorhydria). Of more significance is the decrease in first-pass hepatic extraction that occurs with aging, resulting in an enhancement in systemic bioavailability for drugs such as propranolol, morphine, and meperidine after oral administration.³⁷ The bioavailability of drugs that are cytochrome P450 (CYP450) isoenzyme 3A4 and/or P-glycoprotein substrates (e.g., midazolam, verapamil) may be increased in older women but no dosage adjustment recommendations have as yet been made.³⁸

The effect of aging on drug absorption from other sites of administration such as the rectum, muscle, and skin is poorly understood. For example, conflicting results have been published regarding the effect of aging on the pharmacokinetics of transdermal fentanyl.³⁹

Distribution

A number of changes in physiology occur with aging that may impact drug distribution. Body fat as a proportion of body weight rises from 18% to 36% in males and from 33% to 45% in females from age 20 to 70 years, whereas lean body mass decreases by 19% in males and by 12% in females, and plasma volume decreases by 8% from age 20 to 80 years. Total body water decreases by 17% from age 20 to 80 years and extracellular fluid volume decreases by 40% from 20 to 65 years of age. In addition, cardiac output declines approximately 1% per year from age 30 years, and brain and cardiac vessel blood flow rates decline 0.35% to 0.5% and 0.5% per year, respectively, beyond age 25 years. Additionally, frailty and concurrent disease may result in substantial changes in the serum concentrations of the two major drug-binding plasma proteins (albumin, which binds acidic drugs, decreases, while α_1 acid glycoprotein, which binds basic drugs, remains the same or rises).⁴⁰

As a result of the above factors, the volume of distribution of water-soluble (hydrophilic) drugs is decreased and that of fat-soluble (lipophilic) drugs is increased. Moreover, changes in volume of distribution can directly affect the loading doses of medications. For many drugs, loading doses will be lower in older versus younger patients and lowest in older white and Asian females (thus use weight-based

Table 23-1. Age-Related Changes in Drug Pharmacokinetics

Pharmacokinetic Phase	Pharmacokinetic Parameters
Gastrointestinal absorption	Unchanged passive diffusion and no change in bioavailability for most drugs ↓ active transport and ↓ bioavailability for some drugs ↓ first-pass effect and ↑ bioavailability for some drugs
Distribution	↓ volume of distribution and ↑ plasma concentrations of water-soluble drugs ↑ volume of distribution and ↑ terminal disposition half-life ($t_{1/2}$) for fat-soluble drugs ↑ or ↓ free fraction of highly plasma protein-bound drugs
Hepatic metabolism	↓ clearance and ↑ $t_{1/2}$ for some oxidatively metabolized drugs ↓ clearance and ↑ $t_{1/2}$ of drugs with high hepatic extraction ratio
Renal excretion	↓ clearance and ↑ $t_{1/2}$ of renally eliminated drugs

↑ = increased; ↓ = decreased.

regimens routinely).³⁸ Decreases in serum albumin concentration can lead to a reduction in the degree of plasma protein binding of acidic drugs, such as naproxen, phenytoin, tolbutamide, and warfarin, thus increasing the drug-free fraction. Increases in α_1 acid glycoprotein because of inflammatory disease, burns, or cancer can lead to enhancement in the degree of plasma protein binding of basic drugs such as lidocaine, β -blockers, quinidine, and tricyclic antidepressants, thus reducing the drug-free fraction. Provided there is no compromise in excretory pathways, these potential changes are unlikely to be clinically significant. However, plasma protein binding changes can alter the relationship of unbound (free) and total (unbound + bound) plasma drug concentrations, making drug concentration interpretation more difficult. In these cases, the measurement of free plasma drug concentrations may be preferable to the usual use of total plasma drug concentrations.

Metabolism

Although drug metabolism can occur in numerous organs, most of the available data concern the effects of aging on the liver. Over the age of 30 years, there is an approximate 1% per year decline in liver blood flow and liver mass.⁴¹

Drugs are metabolized by two types of reactions: phase I (oxidative reactions) and phase II (conjugative/synthetic reactions wherein an acetyl group or a sugar is conjugated to the drug to enhance its polarity, water-solubility, and hence, excretion via the kidneys). Most phase I reactions are mediated by CYP450 monooxygenase enzymes. Table 23-2 illustrates five CYP450 isoenzymes of clinical importance and selected substrates. Age-related declines in drug oxidation (which are substrate-specific in their extent) are thought to more closely relate to reductions in liver volume (i.e., hepatocyte mass) than reductions in hepatic enzymatic activity.⁴² Age-related decreased phase I metabolism, resulting in reduced total body clearance and increased terminal disposition half-life, has been reported for diazepam, chlor-diazepoxide, piroxicam, theophylline, and quinidine (Table 23-3). The activities of CYP450 isoenzymes 1X and 3A4, and the drug transporters P-glycoprotein and MDR1, are

Table 23-2. Selected Cytochrome P450 Substrates by Isoenzyme

CYP1A2	CYP2C9	CYP2C19	CYP2D6	CYP3A4
Caffeine	Diclofenac	Diazepam	Codeine	Alprazolam

Levodopa	Triazolam
Lidocaine	Verapamil
Morphine	

not affected by aging or differences between the sexes.³⁸ In contrast, the activities of CYP450 isoenzymes 2C9, 2C19, and 2D6 are reduced by 20% to 25% in older versus younger patients and by a further 10% to 20% in females versus males.³⁸ The effect of aging on polymorphic drug metabolism has not been well studied, although available data suggest that advancing age has no significant effect on acetylator phenotype or cytochrome P450 isoenzyme 2D6 polymorphism.^{43,44} Differences in enantiomeric disposition as a function of age are substrate-specific. For example, age-dependent changes in enantiomeric disposition have been reported for hexobarbital, propranolol, mephobarbital, and warfarin.^{45–47} Phase II reactions appear to be generally spared from any adverse effect of aging.

Age-associated reductions in hepatic blood flow can reduce the clearance of high hepatic extraction ratio drugs, such as tricyclic antidepressants, lidocaine, several opioids, and propranolol (Table 23-3).⁴¹ Numerous confounders such as race, gender, frailty, smoking, diet, and drug interactions can significantly enhance or inhibit hepatic drug metabolism in the elderly.⁴⁸

Elimination

Few data are available regarding the effect of aging on the biliary system. However, aging is associated with a significant reduction in renal mass and number and size of nephrons. In addition, glomerular filtration rate (GFR), tubular secretion, and renal blood flow decrease approximately 0.5%, 0.7%, and 1% per year, respectively, over the age of 20 years. At all ages, these three parameters are lower in women than in men.³⁸ However, elderly people are a heterogeneous group, with up to one third of healthy elders having no decrement in renal function as measured by creatinine clearance, a surrogate for glomerular filtration. In addition, tubular secretion and glomerular filtration may not

decline in parallel.⁴⁹ The estimation of creatinine clearance (CrCl), using any of a number of equations, serves as a useful screen for renal impairment in lieu of the use of serum creatinine (SCr), which is an imperfect marker of renal function in the elderly because of the reduction of muscle mass with advancing age (i.e., a "normal" serum creatinine does not equate with "normal" renal function in the elderly).⁵⁰ One useful estimation equation is that of Cockcroft and Gault⁵¹:

$$\text{CrCl (males)} = \frac{(140 - \text{age in years}) \times (\text{total body weight in kg})}{72 \times \text{SCr in mg/dL}}$$

For females, multiply the result by 0.85.

A more accurate estimation equation for renal function is the Modification of Diet in Renal Disease Simplified Algorithm³⁸:

$$\begin{aligned} \text{estimated GFR (eGFR) (mL/min/1.73 sq.m)} &= 186.3^* \\ &\times (\text{SCr}^\dagger)^{-1.154} \times (\text{age in years})^{-0.203} \end{aligned}$$

*Use 175 if using a standardized SCr assay.

†For SCr in SI units (μmol/L), divide by 88.4.

For African Americans, multiply the result by 1.212

For females, multiply the result by 0.742

An online calculator is available at www.kidney.org.

This equation is superior to that of Cockcroft and Gault in elders and the obese. Adjustment for body surface area is only needed in very small or very large individuals. It must be remembered that all current drug dosage regimen adjustments for impaired renal function are based on CrCl as estimated using the Cockcroft and Gault (or similar) equations. The utility of the MDRD equation in this area awaits further study.

Numerous medications are primarily renally excreted and/or have renally excreted active metabolites. Evidence exists of age-related reductions in the total body clearances of drugs that are primarily renally cleared (Table 23-4). The risk of adverse clinical consequences is likely increased for those drugs with narrow therapeutic margins (e.g., digoxin, aminoglycosides, chemotherapeutics). Dosage adjustment for renal impairment is easily accomplished once CrCl has been estimated. In fact, there are even guidelines available for dosage adjustment of cancer chemotherapeutic agents in elders with cancer.⁵²

Table 23-4. Drugs Whose Renal Elimination Is Impaired With Advancing Age

ACEI	Furosemide
Acetazolamide	Lithium
Amantadine	Metformin
Aminoglycosides	Procainamide/NAPA
Chlorpropamide	Ranitidine
Cimetidine	Vancomycin
Digoxin	

ACEI, angiotensin-converting enzyme inhibitor; NAPA, N-acetylprocainamide.

ALTERED PHARMACODYNAMICS

In contrast to the relationship of aging to altered pharmacokinetics, fewer data are available investigating the effect of aging on pharmacodynamics (drug response). Theoretically, altered pharmacodynamics could be due to two mechanisms: (1) altered sensitivity owing to changes in receptor number or affinity or changes in postreceptor response, and (2) age-related impairment of physiologic and homeostatic mechanisms.⁵³ This section reviews altered responses of elderly people to medications mediated by these two mechanisms.

Altered sensitivity

Table 23-5 lists those medications for which there are reasonable data documenting altered drug sensitivity in elderly people. Firm evidence exists that elders are less responsive to β -blockers and β -agonists.^{54,55} There is a diminished maximal response to furosemide.⁵³ Firm evidence also exists that elders are more sensitive to the effects of benzodiazepines. Using psychomotor testing, this has been established for nitrazepam, temazepam, midazolam, loprazolam, and diazepam.^{53,56} Enhanced sensitivity has also been demonstrated for opioids, metoclopramide, dopamine agonists, levodopa, and traditional neuroleptics.⁵³ It is well established that elderly people have enhanced sensitivity to the effects of oral anticoagulants. The underlying mechanism of this effect is unknown.⁵⁷ There is evidence for both enhanced and reduced sensitivity to calcium-channel blockers in elders measured as blood pressure response or electrocardiographic (P-R interval) response.^{53,56}

Alterations in physiologic and homeostatic mechanisms

Physiologic and homeostatic impairments in elderly people that may affect drug response include autonomic nervous system dysfunction (orthostasis, bowel/bladder dysfunction), impaired thermoregulation, reduced nutrient intake, reduced cognitive function reserve, impaired postural stability, glucose intolerance, and immunosenescence.^{58–64} The loss of efficiency of homeostatic mechanisms puts elders at risk of symptomatic orthostasis/falls (with antihypertensives, traditional neuroleptics, tricyclic antidepressants), urinary retention and constipation (with drugs with anticholinergic properties), falls and delirium (with virtually every sedating drug), and accidental hypothermia or heatstroke (with neuroleptics).

DRUG INTERACTIONS

Drug-drug interactions can be defined as the effect that the administration of one drug has on another drug.⁶⁵ The two major types of drug-drug interactions include

Table 23-5. Drugs Whose Sensitivity Is Altered With Advancing Age

		Ritonavir	

pharmacokinetic interactions, wherein drug absorption, distribution, metabolism, and excretion are affected and pharmacodynamic interactions, wherein pharmacologic effect is altered. Drugs may also interact with food, nutritional status, herbal products, alcohol, and preexisting diseases.^{66–69}

Pharmacokinetic interactions

Increased drug bioavailability may be seen with the concurrent ingestion of grapefruit juice owing to its inhibitory effect on CYP450 isoenzyme 3A4-mediated first-pass metabolism in the gut wall and liver. This may result in exaggerated pharmacologic effects.⁷⁰ Decreased bioavailability can be seen when phenytoin is administered with enteral feedings.⁷¹ Multivalent cations (e.g., antacids, sucralate, iron, calcium supplements) can reduce the bioavailability of tetracycline and quinolone antimicrobials.⁷²

Drug interactions involving drug distribution are primarily related to altered plasma protein binding. Although a number of drugs may displace other drugs from plasma protein binding sites, especially acids such as salicylate, valproic acid, and phenytoin, this type of drug interaction is rarely clinically significant.

Drug interactions most likely to be clinically significant are those that involve the inhibition or induction of metabolism of narrow therapeutic margin drugs.⁷³ Table 23-6 illustrates selected CYP450 enzyme inducers and inhibitors. It does not appear that young and elderly individuals differ in the magnitude of hepatic enzyme inhibition after exposure to drugs such as cimetidine, macrolide antimicrobials (e.g., erythromycin, clarithromycin), quinidine, and ciprofloxacin.^{72,74} However, there is controversy regarding the effect of hepatic enzyme inducers in young versus elderly individuals, with some studies demonstrating no difference between the age groups, whereas others suggest that elders do not

Table 23-7. Most Common Herbal-Drug Interactions⁸¹

Interacting Drug	Herbs (Vernacular Names)	Description of the Effect of Herbs on Drug Kinetics/Activity
Warfarin	St John's wort, ginseng	↓ INR
	Garlic, danshen, ginkgo, devil's claw, dong quai, papaya, glucosamine	↑ INR
ASA, NSAIDs, dipyridamole, clopidogrel/ticlopidine	Garlic, ginseng, ginkgo, ginger, feverfew	↑ bleeding time
	Ginkgo	↑ bleeding time
Amitriptyline	St. John's wort	↓ drug concentration
Warfarin		
Theophylline		
Simvastatin		
Alprazolam		
Verapamil		
Digoxin		
Iron		
Ethanol	Ginseng	
Phenytoin	Shank hapusphi	
Phenytoin	Ginkgo	
Valproate		
Iron	Feverfew	
	Camomile	
Metformin	Guar gum	
Glibenclamide		
Digoxin		
Lithium	Psyllium	
ASA	Tamarind	↑ drug concentration
Nifedipine	Ginkgo	
Sertraline	St. John's wort	Serotonin syndrome (mild)
Paroxetine		
Trazodone		
Nefazodone		
Chlorpropamide	Garlic	↓ glucose concentrations
Antidiabetic drugs	Fenugreek	
MAOIs	Ginseng	Manic-like symptoms, headache, tremors
Thiazides	Ginkgo	↓ drug effect
	Dandelion	
	Uva-ursi	
Thyroxine	Horseradish	
	Kelp	
Phenytoin	Shank hapusphi	
Warfarin	Ginkgo	↑ drug effect
ASA		
NSAIDs		
Dipyridamole		
Clopidogrel/ticlopidine		
Benzodiazepines	Kava	
Barbiturates		
Opioids		
Ethanol		
Barbiturates	Valerian	
Other CNS depressants		
Digoxin	Hawthorne	
Thiazides	Gossypol	
Levodopa	Ginkgo	↑ "off" periods in Parkinson disease
Anabolic steroids	Echinacea	↑ Hepatotoxicity risk
Amiodarone		
Methotrexate		
Ketoconazole		
Caffeine	Ma huang	Hypertension, insomnia, tachycardia, nervousness, tremor, headache, seizures, ↑ MI/stroke risk
Stimulants		
Decongestants		
Tricyclic antidepressants	Yohimbine	Hypertension
Heparin	Fenugreek	↑ bleeding risk
Clopidogrel/ticlopidine		
Warfarin		

Abbreviations: ↓ = decreased; ↑ = increased; *INR*, international normalized ratio (of prothrombin time); *ASA*, aspirin; *NSAID*, nonsteroidal anti-inflammatory drug; *MAOI*, nonselective monoamine oxidase inhibitor; *CNS*, central nervous system; *MI*, myocardial infarction.

Table 23-8. Drug-Disease Interactions to Avoid in the Elderly as Defined by Explicit Criteria by Canadian and U.S. Consensus Panels^{82,83}

Drug or Drug Class	Disease
α -Agonist decongestants	Benign prostatic hypertrophy, insomnia, hypertension
α -Blockers	Stress incontinence
Anticholinergic antihistamines	Benign prostatic hypertrophy, stress incontinence, cognitive impairment, constipation
Anticholinergic tricyclic antidepressants	Benign prostatic hypertrophy, stress incontinence, cognitive impairment, constipation, syncope/falls, arrhythmias, heart block, postural hypotension, glaucoma
Aspirin (>325 mg/day)	Peptic ulcer, blood clotting disorders or while taking anticoagulants
Barbiturates	Cognitive impairment
Benzodiazepines, long half-life	Chronic obstructive pulmonary disease, stress incontinence, depression, falls
Benzodiazepines, short-intermediate half-life	Syncope/falls
Bupropion	Seizures
Calcium-channel blockers	Heart failure, constipation
Chlorpromazine	Postural hypotension, seizures
Clopidogrel	Blood clotting disorders or while taking anticoagulants
Clozapine	Seizures
CNS stimulants	Hypertension, anorexia, malnutrition, cognitive impairment, insomnia
Dipyridamole	Blood clotting disorders or while taking anticoagulants
Disopyramide	Heart failure
Gastrointestinal, genitourinary antispasmodics	Benign prostatic hypertrophy, stress incontinence, cognitive impairment, constipation
Methylphenidate	Insomnia
Metoclopramide	Parkinson's disease
Monoamine oxidase inhibitors	Insomnia
Neuroleptics, traditional	Parkinson's disease
Nonsteroidal anti-inflammatory drugs	Chronic renal failure, heart failure, hypertension, peptic ulcer*
Olanzapine	Obesity
Propranolol	Chronic obstructive pulmonary disease
Pseudoephedrine, phenylephrine	Hypertension, benign prostatic hypertrophy, insomnia
Skeletal muscle relaxants	Benign prostatic hypertrophy, cognitive impairment
Tacrine	Parkinson's disease
Theophylline	Insomnia
Thiazide diuretics	Gout
Thioridazine	Seizures
Thiothixene	Seizures
Ticlopidine	Blood clotting disorders or while taking anticoagulants
Tolterodine	Benign prostatic hypertrophy

*Except celecoxib (in absence of ASA).

respond as well to enzyme induction.^{45,75–77} It may be that these effects are substrate- and/or inducer-specific.

Inhibition of renal clearance of one drug by another drug can also result in clinically significant effects.⁷⁸ Many of these drug-drug interactions involve competitive inhibition of tubular secretion of anionic or cationic drugs. Cationic agents include amiodarone, cimetidine, digoxin, procainamide, quinidine, ranitidine, trimethoprim, and verapamil. Anionic agents include cephalosporins, indomethacin, methotrexate, penicillins, probenecid, salicylates, and thiazides.

Drug interactions with herbal and over-the-counter (OTC) products are frequently overlooked. In one series, 52% of all moderate- or high-risk interactions occurred between prescription drugs and herbal and/or OTC products.⁷⁹ The interaction potential of herbal products is enhanced because of frequent contamination with heavy metals and adulteration with prescription drugs (e.g., NSAIDs, corticosteroids, psychotherapeutics, and phosphodiesterase-5 inhibitors such as sildenafil).⁸⁰ Table 23-7 illustrates the most common herbal-drug interactions.^{80,81}

Pharmacodynamic interactions

Some drugs may alter the response of another drug and produce adverse effects. A good example of this is the synergistic effect of taking more than one anticholinergic agent concurrently, which can result in delirium, urinary retention, constipation, and other problems.⁶⁵ Other examples include

additive bradycardia when β -blockers are administered concurrently with verapamil or diltiazem, additive hypotension when several antihypertensives are administered concurrently, and sedation/falls when several CNS depressants (e.g., benzodiazepines, sedative-hypnotics, antidepressants, neuroleptics) are administered concurrently.

Drug-disease interactions

Drug interactions can also be considered in a broader sense when they involve medications that can affect and can be affected by disease states. Elderly people are at higher risk for adverse outcomes with drug-disease state interactions owing to alterations in homeostatic mechanisms, diminished physiologic reserve, and multiple comorbidities. Recently, a national expert panel from Canada and another from the United States developed a list of potentially clinically important drug-disease state interactions (Table 23-8).^{82,83} Unfortunately, explicit quality indicators (such as the Beers list⁸³) cannot be easily transferred from one country to another, or even from one setting to another, without being modified and revalidated because of contextual differences.⁸⁴

SUMMARY

Elderly people consume a disproportionate share of medications. Factors enhancing medication use include the concurrent presence of multiple diseases, female gender, increasing

level of care, and increasing age. Other factors that probably influence drug use in elderly people include provider prescribing behaviors, cultural milieu, psychosocial issues (i.e., living alone, anxiety, depression), and direct-to-consumer advertising by the pharmaceutical industry.

The most common classes of medications in the elderly include cardiovascular, gastrointestinal, central nervous system, and analgesic agents. Many studies have documented that the aging process alters drug disposition and response. Changes in body composition with aging result in an altered volume of distribution for many drugs. Age-related changes in plasma protein binding may alter the relationship of unbound and total plasma drug concentrations.

Phase I hepatic metabolism is often reduced in older patients, resulting in reduced clearance and increased terminal disposition half-life for many commonly used drugs. Age-related decline in renal function decreases clearance and increases the terminal disposition half-life of renally eliminated drugs. Pharmacodynamic studies indicate that elderly individuals tend to be more sensitive to the effects of benzodiazepines, opioids, dopamine-receptor antagonists, and warfarin. Drug-drug and drug-disease interactions may also impact elders' well-being.

Knowledge of this information is important for achieving the maximal benefits of medications in the elderly while minimizing or preventing drug-related problems.

KEY POINTS

Pharmacology of Aging

- The elderly are avid consumers of medications.
- Age-related alterations in drug pharmacokinetics are most pronounced in terms of the decline in the hepatic metabolism and renal elimination of certain drugs.
- Age-related alterations in drug pharmacodynamics are understudied, but older adults appear to be more sensitive to the effects of benzodiazepines, opioids, dopamine-receptor antagonists, and warfarin.
- Drug-drug and drug-disease interactions are common in older adults and may have a negative impact on health-related quality of life.

Attempts to reverse the aging process stretch back to the time when Adam and Eve were expelled from the Garden of Eden. Since then, both wise sages and charlatans have made numerous pronouncements on what the populace should do to extend their lifespan. In most cases this has required those who wish to benefit to pay exorbitant sums of money to those who have developed the magical elixir of longevity. This has led to the concept that antiaging medicine is a scam.

On the other hand, we have seen a remarkable extension in longevity over the last century. In the United States, at the start of the twentieth century half of the population was dead by 50 years of age, whereas by the dawn of the twenty-first century half of females lived to over 80 years of age. These dramatic changes were brought about by public health measures such as improved sanitation, a greatly improved and available food supply, the introduction of antibiotics, vaccinations, improved care of pregnant women and the birthing process, enhanced surgical techniques, and to a lesser extent a variety of new medications introduced in the second half of the twentieth century. One needs also to give credit to the improved work environment and the decrease in excessive manual labor.

The secret to longevity appears often to be following a healthy lifestyle and avoiding excesses. In the thirteenth century, Friar Roger Bacon in England wrote a best-selling antiaging book.¹ His secrets to longevity were:

- A controlled diet
- Proper rest
- Exercise
- Moderation in lifestyle
- Good hygiene
- Inhaling the breath of a young virgin

Clearly the first five recommendations, although relatively boring, remain today a reasonable approach to prolonging life and improving its quality. However, it was “the breath of a young virgin” that made the book popular. Modern antiaging books tend to follow this same formula with a set of sensible advice mixed in with the modern “breath of a virgin.” These similarly ridiculous suggestions range the gamut from growth hormone, through herbs and megavitamins, to infusions to remove calcium from arteries.

George Valiant, a Harvard psychiatrist, studies inner city persons and Harvard graduates from their mid-50s.² His studies suggest that aging successfully occurred in those individuals who:

- Got some exercise
- Did not smoke
- Managed crises well
- Did not abuse alcohol
- Enjoyed a stable marriage
- Were not obese (although this applied only to inner city folk)

Recently, the Norfolk-EPIC study found that persons who followed four simple lifestyle habits were physiologically 14 years younger than those who did none of them.³ The four magical ingredients that produced this greatly improved outcome were:

- Not smoking
- Getting some exercise
- Eating five helpings of fruit and vegetables each day
- Drinking 1 to 14 glasses of alcohol per week

As long-lived populations tend to come from places such as Japan, Macau, and Hong Kong, where there is a high preponderance of fish in the diet, it is most probably reasonable to suggest that fatty fish intake, rich in eicosahexanoic and docosahexanoic acid, should be included in a diet of a person who wishes to live for a long time.⁴

A BRIEF HISTORY OF ANTIAGING MEDICINE

In ancient Egypt the olive leaf was used to improve beauty and extend life.⁵ This is paralleled in the twenty-first century by the recognition that the Mediterranean diet is associated with longer and healthier lives. Ayurvedic medicine in India developed specific diets, lifestyle practices, and herbs that would extend life.

The search for the Fountain of Youth was first made famous by Ponce de Leon, the Governor of Puerto Rico, who went searching for Bimini, where it was believed that there was a fountain of youth. Instead he discovered Florida, a modern day haven for retirees in the United States. In 1933, in a fictitious book called “Lost Horizon,” James Hilton created a paradise where no one aged, called Shangri-la. So riveting was this concept for the public that a number of expeditions set out to try and find this paradise in the Himalayan Mountains. Nobel Prize winner Elie Metchnikoff mistakenly believed that Bulgarians lived extremely long lives and this was due to yogurt. This created an antiaging cult based on eating yogurt.

The modern quasi-scientific approach to antiaging medicine was expressed in the book *Life Extension* by Durk Pearson and Sandy Shaw, published in 1982.⁶ In an 858-page volume they provided detailed accounts of animal experiments that increased longevity, claiming that their book was “for anyone, regardless of age, who seeks greater youthfulness—*starting right now.*” This book opened the door to multiple others where snippets of animal science were fed to the public, suggesting that these findings should be used by humans who wished to live a long life.

The American Academy of Anti-Aging Medicine (A4M) was founded in 1992 by Drs Ronald Klatz and Robert Goldman. Its avowed purpose is to advance “technology to detect, prevent and treat aging related disease and promote research into methods to retard and optimize the human aging process.” It provides a number of certifications for physicians in antiaging medicine. It claims to have more than 20,000 members from more than 100 countries (www.worldhealth.net;

accessed Sept. 28, 2008). It produces the *International Journal of Anti-Aging Medicine*.

The Life Extension Foundation is based in Florida and produces the monthly magazine, *Life Extension*. Its readership is thought to be in the neighborhood of 350,000. It was founded by Saul Kent in 1980. It also sells dietary supplements by mail order.

Two more mainstream physicians whose books have promoted antiaging philosophies are Andrew Weil and Deepak Chopra.

Aubrey De Grey, a Cambridge-educated scientist, has developed a theory called "Strategies for Engineered Negligible Senescence." He has been extraordinarily successful at promoting his theories to the lay public. He suggests that there are seven types of aging damage, which are readily open to treatment.

- Cancer mutations
- Mitochondrial mutations
- Intracellular junk
- Extracellular junk
- Cell loss
- Cell senescence
- Extracellular cross-links

The De Grey SENS proposal has been widely criticized by gerontologists: "Each one of the specific proposals that comprise the SENS agenda is, at our present stage of ignorance, exceptionally optimistic," and it "will take decades of hard work, if (these proposals) ever prove to be useful."⁷ His approach is a classic example of the quasi-scientific methods that have been used to create antiaging literature.

The most extensive criticism of the modern antiaging medicine came in 2002 from Olshansky, Hayflick, and Carnes.⁸ The article stated, "no currently marketed intervention has yet been proved to slow, stop or reverse human aging.... The entrepreneurs, physicians and other health care practitioners who make these claims are taking advantage of consumers who cannot easily distinguish between the hype and reality of interventions designed to influence the aging process and age-related diseases."

Caloric restriction

In 1934, Mary Crowell and Clive McKay at Cornell University published a series of experiments showing that limiting the food intake of laboratory rats (dietary restriction) resulted in prolongation of their lives.⁹ Subsequently, studies in some, but not all species, have shown that caloric restriction results in a prolongation of lives. Recent studies have suggested that caloric restriction needs to be started in younger animals and it fails to prolong life in older animals.¹⁰

Studies in monkeys have suggested that dietary restriction improves the metabolic profile (glucose, cholesterol) in these animals¹¹ and may attenuate Alzheimer's-like amyloid changes in their brains.¹² However, these animals also show a loss of bone and an increased propensity to develop hip fractures.

Numerous theories exist as to why caloric restriction may enhance longevity. The hormesis theory of caloric restriction suggests that caloric restriction represents a low level of stress, which allows the animal to develop enhanced defenses that slow the aging process. It has also been suggested that caloric restriction reduces oxidative damage,

enhances insulin sensitivity, and decreases tissue glycation. The "silent information regulator" (Sir) gene is upregulated by caloric restriction in yeast and in mammals. However, the role of Sir genes in longevity is controversial.

The Caloric Restriction Society was founded in 1984 by Ray and Lisa Walford and Brian Delaney. Members of this society practice caloric restriction to varying degrees. Studies of members of this society suggest that they have lower blood pressure, glucose, and cholesterol values.¹³ The National Institutes of Health have funded a number of short-term studies to determine the utility of caloric restriction in middle-aged persons. The enthusiasm for caloric restriction in older persons has been tempered by multiple studies in persons over 60 years of age showing that weight loss is associated with increased institutionalization, increased mortality, and increased hip fracture.¹⁴

At present, there are a number of caloric-restriction diets that are advertised to the public as a method for life prolongation. The CRON-diet (Caloric Restriction with Optimal Nutrition) was developed by Roy Walford and Brian Delaney. It was based on the research conducted in the Biosphere. In general this diet recommends a 20% caloric restriction based on determining one's basal metabolic rate. The Okinawa diet is a low calorie, nutrient-rich diet based on the original diet of the people living on the Japanese island of Okinawa (Ryukyu Islands). Its popularity is based on the large number of centenarians who used to live in the Ojime Village on Okinawa. The diet is calorie restricted compared with the Japanese diet. It predominantly consists of vegetables (especially sweet potatoes), a half a serving of fish per day, legumes, and soy. It is low in meat, eggs, and dairy products. The New Longevity Diet by Henry Mallek represents a popularization of other longevity diets. It needs to be recognized that none of these diets has been proven to extend longevity. It is interesting to note that Roy Walford, a major proponent of dietary restriction, died at 79 years of age of amyotrophic lateral sclerosis. Animal studies have suggested that caloric restriction is especially bad for animals with amyotrophic lateral sclerosis.

Exercise

Exercise in moderation appears to be a cornerstone of longevity. Mice with an excess of phosphoenolpyruvate carboxykinase (PEPCK-C) in their skeletal muscle are more active than their controls and can run for 5 km at a speed of 20 m/min compared with 0.2 km for control mice.¹⁵ These mice live longer than controls and females remain reproductively active until 35 months of age.

Observational studies in humans have strongly suggested that those who are physically active live longer. In a study of 70- to 80-year-olds, those with higher total energy expenditure lived longer than those with less energy expenditure.¹⁶ A major factor in enhancing energy expenditure was stair climbing.

Fries found that older runners compared with sedentary older persons tended to become disabled 13 years later.¹⁷ The LIFE Pilot study showed that a structured physical activity program significantly improved functional performance. Walking speed is associated with decreased disability. Physical activity is associated with decreased dysphoria. Persons aged 50 years of age who exercise regularly are less liable to develop Alzheimer's disease as they age.¹⁹ Regular physical activity reduces the rate of deterioration in persons with dementia.²⁰

THE HORMONAL FOUNTAIN OF YOUTH

Since the publication of Wilson's "Feminine Forever" in the 1950s, touting the role of estrogen to maintain youth, there has been increasing interest in the antiaging effects of hormones.⁵ Previously, toward the end of the nineteenth century, Brown-Séquard had suggested a testicular extract produced remarkable antiaging effects. It is unlikely that his extract had any testosterone, demonstrating the powerful effect of the placebo. This led to a large number of rich men in Europe and the United States receiving monkey testicular implants, which were claimed to rejuvenate them. Brinkley in the United States pioneered a series of "goat gland" extracts, which were equally ineffective but made him a rich man. Subsequently, almost every hormone has been touted to produce antiaging effects. In general it can be said that the more enthusiasm that the lay public has expressed in these hormones, the less likely they are to be effective.

25(OH) vitamin D levels decline with aging.²¹ Low levels of vitamin D have been associated with increased mortality.²² In persons with 25(OH) vitamin D levels below 30 ng/mL, replacement has been demonstrated to enhance function, decrease falls, and decrease hip fracture.²³ Vitamin D replacement of more than 625 IU per day in a meta-analysis decreased mortality.²⁴ It is now generally accepted that older persons should either get regular skin exposure (15 to 30 min/day) without sun block or they should take 800 to 1000 IU/day. All persons over 70 years of age should have their 25(OH) vitamin D levels measured at least yearly (preferably in winter) because they may need higher doses of vitamin D to raise their level above 30 ng/mL.

Studies on men with low testosterone have shown conflicting results concerning whether or not low testosterone is associated with an increased mortality rate (Table 24-1).²⁵⁻²⁹ Overall, testosterone should be considered a quality of life drug and not a life extension drug. The major effects of testosterone are to enhance libido and sexual function.³⁰ Testosterone also increases muscle and bone mass and muscle strength in hypogonadal males.³¹ No studies have evaluated its effect on hip fracture. Testosterone also increases visuospatial cognition.³² Recent studies have suggested that testosterone may be cardioprotective.³³ Despite multiple potential positive effects of testosterone, recommendations for its use in older males as set out by the International Society for the Study of the Aging Male are that it should only be given to males who have symptoms and are biochemically hypogonadal.³⁴ Either the Aging Male Survey or the Saint Louis University Androgen Deficiency in the Aging Male

Table 24-1. Does Low Testosterone Predict Death?

Author, Year	Population	Predicts Death
Morley et al, 1996 ²⁵	14-yr follow-up of healthy men in New Mexico	No
Shores et al, 2006 ²⁶	Veteran population, 8-yr follow-up	Yes
Arajo et al, 2007 ²⁷	Massachusetts Male Aging Study	No
Khaw et al, 2007 ²⁹	Europe	Yes
Laughlin et al, 2008 ²⁸	Rancho Bernardo 11.8-yr follow-up	Yes

[ADAM] questionnaire³⁶ (Table 24-2) can be used to screen for symptoms.

Testosterone levels decline rapidly in females between 20 to 45 years of age.³⁷ The reason for this rapid decline is uncertain. Recent studies have suggested that testosterone replacement in females may improve libido to a small extent.³⁸

The role of estrogen replacement in females following the menopause was muddled by the Women's Health Initiative.^{39,40} It appears clear that in women over 60 years of age, estrogen replacement will increase cardiovascular disease and mortality. This is similar to the finding of the HERS study.⁴¹ It remains unclear whether there is a place for estrogen at the time of menopause. In women with premature menopause, estrogen replacement appears to be reasonable until the age of 52 years. Women with menopause between the ages of 45 to 55 may benefit from estrogen replacement in low doses, both to treat symptoms and delay the loss of bone. Its effect at this time on cardiovascular disease is uncertain, but some authorities believe it may be cardioprotective at this time period ("the critical period hypothesis"). In women with normal menopause, estrogen should most probably not be used for more than 5 years. Similar caveats exist for the use of progesterone and, when necessary to use, one should consider a progestagen with aldosterone antagonistic properties.

Dan Rudman and his colleagues⁴² created a craze for growth hormone replacement as a "fountain of youth" by their publication in the *New England Journal of Medicine*. Their paper citing the negative effects of growth hormone in older males was published later in *Clinical Endocrinology* and has been generally ignored by antiaging pundits.⁴³ A meta-analysis published in 2007 could find no positive effects of growth hormone in older persons.⁴⁴ Studies with ghrelin agonists in older persons have been equally disappointing. Ghrelin is a peptide hormone released from the fundus of the stomach that increases appetite, releases growth hormone, and enhances memory.⁴⁵ A Google search for "growth hormone and aging" resulted in 1,200,000 citations. These included a large number of sponsored links selling growth hormone or physicians who prescribe it. These advertisements included statements such as "Using growth hormone combats the ravages of aging," "Can aging be reversed," and "Growth Hormone Releaser: Fight the Aging Process Effectively" (Accessed Sept. 28, 2008).

Table 24-2. The Androgen Deficiency in the Aging Male [ADAM] Questionnaire

A positive answer represents yes to 1 or 7 or any 3 other questions. [Circle one]		
Yes	No	1. Do you have a decrease in libido (sex drive)?
Yes	No	2. Do you have a lack of energy?
Yes	No	3. Do you have a decrease in strength and/or endurance?
Yes	No	4. Have you lost height?
Yes	No	5. Have you noticed a decreased enjoyment of life?
Yes	No	6. Are you sad and/or grumpy?
Yes	No	7. Are your erections less strong?
Yes	No	8. Have you noticed a recent deterioration in your ability to play sports?
Yes	No	9. Are you falling asleep after dinner?
Yes	No	10. Has there been a recent deterioration in your work performance?

Dehydroepiandrosterone (DHEA) and its sulfate levels fall dramatically with aging.⁴⁶ This has resulted in multiple claims that DHEA can rejuvenate older persons. However, large well-controlled studies have failed to show any effects of DHEA on aging.⁴⁷ The Google search for "DHEA and Aging" yielded 758,000 citations. A quotation from one of these sites says: "DHEA stands out as a multititled star with amazing ways..."

On the web, pregnenolone has been called "the feel-good hormone" or "the mother hormone." Our studies in mice have shown that pregnenolone is a potent memory enhancer.⁴⁸ However, the ability to demonstrate similar effects in humans has been largely negative, at present there is no evidence that in humans pregnenolone is a memory enhancer or an antiaging hormone.⁴⁹

Melatonin, a hormone that is produced by the pineal gland, also declines with aging. It has antioxidant properties and as such has been touted as an antiaging hormone and a soporific. Overall, it appears to have minimal effects.

Marcus Tullius Cicero said "Old age must be resisted and its deficiencies restored." With the exception of vitamin D, there is little evidence that hormone replacement should be used in an attempt to reverse the aging process. Despite this it would appear that unscrupulous charlatans will continue to prescribe and supply them inappropriately and the aging populace will hungrily devour them with the hope of staying young forever.

ANTIOXIDANTS AND AGING

Multiple animal studies have shown a role for oxidative stress in aging.⁵⁰ Oxidative damage has also been implicated in the pathogenesis of age-related diseases, such as atherosclerosis and Alzheimer's disease. It is clear that consumption of fruits and vegetables that are rich in antioxidants appear to prevent disease. However, there is no evidence that persons taking vitamin supplements have a longer life than those who do not take supplements. Studies with vitamin E and cardiovascular disease in humans have found that supplementation either has no effect or is harmful.⁵¹ Similarly, effects of vitamin E on cancer have suggested mixed results. Vitamin E had minimal effects on people with Alzheimer's disease.

β -carotene in the ATBC trial resulted in an increase in lung, prostate, and stomach cancer.⁵² The CARET study also resulted in an increase in lung cancer death in people previously exposed to asbestos.⁵³ No positive effects of β -carotene on cardiovascular disease have been found in a number of studies.⁵⁴

Similarly, vitamin C has been shown to have minimal beneficial effects.

α -Lipoic acid is a powerful antioxidant. It has been shown to be useful in the treatment of diabetic neuropathy.⁵⁵ It has reversed memory disturbances in SAMP8 mice, a partial model of Alzheimer's disease.⁵⁶ However, our unpublished studies in mice have shown that it increased mortality rate.

Overall, human studies do not support the use of antioxidant vitamin supplementation. The one exception may be the use of high-dose multivitamins in age-related macular degeneration. Based on the available data, high-dose vitamin supplementation cannot be considered to be benign.

Table 24-3. Cosmetic Antiaging Products

Product	Action	Side Effects
Sunscreens with a sun protection factor [SPF] greater than 15	Decrease actinic keratosis and squamous cell carcinoma	Allergic reactions occur in 1 in 5 persons
α - and β -hydroxyl acids	Exfoliants that decrease roughness and some pigmentation	Irritation of skin
Retinoids (tretinoin and tazarotene)	Decrease pigmentation, wrinkling, and roughness	Irritation of skin
Fluorouracil cream	Actinic keratosis	Irritation of skin
Laser therapy	Wrinkles, pigmentation, telangiectasia	Scarring, hypopigmentation, bruising
Dermabrasion	Wrinkles, actinic keratoses	Scarring, pain, infection
Skin fillers (collagen and hyaluronic acid)	Wrinkles	Pain, allergic reactions
Botox	Wrinkles	Bruising, ptosis, headaches

Photoaging

Aging of skin occurs because of environmental damage, which interacts with chronologic aging.⁵⁷ Photoaging occurs as a result of ultraviolet light exposure. With the aging of the population there has been an explosion of medication, cosmetics, and dermatologic procedures that attempt to reverse the aging process (Table 24-3). These agents are used to remove or prevent wrinkles, rough skin, telangiectasia, actinic keratosis, brown spots, and benign neoplasia. In 2002 more than \$13 billion was spent on 5 million cosmetic procedures and more than 1 million "plastic" surgery procedures. Among relatively common antiaging plastic surgery procedures are rhytidectomy ("face-lift"), blepharoplasty, abdominoplasty ("tummy tuck"), and lipectomy or liposuction. These procedures are costly and pander to the vanity of our new aging population.

CONCLUSION

Amazing breakthroughs in the understanding of the aging process are occurring almost daily in cellular and animal models. Gerontologists, like Tantalus, are consistently being tempted to instantly apply these findings in humans before appropriate controlled trials are carried out. As history has shown, this is a dangerous precedent. Treatments that are highly effective in animals can be highly toxic in humans. The geriatrician plays an important role in being able to educate older persons regarding the positives and negatives of antiaging medicines.

Two areas that have the potential to totally change the antiaging field are stem cells and computers. Studies with stem cells carrying muscle IGF-1 in rodents have shown that they can reverse muscle loss in old animals.⁵⁸ The potential for stem cells to rejuvenate a variety of tissues is enormous but its application to humans is in its infancy.

We are beginning to see computer-enhanced technology used to reverse age-related deficits. Examples are cochlear implants and retinal computer chips. As computer technology advances, Kurzweil has suggested that hippocampal computer chips could be used to treat Alzheimer's disease.

Today's science fiction may well represent tomorrow's antiaging technology. The rapid advances in robotic prosthesis and exoskeletons will further enhance the ability of older persons to function well in late life.

Antiaging medicine raises a number of ethical issues. For instance, in a society of limited resources, is extending the life of the older population appropriate? Is extending life without improved quality appropriate? What if life extension was associated with cognitive impairment? How long is it appropriate to extend life: for 5 years, 10 years, 20 years, 50 years, or 100 years? There are no simple answers to any of these questions and the answers depend not only on scientific and philosophical areas, but also on religious views and fiscal realities.

Every year changes in medical knowledge are leading to increased longevity and improved quality of life. It needs to be recognized that not all advances in mainstream medicine have positive effects, but overall medical advances are at present the strongest antiaging medicine. In contrast the aging public continues to spend billions of dollars on antiaging potions of little proven value. Geriatricians will continue to be at the forefront of educators on how to age successfully.

KEY POINTS

Antiaging Medicine

- The factors best demonstrated to delay aging are fruit and vegetables, exercise, not smoking, drinking one or two glasses of alcohol daily, and fish consumption.
- Vitamin D replacement, in persons with low 25[OH] vitamin D levels, decreases hip fractures, improves muscle strength, enhances function, and decreases mortality.
- Antiaging medicine has been hijacked by charlatans who promote unproven or dangerous remedies to a naïve aging public.
- Too often animal studies that produce longevity are directly applied to humans before appropriate clinical trials have been carried out.
- There is no evidence that hormones or megadoses of vitamins prolong life.
- Numerous products of varying quality are available to slow photoaging and remove skin blemishes.

The Neurobiology of Aging: Free Radical Stress and Metabolic Pathways

Tomohiro Nakamura
Malene Hansen
Sean M. Oldham
Stuart A. Lipton

Environmental stressors and several genetic pathways play complex and crucial roles in the neurobiology and control of aging. This chapter will summarize current knowledge on these two specific research areas divided into two sections: one on free radical stressors and the other on genetic control of metabolic pathways.

SECTION I: NITROSATIVE AND OXIDATIVE STRESS IN THE NEUROBIOLOGY OF AGING

Aging represents a major risk factor for neurodegenerative diseases, such as Parkinson's disease (PD); Alzheimer's disease (AD); amyotrophic lateral sclerosis (ALS); and polyglutamine (polyQ) diseases, such as Huntington's disease, glaucoma, human immunodeficiency virus-associated dementia, multiple sclerosis, and ischemic brain injury, to name but a few.¹⁻⁵ Although many intracellular and extracellular molecules may participate in neuronal injury and loss, accumulation of nitrosative and oxidative stress, because of the excessive generation of nitric oxide (NO) and reactive oxygen species (ROS), appears to be a potential factor contributing to neuronal cell damage and death.^{6,7} A well-established model for NO production entails a central role of the *N*-methyl-D-aspartate (NMDA)-type glutamate receptors in nervous system. Excessive activation of NMDA receptors drives Ca²⁺ influx, which in turn activates neuronal NO synthase (nNOS) and the generation of ROS^{8,9} (Figure 25-1). Accumulating evidence suggests that NO can mediate both protective and neurotoxic effects by reacting with cysteine residues of target proteins to form S-nitrosothiols (SNOs), a process termed S-nitrosylation because of its effects on the chemical biology of protein function. Importantly, normal mitochondrial respiration may also generate free radicals, principally ROS, and one such molecule, superoxide anion (O₂⁻), reacts rapidly with free radical NO to form the very toxic product peroxynitrite (ONOO⁻)^{10,11} (Figure 25-2).

An additional feature of most neurodegenerative diseases is accumulation of misfolded and/or aggregated proteins.¹²⁻¹⁵ These protein aggregates can be cytosolic, nuclear, or extracellular. Importantly, protein aggregation can result from either (1) a mutation in the disease-related gene encoding the protein, or (2) posttranslational changes to the protein engendered by nitrosative/oxidative stress.¹⁶ A key theme of this chapter, therefore, is the hypothesis that nitrosative or oxidative stress contributes to protein misfolding in the brains of neurodegenerative patients. In this chapter, we discuss specific examples showing that S-nitrosylation of (1) ubiquitin E3 ligases such as parkin or (2) endoplasmic reticulum chaperones such as protein-disulfide isomerase (PDI) is critical for the accumulation of

misfolded proteins in neurodegenerative diseases such as PD and other conditions.¹⁷⁻²⁰

PROTEIN MISFOLDING IN NEURODEGENERATIVE DISEASES

A shared histologic feature of many neurodegenerative diseases is the accumulation of misfolded proteins that adversely affect neuronal connectivity and plasticity, and trigger cell death signaling pathways.^{12,15} For example, degenerating brain contains aberrant accumulations of misfolded, aggregated proteins, such as α -synuclein and synphilin-1 in PD, and amyloid- β (A β) and tau in AD. The inclusions observed in PD are called Lewy bodies and are mostly found in the cytoplasm. AD brains show intracellular neurofibrillary tangles, which contain tau, and extracellular plaque, which contains A β . Other disorders manifesting protein aggregation include Huntington's disease (polyQ), ALS, and prion disease.¹⁴ The above-mentioned aggregates may consist of oligomeric complexes of nonnative secondary structures and demonstrate poor solubility in aqueous or detergent solvent.

In general, protein aggregates do not accumulate in unstressed, healthy neurons due in part to the existence of cellular "quality control machineries." For example, molecular chaperones are believed to provide a defense mechanism against the toxicity of misfolded proteins because chaperones can prevent inappropriate interactions within and between polypeptides, and can promote refolding of proteins that have been misfolded because of cell stress. In addition to the quality control of proteins provided by molecular chaperones, the ubiquitin-proteasome system (UPS) and autophagy/lysosomal degradation are involved in the clearance of abnormal or aberrant proteins. When chaperones cannot repair misfolded proteins, they may be tagged via addition of polyubiquitin chains for degradation by the proteasome. In neurodegenerative conditions, intracellular or extracellular protein aggregates are thought to accumulate in the brain as a result of a decrease in molecular chaperone or proteasome activities. In fact, several mutations that disturb the activity of molecular chaperones or UPS-associated enzymes can cause neurodegeneration.^{15,21,22} Along these lines, postmortem samples from the substantia nigra of PD patients (vs. non-PD controls) manifest a significant reduction in proteasome activity.²³

Historically, lesions that contain aggregated proteins were considered to be pathogenic. Recently, several lines of evidence have suggested that aggregates are formed through a complex multistep process by which misfolded proteins assemble into inclusion bodies; currently, soluble oligomers of these aberrant proteins are thought to be the most toxic forms via interference with normal cell activities, whereas

Figure 25-1. Activation of the NMDA receptor (NMDAR) by glutamate (Glu) and glycine (Gly) induces Ca^{2+} influx and consequent ROS/RNS production. NMDAR hyperactivation triggers generation of ROS/RNS and cytochrome C release from mitochondria associated with subsequent activation of caspases, causing neuronal cell death and damage. *SNO-PARK*, S-nitrosylated parkin; *SNO-PDI*, S-nitrosylated PDI.

frank aggregates may be an attempt by the cell to wall off potentially toxic material.^{8,24}

GENERATION OF REACTIVE OXYGEN/ NITROGEN SPECIES (ROS/RNS)

NMDA receptor-mediated glutamatergic signaling pathways induce Ca^{2+} influx

It is well known that the amino acid glutamate is the major excitatory neurotransmitter in the brain. Glutamate is present in high concentrations in the adult central nervous system and is released for milliseconds from nerve terminals in a Ca^{2+} -dependent manner. After glutamate enters the synaptic cleft, it diffuses across the cleft to interact with its corresponding receptors on the postsynaptic face of an adjacent neuron. Excitatory neurotransmission is necessary for the normal development and plasticity of synapses, and

for some forms of learning or memory; however, excessive activation of glutamate receptors is implicated in neuronal damage in many neurologic disorders ranging from acute hypoxic-ischemic brain injury to chronic neurodegenerative diseases. It is currently thought that overstimulation of extrasynaptic NMDA receptors mediate this neuronal damage, while in contrast synaptic activity may activate survival pathways.^{25–27} Intense hyperstimulation of excitatory receptors leads to necrotic cell death, but more mild or chronic overstimulation can result in apoptotic or other forms of cell death.^{28–30}

NMDA receptor-coupled channels are highly permeable to Ca^{2+} , thus permitting Ca^{2+} entry after ligand binding if the cell is depolarized to relieve block of the receptor-associated ion channel by Mg^{2+} .^{31,32} Subsequent binding of Ca^{2+} to various intracellular molecules can lead to many significant consequences. In particular, excessive activation of

Figure 25-2. Pathways of ROS/RNS neurotoxicity. NO activates soluble guanylate cyclase (sGC) to produce cyclic guanosine monophosphate (cGMP), which in turn activates cGMP-dependent protein kinase. Excessive NMDA receptor activity, leading to the overproduction of NO, can be neurotoxic. For example, S-nitrosylation of parkin and PDI can contribute to neuronal cell damage and death, in part by triggering accumulation of misfolded proteins. Other neurotoxic effects of NO are mediated by peroxynitrite (ONOO⁻), a reaction product of NO and superoxide anion (O₂^{•-}). In contrast, S-nitrosylation can also mediate neuroprotective effects, for example, by inhibiting caspase activity and preventing overactivation of NMDA receptors.

NMDA receptors leads to the production of damaging free radicals (e.g., NO and ROS) and other enzymatic processes, contributing to cell death.^{6,11,29,30,33,34}

Ca²⁺ influx and generation of ROS/RNS

Excessive activation of glutamate receptors is implicated in neuronal damage in many neurologic disorders. John Olney coined the term “excitotoxicity” to describe this phenomenon.^{35,36} This form of toxicity is mediated at least in part by excessive activation of NMDA-type receptors,^{6,7,37} resulting in excessive Ca²⁺ influx through a receptor’s associated ion channel.

Increased levels of neuronal Ca²⁺, in conjunction with the Ca²⁺-binding protein Ca²⁺/calmodulin (CaM), trigger the activation of nNOS and subsequent generation of NO from the amino acid L-arginine.^{8,38} NO is a gaseous free radical (thus highly diffusible) and a key molecule that plays a vital role in normal signal transduction but in excess can lead to neuronal cell damage and death. The discrepancy of NO effects on neuronal survival can also be caused by the formation of different NO species or intermediates: NO radical (NO•), nitrosonium cation (NO⁺), nitroxyl anion (NO⁻, with high energy singlet and lower energy triplet forms).¹¹

Recent studies further pointed out the potential connection between ROS/RNS and mitochondrial dysfunction in neurodegenerative diseases, especially in PD.^{5,39} Pesticide and other environmental toxins that inhibit mitochondrial complex I result in oxidative and nitrosative stress, and consequent aberrant protein accumulation.^{17,18,20,40,41} Administration to animal models of complex I inhibitors, such as MPTP, 6-hydroxydopamine, rotenone, and paraquat, which result in overproduction of ROS/RNS, reproduces many of the features of sporadic PD, such as dopaminergic neuron degeneration, upregulation and aggregation of α -synuclein, Lewy bodylike intraneuronal inclusions, and behavioral impairment.^{5,39}

Increased nitrosative and oxidative stress are associated with chaperone and proteasomal dysfunction, resulting in accumulation of misfolded aggregates.^{16,42} However, until recently little was known regarding the molecular and

pathogenic mechanisms underlying contribution of NO to the formation of inclusion bodies, such as amyloid plaque in AD or Lewy bodies in PD.

PROTEIN S-NITROSYLATION AND NEURONAL CELL DEATH

Chemical biology of S-nitrosylation

Early investigations indicated that the NO group mediates cellular signaling pathways, which regulate broad aspects of brain function, including synaptic plasticity, normal development, and neuronal cell death.^{33,43–45} In general, NO exerts physiologic and some pathophysiologic effects via stimulation of guanylate cyclase to form cyclic guanosine-3',5'-monophosphate (cGMP) or through S-nitrosylation of regulatory protein thiol groups^{9,11,42,46–48} (Figure 25-2). S-nitrosylation is the covalent addition of an NO group to a critical cysteine thiol/sulfhydryl (RSH or, more properly, thiolate anion, RS⁻) to form an S-nitrosothiol derivative (R-SNO). Such modification modulates the function of a broad spectrum of mammalian, plant, and microbial proteins. In general, a consensus motif of amino acids comprised of nucleophilic residues (generally an acid and a base) surround a critical cysteine, which increases the cysteine sulfhydryl's susceptibility to S-nitrosylation.^{49,50} Our group first identified the physiologic relevance of S-nitrosylation by showing that NO and related RNS exert paradoxical effects via redox-based mechanisms. NO is neuroprotective via S-nitrosylation of NMDA receptors (as well as other subsequently discovered targets, including caspases) and yet can also be neurodestructive by formation of peroxynitrite (or, as later discovered, reaction with additional molecules such as MMP-9 and GAPDH)^{11,51–58} (Table 25-1). Over the past decade, accumulating evidence has suggested that S-nitrosylation can regulate the biologic activity of a great variety of proteins, in some ways akin to phosphorylation.* Chemically, NO is often a good “leaving group,” facilitating further oxidation of critical thiol to disulfide bonds among neighboring (vicinal) cysteine residues or, via reaction with ROS, to sulfenic (–SOH), sulfinic (–SO₂H) or sulfonic (–SO₃H) acid derivatization of the protein.^{18,20,57,66} Alternatively, S-nitrosylation may possibly produce a nitroxyl disulfide, in which the NO group is shared by close cysteine thiols.⁶⁷

Analyses of mice deficient in either nNOS or iNOS confirmed that NO is an important mediator of cell injury and death after excitotoxic stimulation; NO generated from nNOS or iNOS is detrimental to neuronal survival.^{68,69} In addition, inhibition of NOS activity ameliorates the progression of disease pathology in animal models of PD, AD, and ALS, suggesting that excess generation of NO plays a pivotal role in the pathogenesis of several neurodegenerative diseases.^{70–73} Although the involvement of NO in neurodegeneration has been widely accepted, the chemical relationship between nitrosative stress and accumulation of misfolded proteins has remained obscure. Recent findings, however, have shed light on molecular events underlying this relationship. Specifically, we recently mounted physiologic and chemical evidence that S-nitrosylation modulates the (1) ubiquitin E3 ligase activity of parkin,^{17–19} and (2)

S-nitrosylation and parkin

Identification of errors in the genes encoding parkin (an ubiquitin E3 ligase) and UCH-L1 in rare familial forms of PD has implicated possible dysfunction of the UPS in the pathogenesis of sporadic PD as well. The UPS represents an important mechanism for proteolysis in mammalian cells. Formation of polyubiquitin chains constitutes the signal for proteasomal attack and degradation. An isopeptide bond covalently attaches the C-terminus of the first ubiquitin in a polyubiquitin chain to a lysine residue in the target protein. The cascade of activating (E1), conjugating (E2), and ubiquitin-ligating (E3) type of enzymes catalyzes the conjugation of the ubiquitin chain to proteins. In addition, individual E3 ubiquitin ligases play a key role in the recognition of specific substrates.⁷⁴

PD is the second most prevalent neurodegenerative disease and is characterized by the progressive loss of dopamine neurons in the substantia nigra pars compacta. Appearance of Lewy bodies that contain misfolded and ubiquitinated proteins generally accompanies the loss of dopaminergic neurons in the PD brain. Such ubiquitinated inclusion bodies are the hallmark of many neurodegenerative disorders. Age-associated defects in intracellular proteolysis of misfolded or aberrant proteins might lead to accumulation and ultimately deposition of aggregates within neurons or glial cells. Although such aberrant protein accumulation had been observed in patients with genetically encoded mutant proteins, recent evidence from our laboratory suggests that nitrosative and oxidative stress are potential causal factors for protein accumulation in the much more common sporadic

form of PD. As illustrated below, nitrosative/oxidative stress, commonly found during normal aging, can mimic rare genetic causes of disorders, such as PD, by promoting protein misfolding in the absence of a genetic mutation.^{17–19} For example, S-nitrosylation and further oxidation of parkin result in dysfunction of this enzyme and thus of the UPS.^{17,18,75–78} We and others recently discovered that nitrosative stress triggers S-nitrosylation of parkin (forming SNO-parkin) not only in rodent models of PD but also in the brains of human patients with PD and the related α -synucleinopathy, DLBD (diffuse Lewy body disease). SNO-parkin initially stimulates ubiquitin E3 ligase activity, resulting in enhanced ubiquitination as observed in Lewy bodies, followed by a decrease in enzyme activity, producing a futile cycle of dysfunctional UPS.^{18,19,79} We also found that rotenone led to the generation of SNO-parkin and thus dysfunctional ubiquitin E3 ligase activity. Moreover, S-nitrosylation appears to compromise the neuroprotective effect of parkin.¹⁷ Nitrosative and oxidative stress can also alter the solubility of parkin via posttranslational modification of cysteine residues, which may concomitantly compromise its protective function.^{80–82} Additionally, it is likely that other ubiquitin E3 ligases with RING-finger thiol motifs are S-nitrosylated in a similar manner to parkin to affect their enzymatic function; hence, S-nitrosylation of E3 ligases may be involved in a number of degenerative conditions.

S-nitrosylation of PDI mediates protein misfolding and neurotoxicity in cell models of PD or AD

The ER normally participates in protein processing and folding but undergoes a stress response when immature or misfolded proteins accumulate.^{83–86} ER stress stimulates two critical intracellular responses. The first represents expression of chaperones that prevent protein aggregation via the unfolded protein response (UPR), and is implicated in protein refolding, posttranslational assembly of protein complexes, and protein degradation. This response is believed to contribute to adaptation during altered environmental conditions, promoting maintenance of cellular homeostasis. The second ER stress response, termed ER-associated degradation (ERAD), specifically recognizes terminally misfolded proteins for retro-translocation across the ER membrane to the cytosol, where they can be degraded by the UPS. Additionally, although severe ER stress can induce apoptosis, the ER withstands relatively mild insults via expression of stress proteins such as glucose-regulated protein (GRP) and PDI. These proteins behave as molecular chaperones that assist in the maturation, transport, and folding of secretory proteins.

During protein folding in the ER, PDI can introduce disulfide bonds into proteins (oxidation), break disulfide bonds (reduction), and catalyze thiol/disulfide exchange (isomerization), thus facilitating disulfide bond formation, rearrangement reactions, and structural stability.⁸⁷ PDI has four domains that are homologous to thioredoxin (TRX) (termed a, b, b', and a'). Only two of the four TRX-like domains (a and a') contain a characteristic redox-active CXXC motif, and these two-thiol/disulfide centers function as independent active sites.^{88–91} Several mammalian PDI homologues, such as ERp57 and PDIp, also localize to

the ER and may manifest similar functions.^{92,93} Increased expression of PD1p in neuronal cells under conditions mimicking PD suggest the possible contribution of PD1p to neuronal survival.⁹²

In many neurodegenerative disorders and cerebral ischemia, the accumulation of immature and denatured proteins results in ER dysfunction,^{92,94–96} but upregulation of PDI represents an adaptive response promoting protein refolding and may offer neuronal cell protection.^{92,93,97,98} In addition, it is generally accepted that excessive generation of NO can contribute to activation of the ER stress pathway, at least in some cell types.^{99,100} Molecular mechanisms by which NO induces protein misfolding and ER stress, however, have remained enigmatic until recently. The ER normally manifests a relatively positive redox potential in contrast to the highly reducing environment of the cytosol and mitochondria. This redox environment can influence the stability of protein S-nitrosylation and oxidation reactions.¹⁰¹ Interestingly, we have recently reported that excessive NO can lead to S-nitrosylation of the active-site thiol groups of PDI, and this reaction inhibits both its isomerase and chaperone activities.²⁰ Mitochondrial complex I insult by rotenone can also result in S-nitrosylation of PDI in cell culture models. Moreover, we found that PDI is S-nitrosylated in the brains of virtually all cases examined of sporadic AD and PD. Under pathologic conditions, it is possible that both cysteine sulfhydryl groups in the TRX-like domains of PDI form S-nitrosothiols. Unlike formation of a single S-nitrosothiol, which is commonly seen after denitrosylation reactions catalyzed by PDI,⁶¹ dual nitrosylation may be relatively more stable and prevent subsequent disulfide formation on PDI. Therefore we speculate that these pathologic S-nitrosylation reactions on PDI are more easily detected during neurodegenerative conditions. Additionally, it is possible that vicinal (nearby) cysteine thiols reacting with NO can form nitroxyl disulfide,⁶⁷ and such reaction may potentially occur in the catalytic side of PDI to inhibit enzymatic activity. To determine the consequences of S-nitrosylated PDI (SNO-PDI) formation in neurons, we exposed cultured cerebrocortical neurons to neurotoxic concentrations of NMDA, thus inducing excessive Ca²⁺ influx and consequent NO production from nNOS. Under these conditions, we found that PDI was S-nitrosylated in a NOS-dependent manner. SNO-PDI formation led to the accumulation of polyubiquitinated/misfolded proteins and activation of the UPR. Moreover, S-nitrosylation abrogated the inhibitory effect of PDI on aggregation of proteins observed in Lewy body inclusions.^{20,102} S-nitrosylation of PDI also prevented its attenuation of neuronal cell death triggered by ER stress, misfolded proteins, or proteasome inhibition. Further evidence suggested that SNO-PDI may in effect transport NO to the extracellular space, where it could conceivably exert additional adverse effects.⁶¹

The UPS is apparently impaired in the aging brain. Additionally, inclusion bodies similar to those found in neurodegenerative disorders can appear in brains of normal aged individuals or those with subclinical manifestations of disease.¹⁰³ These findings suggest that the activity of the UPS and molecular chaperones may decline in an age-dependent manner.¹⁰⁴ Given that we have not found detectable quantities of SNO-parkin and SNO-PDI in normal aged brain,^{17,18,20} we speculate that S-nitrosylation of these and similar proteins may represent a key event that contributes

to susceptibility of the aging brain to neurodegenerative conditions.

SECTION II: METABOLIC-INSULIN SIGNALING IN THE CONTROL OF AGING AND NEURODEGENERATION

The insulin/IGF-1 signaling pathway and organismal aging

Experiments using model organisms have provided rapidly increasing evidence that reduced activity of the insulin and insulin-like growth factor (IGF) signaling (IIS) pathways extends lifespan. This discovery is particularly striking as impaired IIS function is also known to have detrimental effects, including death during embryogenesis and diabetes. In addition, alterations of IIS pathway activity can have profound effects on reproduction, stress resistance, and metabolism.¹⁰⁵ Recent research has started to unravel the underlying mechanism of IIS-mediated lifespan modulation. Furthermore, this research has also shown a mechanistic link between IIS and neurodegenerative diseases. In this section, we will provide an overview of the role IIS plays in organismal aging and highlight examples of how IIS, and other longevity genes with metabolic functions, regulate neurodegeneration.

Because of the complex regulatory systems that modulate lifespan, a successful approach to addressing this question has been the use of the simple invertebrate models: the nematode *Caenorhabditis elegans*, and the fruitfly *Drosophila melanogaster*. Indeed, a short lifespan and genetic accessibility of *C. elegans* led to the discovery of the first long-lived IIS mutant (*age-1*) through a genetic screen for genes that alter lifespan.¹⁰⁶ This mutant encodes the worm phosphoinositide-3-kinase (PI3K),^{107,108} which supported additional findings in *C. elegans* demonstrating that mutations in the insulin/IGF-1 receptor DAF-2 increased lifespan and that this effect depended on the FOXO transcription factor DAF-16.^{106,109–111} With the discovery that mutations in the insulin receptor (InR) or its substrate CHICO could extend the lifespan of *Drosophila*,^{112,113} these collective findings suggested that reduced IIS activity is an evolutionarily conserved mechanism to extend lifespan. This remarkable notion was further supported when rodents were shown to live longer if either the insulin or the IGF signaling pathways were disrupted,^{114–117} indicating that the evolutionary conservation extends to mammals. This functional conservation may even extend to humans as alterations in the IGF signaling pathway has been observed in centenarians.¹¹⁸ These findings also provided a possible explanation to the long lifespan observed in growth-hormone deficient Ames dwarf mice and growth hormone receptor knockout mice because growth hormone positively regulates the production of IGF-1.^{119,120}

Figure 25-3 summarizes IIS interventions that have so far been shown to modulate lifespan in worms, flies, and mice.

IIS modulations that affect organismal lifespan

As IIS coordinates nutritional availability and growth, long-lived IIS mutants have effects on the metabolic reserves (altered fat content) and delayed development, decreased adult body size, reduced fecundity, and increased stress resistance.^{105,121} Recent reports have shown that these processes

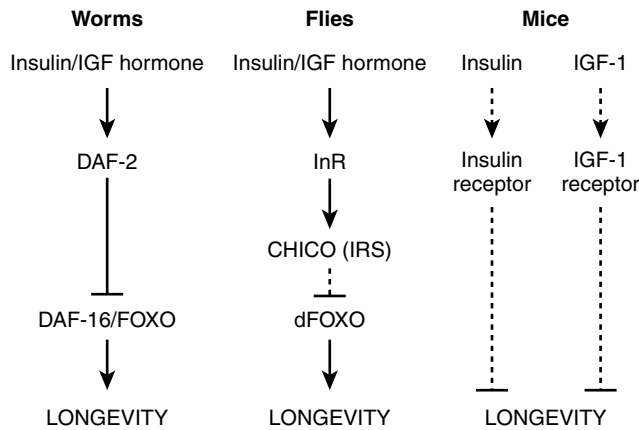

Figure 25-3. The insulin-IGF pathway regulates aging in multiple organisms. Molecular components of the insulin/IGF-1 signaling pathway that have been shown to influence the lifespan of worms, flies, and mice. *Dashed lines*, plausible regulatory relationships.

make individual contributions to the extended longevity phenotype because of reduced IIS pathway activity.¹²¹ Another important feature of reduced IIS function is the promotion of a longer “healthspan” and longer lifespans in some instances. For instance, experiments have demonstrated protective effects of IIS mutants that extend lifespan in invertebrate models against specific aging-related diseases such as cancer,^{122–124} cardiac failure,¹²⁵ and Alzheimer’s disease^{126,127} (see later discussion).

Recent research efforts have focused on understanding when and where IIS modulates lifespan. To address the temporal requirement for reduction of IIS in determining lifespan, IIS was decreased in *C. elegans* during adulthood by administration of bacteria engineered to express double-stranded RNA for *daf-2*, and this treatment was sufficient to extend lifespan.¹²⁸ Consistent with this, adult-only expression of dFOXO in the adipose tissue of flies was also demonstrated to be sufficient to extend lifespan.^{129,130} Similarly, adult-specific overexpression of dPTEN¹²⁹ and ablation of the insulin-producing neurons in the last stage of preadult development is sufficient to enhance longevity.¹³¹

The tissue-specific requirements for IIS to modulate lifespan have also been investigated in some detail and have pointed towards important roles for neuronal and fat tissues. For instance, replacement of the insulin-IGF-1 receptor DAF-2 in neurons in *daf-2(-)* worms shortened lifespan back to that of wild-type.^{132,133} This is in somewhat contrast to the downstream effector of the *daf-2* pathway, the FOXO transcription factor DAF-16, which has been found to primarily function in the intestine—the worms’ adipose tissue—to regulate lifespan downstream of the *daf-2*/insulin/IGF-1 receptor.¹³⁴ Thus insulin signaling in neural tissues controls signals that act in the periphery to modulate lifespan. Consistent with specific roles in neuronal and fat tissues, as mentioned above, ablation of the insulin-producing neurons is sufficient to enhance longevity, whereas fat-specific overexpression of the pathway antagonists dPTEN or dFOXO can extend lifespan in flies via nonautonomous signaling to the insulin-producing neurons.^{129,130} Finally, fat-specific knockout of the insulin receptor in mice can also extend lifespan.¹¹⁵ Determining the nature of the signals and their cross-talk with the peripheral tissues remains a critical area of research. These results also highlight the potential autonomous and

nonautonomous contributions, and acute versus chronic consequences of altering insulin-metabolic signaling in age-dependent diseases. How IIS orchestrates organ senescence, including neurodegenerative diseases, and longevity remains an important area of future studies. Thus these combined results indicate the existence of evolutionarily conserved, complex systemic responses regulated by IIS.

Mechanisms by which IIS affect organismal lifespan and neurodegenerative diseases

What is the basis of the beneficial lifespan effects that reduced IIS induce? Recent studies have used unbiased approaches, including gene-expression profiling to understand the FOXO transcriptome, in worms/flies to gain insight into the downstream effectors of IIS. Several studies have been reported using long-lived IIS mutants.^{135–140} Importantly, genes required for metabolism, stress response, and detoxification of oxidative damage have been identified. Nonetheless, when the effect of altering expression of these genes individually has been investigated directly, their effect on longevity has been minor.¹³⁷ This has been taken to indicate that many FOXO-regulated genes are required to act additively to produce the profound lifespan effects seen in long-lived IIS mutants. In contrast, other genes might work in parallel to FOXO to extend lifespan by reducing IIS in *C. elegans*, for instance the heat-responsive transcription factor HSF-1^{141,142} and genes involved in autophagy—a cellular process by which cytoplasmic components are degraded and recycled.^{143,144} Clearly, these results point to a multimechanistic regulation of the aging process.

Importantly, the aging process has recently been directly linked to neurodegenerative diseases via the IIS pathway. Several studies performed in *C. elegans* and *Drosophila* proteotoxicity models indicate that IIS links directly to the onset of toxic protein aggregation, for example, of the A β peptide causing Alzheimer’s disease and via PolyQ stretches as those found in Huntington’s disease.^{141,145–147} These studies have started to shed light on the mechanism by which IIS affects neurodegeneration and suggest that IIS can protect against misfolded aggregates in Alzheimer’s disease by multiple mechanisms. The main mechanism involves disaggregation of toxic species to enable their degradation via small heat shock proteins (regulated by the HSF-1 transcription factor), whereas the secondary mechanism, regulated by DAF-16/FOXO, involves aggregation of proteins into high-molecular species that are less toxic to the cell.¹⁴⁵ Future research should address if the link between IIS and neurodegenerative diseases exists in mammalian systems.

Other metabolic longevity pathways and genes with links to neurodegeneration

Reduced food intake without malnutrition, referred to as dietary restriction (DR), also extends lifespan of a variety of species and has been extensively studied in model organisms.¹⁴⁸ In *C. elegans*, it was first conclusively addressed if DR regulates longevity via the IIS pathway. This is not likely to be the case because only IIS, but not DR, is completely dependent on the FOXO transcription factor DAF-16 in worms.¹⁴⁹ Similarly, *dFoxo* null mutant flies still show lifespan extensions following DR.^{129,150} The effects of DR on IIS in mammals are less clear because long-lived Ames mice (mentioned previously) subjected to DR show further

increase in lifespan,¹⁵¹ whereas GHRKO mice subjected to DR failed to increase lifespan.¹⁵² The complexity of mammalian Ins-IGF signaling suggests a more integrated interaction with DR because DR leads to increased insulin sensitivity. Importantly, dietary restriction protects against neurodegeneration in mouse models,¹⁵³ and dietary-restricted worms show reduced proteotoxicity mediated by the transcription factor HSF-1, similarly to IIS mutants.¹⁵⁴

The sirtuins were the first reported genetic regulators of DR-induced longevity. These proteins encode NAD⁺-dependent histone deacetylases.¹⁵⁵ There is some controversy about the level of conservation regarding the role in DR of these genes. Overexpression of Sir2 extends the lifespan of yeast, worms, and flies¹⁵⁵; however, this appears to involve a DR-independent mechanism in *C. elegans*.^{156–159} Sirtuins (which include 7 homologs in mammals, SIRT1–7, with SIRT1 being the mammalian ortholog of Sir2) also affect neurodegeneration in mammalian systems; yet, there is some controversy about this role. SIRT1 protects against neurodegeneration in mice,¹⁶⁰ and activation of SIRT2 in cell-based models for neurodegeneration leads to protection against neuronal cell death.¹⁶¹ In contrast, however, loss of SIRT1 also provides protection against neuronal loss in mice.¹⁶² One possibility is that sirtuin effects follow an “inverted U-curve” with benefit at high or low levels of activity. Taken together, these findings suggest that the mechanisms by which sirtuins regulate cellular protection and organismal longevity may be rather complex.

Another potential player in the regulation of lifespan by DR is the nutrient sensor TOR (target of rapamycin). TOR exists in two distinct complexes, termed TORC1 and TORC2.^{163,164} Reduction of TOR function has been shown to increase lifespan in yeast, worms, and flies.^{165–167} TOR regulates multiple processes, including metabolism, protein translation, and autophagy.^{124,163,164} All of these processes have been linked to aging. Longer-lived TOR mutants have an altered metabolic profile.¹⁶⁵ Reduced protein translation extends lifespan in yeast, worms, and flies.¹⁶⁸ Autophagy is required for dietary-restricted animals to live long,¹⁶⁹ similar to IIS mutants (see previous discussion). In this way, it appears as autophagy is linked to longevity processes specifically involved in nutrient sensing. TOR interacts with the IIS pathway,¹⁶³ and this is also true in the context of aging. Inhibition of TOR and insulin/IGF-1 signaling does not further extend lifespan.^{156,170} Furthermore, the TOR binding partner Raptor, called *daf-15* in worms, is a transcriptional target of DAF-16/FOXO.¹⁶⁶ However, mutants with reduced TOR pathway activity do not require the FOXO transcription factor DAF-16.^{166,170} Indeed, the TOR binding partner Raptor is a transcriptional target of DAF-16/FOXO¹⁶⁶ and recent work in *Drosophila* has shown that TOR may function downstream of dFOXO.¹⁶⁵ TOR may also contribute to neuronal survival. Inappropriate activation of the cell cycle by misfolded proteins leads to cell death in postmitotic neurons. This response can be reversed by blocking the cell cycle via increasing cell cycle inhibitors and inhibiting the cell growth regulatory TOR protein.¹²⁷ How TOR regulates growth, metabolism, aging, and neurodegenerative diseases is a critical area of research.

The ATP sensor AMPK has also been suggested to play a key role in DR. Similar to TOR, AMPK plays a role in

Figure 25-4. Signaling processes that regulate aging. Signaling by proteins and processes with metabolic functions that have been shown to modulate organismal aging in metazoans. Dashed lines, plausible regulatory relationships.

aging, stress resistance, and tumorigenesis.^{171–173} AMPK also interacts with the IIS pathway because lifespan extension via reduced IIS is dependent on worm AMPK, *aak-2*, and overexpression of AAK-2 extends *C. elegans* lifespan.¹⁷³ Whether this effect is conserved in other organisms awaits confirmation. Additionally, AMPK may have a neuroprotective role because loss of AMPK causes a dramatic increase in neurodegeneration in flies.^{174,175} AMPK may have additional roles in regulating neural function. The energy sensing factor AMPK may function downstream of actual chemosensory nutrient-sensing pathways, which allows the animal to detect and respond to changes in food availability. Interestingly, worms in which certain gustatory and olfactory neurons have been removed by laser ablation are long-lived.¹⁷⁶ These lifespan extensions are, however, dependent

KEY POINTS

The Neurobiology of Aging: Free Radical Stress and Metabolic Pathways

- Excessive NMDA receptor activation and/or mitochondrial dysfunction trigger excessive nitrosative and oxidative stress that may result in malfunction of the UPS or molecular chaperones.
- Excessively produced ROS/RNS may contribute to abnormal protein accumulation and neuronal damage in sporadic forms of neurodegenerative diseases.
- S-nitrosylation of specific molecules such as parkin and PDI provides a mechanistic link between free radical production, abnormal protein accumulation, and neuronal cell injury in neurodegenerative disorders, such as PD and AD.
- Elucidation of these new pathways may lead to the development of additional new therapeutic approaches to prevent aberrant protein misfolding by targeted disruption or prevention of nitrosylation of specific proteins (e.g., parkin, PDI, and PrxII).
- Single gene mutations in the insulin and insulin-like growth factor signaling pathways can lengthen lifespan in worms, flies, and mice, implying evolutionary conservations of mechanisms.
- Such mutations can keep the animals healthy and disease-free for longer and can alleviate certain aging-related pathologies. Determining the tissue requirement, genetic interactions, and timing of these effects remain important areas for further research.

on DAF-16/FOXO, suggesting that nutrient sensing by these neurons is not involved in the longevity response to DR in *C. elegans*. On the other hand, flies exposed to the odor of abundant food no longer respond fully to the lifespan extending effects of DR treatments,¹⁷⁷ indicating that sensory perception indeed may play a role in DR-mediated longevity. Thus the environment can play an important role in determining lifespan. Future work will determine how IIS-metabolic pathways are linked to neurodegeneration, aging, and lifespan.

Figure 25-4 summarizes signaling by proteins and processes with metabolic functions that have been linked to organismal aging.

While this chapter was under review, too papers establishing longevity roles for TOR and S6 kinase in mammals were published.^{186,187}

Allostasis and Allostatic Overload in the Context of Aging

Bruce S. McEwen

INTRODUCTION

"Stress" is often identified as a factor in accelerated aging¹ and an important factor in disorders such as cardiovascular disease and depression, and a contributor to other disorders.² Being "stressed out" is a commonly used word that generally refers to experiences that cause feelings of anxiety, anger, and frustration because they push a person beyond his or her ability to successfully cope. Besides time pressures and daily hassles at work and home, there are stressors related to economic insecurity, poor health, and interpersonal conflict. More rarely, there are situations that are life-threatening—accidents, natural disasters, violence—and these evoke the classical "fight or flight" response. In contrast to daily hassles, these stressors are acute and yet they also can lead to depression, anxiety, posttraumatic stress disorder and other forms of chronic stress in the aftermath of the tragic event.

The most common stressors are, therefore, ones that operate chronically, often at a low level, and cause us to behave in certain ways. For example, being "stressed out" may promote anxiety or depressed mood, poor sleep, eating of comfort foods and overconsumption of calories, smoking, or drinking alcohol excessively. Being stressed out may reduce social interactions or regular physical activity. Not infrequently, anxiolytics and sleep promoting agents are used, but, with continuation of this state, the body may increase in weight, and develop metabolic dysregulation and atherosclerotic plaques.

The brain is the organ that decides what is stressful and determines the behavioral and physiologic responses, whether health promoting or health damaging. The brain is a biologic organ that changes under acute and chronic stress and directs many systems of the body—metabolic, cardiovascular, immune, renal—that are involved in the short and long-term consequences of being stressed out.

What does chronic stress do to the body and brain, particularly in relation to the aging process? This chapter summarizes some of the current information placing emphasis on how the stress hormones and related mediators can play both protective and damaging roles in brain and body, depending on how tightly their release is regulated, and it discusses some of the approaches for dealing with stress in a complex world.

DEFINITION OF STRESS, ALLOSTASIS, AND ALLOSTATIC LOAD

"Stress" is an ambiguous term and the actual stress response has protective and potentially damaging effects³. On the one hand, the body responds to almost any novel or challenging event by releasing catecholamines that increase heart rate and blood pressure and help adapt to the situation. Yet, chronically increased heart rate and blood pressure produce a chronic wear and tear on the cardiovascular system that can result, over time, in disorders such as atherosclerosis, strokes, and heart attacks. For this reason, the term "allostasis" was introduced by Sterling and Eyer⁴ to refer to the active process by which

the body responds to daily events and maintains homeostasis (*allostasis* literally means "achieving stability through change"). Because chronically increased allostasis can lead to disease, we introduced the term "allostatic load or overload" to refer to the wear and tear that results from either too much stress or from inefficient management of allostasis (e.g., not turning off the response when it is no longer needed). Other states that lead to allostatic overload are summarized in [Figure 26-1](#) and involve not turning on an adequate response in the first place or not habituating to the recurrence of the same stressor, which then fails to dampen the allostatic response.³

PROTECTION AND DAMAGE AS THE TWO SIDES OF THE RESPONSE TO STRESSORS

Thus protection and damage are the two contrasting sides of the physiology that defend the body against the challenges of daily life, whether or not we call them "stressors." Besides adrenalin and noradrenalin, there are many mediators that participate in allostasis, and they are linked together in a network of regulation that is nonlinear ([Figure 26-2](#)), meaning that each mediator has the ability to regulate the activity of the other mediators, sometimes in a biphasic manner. Glucocorticoids are the other major "stress hormones." Proinflammatory and anti-inflammatory cytokines are produced by many cells in the body, and they regulate each other and are, in turn, regulated by glucocorticoids and catecholamines. Whereas catecholamines can increase proinflammatory cytokine production, glucocorticoids are known to inhibit this production.^{5,6} The parasympathetic nervous system also plays an important regulatory role in this nonlinear network of allostasis since it generally opposes the sympathetic nervous system and, for example, slows the heart and also has anti-inflammatory effects.^{7,8}

What this nonlinearity means is that when any one mediator is increased or decreased, there are compensatory changes in the other mediators that depend on time course and level of change of each of the mediators. Unfortunately, we cannot measure all components of this system simultaneously and must rely on measurements of only a few of them in any one study. Yet the nonlinearity must be kept in mind in interpreting the results.

MEASUREMENT OF ALLOSTATIC LOAD

Measurement of allostatic load and overload involves sampling of key mediators that may be elevated in what are called "allostatic states"⁹ and markers of cumulative change such as abdominal fat. Allostatic states refer to the response profiles of the mediators themselves as shown in [Figure 26-1](#). On the other hand, allostatic overload focuses on the tissues and organs and other end points that show the cumulative effects of overexposure to the mediators

Figure 26-1. Four types of allostatic load. The top panel illustrates the normal allostatic response, in which a response is initiated by a stressor, sustained for an appropriate interval, and then turned off. The remaining panels illustrate four conditions that lead to allostatic load: *top, left* repeated “hits” from multiple stressors; *top, right* lack of adaptation; *bottom, left* prolonged response due to delayed shut down; and *bottom, right* inadequate response that leads to compensatory hyperactivity of other mediators (e.g., inadequate secretion of glucocorticoid, resulting in increased levels of cytokines that are normally counter-regulated by glucocorticoids). (From McEwen BS. *Protective and damaging effects of stress mediators*. *N Engl J Med* 1998;338:171–9.)

of allostasis. These are done by collecting samples from subjects in a minimally invasive and cost-effective manner. This limits the choice to the circulating mediators, such as glucocorticoids, DHEA, catecholamines, and certain cytokines. Salivary assays are particularly attractive, but then the question arises as to how to sample over time to get an adequate representation of a dynamic system since the levels of the mediators may fluctuate during the day and night. This is a topic unto itself and has been the subject of a number of methodological studies (see Web site for MacArthur SES and Health Research Network: www.macses.ucsf.edu/). Table 26-1 contains a list of some end points that can be used for cumulative assessment of

allostatic overload in different systems of the body. These are currently in use in the Coronary Artery Risk Development In Young Adults (CARDIA) Study and have been shown to have predictive power for a number of health outcomes.^{10–13}

BEING “STRESSED OUT,” ESPECIALLY SLEEP DEPRIVATION AND ITS CONSEQUENCES

The common experience of being stressed out has as its core the elevation of some of the key systems that lead to allostatic load—cortisol, sympathetic activity, and proinflammatory

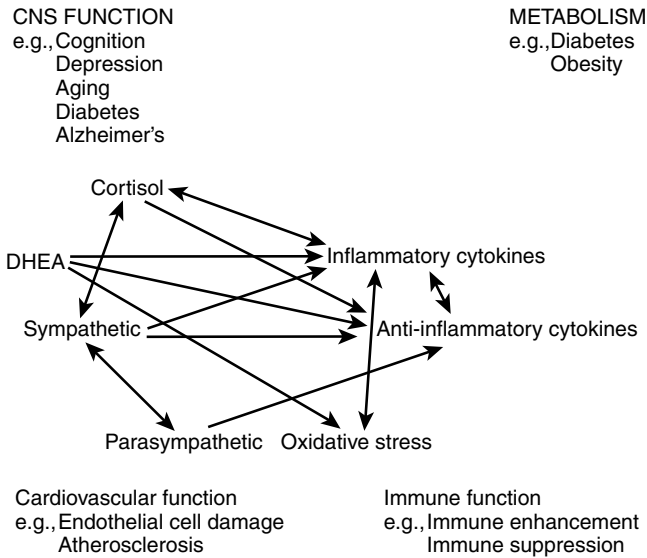

Figure 26-2. Nonlinear network of mediators of allostasis involved in the stress response. Arrows indicate that each system regulates the others in a reciprocal manner, creating a nonlinear network. Moreover, there are multiple pathways for regulation (e.g., inflammatory cytokine production is negatively regulated via anti-inflammatory cytokines, and via parasympathetic and glucocorticoid pathways, whereas sympathetic activity increases inflammatory cytokine production). Parasympathetic activity, in turn, contains sympathetic activity. (From McEwen BS. Protective and damaging effects of stress mediators: central role of the brain. *Dialogues Clin Neurosci* 2006;8:367–81.)

cytokines, with a decline in parasympathetic activity. Nowhere is this better illustrated than for sleep deprivation, which is a frequent result of experiencing a lot of stress. Sleep deprivation produces an allostatic overload that can have deleterious consequences, which are particularly evident in aging: for example, poor sleep in aging women has been associated with elevated levels of IL-6.¹⁴ Sleep restriction to 4 hours of sleep per night increases blood pressure, decreases parasympathetic tone, increases evening cortisol and insulin levels, and promotes increased appetite, possibly through increases in ghrelin and decreases in leptin.^{15–17} Proinflammatory cytokine levels are increased, along with performance in tests of psychomotor vigilance, and this has been reported to result from a modest sleep restriction to 6 hours per night.¹⁸ Moreover, reduced sleep duration has been reported to be associated with increased body mass

and obesity in the NHANES study.¹⁹ Sleep deprivation also causes cognitive impairment.¹⁵

KEY ROLE OF THE BRAIN IN RESPONSE TO STRESS

The brain is the master regulator of the neuroendocrine, autonomic, and immune systems, along with determining behaviors that contribute to unhealthy or healthy lifestyles, which, in turn, influence the physiologic processes of allostasis.³ See Figure 26-3. Alterations in brain function by chronic stress can therefore have direct and indirect effects on the cumulative allostatic overload. Allostatic overload resulting from chronic stress in animal models causes atrophy of neurons in the hippocampus, prefrontal cortex, brain regions involved in memory, selective attention, and executive function, and hypertrophy of neurons in the amygdala, a brain region involved in fear, anxiety, and aggression.¹⁵ Thus the ability to learn, remember, and make decisions may be compromised by chronic stress and may be accompanied by increased levels of anxiety and aggression. A recent study has shown increased reactivity of the amygdala to neutral facial expressions, indicating an increase in anxiety and reactivity, resulting from a few days of sleep deprivation.²⁰

TRANSLATION TO THE HUMAN BRAIN

Much of the impetus for studying the effects of aging and stress on the structure of the human brain has come from the animal studies summarized elsewhere.¹⁵ Age-related reductions in entorhinal and hippocampal volume have been associated with mild cognitive impairment and early stages of Alzheimer's disease, and a longitudinal study of aging Montreal residents revealed a smaller hippocampus and impaired hippocampal spatial and memory functions in those who showed rising cortisol levels during a yearly examination.²¹ Although it is not possible to pinpoint causal factors in these age-related changes, stress and glucose regulation, along with depression and other mood and anxiety disorders, must be considered.

Regarding stress, although there is very little evidence regarding the effects of ordinary life stressors on brain structure, there are indications from functional imaging of individuals undergoing ordinary stressors (such as counting backwards) that there are changes in neural activity.²² There are also long-term effects (e.g., chronic transcontinental air travel with short turnaround time, a type of chronic stress is associated with a smaller hippocampus,²³ and a 20-year history of high perceived stress has been associated with smaller hippocampal volumes).²⁴

Stress causes depressive illness in individuals with certain genetic predispositions,^{15,25} and the hippocampus, amygdala, and prefrontal cortex show altered patterns of activity in PET and fMRI and changes in volume: decreased volume of hippocampus and prefrontal cortex and amygdala, although amygdala volume has been reported to increase in the first episode of depression, whereas hippocampal volume is not decreased.²⁶

There is hippocampal volume loss in Cushing's disease along with cognitive impairment and depressed mood that can be relieved by surgical correction of the hypercortisolemia.²⁷ Moreover, there are a variety of other anxiety-related disorders, such as posttraumatic stress disorder (PTSD) and

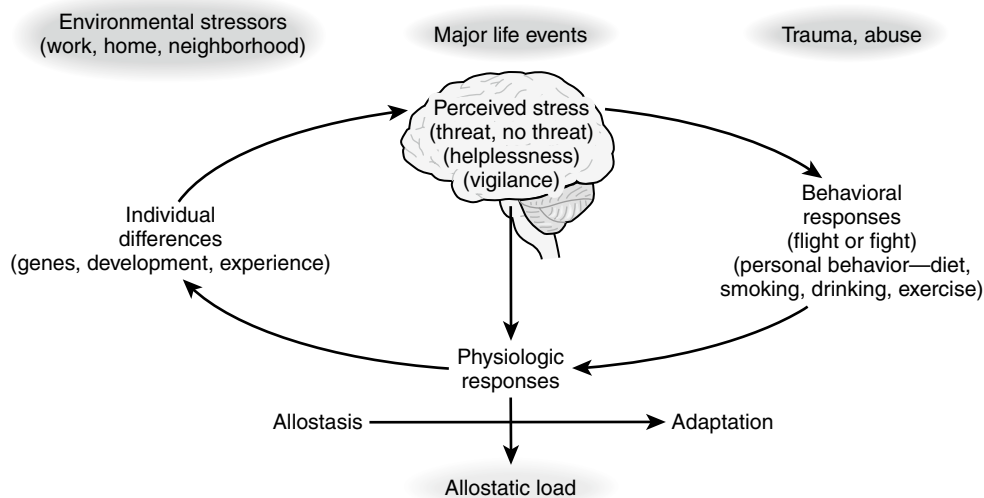

Figure 26-3. Central role of the brain in allostasis and the behavioral and physiologic response to stressors. (From McEwen BS. Protective and damaging effects of stress mediators. *N Engl J Med* 1998;338:171–9.)

borderline personality disorder, in which there is atrophy of the hippocampus.¹⁵ Another important factor in hippocampal volume and function is glucose regulation. Poor glucose regulation is associated with smaller hippocampal volume and poorer memory function in individuals in their 60s and 70s who have “mild cognitive impairment” (MCI),²⁸ and in those with frank type 2 diabetes.²⁹

POSITIVE AFFECT, SELF-ESTEEM, AND SOCIAL SUPPORT

Having a positive outlook on life and good self-esteem appear to have long-lasting health consequences,³⁰ and good social support is also a positive influence on the measures of allostatic load.³¹ Positive affect, assessed by aggregating momentary experiences throughout a working or leisure day, was found to be associated with lower cortisol production and higher heart rate variability (showing higher parasympathetic activity), and a lower fibrinogen response to a mental stress test.³²

On the other hand, poor self-esteem has been shown to cause recurrent increases in cortisol levels during a repetition of a public speaking challenge in which those individuals with good self-esteem are able to habituate (i.e., attenuate their cortisol response after the first speech).³³ Furthermore, poor self-esteem and low internal locus of control have been related to 12% to 13% smaller volume of the hippocampus in both younger and older subjects, and higher cortisol levels during a mental arithmetic stressor.³⁴

Related to both positive affect and self-esteem is the role of friends and social interactions in maintaining a healthy outlook on life. Loneliness, often found in people with low self-esteem, has been associated with larger cortisol responses to wakening in the morning and higher fibrinogen and natural killer cell responses to a mental stress test, and sleep problems.³⁵ On the other hand, having three or more regular social contacts, as opposed to 0 to 2 such contacts, is associated with lower allostatic load scores.³¹

DELETERIOUS ROLE OF ADVERSE EARLY LIFE EXPERIENCE

The aging process begins at conception, and experiences early in life have a profound influence on the quality and length of life. Early life experiences perhaps carry an even greater weight in terms of how an individual reacts to new situations.¹⁵ For example, adverse early life experiences involving physical and sexual abuse carry with it a life-long burden of behavioral and pathophysiologic problems, and cold and uncaring families produce long-lasting emotional problems in children. These adverse experiences impact upon brain structure and function and the risk for later depression and posttraumatic stress disorder.^{36,37}

CONCLUSIONS

Because environmental factors and experiences play a large role in the aging process, understanding and manipulating those factors can reduce the accumulation of allostatic overload. There are a number of approaches to deal with stress and allostatic overload as they affect the life course and affect health later in life. For the individual, these include lifestyle, personal habits, and pharmaceutical agents. For society, there are policies of government and the private sector.

For the individual, life-long habits may be hard to change, and it is often necessary to turn to pharmacologic interventions: sleeping pills, anxiolytics, β -blockers, and antidepressants are all drugs that are used to counteract some of the problems associated with the accumulation of allostatic overload. Likewise, drugs that reduce oxidative stress or inflammation, block cholesterol synthesis or absorption and treat insulin resistance or chronic pain can help deal with the metabolic and neurologic consequences of being chronically stressed out. All of these agents have value, and yet each one has side effects and limitations that are based in part on the fact that all of the systems that are dysregulated in allostatic overload are also systems that interact with each other and perform normal functions when properly regulated, as

described in Figure 26-2. Because of the nonlinearity of the systems of allostasis, the consequences of any pharmaceutical treatment may be either to inhibit the beneficial effects of the systems in question or to perturb other systems in a direction that promotes an unwanted side effect. Examples of the former include the problems with cox 2 inhibitors³⁸ and examples of the latter include the obesity-inducing effects of some of the atypical antipsychotics that are widely used to treat schizophrenia and bipolar disorder.³⁹

The private sector has a powerful role, and businesses that encourage healthy lifestyle practices among their employees are likely to gain reduced health insurance costs and possibly a more loyal workforce.^{40,41} Moreover, governmental policies are important, and the Acheson Report⁴² from the United Kingdom in 1998 recognized that no public policy should be enacted without considering the implications for health of all citizens. Thus basic education, housing, taxation, setting of a minimum wage, and addressing occupational health and safety and environmental pollution regulations are all likely to affect health via a myriad of mechanisms. At the same time, providing higher quality food and making it affordable and accessible in poor and affluent neighborhoods, is necessary for people to eat better, providing they also learn what types of food to eat and can afford them. Likewise, making neighborhoods safer and more congenial and supportive⁴³ can improve opportunities for positive social interactions and increased recreational physical activity. For the elderly population, community centers and activities that promote social interactions and physical activity have been demonstrated to be beneficial.^{44,45}

Finally, there are programs that combine some of the key elements just described, namely, education, physical activity, and social support, along with one other ingredient that is hard to quantify: namely, finding meaning and purpose in life. One example is the Executive Volunteer Corps and another is the Experience Corps, which takes elderly volunteers and trains them as teachers' assistants for younger children in the neighborhood schools.⁴⁶ Not only does this program improve the education of the children, it also benefits the elderly volunteers and improves their physical and mental health.⁴⁷ Thus finding ways of improving the

social and physical environment in which people live their lives should reduce the need for more direct medical and psychiatric interventions for everyone, particularly the elderly.

KEY POINTS

Allostasis and Allostatic Overload in the Context of Aging

- Events of daily life can produce the feeling of being "stressed out" and elevate and sustain activities of physiologic systems and promote health damaging behaviors and poor sleep.
- Accumulated over time, this results in wear and tear on the body, which is called "allostatic load/overload." This accumulated wear and tear reflects not only the impact of experiences, but also genetic constitution, individual behaviors and lifestyle habits, and early life experiences that set life-long patterns of behavior and physiologic reactivity.
- Hormones and other mediators associated with stress and allostatic overload protect the body in the short run and promote adaptation by the process known as allostasis.
- The brain is the key organ of stress, allostasis, and allostatic overload because it determines what is threatening and therefore stressful, and also determines the physiologic and behavioral responses. Brain regions such as the hippocampus, amygdala, and prefrontal cortex respond to acute and chronic stress by undergoing structural remodeling, which alters behavioral and physiologic responses.
- Imaging studies of the human brain show smaller hippocampal volume in mild cognitive impairment in aging, Type 2 diabetes and prolonged major depressive illness, and in individuals with low self-esteem. Structural and functional alterations in amygdala and prefrontal cortex are also reported.
- Besides pharmaceutical agents, approaches to alleviate chronic stress and prevent diseases related to allostatic overload include changes in personal habits and lifestyle, and policies of government and business that would improve the ability of individuals to reduce their own chronic stress burden as they become older.

Neuroendocrine senescence is a multifactorial process with a high degree of interpersonal variability and subject to a host of beneficial or detrimental influences. As such, neuroendocrine aging is an illustrative example of both the aging process and of modifiers of aging¹ (also see Chapter 20). Neuroendocrine aging is inextricably linked with reproductive aging. In this regard, reproductive senescence and the stages therein provide a window into the dysregulation of endocrine systems that ultimately results in the aging profile. For both women and men reproductive aging results from the complex interplay of age-dependent endocrine changes and the hypothalamus-pituitary-gonadal axis.² Although reproductive senescence leads to a loss of function, the neuroendocrine profile is characterized by both gains and loss of function. This brief review focuses on reproductive aging in women and men as an illustrative case of neuroendocrine aging. Further reviewed is the impact of neuroendocrine changes of reproductive senescence on a hallmark of aging—decreased metabolism.

Reproductive Aging in Women

The female reproductive axis is composed of the hypothalamic-pituitary-ovarian-uterine axis and undergoes accelerated aging relative to other systems that are otherwise healthy. Reproductive senescence in women is defined by oocyte depletion, which begins at birth and proceeds as a continuum until menopause is achieved. A woman is endowed at birth with a finite number of oocytes that are arrested in prophase I of meiosis. Reproductive aging consists of a steady loss of oocytes through ovarian follicular atresia or ovulation, which does not necessarily occur at a constant rate.^{3–5} The relatively wide age range (42 to 58 years) for menopause in normal women seems to indicate that women are either endowed with a highly variable number of oocytes or that the rate of oocyte loss varies greatly. Menopause occurs at an average age of 51.4 years with a Gaussian distribution from 40 to 58 years.² In the United States, approximately 1.5 million women reach menopause each year, and more than 45 million women will be over the age of 55 in 2020.⁶

Normal reproductive aging in women is characterized by three distinct phases that can span years: perimenopause (also known as the menopause transition), menopause, and postmenopause. According to the Stages of Reproductive Aging Workshop (STRAW),⁶ reproductive senescence occurs over the span of years that can be subdivided into three distinct stages.⁶ Variable cycle length, variable cycle intervals, and high FSH characterize the menopausal transition or perimenopause, subdivided into early and late transition states. A year of amenorrhea is considered the end to the perimenopause state. The end of the amenorrhic year constitutes the onset of the postmenopausal stage, which is also subdivided into early and late components. Early postmenopause is defined by 4 years since the last menstrual period. Subsequent to these 4 years, late stage postmenopause then ensues and lasts until the woman's death.

PERIMENOPAUSE TO MENOPAUSE

The menopause transition or perimenopause is characterized by menstrual and endocrine changes in the hypothalamic-pituitary-ovarian-uterine axis that lead inexorably to reproductive senescence.⁷ During perimenopause, ovulation occurs irregularly as a result of fluctuations in the hypothalamic and pituitary hormones.^{3,5,8} In late phase perimenopause, nearly half of cycles are anovulatory.⁵ In the ovulatory cycles, FSH, LH, and E2 levels increase with progression of STRAW stage, and in the luteal phase, serum progesterone decreases. Early cycle (ovulatory and anovulatory) inhibin B decreases steadily across the STRAW stages and is largely undetectable during elongated ovulatory and anovulatory cycles during the transition. The decline of inhibin B during early perimenopause results in the rise in follicle-stimulating hormone (FSH), with no significant change in inhibin A or estradiol levels.⁹ FSH levels may rise during some cycles but return to premenopausal levels in subsequent cycles.⁹ Further complicating the determination of FSH concentration is the pulsatile pattern of secretion. The variability in hormone levels creates difficulties in interpreting a single laboratory test value³ but an increase in FSH continues to be a clinical marker of ensuing menopause and postmenopause.⁶

In late stage perimenopause, concentrations of 17 β -estradiol are highly variable.⁵ Estrogen levels can be both persistently low, as might be expected, but can also be abnormally high. High 17 β -estradiol concentration is associated with increased vulnerability to neurodegenerative insults and neuronal cell death.¹⁰ A high level of 17 β -estradiol does not reduce the persistently high FSH and LH levels.^{4,5} Remarkably, the cyclicity of progesterone appears to remain generally intact, whereas the level of progesterone can vary between normal values, to high spikes of progesterone, to undetectable levels.⁹

Menopause is the final stage of perimenopause and is complete after 12 months of amenorrhea following the final menstrual cycle, which reflects a near complete but natural decrease in ovarian hormone secretion. Three to 11 months of amenorrhea or of irregular periods in women aged 45 to 55 years were most predictive of menopause within the following 3 years.³

Symptomatically, hot flashes (also referred to as flushes) are most likely to occur during late stage perimenopause and early stage postmenopause.⁶ The prevalence of hot flashes in women is low but present in ~10% of women during the late stage of reproductive life.¹¹ Prevalence increases substantially in early perimenopause, reaches a maximum in late stage perimenopause, remains high into the early postmenopausal stage, and returns to a low but persistent prevalence in late stage postmenopausal women.¹¹ Prevalence for hot flashes can range from 30% to 80%.¹² Women aged 40 to 60 years who have had a hysterectomy and oophorectomy are at high risk for hot flashes.^{11,12} In most women, hot flashes are transient. The condition improves within a few months in about 30% to 50% of women and resolves in 85% to 90% of women within 4 to 5 years. However,

10% to 15% of women continue to have hot flashes into late stage postmenopause. Although the mechanism leading to hot flashes remains unknown, the resemblance to heat-dissipation responses has led to the dysfunction of thermoregulation by the anterior hypothalamus hypothesis. The exact role of estrogen in the pathogenesis of hot flashes remains unresolved. While estrogen levels do not differ substantially between postmenopausal women who have hot flashes and those who do not, the withdrawal of estrogen can induce hot flashes in women with gonadal dysgenesis who received estrogen therapy that was subsequently discontinued, suggesting that estrogen withdrawal plays a role in the cause of hot flashes.¹¹ In the Study of Women's Health Across the Nation (SWAN), a large U.S. multicenter cohort study, higher levels of FSH were the only hormonal measure independently associated with flushing after adjustment for levels of estradiol and other hormones.¹¹ Women undergoing pharmacologic therapies to antagonize estrogen receptor activation by selective estrogen receptor modulators (SERMs) or to inhibit estrogen synthesis using 5 α -reductase inhibitors for breast cancer experience a significant rise in the frequency of hot flashes.

POSTMENOPAUSE

Like the perimenopause, postmenopause is separated into an early and late stage. Early postmenopause is defined as 5 years since the final menstrual cycle.⁶ Levels of FSH continue to be high during early menopause and remain elevated throughout the late stage of postmenopause.⁶ During the early postmenopause phase there is a significant decline in ovarian hormones to a permanently low level, which is associated with accelerated bone loss.^{13,14} Postmenopausal women undergo two phases of bone loss, whereas aging men undergo only one.¹⁴ In women, the menopause initiates an accelerated phase of predominantly trabecular bone (also known as cancellous and spongy bone) loss that declines over 4 to 8 years, followed by a slow phase that disappears after 15 to 20 years when severe depletion of trabecular bone stimulates counter-regulatory forces that limit further loss.¹⁴ The accelerated phase results from the loss of the direct repressive effects of estrogen on bone turnover, which is mediated by estrogen receptors in both osteoblasts and osteoclasts. During menopause, bone resorption increases by 90%, whereas bone formation markers increase by only 45%. In the ensuing slow phase, the rate of trabecular bone loss is reduced, but the rate of cortical bone loss can be increased.¹⁴ Both serum-bioavailable estrogen and testosterone decline in aging men, and bioavailable estrogen is the major predictor of their bone loss. Thus both sex steroids are important for developing peak bone mass, but estrogen deficiency is the major determinant of age-related bone loss in both sexes.¹⁴ Trabecular bone has low density and strength but very high surface area and fills the inner cavity of long bones. The external layer of trabecular bone contains red bone marrow, where hematopoiesis occurs and where most of the arteries and veins of bone organs are found. A wide range of pharmacologic agents are available to prevent and treat osteoporosis, including antiresorptive estrogen, selective estrogen receptor modulators (SERMs), bisphosphonates, calcitonin, or anabolic therapies including parathyroid hormone (PTH1-34 or PTH 1-84) and agents with yet undetermined mechanism of action such as strontium ranelate.^{15,16}

Corrections in general deficiencies in calcium, vitamin D, or both are a first line of therapeutic intervention.^{15,16}

Therapeutic horizons

Multiple pharmacologic and nonpharmacologic interventions have been used to treat hot flashes, with the most common pharmacologic intervention being estrogen or hormone therapy.^{11,17} Multiple types of estrogen, doses, and routes of administration have been developed. Each formulation targets cessation of hot flashes and prevention of osteoporosis with near equal efficacy depending on the dose.¹¹ A recent position statement from the North American Menopause Society (NAMS) supports initiation of estrogen or hormone therapy around the time of menopause to treat menopause-related symptoms.¹⁸ Use of hormone therapy was supported to treat or reduce the risk of certain disorders, such as osteoporosis or fractures and hot flashes in select postmenopausal women.¹⁹ Analysis of the benefit-risk ratio for menopausal hormone therapy indicated favorable benefit close to menopause but decreased benefit with aging and advanced time after menopause in previously untreated women.¹⁸ The attendant risks and side effects of estrogen or hormone therapy are substantial,²⁰ which has led to behavioral and alternative therapies. However, there is no convincing evidence that acupuncture, yoga, Chinese herbs, dong quai, evening primrose oil, ginseng, kava, red clover extract, or vitamin E improve hot flashes.¹¹ Clinical trials of soy phytoestrogens have been inconsistent in showing benefit, with most randomized double-blind clinical trials indicating no significant benefit for treatment of hot flashes.²¹

The association between hormone therapy and increased risk of neoplasias in reproductive organs (see Chapter 89) has led to the development of selective estrogen receptor modulators in an attempt to selectively activate the beneficial effects of estrogen while reducing the risks of therapy. In recent years, an increasing number of estrogen receptor ligands and novel SERMs have been identified from nature, whereas others have been designed and synthesized *de novo* within academia and the pharmaceutical industry.²² The FDA-approved indications for hormone therapy in women are for treatment of hot flashes and prevention of osteoporosis, whereas SERMs are approved for breast cancer prevention and treatment of osteoporosis. Thus pharmaceutical industry efforts focus on the FDA-approved indications along with antineoplastic action in the breast and uterus. Although these molecules are diverse, the unifying feature of these development efforts is that they do not specifically target estrogenic actions in the brain and they typically increase the occurrence and frequency of hot flashes.²² The oldest and most studied SERM is tamoxifen (TMX), a triphenylethylene derivative, nonsteroidal first-generation SERM.²² 4-hydroxytamoxifen (OHT) is a minor metabolite of TMX, with a shorter half-life but binds to ER with a binding affinity 20 to 30 times greater than TMX and equivalent to that of 17 β -estradiol.²² Tamoxifen functions as an ER antagonist in the breast, but can act as an ER agonist activity in bone, liver, and uterus.²² Since 1971 TMX has been used to treat breast cancer in premenopausal and postmenopausal women and in 1999 TMX was recommended for use in breast cancer prevention.²² Another nonsteroidal SERM for the treatment of osteoporosis is raloxifene (RAL), a benzothiophene derivative nonsteroidal second-generation SERM. Similar to TMX,

RAL has a mixed pharmacologic profile, acting as both an ER agonist and antagonist in a tissue-specific manner. In the breast and uterus, RAL acts as a classic antiestrogen to inhibit the growth of mammary or endometrial carcinoma, whereas in nonreproductive tissues, it acts as a partial estrogen agonist to prevent bone loss and lower serum cholesterol with a pharmacologic profile similar to that of 17 β -estradiol in both ovariectomized rats and postmenopausal women.²² In recent years, an increasing number of third and fourth generation novel SERMs has been identified and developed within both academia and the pharmaceutical industry.²² With enhanced efficacy, specificity, and antineoplastic action in the breast and uterus, novel SERMs demonstrate more potential clinically therapeutic uses for prevention or treatment of menopause-related symptoms, such as hot flashes and osteoporosis. One such molecule is bazedoxifene, developed by Wyeth in collaboration with Ligand Pharmaceuticals. Available data for tolerability and efficacy suggest that bazedoxifene can significantly reduce bone loss, prevent fractures, and is expected to be an attractive choice for a wide range of postmenopausal women who are estimated to have osteoporosis or are at risk for developing the disease.²³ The combined use of bazedoxifene and conjugated estrogens is currently under clinical development for the prevention of postmenopausal osteoporosis and the treatment of vasomotor symptoms associated with menopause.²³ Eli Lilly, which originally developed RAL marketed under the trade name of Evista, is currently testing its next generation SERM arzoxifene in a phase III clinical trial for preventing or treating osteoporosis and breast cancer in postmenopausal women. Preclinical data have demonstrated that arzoxifene is a potent estrogen antagonist in mammary and uterine tissue while acting as an estrogen agonist to maintain bone density and lower serum cholesterol.^{22,23} SERMs that target estrogen action in the brain are being developed as NeuroSERMs and PhytoSERMs and are in early stage preclinical development.^{24,25}

Unresolved issues in reproductive senescence in women

To date, there is no pharmacogenomic strategy for identifying women appropriate for hormone therapy or which hormone therapy would be most efficacious. Genomic strategies to date have identified estrogen receptor polymorphisms associated with increased risk of cognitive impairment in aged women. However, several single nucleotide polymorphisms (SNPs) on *ER α* (*ESR1*) and *ER β* (*ESR2*) genes have been associated with a range of hormone-sensitive diseases, such as breast cancer and osteoporosis. Estrogen receptor genetic variations may also influence cognitive aging and were investigated in a cohort of 1343 women (mean age 73.4 years) and 1184 men (mean age 73.7 years).²⁶ Among women, two of the *ER α* SNPs (rs8179176, rs9340799)^{26,27} and two of the *ER β* SNPs (rs1256065, rs1256030) were associated with the likelihood of developing cognitive impairment.²⁶ In men, one of the *ER α* SNPs (rs728524) and two of the *ER β* (rs1255998, rs1256030) were associated with cognitive impairment. These findings suggest that estrogen receptor genetic variants may play a role in cognitive aging. Tailoring hormone therapy based on SNP profile remains uncharted territory.

Timing of hormone therapy intervention is of critical importance and several studies are underway to determine the impact of timing of hormone therapy. Emerging

evidence supports a critical window of therapeutic opportunity²⁸ that is related to the healthy cell bias of estrogen action.^{29,30} The healthy cell bias of estrogen action hypothesis predicts that estrogen therapy, if initiated at the time of perimenopause to menopause when neurologic health is not yet comprised, will be of benefit as manifested as reduced risk for age-associated neurodegenerative diseases, such as Alzheimer's and Parkinson's.^{29,30}

The issue of whether oophorectomy before undergoing the menopause transition has implications for neuroendocrine and neurologic aging remains unresolved. However, increasing evidence indicates that the natural process of reproductive senescence is a systematic biologic strategy to transition from reproductive fertility to reproductive senescence. In contrast, women undergoing oophorectomy typically have not undergone this systematic transition that requires years to complete. Emerging evidence indicates that oophorectomy before menopause transition has profound consequences for subsequent risk of neurodegenerative disease. Women who underwent either unilateral oophorectomy or bilateral oophorectomy before the onset of menopause had significant increased risk of parkinsonism, cognitive impairment or dementia, and diagnosed depressive illness relative to referent women.^{31–33} The increased risk for either parkinsonism or cognitive impairment was similar regardless of the indication for the oophorectomy, and for women who underwent unilateral or bilateral oophorectomy, they were considered separately.^{31,32,34} The risk of parkinsonism and of cognitive impairment or dementia increased following oophorectomy with significant linear trends of increasing risk for either outcome with a younger age at oophorectomy.³⁴ In women who underwent bilateral oophorectomy at younger ages with depressive illness, treatment with estrogen to age 50 years did not modify the long-term risk of depressive and anxiety symptoms.³³ Further, mortality was significantly higher in women who had received a prophylactic bilateral oophorectomy before the age of 45 years relative to referent women (hazard ratio 1.67 [95% CI, 1.16–2.40], $p = 0.006$).³⁵ Increased mortality was observed principally in women who had not received estrogen therapy up to the age of 45 years.³⁵ Collectively, these emerging data indicate a significant and profound impact of prohibiting the menopause transition.

The long-lasting changes in the brain that underlie the transition are largely unexplored beyond the changes in hypothalamic hormones involved in the reproductive cycle. The early, unrelenting, and persistent elevated levels of FSH and the consequences at the cellular and systems level in the brain remain unknown. The rise in FSH is a remarkable example of a gain of function associated with aging.

Major challenges for optimal estrogen and hormone therapy remain. Beyond the timing issue,^{28,29} the real and perceived risks of hormone therapy remain and are amplified by results of both the WHI and WHIMS trials.^{36–38} It is clear that many, *but not all*, women could potentially benefit from estrogen or hormone therapy intervention. Biomarkers to identify women appropriate for treatment and the type of hormone regimen remains largely undeveloped beyond hot flashes. Hormone therapy interventions that selectively target the benefits of estrogen while avoiding untoward risk factors remain an unmet need in women's health. Estrogen alternatives that activate estrogen mechanisms in the brain

but not in the breast or uterus, such as NeuroSERMs and PhytoSERMs, are promising strategies for sustaining the benefits of estrogen in the brain to prevent age-associated neurodegenerative disease.^{30,39}

ANDROPAUSE

Like the female reproductive endocrine system, the male system reproductive axis is composed of the hypothalamic-pituitary-gonadal (HPG) axis, but unlike women the male reproductive system does not undergo accelerated aging, and fertility can be sustained throughout a man's lifespan.⁴⁰ Unlike women, for whom menopause leads to the irreversible end of reproductive life, an end of gonadal function and as a consequence low sex hormone levels in all postmenopausal women, fertility persists in men until very old age and the age-associated decrease in testosterone levels is slowly progressive.

Even though the age-associated decrease in testosterone levels is slowly progressive, a substantial proportion of men in their 80s still have bioavailable testosterone levels comparable to the normal range of young men. Therefore a significant decline in androgen levels is not a generalized feature of male aging, and as a rule androgen deficiency is only partial.⁴⁰ Moreover, the threshold level(s) of testosterone below which consequences of androgen deficiency become manifest, and which or how many clinical symptoms best establish the diagnosis of androgen deficiency, remains uncertain.⁴¹ Thus the existence of andropause as a medically definable condition remains controversial.⁴² Arguments in favor of clinical significance are the similarities between the symptomatology of aging and that of androgen deficiency in young hypogonadal men.⁴⁰ Opposing arguments cite the near ubiquitous decline of almost all physiologic systems and thus the decline in testosterone synthesis by the gonads is considered just one part of the complex mosaic of aging.⁴³ As such, the terms partial androgen deficiency of the aging male or late onset hypogonadism have been proposed as alternatives to andropause or male climacteric because of the connotation of a generalized phenomenon and of permanent infertility.

Consistent with a primary testicular cause of decreased testosterone production, mean serum luteinizing hormone (LH) levels in the male population tend to increase with age but this increase is of modest amplitude and is inconsistent.⁴⁰ For example, many elderly men with a serum testosterone concentration below that of young men do not have elevated LH levels. Moreover, the modest increases in basal serum LH in elderly men appear to result in part from a slower plasma clearance rather than from increased pituitary secretion.⁴⁰ Neuroendocrine aging in men is characterized by dysregulation of the pulsatile release pattern of LH secretion, whereas the regulation of FSH secretion is essentially maintained.⁴⁰ Therapeutically this is of significance as the testicular residual secretory capacity could allow many elderly men to substantially raise their serum testosterone levels, provided there was physiologically appropriate LH activation. The change in LH secretory pattern is due to changes in the feedback regulatory mechanisms within the hypothalamus as pituitary secretory capacity is preserved in the elderly.⁴⁰

Testosterone is largely bound to plasma proteins, only 1% to 2% being free, with 40% to 50% loosely bound to

albumin, and 50% to 60% specifically and strongly bound to steroid hormone binding globulin (SHBG).^{40,44} Unbound testosterone diffuses passively through the cell membranes into the target cell, where it binds to the specific androgen receptor (AR).⁴⁰ Androgen concentration in target tissues depends on plasma concentration of bioavailable androgen, local androgen metabolism, and the presence of androgen receptor. As would be expected, total androgen (testosterone + dihydrotestosterone [DHT]) concentration is highest in the prostate and scrotal skin, and higher in pubic skin than in striated muscle. In prostate and scrotal skin, the concentration of DHT is 5 to 10 times higher than that of testosterone, whereas in muscle DHT levels are extremely low. In the prostate, almost all androgenic effects are exerted by DHT via conversion of testosterone by type 2 5 α -reductase.⁴⁰ In many tissues DHT mediates most androgenic effects of testosterone. A notable exception is muscle, where testosterone is the active androgen.⁴⁰ Androgen deficiency is characterized by total testosterone levels of less than 300 ng/dL or bioavailable testosterone level of less than 5 ng/dL.⁴⁵

Androgenic actions of testosterone and DHT are mediated via binding to the androgen receptor (AR). Although testosterone and DHT bind to the same receptor, the affinity of DHT for the AR is greater than that of testosterone. Expression of AR is increased by androgens and estrogens (especially in the prostate), and decreased in aging in different tissues. In addition to the well-characterized nuclear androgen receptor that activates gene transcription, testosterone can also exert rapid, nongenomic effects, in part via binding to a G protein-coupled membrane receptor. The SHBG-testosterone complex initiates a cAMP-mediated, transcription-independent signaling pathway affecting calcium channels.⁴⁰ AR is highly expressed in male accessory sex organs and in some areas of the brain, whereas a lower level of AR expression occurs in skeletal muscle, in the heart and vascular smooth muscle, and in bone.⁴⁰ Sensitivity of AR to androgens is modulated by polymorphisms of the AR. The AR gene contains a polymorphic trinucleotide CAG-repeat in exon 1, which encodes a functionally relevant polyglutamine tract of variable length. A CAG-repeat length exceeding the normal range of 15 to 31 results in diminished AR transactivation function. Clinical studies have indicated that AR polymorphisms are associated with a higher prevalence of several androgen-sensitive diseases, including prostate cancer.⁴⁰

A subset of the physiologic actions of testosterone derives from its aromatization to 17 β -estradiol, which binds to estrogen receptors (ERs).⁴⁰ Documented estrogen-mediated actions of testosterone in men include a role in the feedback regulation of LH, a role in the regulation of skeletal homeostasis, and a role in lipid metabolism and cardiovascular physiology; among other possible estrogen actions in men, there are indications for a role in the brain and in spermatogenesis.⁴⁰ It appears that similar to women, declining bioavailable estrogen levels can play a significant role in age-related bone loss and fracture risk in men.⁴⁶ Consistent with a role of estrogen in bone development and remodeling, males with a homozygous deletion of the *ER α* gene or aromatase deficiency have unfused epiphyses, elevated markers of bone remodeling, and low bone mass despite normal or elevated testosterone levels.⁴⁶ Moreover, aromatase-deficient males responded to estrogen therapy with marked

increases in bone mass, consistent with an “anabolic” effect of estrogen, in contrast to its predominantly antiresorptive action in postmenopausal women.⁴⁶ As in women, aging in men is associated with continuous loss of bone and an exponential increase of the incidence of fractures of the hip and the spine.⁴⁶ Moreover, in older men the consequences of fractures in terms of morbidity and mortality appear to be more severe than in their female counterparts.⁴⁶ Acquired profound hypogonadism in men induces high bone turnover and accelerated bone loss, which parallels bone loss in elderly men.⁴⁶ Placebo-controlled clinical studies have shown that the benefits of testosterone to bone in older men are likely to depend largely, but not completely, on aromatization of the steroid to estradiol.⁴² However, declining bioavailable testosterone levels may also contribute as testosterone is an antiresorptive agent and promote maintenance of bone formation along with being aromatized to estradiol.⁴⁶

Therapeutic horizons

Androgen hormone therapy is available in multiple formulations that range from oral tablets to transdermal gels and patches to buccal adhesives to long-acting intramuscular injectables.⁴⁵ As with hormone therapy in women, testosterone therapy may be associated with increased risk of serious adverse effects in men. Metastatic prostate cancer and breast cancer are hormone-dependent cancers that may be stimulated to grow during testosterone treatment.⁴⁵ Consequently, the use of testosterone therapy, with its potential to increase risk and/or progression of prostate tumorigenesis, has been controversial and has led to the development of selective androgen receptor modulators (SARMs) that lack significant androgen action in the prostate but exert agonist effects in select androgen-responsive tissues of interest, including brain, muscle, and bone.⁴⁷ Several strategies of SARM design are being pursued.^{48,49} The first strategy is to develop novel steroidal compounds that are not substrates for the enzyme 5 α -reductase, which converts testosterone to DHT. As mentioned above, prostate growth is largely induced by DHT rather than testosterone as DHT exhibits ~tenfold greater potency for AR, which reflects both a higher binding affinity for AR and a slower dissociation rate from AR.⁴⁷ SARMs that are not 5 α -reductase substrates and thus do not form DHT or DHT-like derivatives have relatively low androgen action in the prostate. There are several synthetic androgens in this class that are potentially promising candidates with varied affinity for AR and androgenic activity, including 7 α -cyano-19-nortestosterone, 7 α -acetylthio-19-nortestosterone, 19-Nor-4-androstene-3 β ,17 β -diol 3 β ,19-nortestosterone, and 4-estren-3 α ,17 β -diol.⁴⁹ At this time, the most promising SARM in this category is 7 α -methyl-19-nortestosterone, commonly referred to as MENT.^{50–53} MENT, developed by the Population Council, is currently in clinical trials as an androgen therapy for hypogonadal men and exhibits low androgen activity in the prostate but is more potent than testosterone in other peripheral androgen-responsive tissues including bone.⁴⁹ Although not a substrate for 5 α -reductase, MENT is a substrate for aromatase and thus, like testosterone, can be converted to estradiol. Because many cellular effects of testosterone result from aromatization to estradiol and subsequent activation of ER-dependent signaling, there is potentially strong benefit in a SARM that exhibits both androgen and estrogen

functions. The effects of MENT on neural function are virtually unknown. The testosterone-based structure of MENT strongly suggests blood-brain barrier permeability. Another promising SARM in this class is 19-Nor-4-androstene-3 β ,17 β -diol (also called estren- β). Estren- β has high affinity for both estrogen and androgen receptors, a property that has benefits and liabilities as a SARM.⁴⁹ A second SARM design strategy is the development of non-steroidal synthetic AR ligands.⁵⁴ Of particular interest are compounds that bind AR but have altered interaction with AR binding pocket side chains that underlie tissue specificity.⁴⁹ An example of this class is BMS-564929, which is currently in clinical trials to improve musculoskeletal end points in hypogonadal men.

Unresolved issues in reproductive senescence in men

Many of the issues that are unresolved for reproductive senescence are applicable to men. The issue of hormone therapy for androgen deficiency remains controversial. Lowering of testosterone concentrations in adult men by surgical orchiectomy or by GnRH agonist or antagonist administration is associated with rapid and marked loss of bone mineral density, an increase in fat mass, and a loss of muscle mass and strength.^{41,46} Lowering of testosterone concentrations also results in hot flashes and a decrease in overall sexual activity, thoughts, and fantasies.⁴⁵ Hot flashes are common among men treated with androgen deprivation therapy for prostate cancer.¹¹

Testosterone therapy may be associated with increased risk of serious adverse effects in men. Metastatic prostate cancer and breast cancer are hormone-dependent cancers that may be stimulated to grow during testosterone treatment.⁴⁵ As prostate cancer is most typically a function of age, the long-term consequence of surgical or pharmacologic orchiectomy beyond the impact on bone and blood has not been established in men. Nor have biomarkers been developed to adequately identify men appropriate for androgen or SARM therapy.

Neuroendocrine aging and brain metabolism: implications for neurodegenerative disease

On average, the adult human brain represents approximately 2% of body weight but accounts for 20% of the oxygen and, hence, calories consumed by the body, which is 10 times that expected on the basis of its weight alone.⁵⁵ The high rate of metabolism is remarkably constant despite widely varying mental and motor activities.⁵⁵ Ongoing metabolic activity consists largely of the oxidation of glucose to carbon dioxide and water, resulting in the production of large amounts of energy in the form of ATP. Most of the energy used in the brain is required for the propagation of action potentials and for restoring postsynaptic ion fluxes after receptors have been stimulated by the neurotransmitter. Thus the greatest majority of the metabolic activity in the brain is devoted to synaptic processes.⁵⁵

The significant portion of energy metabolism in the brain devoted to maintaining synaptic transmission and integrity suggests that decrements in energy production would first affect synaptic transmission and physiology. Consistent with this postulate, mounting evidence suggests that Alzheimer’s disease (AD) begins with subtle alterations of

hippocampal synaptic efficacy before frank neuronal degeneration.⁵⁶ Further, hypometabolism in the brain predicts cognitive decline years in advance of the clinical diagnosis of AD.⁵⁷ The association between mitochondrial dysfunction and neurodegenerative diseases, such as Alzheimer's and Parkinson's, is mounting along with evidence that hypometabolism and a concomitant reduction and dysfunction in mitochondrial gene expression in the brain are antecedents to the cognitive deficits of AD.^{57–60} The association between hypometabolism and AD is based on multiple levels of analysis and experimental paradigms that range from genomic analyses in animal models and the postmortem autopsy human brain to *in vitro* cell model systems to brain imaging in humans. Overall, each of these levels of analyses indicate that dysfunction in glucose metabolism, bioenergetics, and mitochondrial function are consistent antecedents to development of Alzheimer pathology.^{57,60–67} The decline in brain glucose metabolism and mitochondrial function can appear decades before diagnosis and thus may serve as a biomarker of AD risk and a therapeutic target.^{57,63,67,68}

The circumstances that initiate hypometabolism remain to be fully determined but one clue is the shift in the brain from glucose as the primary energetic fuel to ketone bodies. Under metabolically challenging conditions (*i.e.*, starvation, aging, and neurodegeneration), neurons can use acetyl-CoA generated from ketone body metabolism (ketolysis) produced by the liver or under conditions of starvation in neighboring glial cells.³⁰ In AD there is a generalized shift toward use of an alternative fuel, ketone bodies. This is evidenced by an observed 45% reduction in cerebral glucose use in AD patients,⁶⁹ which is paralleled by a decrease in the expression of glycolytic enzymes that are coupled to a decrease in the activity of the pyruvate dehydrogenase complex.⁷⁰ Further, although there is a 100:0 ratio of glucose to other substrates utilization in young controls, there is a 2:1 ratio in incipient AD patients compared with a ratio of 29:1 in healthy elderly controls.⁷¹

Basic science analyses indicate that the endogenous estrogen, 17 β -estradiol, significantly increases glucose uptake, glucose metabolism, insulin growth factor signaling, and the energetic capacity of brain mitochondria by maximizing aerobic glycolysis (oxidative phosphorylation coupled to pyruvate metabolism).^{30,39} The enhanced aerobic glycolysis in the aging brain would be predicted to prevent conversion of the brain to use alternative sources of fuel such as the ketone body pathway characteristic of AD.^{30,39} The ability of estrogen to sustain glucose as the primary fuel source in the brain by enhancing glucose transport, uptake, and aerobic glycolysis (oxidative phosphorylation coupled to pyruvate metabolism) is likely linked to its ability to prevent age-associated metabolic decline in the brain and thus could be a key mechanism whereby estrogen reduces the risk of AD in postmenopausal women.^{30,39}

A growing body of evidence indicates that postmenopausal women experience a decline in brain metabolism that is prevented by estrogen therapy. As part of a 9-year study in the Baltimore Longitudinal Study of Aging, Resnick et al conducted positron emission tomography (PET) to assess regional cerebral blood flow in a small cohort of women who were estrogen therapy (ET) users versus women who were not. Results of this analysis showed that ET users and

nonusers showed significant differences in PET-regional cerebral blood flow—relative activation patterns during the memory tasks. ET users showed better performance on neuropsychological tests of figural and verbal memory and on some aspects of the PET activation tests.⁷² In a follow-up longitudinal study of the same cohort of healthy menopausal women, Maki and Resnick⁷³ found that regional cerebral blood flow was increased in estrogen therapy users relative to nonusers in the hippocampus, parahippocampal gyrus, and temporal lobe, regions that form a memory circuit and that are sensitive to preclinical AD.⁷³ Further, these investigators found that the increase in regional cerebral blood flow was associated with higher scores on a battery of cognitive tests.⁷³ In a separate 2-year follow-up analysis, Rasgon et al detected a significant decrease in metabolism of the posterior cingulate cortex among postmenopausal women at 2-year follow-up who did not receive estrogen, whereas those women who were estrogen users did not exhibit significant metabolic change in the posterior cingulate.⁷⁴ These findings that estrogen use may preserve regional cerebral metabolism and protect against metabolic decline in postmenopausal women, especially in the posterior cingulate cortex, is particularly important given that metabolism in this region of the brain declines in the earliest stages of AD.^{60,74}

As might be expected from reduced energy metabolism, postmenopausal women are at greater risk for developing metabolic syndrome. A longitudinal, 9-year study of 949 participants in the Study of Women's Health Across the Nation (SWAN) investigated the natural history of the menopausal transition in women of five ethnicities at seven geographic sites.⁷⁵ By the onset of menopause, 13.7% of the women had new-onset metabolic syndrome. Odds of developing the metabolic syndrome per year in perimenopause were 1.45 (95% confidence interval, 1.35–1.56); after menopause, 1.24 (95% confidence interval, 1.18–1.30). Surprisingly, an increase in bioavailable testosterone or a decrease in sex hormone-binding globulin levels increased the odds of developing metabolic syndrome. This longitudinal study of the largest cohort of middle-aged women undergoing the menopausal transition indicated that the prevalence of the metabolic syndrome increased significantly during the perimenopausal and early postmenopausal years, independent of aging and other known cardiovascular disease risk factors such as weight gain and smoking. Increased bioavailable testosterone emerged as an independent predictor, after controlling for aging and cardiovascular disease risk factors. These findings suggest that progression through menopause, with the associated decrease in estrogen level, results in a progressively androgen-dominated hormonal milieu, which then increases the risk of developing metabolic syndrome.⁷⁵

In contrast to the positive association of testosterone and metabolic syndrome in women, in healthy men there is a negative correlation between serum testosterone and free testosterone with visceral fat.⁴⁰ In a cohort study of 571 men aged 30 to 79 years, low testosterone levels predicted central obesity in men 12 years later.⁴⁰ Increased adiposity is itself partially responsible for a decrease of testosterone levels. Moreover, decreased growth hormone levels, as observed in elderly males, may also play a role in the age-associated changes in body composition.⁴⁰ Genetic analyses, functional imaging, and animal models of differential

aerobic capacity indicate a role of decreased mitochondrial function in inducing the metabolic disturbances characteristic of insulin-resistant states in men.⁷⁶ Dysfunctional mitochondria were evidenced by decreased maximal aerobic capacity and decreased expression of mitochondrial genes involved in oxidative phosphorylation in men of northern European descent with impaired glucose tolerance (IGT) and type 2 diabetes.⁷⁶ Hypogonadal men with low testosterone levels had a threefold higher prevalence of the metabolic syndrome relative to men with normal testosterone level.⁷⁶ Low serum testosterone levels were associated with an adverse metabolic profile to suggest that low testosterone levels and impaired mitochondrial function promote insulin resistance in men.⁷⁶

Remarkably, cognitively normal children, both male and female of 50 to 80 years old, with a maternal but not paternal history of Alzheimer's disease showed a reduction in the cerebral metabolic rate of glucose use in the same regions as clinically affected AD patients, involving the posterior cingulate cortex/precuneus, parietotemporal and frontal cortices, and medial temporal lobes.⁶⁷ As mitochondrial DNA is maternally inherited, these findings strongly suggest a relationship between mitochondrial function and hypometabolism characteristic of AD.⁶⁷

Collectively, these findings indicate that decrements in gonadal hormones are associated with hypometabolism in the brain, increased risk of metabolic syndrome, and decreased glucose metabolism in the brain characteristic of Alzheimer's disease. Further, early intervention with hormone therapy reversed the hypometabolism associated with hypogonadal hormone status.

ACKNOWLEDGMENTS

Research and preparation of this review were supported by grants from the National Institute on Aging (P01 AG026572), National Institute of Mental Health (1R01 MH67159), the Alzheimer's Drug Discovery Foundation, and the Kenneth T. and Eileen L. Norris Foundation to RDB.

KEY POINTS

Neuroendocrinology of Aging

- Neuroendocrine senescence is a multifactorial process with a high degree of interpersonal variability and subject to a host of beneficial or detrimental influences.
- Normal reproductive aging in women is characterized by three distinct phases that can span years: perimenopause (also known as the menopause transition), menopause which typically occurs between 49 and 51 years of age, and postmenopause.
- Increasing evidence indicates that an oophorectomy before the natural menopause transition has profound consequences for subsequent risk of neurodegenerative disease.
- In men, fertility persists until very old age and the age-associated decrease in testosterone levels is slowly progressive.
- Loss of gonadal hormones can be associated with dysfunction in glucose metabolism, bioenergetics, and mitochondrial function in the brain. Decreased brain metabolism precedes development of Alzheimer pathology, can be manifested decades before diagnosis, and may serve as a biomarker of Alzheimer disease risk and as a therapeutic target.

Normal Cognitive Aging

Jane Martin

Michelle Gorenstein

This chapter provides an overview of the principal features of cognitive functioning in normal aging adults. The first part of this chapter considers intelligence and the importance of estimating premorbid intellectual ability to detect discrepancies in functioning, followed by the concept of cognitive reserve being protective as we age. The cognitive functions of attention and processing speed, memory, verbal abilities, and executive functions are discussed in turn before a final section regarding the lifestyle factors associated with cognitive functioning. "Normal" in the present context refers to older individuals with no discernible mental illness and whose physical health is typical of their age group.

Intelligence and Aging

The figure of 5 million Americans aged 85 and above in 2007 is expected to grow to more than 19 million by the year 2050 based on projections by the U.S. Bureau of the Census.¹ By 2050 it is estimated there will be approximately 600,000 Americans aged 100 and above. As a consequence, cognitive studies of this age group are a necessary area of research. There is a need to understand what is normal or typical aging in contrast to the development of a disease process and additionally to understand what factors contribute to improved cognitive status with increasing age.

Literature on cognitive aging is based on studies of performance on standardized intelligence and neuropsychological tests. "IQ" refers to a derived score used in many test batteries designed to measure a hypothesized general ability: intelligence. The accepted definition is that general intelligence is a measure of overall ability on all types of intellectual tasks. General intelligence can be more specifically divided into the concepts of *fluid intelligence* and *crystallized intelligence*.² Fluid intelligence is the primary factor of most intelligence tests, measuring the degree to which an individual can solve novel problems without any previous training. On the other hand, crystallized intelligence is the amount of knowledge and information from the world that one brings to the testing situation. It has been established that fluid intelligence declines in older adults and crystallized intelligence is well preserved. The general theory is that fluid intelligence increases throughout childhood into young adulthood, but then plateaus and eventually declines; crystallized intelligence increases from childhood into late adulthood.²

Since a multitude of cognitive functions are assessed in an intelligence battery and IQ scores represent a composite of performances on different kinds of items, the meaningfulness of IQ is often questioned.³ The only widely agreed-upon value of IQ tests is that IQ scores are good predictors of educational achievement and consequently, occupational outcome. The argument about the usefulness of IQ scores is that a composite score does not highlight important information that is only obtainable by examining discrete scores and, for that reason, most widely used tests, such as the Wechsler's Adult Intelligence Scale (WAIS-III),⁴ now include measures of more discrete factors and domains. Even with the limitations, IQ scores help to provide a baseline of

overall intellectual functioning from which to assess performance on cognitive tests as we age.

PREMORBID ABILITY

Lezak, Howieson, and Loring caution that an estimate of premorbid ability should never be based on a single test score, but instead should take into account as much information about the individual as possible.³ Thus a good premorbid estimation of intelligence in adults uses current performance on tasks thought to be fairly resistant to neurologic change and demographics, such as educational and occupational attainment. This approach uses test scores obtained in the formal testing session of "hold" tests (i.e., tests that tap the abilities that are considered resistant to the effects of cerebral insult).⁵ Aspects of cognitive functioning that involve overlearned activities change very little in the course of aging, whereas functions that involve processing speed, processing unfamiliar information, complex problem-solving, and delayed recall of information typically decline with age.⁶ On the WAIS-III,⁴ tests such as vocabulary, information, and picture completion are considered relatively resistant to the effects of aging and thus are useful "hold" tests to help estimate overall premorbid levels of cognitive functioning. However, limitations exist that must be considered. For example, the information subtest reflects an individual's general fund of information and the score may be misleading because this test is strongly affected by level of education. Scores on word reading tests, such as the National Adult Reading Test (NART)⁷ developed in Britain and the subsequent AMNART⁸ for use in the United States, correlate highly with IQ and have been found to be relatively resistant to cerebral insult.⁵ However, the AMNART is not useful for an aphasic individual or someone with visual or articulatory problems. Again, the practice of using many sources of information to estimate an individual's premorbid level of cognitive functioning is essential.

Premorbid estimation of overall intellectual functioning is important to establish to compare current performance against some standard measure. However, comparing an individual's performance to a general population average score is misleading because it is only useful if the individual matches the population in terms of demographic measures, such as IQ and education. For example, *average* performance may be considered functioning at a normal level for one individual and may represent a significant decline for another individual. Thus a more useful approach is to compare an individual's current performance against an individualized standard. Only in this way can deficits or a diagnosis be discerned. Since premorbid neuropsychological test data are rarely available, it becomes necessary to estimate an individual's premorbid level of intellectual functioning against which present test scores can be compared to determine a change in cognitive functioning. Assessing a deficit involves comparing an individual's present performance on cognitive tests to an estimate of the individual's original ability level (premorbid level) and evaluating the discrepancies.³

COGNITIVE RESERVE

The concept of cognitive reserve^{9,10} proposes that there are differences in how individuals are able to compensate once pathology disrupts the brain networks that normally underlie performance. Thus variability exists across individuals in their ability to compensate for cognitive changes as they age. The cognitive reserve model evolved in response to the fact that often there is not a direct relationship between the degree of brain pathology that disrupts performance and the degree of disruption in actual performance across individuals. In other words, often individuals with a similar degree of brain pathology differ in their clinical presentation of functional ability. Reserve may represent naturally occurring individual differences in the ability to perform a task or deal with increases in task difficulty. These differences may be due to innate intellectual ability, such as IQ, and/or they may be altered by experiences of education, occupation, or leisure activities.¹⁰ Stern et al¹⁰ suggest that a higher neural reserve might mean that brain networks that are either more efficient or more flexible in the face of increased demand may be less susceptible to disruption. This model suggests that the brain actively attempts to compensate for the challenge represented by brain disease and hypothesizes that adults with higher initial cognitive ability are better able to compensate for the effects of aging and dementia.⁹

According to the cognitive reserve model, impairments in cognition become apparent only after a reserve is depleted. Individuals with less reserve are likely to exhibit clinical impairments because they have relatively fewer resources to maintain them in the course of normal aging and disease-related changes, whereas individuals with more initial reserve can function longer without obvious clinical impairments because their supply of resources is greater.¹¹ The initial level of cognitive reserve may be determined by numerous factors, such as innate intellectual ability and differences in cognitive activity as the brain matures throughout the lifespan. It has been found that early education and higher levels of intellectual ability and activity are associated with slower cognitive decline as individuals age.^{11–14} Fritsch et al¹¹ found that IQ and education had direct effects on global cognitive functioning, episodic memory, and processing speed, but that other midlife factors, such as occupational demands, were not significant predictors of late-life cognition. Studies of the relationship between childhood intelligence and cognitive decline in later life have found that individuals with lower childhood mental ability experience greater cognitive decline than those with higher childhood mental ability, suggesting that higher premorbid cognitive ability is protective of decline in later life.¹² Kliegel, Zimprich, and Rott¹³ found that both early education and life-long intellectual activities seem to be of importance to cognitive performance in old age; higher early education and the greater number of intellectual activities continued throughout life served as a buffer against becoming cognitively impaired. Cognitive reserve research suggests that an active, engaged lifestyle, emphasizing mental activity and educational pursuits in early life, has a positive impact on cognitive functioning in later life. Thus individuals whose baseline cognitive functioning is at higher levels and who have an engaged lifestyle that typically includes interpersonal relationships and productive activities, will likely show less cognitive decline with age.

Attention and Processing Speed

Attention relates to one's ability to focus and concentrate on a given stimuli for a sustained period of time. Attention is a complex process that allows one to filter stimuli from the environment, hold and manipulate information, and respond appropriately.⁵ Models of attention typically divide attention into various processes, such as alertness/arousal, selective attention, divided attention, and sustained attention. There is a limited amount of information that the brain can process at a given time. Attention allows one to function effectively by selecting the specific information to be processed and filtering out the unnecessary information.

It is difficult to assess pure attention as many tests of attention overlap with tests of executive function, verbal and visual skills, motor speed, information processing speed, and memory. Traditional methods of assessing attention involve timed tasks and tests of working memory. The Wechsler subtest, Digit Span,⁴ is a common method for assessing attention span for immediate verbal recall of numbers. Digit span involves the examiner reading progressively longer strings of digits for the individual to repeat both forwards and backwards. Thus both digits forward and backward require auditory attention and are dependent on short-term memory retention. Another commonly used test to assess attention is the Continuous Performance Test of Attention (CPTA).¹⁵ The CPTA consists of the individual listening to a series of letters on an audiotape and tapping his or her finger each time the target letter is presented.

Attentional processes, like other cognitive functioning, change over the course of the lifespan, but attention is particularly vulnerable to the process of aging. However, the effects of aging on attention are related to the complexity of the task. Attention on simple tasks, such as digit span, is relatively well preserved into the 80s. On the other hand, on tasks that require divided attention, elderly individuals respond more slowly and make more errors. In normal aging there is typically a decline in sustained attention, selective attention, and an increase in distractibility.¹⁶

With regard to aging and cognition, attention is a prerequisite for healthy memory functioning. Attention is necessary in the process of encoding information for future retrieval from memory, and as we age, the complex processes of encoding and retrieving information require greater attentional resources. Intact attention is also required for the processing of information; processing speed is the rate at which one can process information. It is often difficult to assess pure processing speed because many tasks also reflect a visual and/or motor component. Timed tests can measure processing speed and also help the examiner to gain a better understanding of attentional deficits.¹⁷ Slowed processing speed is demonstrated in slower reaction times and in a longer than average performance time.⁵ One test frequently used to assess processing speed is the Trail Making Test, Part A.⁵ The Trail Making Test, Part A is a timed sequencing test that requires individuals to draw a line from one number to the next in numerical order. Timed visual scanning tasks, requiring one to identify a target letter, number, or symbol, are also used to assess processing speed.

The processing-speed theory proposes that the decline seen in memory and other cognitive processes with normal aging is in part due to slow processing speed. It has been estimated that older adults' response time is approximately

1.5 times slower than younger adults.¹⁸ It is hypothesized that slower processing speed impacts cognition in two ways: the limited time mechanism and the simultaneity mechanism.¹⁹ The limited time mechanism occurs when relevant cognitive processes are performed too slowly and therefore, cannot be accomplished in the expected time. The simultaneity mechanism occurs when slower processing reduces the amount of information available for later processing to be completed. In other words, relevant information may not be accessible when it is needed because it was not encoded. However, slower processing speed associated with normal aging does not impact an individual's performance across all tasks. Processing speed has a stronger relationship with tasks of fluid intelligence than crystallized intelligence. Slower processing speed in the elderly accounts for the decline in fluid ability (e.g., memory and spatial ability) with aging, but not crystallized ability (e.g., verbal ability).²⁰

Memory

Memory is commonly thought of as the ability to recall past events and learned information. However, aside from remembering information from the past, memory includes memory for future events (remembering an appointment), autobiographical information, and keeping track of information in the present (e.g., a conversation or reading prose). Memory can be discussed in terms of the complex processes by which the individual encodes, stores, and retrieves information. Memory can also be divided into the length of time the items have been mentally stored; thus the distinction between short-term memory and long-term memory. In addition, memory can be organized by the type of material being stored, such as visual or verbal or autobiographical information. Similar to other areas of cognitive functioning, different aspects of memory differ in how they change with aging.

WORKING MEMORY (SHORT-TERM MEMORY)

Working memory or short-term memory is seen as a limited-capacity store for retaining information over the short term (seconds to 1 to 2 minutes) and for performing mental operations on the contents.⁵ Immediate memory, the first stage of short-term memory, temporarily holds information and may also be thought of as one's immediate attention span. The recognized limited capacity store of approximately seven bits of information²¹ requires that information get transferred from short-term memory to a more permanent store for later recall. Baddeley and Hitch²² proposed a model that divides short-term or working memory into two systems: one phonological, for processing language (verbal) information and one visual-spatial, for processing visual information.²²⁻²⁴ This model holds that short-term memory is controlled by a limited-capacity attentional system and thus organized by a "central executive." The "central executive" assigns information to be remembered to either the visuo-spatial sketchpad (for memory of visual and spatial information) or the phonological loop (for verbal materials). The overall concept is that more specialized storage systems exist in the limited short-term store that distinguish between verbal and visual information to be stored. Through rehearsal in working memory (e.g., repetition), copies of the information are sent for long-term storage. Regardless of the particular memory model, the overall idea is that short-term memory

is a temporary holding ground for information that can be processed or encoded into long-term memory.

Working memory is typically assessed by asking an individual to recall or repeat back words, letters, or numbers, often with sequences of varying length. Using this method, short-term memory span shows only a slight age effect.³ However, short-term memory becomes vulnerable to aging when the task becomes more complex and requires mental manipulation. For example, on the Wechsler's subtest, Digit Span, individuals are presented with progressively longer strings of numbers verbally and are asked to immediately recall digits in a forward sequence and in reverse order. It is when the task requires more than attention span and individuals have to recall the numbers in reverse sequence, thus manipulating the material, that older adults perform disproportionately weaker than younger adults.³

The issue of how aging affects short-term or working memory is associated with the level of complexity of the particular task and the presence of a distracting task. Older adults have been found to have difficulty suppressing irrelevant information from the recent past.²⁵ Difficulties in processing due to changes in inhibitory control result in increased difficulty selecting relevant information on which to focus in working memory and difficulty in shifting focus while ignoring distracting information.²⁶ Although working memory capacity is an important facet in the process of learning new information, attention and processing speed are inextricably linked to one's ability to learn. In daily life, older adults perform cognitively best when they focus on one task at a time because attention and processing speed are not divided. Simple memory strategies, such as writing down information or rehearsing information aloud, can help to compensate for memory changes as we age. Such mental techniques aid older adults' ability to move information from short-term to long-term memory. It is important to note that short-term memory decline is part of normal aging and generally these age-related changes do not affect daily functioning in the disruptive way that the presence of dementia affects daily functioning.

LONG-TERM MEMORY

Long-term memory refers to the acquisition of new information that is available for access at a later point in time and involves the processes of encoding, storage, and retrieval of information. Although long-term memory typically means memory for information from the past, it also involves memory for future events or what is called *prospective memory*. An example of prospective memory is remembering a future doctor appointment or remembering to take medication and requires that a memory be maintained about what must be done before the action takes place. Despite numerous theories about the stages of memory or processing levels, the dual system conceptualization of two long-term memory systems (explicit and implicit) provides a useful model for clinical use to understand patterns of functioning and deficits.^{3,5,24,27} *Explicit memory* refers to the intentional recollection of previous experiences; an individual consciously attempts to recall information and events. To assess explicit memory, verbal or visual information (e.g., words or pictures) is presented and after a delay, the individual is asked to recall the material either through simple recall or a recognition task. *Implicit memory*, on the other hand, relates to knowledge that is

observable in performance, but without the awareness that one holds this information. For example, the ability to ride a bicycle does not depend on the conscious awareness of the particular skills involved in the activity.

Explicit memory. Explicit memory, often referred to as declarative, can further be divided into episodic memory and semantic memory. Episodic memory refers to the ability to recollect everyday experiences.²⁸ More specifically, *episodic memory* is the conscious recollection of personal events along with the specific time and place (context) that they occurred. Episodic material includes autobiographical information, such as birth of a child or graduation from high school, and includes personal information, such as a meal from the previous day or a recent golf game; these are memories that relate to an individual's own, unique experience and include the details of "when and where" an event occurred. Most memory tests assess episodic memory and usually involve a free recall (retrieval), a cued recall, and a recognition trial, and rely on an individual's ability to recollect the material to which they were previously exposed.⁵ Compared to younger adults, older adults typically perform better on recognition tasks as opposed to recall tasks. Recognition requires less cognitive effort since a target or cue is provided as a prompt to aid recall as opposed to a recall task, which requires an individual to recall the material to which they were previously exposed without any prompt. Overall, aged adults are most disadvantaged when tests use explicit memory, in particular episodic memory, compared with younger adults.^{29,30}

Semantic memory is an individual's knowledge about the world and includes our memory of the meanings of words (vocabulary), facts, concepts, and contrary to episodic memory, is not context dependent. Knowledge is remembered regardless of when and where it was learned, such as word definitions or knowing the years that World War II occurred. Tests that assess semantic memory include vocabulary and word identification tests (AMNART),⁸ category fluency tasks (e.g., Animal Naming Test),³¹ and confrontational or object naming tests (e.g., Boston Naming Test).³² When most aged adults report memory complaints, they are often referring to the difficulty remembering words and names of objects and people.³³

Tests that require recall of semantically unrelated material, such as the Rey Auditory-Verbal Learning Test (RAVLT)³⁴ word lists, are seen as more difficult because they require more effortful strategies for encoding and retrieval than do story recall tests, such as Wechsler's Logical Memory (WMS-III Logical Memory)³⁵ or semantically related word lists, such as California Verbal Learning Test (CVLT).³⁶ When information is presented in a context or words on a list belong to a category and are semantically related, the material presented is already organized in a meaningful way, which aids the recall processes. Such aforementioned memory tests include both delayed recall and recognition trials to discern whether a deficit relates to the storage rather than to the retrieval of information.³

Implicit memory (procedural memory). Implicit memory, often referred to as nondeclarative, does not require the conscious or explicit recollection of past events or information and the individual is unaware that remembering has occurred. Implicit memory is usually thought of in terms of procedural memory, but also involves the process of priming. *Priming* is a type of cued recall in that an individual is

exposed to material without his or her awareness and this prior exposure aids a future response. For example, having been shown the word *green*, individuals will be more likely to respond "green" when later asked to complete the word fragment *g_e_ _*, even though *great* is a more common word.³⁷ Similarly, the prior brief presentation of a word increases the likelihood of identifying it correctly when presented with a choice of words at a later time.³⁸ Advertising is based on the concept of priming because the exposure to a product may lead to selecting that product for future purchase.

Procedural memory relates to skill learning and includes motor and cognitive skill learning, and perceptual or "how to" learning.³ Riding a bicycle, driving a car, and playing tennis are examples of procedural memory. It is generally accepted that implicit memory processes are relatively unimpaired in older adults, on simple tasks there is little or no difference between older and younger adults although greater age deficits emerge when the implicit learning task is more complex.²⁹ A good example of how implicit (procedural) memory is preserved with aging is the observation of patients with amnesia who lack the ability to learn new information, but still remember how to walk, dress, and perform other skill-dependent activities.³⁹ Most research on implicit memory has focused on the finding that the repetition of information aids performance even when conscious memory of the prior experience is not needed.³⁸ The overall conclusion from research on implicit memory is that there is relatively little age-related change in this area compared with explicit memory tasks that involve active recall or recognition of information.

OVERALL AGE-RELATED CHANGES IN MEMORY

Retrieval of information is an important part of daily functioning. With normal aging, memory deficits are associated primarily with the storage of long-term episodic memories. Information that places little demand on attention, such as implicit memory tasks, results in very little age-related changes in performance. The advantage that older adults experience on recognition tasks indicates that their memory storage and retrieval may be much less efficient than that of younger adults. A processing speed perspective illustrates that normal aging is accompanied by a slowing in overall cognitive processing and it is accepted that older adults process information at a slower rate compared with younger adults. Salthouse¹⁹ found that after statistically controlling for processing speed, age was only weakly related to memory. Memory functioning in normal aging is thus mediated by processing speed. The reduced attentional resources concept^{18,40} suggests that a limited amount of cognitive resources are available for a given task and consequently, a more complex task requires more attentional capacity than a simpler task. It follows that because the amount of attentional resources is reduced with aging, the processes of encoding and retrieval of information use a larger proportion of available resources for older adults than for younger adults. In sum, research suggests that overall cognitive slowing and changes in attentional ability account for much of the change in memory functioning as we age.

Verbal Abilities

Most verbal abilities remain intact with normal aging.⁴¹ Therefore vocabulary and verbal reasoning scores remain relatively constant in normal aging and may even show

minor improvements. The two main areas of verbal abilities that are frequently discussed in terms of aging are verbal fluency (semantic and phonemic) and confrontation naming. Verbal fluency is the ability to retrieve words based on their meaning or their sounds. Confrontation naming describes the ability to identify an object by its name.

Two common tests used to assess verbal fluency are the Controlled Oral Word Association Test (COWAT)⁴² and the semantic fluency test.³¹ The COWAT is perhaps the most widely used test of phonemic fluency. The COWA task requires an individual to generate as many words that begin with a specific letter as quickly as they can. The semantic fluency task is a timed-test that requires the individual to generate examples in a specific category (e.g., animal naming test).

The Boston Naming Test³² is a commonly used test to measure confrontation naming ability as individuals are required to name the object in the presented picture. Confrontation naming is composed of several different processes; an individual must perceive the object in the picture correctly, identify the semantic concept of the picture, and retrieve and express the appropriate name for the object.⁴³ Confrontation naming ability is associated with the tip-of-the-tongue (TOT) phenomenon. The TOT phenomenon occurs when an individual knows the name of a person or object and is able to retrieve the semantic information about the object, but cannot retrieve the name of the object.⁴⁴ Although an individual is unable to retrieve the target word, he or she will often try to describe the term using other words.⁴⁵ Throughout all of adulthood, proper nouns comprise the majority of TOT experiences. However, the increase in TOT phenomenon among older adults is due to their greater difficulty in retrieving proper nouns.⁴⁴ There is not a significant age difference in the frequency of TOT episodes for simple words. However, older adults have significantly more TOT experiences than younger adults for difficult words.⁴⁵ Thus, word-finding difficulty and TOT moments are the most common cognitive complaints of older adults.

The majority of cross-sectional studies have found that older adults have lower scores on the Boston Naming Test compared with younger individuals. It should be noted that while subjective complaints of word-finding difficulties increase with age, significantly lower performance on tasks of confrontation naming only emerges after age 70.⁴⁴ Zec et al⁴⁶ found that confrontation naming ability as measured by the Boston Naming Test improves when individuals are in their 50s, remain the same in their 60s, and decline in the 70s and 80s; it should be noted that the magnitude of these age-related changes is relatively small. It was found that there was an approximate one word improvement in the 50s age group and a 1.3 word decline in the 70s age group. There is some indication that there is an accelerated rate of decline in confrontation naming ability with age.⁴⁴

Normal aging is associated with a decline in verbal fluency. It is important to note that the normal age-related decline seen in verbal fluency performance may be partially mediated by reduced psychomotor speed rather than true deficits in verbal ability. Slowed handwriting and reading speed in the elderly was predictive of poorer performance on verbal fluency tests.⁴⁷ Rodriguez-Aranda and Martinussen⁴⁸ found a decline in verbal fluency as measured by the COWAT after age 60. The ability to generate words beginning with a particular letter improves until the third decade of life and

remains constant through the 40s. Subsequently, a significant decline occurs in phonemic naming ability and continues to worsen gradually until the late 60s. Phonemic verbal fluency ability continues to decline rapidly through the late 80s. Gender and education may impact one's phonemic verbal fluency across the lifespan. Women may slightly outperform men on tasks of phonemic verbal fluency. Individuals with higher levels of education (beyond high school) show greater verbal fluency ability as measured by the COWAT compared with individuals with lower levels of education (12 years or less).⁴⁹

Executive Functions

Executive functions describe a wide range of abilities that relate to the capacity to respond to a novel situation.¹⁶ Executive functions include abilities such as mental flexibility, response inhibition, planning, organization, abstraction, and decision-making.^{50,51} Executive function can be thought of as having four distinct components: volition, planning, purposive action, and effective performance.³ Volition is a complex process that refers to the ability to act intentionally. Planning is the process and the steps involved in achieving the goal. Purposive action refers to the productive activity required to execute a plan. Effective performance is the ability to self-correct and monitor one's behavior while working. All of the components of executive functioning are necessary for problem solving and appropriate social behavior.

Another term for executive functions is frontal lobe functions because these abilities are localized in the prefrontal cortex.⁵² The frontal aging hypothesis refers to the idea that normal aging leads to deterioration of the frontal lobes. Deterioration is due to a loss of volume in the prefrontal cortex and is associated with cognitive deficits. Prefrontal deterioration plays a key role in many of the age-related changes in cognitive processes, such as memory, attention, and executive function.⁵³

Like many cognitive processes, it is difficult to assess pure executive function as many of the measures used in its assessment rely on other cognitive processes such as working memory, processing speed, attention, and visual spatial abilities. The Wisconsin Card Sorting Test (WCST)⁵⁴ is a popular test used to measure executive function. The WCST requires an individual to sort a set of cards based on different categories. Individuals are not informed about how to sort the cards and must deduce the correct sorting strategies through the limited feedback that is provided. After a particular category is achieved (i.e., a set number of correct responses) based on a particular characteristic (e.g., color or shape), the sorting strategy changes and the individual must shift strategies accordingly. Once the test is completed, the examiner is provided with several measures related to executive function, for example, categories and perseverative errors. A category is achieved when a specific number of cards have been sorted correctly based on the particular criterion such as color. Perseverative errors occur when an individual continues to give the wrong response when provided the feedback that the strategy is not or is no longer correct, thus demonstrating a lack of cognitive flexibility.

On the WCST older adults achieve significantly fewer categories than younger adults.⁵² The most significant decline in performance on this test is seen in adults age 75 and older. Individuals of this age group achieve significantly fewer categories and more perseverative errors compared with younger

individuals. However, changes in executive functioning as measured by neuropsychological assessments, such as the WCST, can be seen in adults aged 53 to 64, but adults ages 53 to 64 do not show deficits on more real-world executive tasks.⁵⁵ Thus although individuals in midadulthood may show a decline in executive functioning on structured neuropsychological tests, their real-world executive skills remain intact.

Other measures used in the assessment of executive functioning included Trail Making Test, Part B⁵ and the WAIS-III subtests,⁴ Matrix Reasoning and Similarities. Trail Making, Part B, is a timed visual-spatial sequencing task requiring an individual to draw connecting lines alternating between numbers and letters in numerical and alphabetical order. Matrix Reasoning is an untimed task that measures one's nonverbal analytic thinking abilities. The Matrix Reasoning task requires an individual to identify the missing element of an abstract pattern from a variety of choices. Wechsler's Similarities subtest measures an individual's verbal abstract reasoning skills by asking an individual to describe how two different objects/concepts are alike.

Normal aging is generally associated with a decline in executive functioning.⁵⁶ When reasoning and problem-solving involve material that is novel, complex, or requires the ability to distinguish relevant from irrelevant information, the performance of older adults suffers because they tend to think in more concrete terms and the mental flexibility required to form new abstractions and concepts declines.³ Compared with younger adults, older adults also show a decreased capacity to form conceptual links as mental flexibility diminishes.³ Executive functions serve as the overseer of brain processing and are essential for purposeful, goal-directed behavior. Deficits in executive functioning can be seen in difficulties with planning and organizing, difficulties implementing strategies, and inappropriate social behavior or poor judgment.

Lifestyle Factors Associated with Cognitive Functioning

LEISURE ACTIVITIES

The mental exercise hypothesis refers to the notion that keeping mentally active will help maintain an individual's cognitive functioning and prevent cognitive decline. Many activities, such as playing bridge, doing crossword puzzles, studying a foreign language, and learning to play an instrument, have been suggested to help in preventing cognitive decline.⁵⁷ The research regarding the mental exercise hypothesis has been varied and there is currently not a definitive answer regarding the role of leisure activities in preventing cognitive decline.

It is suggested that engaging in leisure activities, especially ones that are cognitively demanding, maintains or improves cognitive functioning.⁵⁸ However, there is also evidence that individuals with high levels of intellectual functioning engage in more cognitively demanding activities, making it difficult to discern the exact role of mental activities in preventing cognitive decline. This line of research suggests that it is not the activity per se that is responsible for maintaining cognitive functioning, but rather specific lifestyles and living conditions.⁵⁸

Although there is not conclusive evidence regarding the protective factors of leisure activities, several research

studies^{59,60} have shown that leisure activities reduce the risk of dementia in the elderly. Reading, playing board games, learning a musical instrument, visiting friends or relatives, going out (i.e., to movies or a restaurant), walking for pleasure, and dancing are associated with a reduced risk of dementia.^{59,60} Such leisure activities have been shown to protect against memory decline even after controlling for age, sex, education, ethnicity, baseline cognitive-status, and medical illness. Participation in an activity for 1 day per week was found to reduce the risk of dementia by 7%.⁵⁹ Individuals who participated in many leisure activities (i.e., six or more activities a month) had a 38% less risk of developing dementia.⁶⁰

It has been also hypothesized that leisure activities reduce the risk of cognitive decline by enhancing cognitive reserve. A decrease in activity results in reduced cognitive abilities.⁶¹ Engaging in leisure activities may also provide structural changes in the brain that protect against cognitive decline given that certain areas of the adult brain are able to generate new neurons (i.e., plasticity). Stimulation, such as engaging in social, intellectual, and physical activities, is suggested to promote increased synaptic density. Enhanced neuronal activation has been proposed to hinder the development of disease processes, such as dementia.⁶⁰ However, research has also shown that changes in cognitive reserve are more likely to occur early in life; it is primarily the early experiences of education and intellectual activity that increases cognitive reserve the most.¹¹ Despite the varied findings,

“people should continue to engage in mentally stimulating activities because even if there is not yet evidence that it has beneficial effects in slowing the rate of age-related decline in cognitive functioning, there is no evidence that it has any harmful effects, the activities are often enjoyable and thus may contribute to a higher quality of life, and engagement in cognitively demanding activities serves as an existence proof—if you can still do it, then you know that you have not yet lost it.”⁵⁷

PHYSICAL ACTIVITIES

It has been hypothesized that engaging in physical activities may enhance cognition and prevent decline in late life as physical activities enhance blood flow to the brain and oxygenation, processes which are known to slow biologic aging.¹¹ Physical activities reduce cardiovascular and cerebrovascular risk factors, which may reduce the risk of vascular dementia and Alzheimer disease.⁶² There is also evidence that physical activity may directly affect the brain by preserving neurons and increasing synapses.⁶³

Moderate and strenuous physical activity is associated with a decreased risk of cognitive decline. Moderate activity includes playing golf on a weekly basis, playing tennis twice a week, and walking 1.6 m/day. Research has found that long-term regular physical activity, such as walking, is associated with less cognitive decline in women.⁶⁴ The benefits of walking at least 1.5 hr/wk at a 21 to 30 min/mile pace are similar to being about 3 years younger and are associated with a 20% reduced risk of significant cognitive decline.

SOCIAL ACTIVITIES

Social support has also been suggested to serve as a protective factor in cognitive decline. Social support may serve as a buffer against stress and may lead to decreased cortisol production in the brain. Lower levels of cortisol result in better performance on tests of episodic memory.⁶⁵ Interacting with others may also prevent cognitive decline by providing an individual with increased mental stimulation⁶⁶ and may also protect an individual from depression, which has been shown to negatively impact cognition.⁶⁷ Depression and mood disorders are associated with an accelerated cognitive decline as people age.⁶⁸ Processing speed, attention, and consequently, memory may all be affected by depression. In addition, a lack of social interaction also impacts an older adult's well-being. It has been found that individuals who live alone or have no intimate relationships are at an increased risk of developing dementia; those individuals who are classified as having a poor social network are 60% more likely to develop dementia.⁶⁹ Individuals in their 70s who report having limited social support at baseline show greater cognitive decline at follow-up assessments.⁶⁷ On the other hand, individuals with greater emotional supports have better performance on cognitive tests.⁶⁷ Rowe and Kahn⁷⁰ proposed a model of successful aging as being composed of three main components: avoidance of disease-related disability, maintenance of physical and cognitive functioning, and active engagement in life. Active engagement with life involves maintaining interpersonal relationships and it has been found that social environment and emotional supports may be protective against cognitive decline and result in a slower decline in functional status.

HEALTH FACTORS

Several medical conditions are associated with cognitive decline. Hypertension is the most prevalent vascular risk factor in the elderly.⁷¹ Chronic hypertension has been shown to result in deficits in brain structure including the reduction of white and gray matter in the prefrontal lobes, atrophy of the hippocampus, and increased white matter hypertensities.⁷² Research has found that uncontrolled hypertension can lead to cognitive decline that is independent of normal aging,^{71,73} aside from posing a risk for stroke. Older adults with hypertension have mild but specific cognitive deficits in the areas of executive function, processing speed, episodic memory, and working memory.⁷³

Diabetes mellitus has also been associated with cognitive decline.^{74,75} Lipids and other metabolic markers may play a role in the relationship between diabetes and cognition.⁷⁶ Diabetes may also impact cognition through confounding factors such as hypertension, heart disease, depression, and decreased physical activity.⁷⁶ Individuals with type 1 diabetes display a slower processing speed and a decline in mental flexibility.⁷⁵ Type 2 diabetes is also associated with cognitive decline; longer duration of type 2 diabetes results in greater cognitive decline.⁷⁷ Elderly women with type 2 diabetes have a 30% greater risk of cognitive decline compared with those without diabetes, with a 50% greater risk for individuals with a 15-year or greater history of diabetes.

Dietary factors and vitamin deficiencies have also been associated with cognitive decline in the elderly population. Individuals with cognitive decline associated with normal

aging should be investigated for B₁₂ deficiency. Research has demonstrated that vitamin B₁₂ injections may improve executive and language functions in patients with cognitive decline, but will rarely reverse dementia.⁷⁸ Low vitamin B levels may be associated with impaired cognitive performance through several possible mechanisms including, multiple central nervous system functions, reactions involving DNA, and the overproduction of homocysteine that could potentially damage neurons and blood vessels.⁷⁹ Low levels of vitamin B₁₂ and folic acid result in poorer performance on tasks of free recall, attention, processing speed, and verbal fluency.⁸⁰ Overall, research suggests that the effects of vitamin deficiency are most likely seen on complex cognitive tasks that demand greater executive functions.

Conclusion

Cognitive decline is a natural part of aging. However, the extent of decline varies across individuals and across the specific cognitive domain being assessed. The cognitive reserve perspective maintains that individual differences with regard to cognitive aging are related to an individual's reserve built upon early life factors (i.e., educational and intellectual experiences).⁹

Although cognitive reserve can be increased in later life, it is more amenable to change in early life. Although cognitive decline is inevitable, all areas of functioning do not change equally. It is well established that older adults process, store, and encode information less efficiently than younger adults. The cognitive functions related to fluid intelligence, such as the ability to solve novel or complex problems, tend to decline with aging, whereas cognitive functions related to crystallized intelligence, such as school-based knowledge, vocabulary, and reading, generally remain stable throughout life. Processing speed and attentional capacity are particularly vulnerable to aging, especially on more challenging tasks, and mediate multiple areas of cognitive functioning. For example, a memory problem is often, more accurately, a problem with poor attention and/or slowed speed of processing information.

KEY POINTS

Normal Cognitive Aging

- Variability exists across individuals in their ability to compensate for cognitive changes as they age.
- An active, engaged lifestyle, emphasizing mental activity and educational pursuits in early life, has a positive impact on cognitive functioning in later life.
- In normal aging there is typically a decline in sustained attention and selective attention and an increase in distractibility.
- Older adults' response time is approximately 1.5 times slower than younger adults.
- Most verbal abilities remain intact with normal aging.
- Normal aging is generally associated with a decline in executive functioning.
- Memory deficits associated with normal aging are primarily related to the storage of long-term episodic memories.
- Implicit memory tasks, results in very little age-related changes in performance.

Although research has found cognitive decline in the areas of attention, processing speed, episodic memory, and executive function, research has also shown that older adults have cognitive (or brain) plasticity and may benefit from cognitive training and other mental activities.⁸¹ However, the results of cognitive training with normal aging adults has been varied; although improved performance on a specific task can be found, there is a lack of generalizability to daily functioning in the long term.⁸² Nevertheless, maintaining an engaged and healthy lifestyle (social, physical, and intellectual) improves one's quality of life and may add to successful aging. One problem is the assumption that "successful aging" means that there is no discernable change in memory and overall cognitive functioning from

one's previous level of functioning. Changes in cognition are a normal part of aging and not something that is necessarily a cause for concern or precursor to dementia. Older adults need to adjust their idea of normal aging to a more realistic standard.

The Aging Personality and Self: Diversity and Health Issues

Julie Blaskewicz Boron
K. Warner Schaie
Sherry L. Willis

Personality may be defined as the pattern of thoughts, feelings, and behaviors that shape an individual's interface with the world, distinguish one person from another, and manifest across time and situation.¹⁻³ Personality is impacted by biologic, cognitive, and environmental determinants, including the impact of culture and cohort. Theoretical approaches to personality are as varied as the breadth of the construct they attempt to describe and explain. Yet each approach, to varying degrees, emphasizes stability and change within individuals across time and situations.

The impact of personality across the adult life span touches every domain: personal, professional, spiritual, and physical. Certainly, personality characteristics have direct and indirect influences on health status, health behaviors, and behavioral interactions with health care professionals. Although no single chapter can adequately condense such rich empirical and theoretical research, we will attempt to provide a concise overview of stage models, trait theory, and social-cognitive approaches to personality. As such, we will focus on aspects of personality development among cognitively intact older adults, not personality changes that may ensue as the result of dementia.

Each section of this chapter contains four subsections. For each of the three major approaches (stage, trait, social-cognitive), we first provide an overview of classic along with the most current research on stability and maturational and environmental change within adult personality. Our focus will be on findings from longitudinal data. Second, we include cross-cultural comparisons of adult personality where available. This focus provides a unique contribution to recent reviews of adult personality and aging.^{4,5} Third, we examine the health correlates of adult personality, focusing on morbidity and mortality, well-being, life satisfaction, positive and negative affect, anxiety, and depression. Finally, we discuss measurement issues and provide examples of current assessment instruments.

PERSONALITY STAGES AND EGO DEVELOPMENT

Freudian theory

The psychoanalytic approach to adult personality development has its roots in the theories of Sigmund Freud. His theories encompassed four domains: level of consciousness, personality structure, defense mechanisms, and stages of psychosexual development.^{6,7} Freudian theory postulates that adult personality is made up of three aspects: (1) the id, operating on the pleasure principle generally within the unconscious; (2) the ego, operating on the reality principle within the conscious realm; and (3) the superego, operating on the morality principle at all levels of consciousness. The interplay of these personality structures generates anxiety that must be reduced through various defense mechanisms. These mechanisms act to obscure the true, anxiety-laden reasons for one's behavior.

Although seminal in the expansion of our understanding of the human psyche, Freud's specific theories receive little attention in the scientific study of personality today.⁶ His theories are not easily amenable to scientific inquiry in that they frequently lead to nonspecific hypotheses, wherein failure to find expected effects may simply be a result of unknown defense mechanisms. Additionally, having postulated that personality development associated with his stages of psychosexual development essentially ends in adolescence, Freud's theories have limited applicability to the fields of gerontology and geriatric medicine.

Post-Freudian theorists

In contrast, some post-Freudian theorists have conceptualized personality development as a continuing process focused on current interpersonal and/or family-of-origin issues as the source of individual distress and coping patterns. Carl Jung proposed that as individuals age, they achieve a balance between the expression of their masculine characteristics (animus) and feminine characteristics (anima).^{8,9} Findings regarding increased balance of gender roles with age have emerged in different cultures, lending some support to Jung's hypothesis.²

Erik Erikson's stages of psychosocial development are perhaps the best known of the stage theories of adult personality. The sequence of Erikson's eight stages of development is based on the epigenetic principle, which means that personality moves through these stages in an ordered fashion at an appropriate rate.^{3,10} Two of the eight stages describe personality change during the adult years. Although the identity crisis is placed in adolescence, deciding "who you are" is a continual process that is reflected throughout adulthood, even in old age.¹¹ In the midlife stage of *generativity versus stagnation*, individuals seek ways to give their talents and experiences to the next generation, moving beyond the self-concerns of identity and the interpersonal concerns of intimacy.⁵ Successful resolution of this stage results in the development of a sense of trust and care for the next generation and the assurance that society will continue. Unsuccessful resolution of this stage results in self-absorption.

Ego integrity versus despair is Erikson's final stage of ego development, beginning around age 65 and continuing until death. In this stage, individuals become increasingly internally focused and more aware of the nearness of death. Successful resolution of this stage results in being able to look back on one's life and find meaning, developing a sense of wisdom before death. Alternatively, meaninglessness and despair can ensue if the process of life review results in focus on primarily negative outcomes.

Difficulties arising from attempts to empirically investigate Erikson's theory include the assertion that stages must be encountered in order and the lack of specification regarding how developmental crises are resolved so that an individual may move from one stage to the next. However, the environmental influences of culture and cohort on adult

personality have been minimized. One 22-year investigation found significant age changes supportive of Erikson's theory.¹² Middle-aged adults expressed emotions and cognitions consistent with successful completion of more psychosocial developmental crises than younger adults. In addition, Ackerman et al found a stronger association between generativity in midlife compared with young adulthood.¹³ Some theorists postulate that the ego integrity versus despair period initiates a process of life review.¹⁴

Life review

The concept of life review is the exception to this lack of empirical investigation regarding stage theories of adult personality.^{14,15} *Life review* can be thought of as a systematic cognitive-emotional process occurring late in life in which an individual thinks back across his or her life experiences and integrates disparate events into general themes. The portion of life review focusing on recall of primarily positive life experiences is reminiscence. Reminiscence has been linked to successful aging¹⁶ by contributing to sustained identity formation and self-continuity, a sense of mastery, meaning, and coherence in life, and acceptance and reconciliation of one's life.¹⁷ Although this approach to adult personality development can be conceptualized as a cognitive process in which identity emerges from the story of one's life, we have chosen to include it with stage models because it is most frequently described as occurring near the completion of one's life. Nevertheless, it should be acknowledged that individuals likely undergo a process of life review periodically throughout the adult years including young adulthood¹⁸ and midlife.^{19,20}

Stage theories and diversity

Few studies investigating stage theories of personality have focused on diverse cultural or racial/ethnic groups. Most of the stage models, such as Freud's original theories, were based on highly select samples. Only a few investigations of life review have succeeded in recruiting participants reflecting the general population of interest.^{21–23} In one study, cross-cultural evidence indicated life review programs have improved self-esteem and life satisfaction in Taiwanese elderly.²⁴ Data reflecting the broader diversity of the population is needed for examining the universality of life review and the generalizability of the basic assumptions.

Stage theories and health

There has been limited investigation of the relation between stage approaches to adult personality and health. Once again, the exception to this rule is the investigation of life review processes. Several intervention studies support the contention that life review, in comparison with nonspecific but supportive interventions, has a positive impact on health, life satisfaction, well-being, and depression.

A recent meta-analysis on reminiscence and well-being in older adulthood demonstrated that although reminiscence was moderately (effect size 0.54) associated with life-satisfaction and well-being in older adulthood, engaging in life review had a stronger effect.¹⁷ This suggests that consideration of all major life events, both positive and negative, as is typical for life review, has a greater impact on well-being in older adulthood. Furthermore, another meta-analysis by Bohlmeijer et al investigated the effects of life review on

late-life depression.²⁵ Results suggested that life review and reminiscence may be an effective treatment for depressive symptoms in older adults. Additional research has supported the utility of life review interventions to decrease depressive symptoms and improve life satisfaction in the elderly.^{26–28} Finally, participants in life review programs have demonstrated wider psychological benefits, including increased autonomy, environmental mastery, personal growth, positive relations with others, purpose in life, and self-acceptance in comparison to control groups.²⁹

Measurement issues

The primary methodological problem plaguing empirical research involving stage theory approaches to adult personality development is the lack of specification of change mechanisms and limitations in psychometrically reliable and valid measures. The most current stage approach to adult personality in our organizational scheme involves the concept of life review near the end of life. Bohlmeijer et al note the lack of standardized protocols to life review as a therapeutic technique in the delivery of interventions.¹⁷

A common methodological limitation in much of this research is the problem of making causal inferences of age-related personality change from cross-sectional studies. In these studies, age-related differences could be observed because of the impact of aging or due to cohort differences. Without cohort-sequential data, it is impossible to tease apart these influences. Thus, although stage theories of adult personality have intuitive appeal, their contribution is limited by vague delineation of constructs and methodology.

Personality traits

In contrast to stage approaches to adult personality development, empirical research regarding trait approaches has experienced a significant boom in recent years. The Big 5 Model of personality provides a broad framework for organizing the hundreds of traits, or individual differences, that characterize people.³⁰ These five core dimensions have been demonstrated at most life stages through extensive factor analyses of personality descriptors.^{31,32} A description of the most commonly identified five factors can be found in Table 29-1.

Early studies suggested that maturational changes in personality occur in young adulthood until approximately age 30 with relative intraindividual stability in traits thereafter.^{33–37} However, stability of personality across adulthood lacks consensus. The debate as to whether personality

Table 29-1. The Big 5 Personality Traits³⁰

Emotional Stability vs. Neuroticism. Anxiety, depression, emotional instability, self-consciousness, hostility, and impulsiveness vs. relaxation, poise, and steadiness.
Extraversion or Surgency. Gregariousness, assertiveness, activity level, and positive emotions vs. silence, passivity, and reserve.
Culture/Intellect or Openness to Experience. Imagination, curiosity, and creativity vs. shallowness, imperceptiveness, and stupidity.
Agreeableness or Pleasantness. Attributes such as kindness, trust and warmth that are considered pleasant and attractive to others vs. hostility, selfishness, and distrust.
Conscientiousness or Dependability. Encompasses organization, responsibility, ambition, perseverance, and hard work vs. carelessness, negligence, and unreliability.

remains stable or changes in adulthood may be based upon different criteria for determining change. Roberts and Mroczek described various forms of change including mean-level change, rank-order consistency, structural consistency, and individual differences in change.³⁸ Most often, research supporting stability refers to rank-order consistency, whereas research emphasizing change focuses on individual differences in change. Consistent with cross-sectional results,³¹ longitudinal assessments have shown small age-related declines in neuroticism, extraversion, and openness to experience, with age-related increases in agreeableness and conscientiousness in adults up to age 70 (declines in neuroticism persisted until age 80); however, this research is often cited as supporting stability of personality in adulthood. Although mean-level changes are shown, individuals maintain their rank-order on the personality domains.³⁹ Findings from other research teams contribute support for stability.^{40–44}

Study of variability in individual rates of change has provided support for the notion that personality may change, even in adulthood.^{45–48} Together these studies suggest that some individuals change more or less than other individuals in terms of personality traits. Thus recent research has attempted to investigate factors that may contribute to these varying rates of individual change. In a 12-year longitudinal study of middle-aged to older men, Mroczek and Spiro found cohort, incidence of marriage or remarriage, spousal death, and memory complaints to be associated with differential rates of change in personality.⁴⁷ Individual differences in life circumstances were also found to be associated with differential rates of change in personality in a sample of older women.⁴⁹ Social support, unmet needs, health, and psychosocial needs are examples of various life circumstances found to be significant predictors of differential rates of change in older women.⁴⁹ Thus specific life experiences may have an impact on personality. Consideration of the various definitions of change and the factors accounting for change is important when reviewing research on personality stability or change.

Trait theories and diversity

Cross-cultural studies have most frequently compared non-Hispanic whites in the United States with individuals living in other countries.^{50–52} These studies seek to estimate the effects of environment on different age cohorts by comparing adults in cultures with different recent histories. Using the NEO Personality Inventory-R, McCrae et al studied parallels in adult personality traits across cultures in five countries: Germany, Italy, Portugal, Croatia, and South Korea.⁵¹ Once again, different patterns of age changes would result if environmental factors play a major role in adult personality development. In contrast, intrinsic maturational perspectives would suggest that even widely different cultures should show similar age trends. Results showed that, across cultures, midlife adults scored higher on measures of agreeableness and conscientiousness and lower on neuroticism, extraversion, and openness than 18- to 21-year-olds. Congruence was strongest for openness and weakest for neuroticism, for which only two cultures (Germany and South Korea) replicated the American pattern.

Using the California Psychological Inventory (CPI), factor structures similar to the Big 5 were compared among

adults in the United States and the People's Republic of China; comparisons revealed very similar patterns of age correlations.^{50,52} In the Yang study, the Chinese sample was an average of 25 years younger than the U.S. sample, and age effects were smaller in the U.S. sample. Likewise, Labouvie-Vief et al found high congruence on all four personality factors derived from the CPI: extraversion, control/norm orientation, flexibility, and femininity/masculinity.⁵⁰ Older cohorts across cultures had lower scores on extraversion and flexibility and higher scores on control/norm orientation. Once again, age differences were more pronounced among Chinese than U.S. adults. Smaller cultural differences were found among the youngest age groups than among the oldest groups.

In general, the results of these cross-cultural studies are consistent with the hypothesis that there are universal intrinsic maturational changes in personality.^{50–52} Yang et al reported, however, that across the span from 18 to 65 years, age never accounted for more than 20% of the variance in CPI scale scores.⁵² Gender did not influence the pattern of results in these cross-cultural studies. The authors differed in their interpretation of the influence of environmental factors. In the Yang and McCrae studies, the authors maintained that the results offered little support for historical cohort effects being major determinants of cross-sectional age differences in adult personality traits. Although noting the high degree of similarity in personality traits across cultures, Labouvie-Vief et al also noted that cultural climate and cultural change do impact the relation between age and personality.

Trait theories and health

There is extensive literature on the relation of adult personality and health. Neuroticism is one of the traits most frequently studied in relation to health. Neuroticism has been associated with greater reactivity to stress,⁵³ whereas high levels of personal control or mastery serve as a protective factor in regards to the impact of stress on health.^{54,55} Siegman et al found the dominance factor derived from the Minnesota Multiphasic Personality Inventory (2-MMPI) to be an independent risk factor for incidence of fatal coronary heart disease and nonfatal myocardial infarction among older men with an average age of 61.⁵⁶ Niaura et al found that among older men, greater hostility may be associated with a pattern of obesity, central adiposity, and insulin resistance, which can exert effects on blood pressure and serum lipids.⁵⁷ Finally, several studies have documented an association between personality and mortality, indicating that higher levels of neuroticism and lower levels of conscientiousness serve as risk factors of mortality.^{58–61}

Measurement issues

There are multiple instruments of personality traits that measure the Big 5.^{62–64} Regardless of the specific measurement instrument used, however, these measures demonstrate remarkable consistency in the derivation of five dimensions of personality via factor analysis.³⁰ However, multiple methodological issues remain. One major complication of stability estimates in adult personality research involves what kind of stability is under consideration. The impact of cohort and time of measurement on trait consistency within the longitudinal studies conducted to date has not been fully considered.⁴⁴ Studies of gender role differences have shown that

age is not as good a predictor as the life experiences of different cohorts on personality traits of men and women across time.^{65–67} Thus it may be that earlier-born cohorts developed more consistent personality traits earlier in life as the result of numerous social/historical and life span–related influences.

More extensive consideration of the relative impact of biologic and environmental variables on stability and change in adult personality is essential. Although the influence of genetic factors has been investigated in the development of personality among monozygotic and dizygotic twins over a 10-year period, no such investigations have addressed the contribution of genetics to the maintenance of personality across the adult age range. Regarding the impact of environmental influences, with time and age individuals may encounter fewer novel experiences.⁴⁴ Thus the stability of personality factors may be causally related to the decreasing novelty of the environment in which individuals live rather than genetic factors. Finally, prior research on traits has been primarily descriptive and would profit from a theory-driven approach.

SOCIAL-COGNITIVE APPROACHES TO PERSONALITY

The social-cognitive approach to the study of adult personality and the self focuses on the processes underlying stability and change in one's perception of the self, and emphasizes the impact of necessary, adaptive adjustments in one's personality. An individual's sense of self is proposed to develop through the interaction of internal and environmental factors, influencing maturational changes and cohort differences. Although the content of the developing self may change, this model proposes that the mechanisms by which changes are integrated into the concept of self are stable. Thus the development of the self as a dynamic construct reflects one's identity, perception of possible selves, need for affiliation, and perception of the remaining life span.

Identity and the self

Whitbourne describes a life span approach to one's core identity development. *Identity* is defined as an individual's developing sense of self, an organizing schema through which internal and external life experiences are interpreted.⁶⁸ Identity includes physical functioning, cognition, social relationships, and environmental experiences.⁶⁹ The identity process theory posits that changes in identity with age occur through assimilation, accommodation, and balance.⁷⁰ Successful aging consists of integrating information about the self and achieving equilibrium between assimilation and accommodation.

Whitbourne and Collins examined the self-reports of adults aged 40 to 95 years regarding the relation between identity and changes in physical functioning.⁷¹ Forty-year-olds were sensitive to age-related changes. Individuals aged 65 and older reported paying particular attention to perceived changes in competence. These individuals were more likely to use identity assimilation (i.e., reinterpretation of experiences to coincide with the self) in the area of cognitive functioning than were other age groups. In a subsequent study, Sneed and Whitbourne found that identity assimilation and identity balance were associated with increased self-esteem, whereas accommodation resulted in decreased self-esteem.⁷² Finally, in a study of identity and self-consciousness, identity

accommodation was positively associated with self-reflection and public self-consciousness.⁷³

Researchers interested in understanding the self from a life span perspective often use the theoretical framework provided by the "possible selves" model.⁷⁴ The construct of "possible selves" postulates that individuals are guided in their actions by aspects of the self that represent what the individual could become, would like to become, and is afraid of becoming. Possible selves serve as psychological resources that may motivate an individual and direct future behavior.

Ryff's research provides empirical support for the concept of possible selves.⁷⁵ Young, middle-aged, and older adults were asked to judge their past, present, future, and ideal selves on dimensions related to self acceptance, positive relations with others, autonomy, environmental mastery, purpose in life, and personal growth. Older people were more likely than younger adults to downwardly adjust their ideal self and to view their past more positively.⁷⁵ Over a 5-year period in old age, hoped and feared possible selves were found to remain stable.⁷⁶ Goal orientation shifted with age, specifically older adults focused on maintenance and loss prevention, and this orientation was associated with well-being.⁷⁷ A shift in goal orientation in regards to possible selves may contribute to perceived control and stability of possible selves. Perceived control over development is associated with subjective well-being across adulthood.⁷⁸

Socioemotional selectivity theory

Carstensen's socioemotional selectivity theory (SST) focuses on the agentic choices made by adults in their social world for the purpose of regulating knowledge-oriented and emotion goals.^{79–81} The purposeful selective reduction in social interaction begins in early adulthood, and emotional closeness remains stable or increases within selected relationships as one ages.^{79–81} When time is perceived as open-ended, acquisition of knowledge is prioritized. When time is perceived as limited, however, emotional goals assume primacy. Older adults select social relationships in which they want to invest their resources and in which they expect reciprocity and positive affect, thereby optimizing their social networks. Thus older adult's social networks are reduced by choice, as individuals decrease contact with acquaintances but seek to maintain contact with relatives and friends as a function of increased saliency of emotional attachment to one's life goals.^{79–81}

The perception of time left in life (future time perspective) is postulated to be fundamental to motivation, and age is correlated with time perspective.⁸² Perceiving an ending plays an important role in identity processes, such that endings promote greater self-acceptance and less striving toward an abstract ideal.^{75,83} Thus due to changes in the perceived time left to live, older adults have been shown to be more present-oriented than concerned about the past and less concerned than young adults about the future.⁸⁴ Rather than age being the causal factor in shifts in self-perception and social goals, it is the inverse association of chronologic age with number of years left to live that produces observed relations.

Social-cognitive theories and diversity

There have been few empirical investigations of cultural or racial/ethnic diversity in the study of social-cognitive approaches to adult personality development. Cross-cultural

research on socioemotional selectivity theory mostly supports similarities in age differences across cultures, rather than cultural differences.

Waid and Frazier compared older Spanish-speaking natives and white non-Hispanic English-speaking natives.⁸⁵ Cultural differences in hoped and feared possible selves were present, primarily reflecting traditional differences in individualistic (English-speakers) and collectivist (Spanish-speakers) cultures. Common feared selves included physical concerns for English-speaking natives, and loss of loved ones for Spanish-speaking natives. Frequently cited hoped for selves included family-oriented domains for Spanish-speaking natives and advances in the abilities/education domain for English-speaking natives. Thus the cultural differences evident for possible selves and control revolve around differences attributed to individualistic and collectivist cultures.

Gross et al found consistent age differences in the subjective report of emotional experience and control across diverse cultures: Norwegians, Chinese-Americans, African Americans, European-Americans, and Catholic nuns.⁸⁶ Across all groups, older adults reported fewer negative emotional experiences and greater emotional control. Likewise, Fung et al found support for the notion that socioemotional selectivity is due to perceived limitations in time among adults in the United States and Hong Kong,⁸⁷ and among adults in Taiwan and Mainland China.⁸⁸

An investigation exemplifying the importance of perceived time left to live was conducted following the terrorist attacks of September 11, 2001, in the United States, and the SARS epidemic in Hong Kong. By investigating social goals before and after these events, Fung and Carstensen found increased motivation to focus on emotional goals, regardless of age.⁸⁹

Social-cognitive theories and health

In general, empirical research regarding identity and the self has explored relations with physical health outcomes, whereas research regarding socioemotional selectivity theory has focused on relations with emotional outcomes. As one advances in age, people define themselves increasingly in terms of health and physical functioning.²¹ In a study of older adults aged 60 to 96 years, leisure was an important domain for the young-old, whereas health was the most important self-domain for the oldest-old.⁹⁰ It appears that adults cognitively manage their expectations and social comparison processes so that they are, in general, no less satisfied with their health status despite increasing physical limitations.

The content of possible selves and perceived control have been examined in relation to subjective well-being, health, and health behaviors. Hooker and Kaus found that having a possible self in the realm of health was more strongly related to reported health behaviors than was a global measure of health values.⁹¹ Stability in perceived control provides a protective benefit to health. Older adults exhibiting variability in perceived control had poorer health, functional status, more physician visits and hospital admissions.^{92,93} Individuals with higher self-efficacy, the belief that one has the ability to exert control over themselves and their environments, interpret and manage stressors in ways that promote health.⁹⁴

With regard to socioemotional selectivity theory, negative exchanges with one social network have a detrimental

impact on daily mood, and if encountered frequently, can increase incidence of depression, whereas positive exchanges can serve to buffer the impact of negative exchanges.⁹⁵

Measurement issues

Comparison of findings from studies focusing on possible selves compared with socioemotional selectivity are limited by the different measurement approaches used. The possible-selves construct is measured using a questionnaire inventory.⁸³ Socioemotional selectivity theory, in contrast, has relied on self-report, observation of marital interactions, and card sorting of potential social partners on the basis of similarity judgments, with the resulting categories submitted to multidimensional scaling analysis.⁸²

A strength of social-cognitive approaches is the positing of explanatory processes for personality development; the identification of specific, testable processes such as identity assimilation, identity accommodation, possible selves, or socioemotional selectivity promotes theoretical advances via empirical hypotheses testing.

Social cognitive researchers interested in personality and self in later life investigate domains emphasizing growth and development in old age, and contribute to an individual's perception of possible selves, need for affiliation, and content of life review.

SYNTHESIS AND FUTURE DIRECTIONS

In this chapter, we have reviewed the psychological literature concerning personality development across the adult life span. We considered stage, trait, and social-cognitive approaches to the study of adult personality. Within each section, we reviewed literature on diversity and health outcomes where available. We also included a measurement section highlighting particular assessment instruments and providing an overview of methodological strengths and weaknesses for each approach.

This chapter has reviewed several issues central to the conceptualization of adult personality. The issue of stability versus maturational change or cohort differences in personality development is dependent on the theory and measurement approach used. For example, the relative stability found in the trait approaches (e.g., the Big 5) may be in part a result of the aggregation of multiple personality facets. Examination of stability at both the facet and aggregate level is needed to investigate whether personality may be dependent on genetic or biologic factors. In contrast, measurement of more precise traits (e.g., facets) may be more influenced by cognitive and environmental (i.e., cohort) influences. Thus specific individual traits would be expected to be less stable across time than the Big 5 personality aggregates. As stated in the section on trait theory, clarity in the definition of stability (i.e., intraindividual, mean-level, or ordinal) is critical to ensure that conclusions drawn from differing research methodologies are interpreted uniformly.

In the effort to tease apart the influence of environmental and biologic influences on stability and change, cross-cultural comparisons of adult personality have been particularly useful. Comparisons of adults of the same age who have experienced different environments across the life span provide evidence regarding the extent of environmental influence on personality. More research is needed, however, addressing

personality development of very old individuals in diverse cultures. Additionally, investigation of health effects of adult personality in diverse cultures provides invaluable information for health service provision and the development of preventive interventions.

Finally, it would be useful to apply the wealth of accumulated information regarding personality across adulthood to the provision of services designed to enhance quality of life. Identification of personality processes that drive specific behaviors and choices (i.e., medical treatments) is needed. There is powerful evidence that personality characteristics can affect health status and health behaviors. For example, interventions such as life review have successfully enhanced quality of life. Using social-cognitive approaches to adult personality development and the processes of identity assimilation, identity accommodation, and socioemotional selectivity could inform interventions designed to improve the process of advance care planning for the implementation of life-sustaining or palliative treatments at the end of life.

Furthermore, applied intervention research will not only enhance service provision but also drive theoretical advances in the concept of the self in old age. For example, palliative care and/or hospice interventions designed to provide services targeting personal, physical, and spiritual needs can inform aspects of socioemotional selectivity theory involving present-time orientation and time remaining to live. Incorporating aspects of life review could also provide advances in theories driving therapeutic approaches for depression. Interventions for bereaved personal and professional caregivers and interventions for the terminally or chronically ill older adult are desperately needed. It is our contention that the time to apply our knowledge of adult personality across the life span is now, thereby deriving benefit from our accumulated knowledge and driving advances in theory.

ACKNOWLEDGMENT

Dr. K. Warner Schaie and Dr. Sherry L. Willis are now faculty at the University of Washington, Department of Psychiatry and Behavioral Sciences, Seattle Longitudinal Study, 180 Nickerson Street, Suite 206, Seattle, WA 98109.

KEY POINTS

The Aging Personality and Self

- Personality is the pattern of thoughts, feelings, and behaviors that shape an individual's interface with the world, distinguish one person from another, and manifest across time and situations. It is impacted by biologic, cognitive, and environmental determinants.
- Stage theorists include Freud, Jung, and Erikson. The psychoanalytic approach to adult personality encompasses four domains: level of consciousness, personality structure, defense mechanisms, and stages of psychosexual development. Erikson's eight stages of development are based on the idea that the growing personality moves through stages in an ordered fashion. Few studies investigating stage theories of personality have focused on diverse cultures, racial/ethnic groups, or health.
- Trait approaches are the standard method of personality assessment today with multiple instruments available. The Big 5 personality traits are: neuroticism, extraversion, openness to experience, agreeableness, and conscientiousness. In general, the results of cross-cultural studies are consistent with the hypothesis that there are universal intrinsic maturational changes in personality. Neuroticism in particular has been associated with several health outcomes including stress, chronic conditions, and mortality.
- The social-cognitive approach focuses on the individual's sense of self, developing through the interaction of internal and environmental factors. Social-cognitive theories have incorporated physical health and emotional outcomes.
- The socioemotional selectivity theory focuses on the agentic choices made by adults in their social world for the purpose of regulating knowledge-oriented emotion goals. In socioemotional selectivity theory, individuals alter their environmental interactions such that optimization of emotional experience is prioritized later in life. There are few empirical investigations incorporating diverse cultural or racial/ethnic groups in the study of social-cognitive approaches to adult personality development; existing evidence suggests similar age differences across cultures.

Successful Aging: The Centenarians

Thomas T. Perls

Demography of centenarians

According to the United States Social Security Administration, in 2006 approximately 40,000 people age 100 years and older collected Social Security benefits. On the other hand, the U.S. census reported 50,000 centenarians for the year 2000.¹ Thus, in the United States, there can be substantial variation in the reported prevalence of centenarians. Suffice it to say that centenarians are relatively rare, somewhere in the range of 1 to 2 per 10,000 in the United States. Although the growth of centenarians has been noted to be the fastest of any age group, that growth appears to be slowing to about 4% in the United States.²

Other countries note similar findings. Scotland recently reported 680 centenarians for 2006, for a population of 5,116,900³; a rate of approximately 1 centenarian per 7500 people. The Scottish report also noted that the relative prevalence of male centenarians was rising, from 10% of centenarians in 2002, to 12.5% in 2006. In 2000, in the United States, male prevalence among centenarians was 14.1%.² In England plus Wales, centenarians have been noted to be the fastest growing age group since the 1950s. Since 2002, the annual growth rate is 5.8% according to a 2007 report.⁴ In Canada, in 2006, there were 4635 people age 100 years and older or 1.5 centenarians per 10,000 in the population.⁵ Statistics Canada states that the highest centenarian prevalence is in Japan, where there were 29,000 centenarians in 2006, a rate of about 2.3 centenarians per 10,000 people.⁵

Definitions of healthy aging

In the New England Centenarian Study (<http://www.bumc.bu.edu/centenarian>), we study centenarians and their family members primarily because of our long-held belief that these individuals are a model of successful aging. By determining exposure and genetic factors that are more or less common compared to other groups, we should be able to determine risk factors for premature versus healthy aging and to formulate strategies that enhance a person's ability to compress their disability toward the end of a longer life. An important question to ask, however, is: are centenarians and/or their family members in fact models of successful or healthy aging?

The answer depends upon the definition of successful or healthy aging, which geriatricians and gerontologists continue to grapple with. In a very helpful attempt at dealing with this issue, Depp and Jeste looked at various components of 29 different definitions of successful aging from 28 studies. For 26 of these definitions, the predominant feature was being disability-free.⁶ Robine and Michel have also stressed the importance of quality of life and sense of well-being in considering a definition.⁷

Of factors important in successful aging, they stress the impact of genetics, environment, economics, and culture over the life span.⁷ Crimmins notes the importance of allostatic load (the cost of compensating for and adapting to stressors) upon a person's ability to age well.^{8,9} The ability

to deal with stressors and more generally age-related diseases leads to the as-of-yet poorly defined notions of adaptive capacity, functional reserve, and resilience, which may be important distinguishing features in the ability to achieve exceptional old age.¹⁰

Based upon their ability to compress disability toward the end of their lives, we believe, at least retrospectively, that centenarians are a human model of healthy aging (based upon disability prevalence). Early on in our study of approximately 50 centenarians, we noted that approximately 90% of the centenarians in a population-based study were functionally independent at the average age of 92 years.¹¹ We subsequently also noted that a number of centenarians were compressing their disability well into their 90s while noting a long history of age-related disease(s). Christensen et al longitudinally studied Danish nonagenarians from the 1905 birth cohort from 1998 to 2005, quantifying at multiple time points their cognitive and physical function. Over this time period, the proportion of functionally independent individuals, beginning at 39% and ending at 32%, remained fairly stable.¹² Their results suggest that functional independence is an important marker of future survival at very old ages. From these and other studies, disease prevalence in some older individuals might not be a reliable marker of disability.

DISTINGUISHING BETWEEN COMPRESSION OF MORBIDITY AND COMPRESSION OF DISABILITY AND THE ROLE OF RESILIENCE (FUNCTIONAL RESERVE AND ADAPTIVE CAPACITY)

Many centenarians do not compress their illnesses (morbidity) toward the end of their lives. Approximately 45% have sustained some chronic age-related illness before age 80 years, 42% develop such a disease after the age of 80, and about 13% remain disease-free at age 100; we have termed these groups respectively, survivors, delayers, and escapers.¹³ The Tokyo and Greek centenarian studies recently determined a similar prevalence of escapers in their study.^{14,15}

Despite the fact that most centenarians do not compress their morbidity, we suspected from our previous work that most, nonetheless, compress their disability. We therefore hypothesized that compression of disability, perhaps more so than morbidity, is an important marker and determinant of exceptional longevity.¹⁶ To investigate this hypothesis, Lara Terry led the analysis of disease and functional status history from 523 women and 216 men ages 97 years and older. Subjects were divided into those who developed age-related diseases (chronic obstructive pulmonary disease, dementia, diabetes, heart disease, hypertension, osteoporosis, Parkinson disease, and/or stroke) at or before the age of 85 years (termed "survivors") and those who developed any of these diseases after the age of 85 (termed "delayers"). We then also classified these individuals according to their last-assessed functional status (e.g., at age 97 years old or older).

DISENTANGLING THE ROLES OF DISABILITY AND MORBIDITY IN SURVIVAL TO AGE ≥ 97 YEARS

Figure 30-1. A group of 523 women and 216 men age greater than 97 years were studied retrospectively for age of onset for age-related diseases, and at the time of interview, their current level of function. Left panel: Frequency of men and women whose age of onset of age-related diseases was before age 85 years ("survivors" of disease) or at 85 years or older ("delayers" of disease). Right panel: Frequency of male and female survivors and delayers who at the time of interview (age >97 years) were independently functioning.

Overall, 32% of the subjects were survivors and 68% were delayers. Further results are depicted in Figure 30-1. As the first panel reveals, the majority of these very old subjects were delayers of disease (73% of males and 66% of females), and 27% of males and 34% of females were survivors of disease. In the second panel of Figure 30-1, we see that despite being survivors of disease, 60% of the males were independently functioning at age 97 years or older. On the other hand, just 18% of the female survivors were independently functioning. Among the disease delayers, 50% of the males and 27% of the females were independently functioning at age 97 years or older.

Therefore, it is remarkable that whereas many people have significant morbidity and mortality associated with numerous age-related diseases, the above centenarian survivors and delayers have a resilience (or functional reserve or adaptive capacity) that allows them to not only live to extreme old age, but to do so while compressing their disability until very old age. Quantifying and understanding the underlying determinants and mechanisms of this resilience should be an important priority in the study of healthy aging and exceptional survival.

The gender disparity

As seen in the second panel of Figure 30-1, male centenarians tend to have significantly better functional status than their female counterparts. The fact that male centenarians more frequently have better physical and cognitive function than their female counterparts has been noted in most centenarian studies, most notably the Italian Centenarian Study.¹² It might first seem paradoxical that male centenarians fare better than female centenarians, the females outnumber the males approximately 8:1. The female survival advantage begins at around age 50, when men generally begin to experience

particularly vascular-related diseases such as myocardial infarction and stroke, whereas women delay the clinical expression of these diseases by 10 or so years, until their 60s to 70s. A plausible hypothesis for why male centenarians fare better is that only those who are functionally independent are able to achieve such extreme old age. Women on the other hand appear to be able to survive with age-related diseases more readily and thus experience the double-edged sword of being able to live longer while also more frequently living with age-related illnesses and disability. This hypothesis is supported by findings in the above-cited Danish study in which 38% of males at age 98 years were functionally independent but then this proportion rose to 53% among 100-year-olds.¹² The proportion of women who were independent, however, continued to fall, from 30% of 98-year-olds to 28% of 100-year-olds. The most obvious explanation for these trends would be a selection phenomenon among the men, where the frail die, leaving behind a cohort of exceptionally fit survivors. The other paradox I would mention here is that while the male centenarians might be exceptionally fit relative to the females, it would appear that they still have higher age-related disease associated mortality rates, so that once they do develop a disease, such as dementia or stroke, their mortality risk probably is much higher than it might be for women. Such hypotheses point to the possibility that women are much more resilient than men with regards to aging and age-related diseases.

Heritability and familiarity of exceptional longevity

Twin studies demonstrate that only 20% to 30% of life expectancy is genetic, whereas 70% to 80% of the variation is due to environment, behavior, and luck.^{18,19} Epidemiologic studies such as the Seventh Day Adventist Health

Study also suggest that the majority of variation around average life expectancy is due to people's health behaviors. Fraser and Shavlik found that the healthy behaviors dictated by the Seventh Day Adventist religion (e.g., no tobacco or alcohol use, regular exercise, vegetarian diet, emphasis of time spent with faith and family) can explain a 10-year advantage in life expectancy.²⁰ If average life expectancy in developed countries is approximately 78 to 80 years, then one might optimistically expect that most people, if they were to emulate the behaviors of Seventh Day Adventists, should be able to live to 88 to 90 years.

If optimal health behaviors can get people to age 90 years, then one must assume that genetics and luck come into play in achieving even older ages. A number of studies suggest that genetic variation might play an increasingly important role at the oldest ages (e.g., greater than age 90 years), which should be encouraging for the potential discovery of genetic determinants of exceptional longevity.^{21–24} Such a genetic advantage likely takes the form of lacking variations that increase risk for premature mortality and more controversially, also variations that slow down the rate of aging and decrease the risk for age-related diseases.^{25,26}

We have observed a marked predisposition of the siblings of centenarians to also achieve exceptional longevity.^{27,28} The children of centenarians appear to be very much following in the footsteps of their parents with 50% to 60% reduced rates of cardiovascular disease, stroke, diabetes, hypertension, and cancer compared with the children of parents that belonged to the same birth cohort as the centenarians but who died at average life expectancy.^{29,30} Furthermore, already in the septuagenarian years, the centenarian offspring experience 20% reduced mortality rates compared with the referent cohort.³¹ Barzilai et al noted that both centenarians and their children, more frequently than their referent cohort (the spouses of the offspring), had large high- and low-density lipoprotein (HDL and LDL) particle size, which is associated with lower cardiovascular disease risk. This phenotype was associated with a higher frequency in both generations of a specific variation of the cholesteryl ester transfer protein (CETP) gene.³²

Supercentenarians

Supercentenarians, who are people age 110 years and older, were virtually unheard of before 1960. Currently there are approximately 70 such individuals in the United States and approximately 300 worldwide. Over the past 10 years, we have enrolled enough supercentenarians to name a new study, The New England Supercentenarian Study (<http://www.bumc.bu.edu/supercentenarian>). The oldest supercentenarian whose age has been well validated was Jeanne Calment, who died at the age of 122 years in 1997. Even older claimed ages are immediately suspect and often come

from less developed countries where such old vital records are either nonexistent or unreliable and there is secondary gain for claiming such ages.

Supercentenarians appear to be different in terms of their resilience and the ability to live with age-related diseases that are normally associated with increased mortality risk. In our case series review of the medical histories of 32 supercentenarians, we found cardiovascular disease, diabetes, and hypertension to be very rare (<3%).³³ Stroke was a bit more common at 10%, but this is still remarkable given the ages of these subjects. Cancer, though, was unexpectedly frequent, with 25% reporting a cancer history. We also found that 41% of the subjects required only minimal assistance or were independently functioning. Thus, the supercentenarians, 90% of whom are women, are similar to male centenarians in terms of probably lacking functional reserve to deal with an age-related disease and therefore once such a disease becomes clinically evident, the mortality risk is very high. The cancer history is interesting, particularly given the well-known interplay between mechanisms of aging and of cancer.³⁴ Anecdotally we have found extremely old individuals who present with unusually large tumors that have not metastasized. We suspect that cancers and their ability to spread behave quite differently in the extreme old compared with people of younger ages and this represents another important avenue of further research.

KEY POINTS

Successful Aging: The Centenarians

- Centenarians are among the fastest growing age groups in developed countries. Much of this growth is due to the few number of centenarians before 1960, major improvements in public health measures throughout the early to mid 1900s, and marked improvements in the health of people age 80 and older.
- Whereas the compression of both morbidity and disability are essential features of survival to old age for some centenarians, for others, the compression of disability alone may be the key prerequisite. Functional status and not necessarily the presence of disease, and certainly not age alone, are important factors to consider in assessing a person's prognosis.
- Although far fewer in number, male centenarians tend to have significantly better cognition and physical function than their female counterparts.
- Exceptional longevity runs strongly in families and the importance of genetic factors in achieving older age might increase at the most extreme ages.

INTRODUCTION

Social gerontology, as its name implies, is concerned with the study of the social aspects of old age. This remit is broad, encompassing a large range of topics, disciplines, and methods, and requiring a good understanding of the clinical and economic dimensions of aging. Factors studied cover: individual experiences of aging (age identities, social networks and supports, life events, coping and resilience, etc.); the social institutions that provide health and social care services to older people; how old age is socially constructed and the age-related inequalities that flow from this; the factors that drive social and health inequalities in older age, such as class, gender, and ethnicity/race; and the broad social impacts of our aging populations. But central to these studies has been a concern to understand the factors that promote or undermine the well-being, or quality of life, of older people.

The main conclusions from research on older people's quality of life, and their clinical implications, were well summarized in Hepburn's chapter in the previous edition of this volume, which focused on factors that contribute to "social functioning"—social status, social connections, occupations/activities, personal resources, and life events.¹ Here we take a broader view of the social context of aging, describing the development of approaches within social gerontology that seek to theorize and understand the aging experience. We illustrate how these ideas have developed in ways that reflect changes in the experience of aging and show how the drivers of these changes relate to social inequalities at older ages. We begin by describing the tendency within social gerontology to problematize the circumstances of later life, through accounts of adjustment, disengagement, dependency, and poverty and through a conceptualization of increasing life expectancy in terms of the potential difficulties that are brought about as populations age. We go on to argue that as later life becomes more of a potentially positive experience for greater numbers of people, such an approach is not the most useful way to view old age in today's world. We suggest that we are seeing dramatic changes in the experience of aging that need to be understood both in terms of changes to the health and wealth of older people and in terms of the cultural context of cohorts—such as the baby boomer generation—now entering retirement. These "new" older people challenge much of the thinking about old age and how it relates to gerontology. We conclude by returning to the theme of inequality, by exploring the heterogeneity of aging experiences and how these relate to class, gender and ethnicity/race.

THE "PROBLEM" OF OLD AGE

As Cole, Achenbaum, and Katz have observed, current academic concerns with aging have tended to focus on the "problem of old age."^{2,3,4} Indeed, the perception of older people as a social problem has a long history in both social and health research, and this preoccupation with the problems of senescence characterizes the development of

gerontology, including social gerontology. Katz⁴ quotes the first article in the first issue of the newly established *Journal of Gerontology* in 1946, which stated that "Gerontology reflects the recognition of a new kind of problem that will increasingly command the interest and devotion of a variety of scientists, scholars, and professional workers."⁵ How this influenced the development of specifically social approaches to later life can be seen with the establishment of a Committee on Social Adjustment in Old Age by the Social Science Research Council in 1944 and a Research Unit into the Problems of Aging by the UK Nuffield Foundation in 1946. In this immediate postwar period, Sauvy (1947) suggested that Britain's economic difficulties were largely the result of an aging population. Furthermore he claimed that:

"The danger of a collapse of western civilization owing to a lack of replacement of its human stock cannot be questioned. Perhaps we ought to regard this organic disease, this lack of vitality of the cells, as a symptom of senility of the body politic itself and thus compare social biology with animal biology".⁶, pg. 124

This sense of foreboding had been a strong theme driving earlier developments in social policy. The introduction of old age pensions in Britain in 1908 was not only intended to eliminate extreme poverty in old age, but also to lower "poor law" expenditure on older people.⁷ By the mid 1920s the effects of economic turbulence had moved the terms of debate in the direction of the capacity of retirement to alleviate unemployment. In this formulation removal from active participation in the workforce was the main motivation for retirement, which in time led to a lowering of the retirement age to 65.

In the United States there were similar concerns to take older workers out of the workforce, with the economic depression of the 1930s creating an impetus for change. However, several factors complicated matters, including the fact that the majority of older people in the United States were still in employment. In addition legislators had to deal with the federal structure of the government, the confusing pattern of Civil War pension entitlements that many were eligible for, and the wide array of pension schemes operating across companies and occupations.^{8,9} In this context, the Townsendite movement of the 1930s (named after Dr. Francis E. Townsend) argued for a tax-funded state pension rather than one based on a contributory principle. Furthermore, in advocating the reflationary potential of creating a large number of state-funded consumers, the movement reconceptualized retirement with the slogan "youth for work/age for leisure."⁹ However, the New Deal and its Social Security pension when it was established in 1935 was much more conventional in its conception, acting as both a poverty alleviation program and as a way of dealing with unemployment by using retirement to release jobs to younger workers.

The identification of the old as a problem that needed to be resolved continued along these lines for much of the second half of the twentieth century, although with different national emphases. In the United Kingdom the tradition that includes Rowntree's studies of poverty,^{10,11} continued in the work of Townsend,¹² and has been a continuing theme of social gerontologists into the twenty-first century.¹³ Conversely, in the United States, the successful selling of retirement after World War II led to research initiatives and programs on both successful and productive aging, concerned with investigating adaptation to the circumstances of retirement. Whatever the national differences, the collection of data to answer questions posed as the "problem of aging" has continued to the current day, although more recently within the context of population aging and the economic consequences that accompany it. Paradoxically, this has meant that research is now directed at the problems posed by "a rapidly growing population of rather healthy and self-sufficient persons whose collective dependence is now straining the economies of western nations".⁴ We return to this theme shortly, but first describe the early theoretical perspectives that have underpinned social gerontology.

THEORETICAL APPROACHES: FROM FUNCTIONALISM TO STRUCTURED DEPENDENCY

Much of the reason for social gerontology's focus on the problems associated with later life lies in the emergence of retirement, in the 1940s in the United States,⁹ and the 1960s in the United Kingdom,¹⁴ as a distinct part of the life course. This led sociologists working within the functionalist tradition, such as Parsons and Burgess,^{15,16} to worry about the "roleless role" of the retired person, a population defined by their permanent exit from the labor market rather than indigence. Obviously this referred mainly to men for whom social role and employment were seen as largely interchangeable, whereas a consistent domesticated role was assumed for women. Criticism of this view, and the corresponding assumption that retirement was therefore relatively nonproblematic for women, came from Beeson,¹⁷ who pointed out that it was not based on any empirical evidence and ignored the existence of working women.

Some approached this "roleless" state through the prism of "disengagement" theory,¹⁸ focusing on the social and psychological adjustment of the older person to postwork/postmarried life. Theorizing the wider processes that went alongside retirement, this hypothesized that older people in industrial societies disengaged themselves from the roles that they occupied so that younger generations would have opportunities to develop and take on their socially necessary roles. Consequently, disengagement was assumed to not only occur in relation to work roles, but also in relation to families, when retired generations became much less central to the lives of their children. Focusing on a psychological approach, disengagement theory saw itself as influenced by the work of Erikson and notions of life review.¹⁹ A considerable amount of research was undertaken in the United States during the 1960s to provide evidence for this theory. A longitudinal study in Kansas City showed that older people did indeed "disengage", although women were observed to start this process at widowhood, whereas men began on retirement.²⁰ This approach,

which for a long time was one of the dominant paradigms in social gerontology, saw the way in which old age occurred in modern societies as an inevitable and natural process. Questions about whether older people wanted to "disengage", or were forced to do so by society, were not asked. The emphasis on psychological adjustment also avoided looking at the very real social processes that structured old age.

Although disengagement theory centered on the perspective of the individual older person, the analysis put forward by the predominantly British "structured dependency" approach stressed the importance of social policy.²¹ For writers in this school and those who described themselves as adopting the "political economy" approach to aging, the problem of old age was not one of individual social and psychological adjustment but of a dependency "structured" by the circumstances of retirement, something that was set by government social policy.^{22,23,24} Townsend noted that retirement not only marks a withdrawal from the formal labor market, it also marks a shift from making a living through earning a wage to being dependent on a replacement income.²¹ That this income was often funded by the state demonstrated the role of social policy in structuring the dependency that many older people experienced postretirement. In the United Kingdom, for example, the relatively low levels at which the state pension was paid out indicated the low priority older people had in decisions about state welfare. But as Walker,²² and others, pointed out, the continuing impact of social class into later life was also indicated in the relative imbalance between the level of state retirement pensions, which funded the majority of working class retirees' old age, and the amounts paid out by the better funded occupational pensions enjoyed by the middle class. Those reliant on state retirement pensions, consequently, were seen as a residual category of the population drawing resources from public funds, a "problem" that led to considerable interest in researching poverty in later life.

It is also argued that structured dependency is not just limited to the economic sphere, but pervades social processes more generally. Townsend suggested that the association of age with infirmity and dependency not only "represents" the position of older people, but also justifies the inferior status of older people and their exclusion from various forms of social participation.²⁵ Ageism also emerges out of the cultural valorization of "youthfulness", which not only defines aging in negative terms, but also clears the way to make it acceptable to discriminate against older people. This can manifest itself in policies seeking to limit medical or health care resources to older people, in discriminatory employment practices, and in the treatment of physically frail or mentally confused older people.²⁵ For writers such as Townsend and Walker, with a focus on well-being and social inequality, the "disengaged" position of later life is not only a social construction, but also something that should be challenged by campaigns for the restoration of full citizenship rights to older people.²⁶

INCREASING LIFE EXPECTANCY AND COMPRESSION OF MORBIDITY—A GOLDEN AGE

As described elsewhere in this volume, there are many who argue that the human life span is malleable, mortality only occurring as a result of an accumulation of damage in

cells and tissues and limitations in investments in somatic maintenance.²⁷ And more controversially writers such as de Grey argue that longevity can be extended upwards once the basic biologic processes have been understood.²⁸ Although his views have been heavily criticized, at a population level there is now a widespread recognition that life expectancy is increasing rapidly, at an accelerating rate. For example, Rau et al show that for men aged 80 to 89 mortality rates dropped by 0.81% between the 1950s and 1960s, but by 1.88% between the 1980s and 1990s, whereas for women of the same age group the figures were 0.91% and 2.45%, and the rate of acceleration in decline in mortality rates is greatest for older people.²⁹ Given a focus on the problem of age, it is not surprising that concerns have been expressed that increased longevity might lead to higher rates of morbidity and/or disability; a "failure of success" where industrial societies have passed through an epidemiologic transition that has shifted the burden of disease onto chronic conditions in later life.³⁰ However, this conclusion has been challenged by evidence that suggests that increased life expectancy does not come at the cost of an "expansion of morbidity".³¹ Writers such as James Fries have proposed a thesis built around a "compression of morbidity", where even under the conditions of increased life expectancy the proportion of life spent in ill health is concentrated into an ever shorter period before death.^{32,33} Although this view challenged many of the assumptions made about the connection between aging and chronic illness, there has been considerable support for the claim that chronologic age in itself is not a factor in increasing levels of disability and chronic illness.³⁴ Although analysis based on subjective measures of health have suggested an increasing disease burden in later life,³⁵ more objective indicators of disability suggest a more positive view of healthy life expectancy.^{36,37} Indeed, recent analyses of disability rates in the United States suggest that not only are disability rates falling, they are falling at an accelerating rate, much in the same way as mortality rates are falling at an accelerating rate. For example, in 1982–1984 rates were falling at a rate of 0.6% per annum, a figure that increased to almost four times that level (2.2%) by 1999–2004/2005, and rates decreased most rapidly for oldest people.³⁸

However, to this must be added the emergence of an "obesity epidemic", which may reverse the decline in both mortality and disability and may lead to new patterns of chronic illness. Olshansky et al argue that current trends in obesity in the United States may result in a decline in life expectancy for future cohorts.³⁹ Based on current rates of death associated with obesity they predict that life expectancy will be reduced by between one third and three quarters of a year. So, the trends are complex. In Canada a study of health lifestyles among baby boomers identified a number of contradictory changes. A substantial fall in smoking rates, increase in levels of excessive drinking, and reductions in levels of exercise over the last quarter of the twentieth century were accompanied by a sharp increase in rates of obesity and diabetes.⁴⁰ Manton uses the notion of "dynamic equilibrium" to suggest that mortality in later life is affected by the rate of "natural aging" and the distribution of risk factors for specific diseases in the population.⁴¹ Interventions aimed at risk factors will bring improvements in both mortality and reduce the severity of associated disabilities. Schoeni, Freedman, and Martin have noted how

changes in smoking behavior, greater educational attainment, and declines in poverty have impacted on the decline in disability levels in the United States.³⁶ This, however, raises the issue of whether the achievement of a successful postretirement later life is the province of the disciplined individual, rather than the expectation of the ordinary person, and again raises questions as to the role, and contribution, of the healthy retired.

OPPORTUNITY AGE—SUCCESSFUL AGING AND THE THIRD AGE

The implicit concerns regarding the status of older people has also been a theme of what has come to be known as the "productive aging" approach.⁴² This position has antecedents in Rowe and Kahn's notion of "successful aging",^{43,44} which sought to separate this positive state, characterized by good health and social engagement, from what was termed "usual" aging. Productive aging adopts a broader approach than that of successful aging. It is concerned to make it possible for the increasing numbers of people who are living longer and healthier lives, under changes in the circumstances of retirement and in the nature of work, to make significant social or economic contributions, rather than simply retiring to a state of leisure. Again the focus is on social engagement, with productive aging going beyond conventional meanings of economic productivity to include volunteering and civic participation.^{45,46} Older people acting in this way would therefore demonstrate that they were not just consumers of resources, but also made a valuable contribution to the societies in which they lived. The benefits of engaging in productive aging for the individual and society are argued to be considerable as they not only engaged individuals in society, but also used otherwise wasted capacities and capabilities.

Many of the criticisms of the productive aging approach have focused on the possibility that such laudable intentions could be easily interpreted as a simple invocation of the need to be productive in conventional economic terms.⁴⁷ Estes and Mahakian go further in their criticism by linking both successful and productive aging approaches with an extension of market principles into the process of aging itself, arguing that this acts to benefit what they call the "biomedically oriented medical-industrial complex" and ignores the social and economic disadvantages operating in both society and social policy.⁴⁸ As a result, while the advocates of the productive aging approach have moved the debate on aging away from a simple equation of age and dependency, a tendency to identify those aspects of later life that mesh with normative assumptions about desirable social and economic worth remains in this approach. So, the problematizing of old age has not occurred only around perceived role deficits and social exclusion, it has also focused on the responsibilities that older people should take on.

This is also reflected in discussions of the potential for older people to enjoy a fulfilling "third age" of relative good health and affluence. The idea of the third age is most associated with the work of Laslett, who argued that later life can no longer be viewed in a pessimistic fashion.⁴⁹ Not only is the portion of most people's lives spent in retirement increasing, the idea of a fixed retirement age is being challenged by the many individuals who have chosen to take retirement at ages other than that set by eligibility for the state retirement

pension. For many, Laslett argued, retirement offers possibilities for undertaking the self-enriching activities denied earlier in life when the tasks of earning a living, or bringing up children, or both, got in the way.

"The life phase in which there is no longer employment and child raising to commandeer time, and before morbidity enters to limit activity and mortality brings everything to a close, has been called the third age. Those in this phase have passed through a first age of youth, when they are prepared for the activities of maturity, and a second age of maturity, when their lives were given to those activities, and have reached a third age in which they can, within fairly wide limits, live their lives as they please, before being overtaken by a fourth age of decline."⁴⁹, pg. 3

In discussing a long positive third age underpinned by relatively good health and a short, but ultimately terminal, fourth age, Laslett demonstrated the opening up of the period of retirement away from a simple conflation with old age. However, in his focus on the third age, Laslett is wary that later life should not become self-indulgent. To this end he warns of the dangers of indolence and the importance of accepting the responsibilities of the third age. In particular, he identifies education as one of the key areas necessary for a successful third age, and to this end he was a proponent of the University of the Third Age. He also saw the duties of the third age as going much further than just using time well and explicitly called for older people to act as cultural trustees for society.⁴⁹ The challenge, as Laslett sees it, is to get those in the third age to accept their responsibilities rather than simply enjoy a leisure retirement.

However, this moral reading of the third age has become more difficult to maintain as the conflation between the third age and the baby boomer generation has become widely accepted, particularly in the United States.^{50,51} For the baby boomer generation there is the real potential for retirement to be transformed into an arena of lifestyle and consumption, rather than education and responsibility. A blurring of the distinction between "middle" and "old" age is fostered by the increasing influence of lifestyle consumerism on significant numbers of older people, rather than just the younger age groups typically associated with these developments.⁵² Here the third age can be seen as a space in which old age can be avoided and an ill-defined middle age can be extended further and further up the life course.⁵³ For example, the submergence of clear age-appropriate divisions in dress, along with the greater acceptability of leisure clothing, has meant that jeans and T-shirts can be worn by people of very different ages without social sanction.⁵⁴ The signs of old age become seen as a "mask" detracting from the person beneath.⁵² This relates to the individualization, or destandardization, of the life course, where the idea of a linear life course, with clearly defined stages, has become less applicable.^{55,56}

Gilleard and Higgs have argued that to better grasp the contemporary experiences of aging there is a need for an understanding of the implications of this increasing cultural engagement with lifestyle and consumerism by successive

cohorts of retirees.⁵⁷ Such an approach suggests that we are witnessing the aging of generations whose adult life has been organized through the prism of a youth-oriented consumer culture. The postwar "baby boomer" cohorts who grew up in circumstances of expanding consumer choice and economic prosperity created a "generational schism" between themselves and those older than they, who had grown up in less prosperous times. This schism manifested itself in attitudes, music, and clothes, but most significantly in lifestyles, where there have been cumulative changes to the nature of families, relationships, and sexuality. And this has not been discarded as the teenagers of the sixties became the retirees of the twenty-first century.^{51,58} It is this generationally located set of attitudes and behaviors that may lie behind many of the features of contemporary aging.

The identification of retirement in terms of its opportunities for leisure, rather than simply being a "roleless role," or a moment for life review, can be seen among those older workers who do not wait until the state retirement pension age, or forced redundancy, to retire. Retirement as choice is valorized by a consumer culture, whereas those who face redundancy or conventional retirement patterns are seen as less agentic and less able to deal with the new circumstances of later life. That contemporary retirement and later life is more structured by these contemporary cultural pressures than by concerns for the social worth of older generations can be seen in the concerns of governments and social commentators as they seek to reflect, and adapt, this image of later life to their more pressing objectives of deregulation and commodification of social policy. Indeed it is the emphasis on leisure retirement over civic participation, rather than inequality, that is most reflected in the writings of Laslett on the third age and those advocating productive aging. Whether the so called "greedy geezers" will take the resources without reciprocating is a question that motivates much of the research agenda.⁵⁹ Equally the opportunities of current retirees cannot be assumed to continue indefinitely as some of the unique factors associated with the "baby boomer" generation may disappear and the prorotired stance of many welfare regimes may become the focus for reform.

INEQUALITIES IN LATER LIFE— CONTINUITIES AND IMPACT

The transformation of later life along the lines suggested in the preceding section depends on older people having the resources to be able to participate in the various cultural activities now open to them. The incomes and standard of living of the majority of retired people in the European Union and North America have improved greatly over the past few decades. For example, in 1979 in Britain 47% of pensioners were in the bottom fifth of the income distribution, but by 2005–2006 this had fallen to just under 25%.⁶⁰ So while the association of age with poverty has been a historic reality, the relationship is not deterministic and, as the figure of 25% in the bottom 20% of incomes indicates, is no longer the case. Indeed, as those writing from a structured dependency position have argued in a different context, income poverty is not driven by retirement *per se*. As the cohorts who were working in the latter part of the twentieth century, who were on average relatively more affluent than their predecessors, have retired, they have brought into retirement some of the

benefits they had accrued during their working lives, allowing them to continue to pursue the lifestyles they had developed earlier in their lives. However, this affluence has not necessarily been equally shared among these cohorts. There is a diversity of locations within the older population, some of whom are not as well off as others. Levels of poverty are, of course, also influenced by state policies. For example, in England only 25% of those aged above the state pension age were in income poverty (defined as those receiving 60% or less of the median household income for all ages) in 2004–2005, and that this figure had fallen substantially from 31% over the short period since 2002–2003 as a result of changes in the tax benefit system.⁶¹ But most relevant to changes in the average level of poverty among the postretirement population is the changing preretirement circumstances of successive cohorts moving into retirement.

These changed circumstances have not, however, led to reductions in the level of inequality among the older population (rather than between older and younger people). Analyses of the incomes of people aged 50 and older in England, for example, show the income distribution to be heavily skewed, with more than two thirds of individuals having household incomes below the mean level.⁶¹ Single women are substantially more likely to be in income poverty than others, and women who are divorced, separated, or widowed face the highest risk of income poverty.⁶¹ Not surprisingly, another key determinant of income poverty is education level, with higher levels of education negatively associated with income poverty.⁶¹ Wealth is, perhaps, a more accurate reflection of economic well-being at older ages, reflecting as it does both the accumulation of advantage over the life course and resources to support consumption in postwork life. Data on the wealth distribution show similar levels of inequality. In England, those making up the top 10% of the wealth distribution of the 50 and older population have an average net total wealth (excluding pension wealth) of approximately £1,200,000, compared with the mean figure of approximately £300,000 and a median figure of approximately £205,000.⁶¹ If housing wealth is excluded (on the basis that not all housing wealth can be realized to support nonhousing consumption), the figures are an average of £500,000 for the top 10% of the wealth distribution, compared with a mean of £110,000, a median of only £22,500, and approximately 20% of the population having no wealth.⁶¹ The wealthiest tenth of the population aged 50 and older hold 40% of the total wealth and 63% of nonhousing wealth.⁶¹

Returning to the importance of preretirement circumstances, it is obvious to state that such inequalities among the older population reflect those occurring earlier in the life course. But there is a distinct possibility that they are aggravated by the retirement process. In England less than half of men and a third of women in the 5 years before state pension age are in paid employment, and a significant proportion of those in paid employment are part-time employment (a fifth of men and two thirds of women).⁶² However, such early “retirement” is not unrelated to wealth, with those at the bottom of the wealth distribution being most likely to not be working followed by those at the top of the wealth distribution.⁶² And route into retirement also varies by occupational grade and wealth, with those in the highest grades and with the highest wealth more likely to have taken some form of voluntary retirement, and those in the lowest grades

and with the lowest wealth more likely to have left work because of poor health or redundancy.^{63,64}

Such inequalities extend beyond the financial realm and extend to cultural activities, social and civic participation, and health. For example, in the 50 and older population in England, less than a quarter of those with managerial and professional occupational class backgrounds are not a member of an organization, compared with almost two fifths of those with an intermediate class background and almost half of those with a routine or manual class background.⁶⁵ Similarly, almost three quarters of those in the managerial and professional class group visit museums and art galleries, compared with close to three fifths of those in intermediate classes and just over a third of those in routine and manual classes.⁶⁵

In terms of health, socioeconomic inequalities persist despite dramatic increases in life expectancy.⁶⁶ In terms of risk of mortality, in a 5-year follow-up of an English sample age 50 and over, 5% of men in the richest wealth quintile had died compared with 18% of men in the poorest wealth quintile, with equivalent figures of 3.3% and 15.6% for women.⁶⁷ Similar differences can be found in relation to morbidity, with measures of self-evaluated health, symptoms of disease, diagnoses of disease, limitations in physical and cognitive function, risky health behaviors, and biomarkers of disease all showing marked inequalities by occupational class, income, wealth, and education at older ages.^{68–71}

Such inequalities in economic position, cultural activities, social participation, and health may be aggravated by the general move in developed countries toward individual responsibility for achieving a comfortable postretirement income. Those adopting the structured dependency approach see this increasingly individualized approach to social policy as perpetuating class, gender, and ethnic/race inequalities. Taking class inequality as their cue, the “political economy” strand has linked the position of older people to more neo-Marxist themes around the role of the older person within the capitalist economy.^{22,23} Equally gender and ethnic/race inequality in relation to pensions and consequent postretirement economic inequalities have been explored.^{72–75} And in more recent works the mixed fortunes of older people in the globalized economy have been a focus for theorizing.⁷⁶ All of this literature points to a need to consider the ways in which lives of older people are socially structured, but also how the nature of this might be changing (perhaps differentially across classes, genders, and ethnicities) with time and across generations.

CONCLUDING COMMENTS

Social gerontology's concern with the study of old age has meant that of necessity it has had to embrace the changes that have occurred to the nature of aging and old age over the past 60 years. Most significantly this has meant understanding the changing nature of retirement, a period that is an expected life stage for the vast majority of people in developed countries and a life stage that is no longer necessarily marked “by the shadow of the workhouse”. Indeed, what it means to be retired, as well as the way in which age, health, and retirement interact, has undergone profound change. Many of the afflictions and disabilities of old age no longer define the whole period after working age, even if they are a constitutive part of old age. Such positive changes in retirement, postretirement life, and aging are distributed in unequal ways

that reflect previously existing imbalances in resources, but this does not suggest that there has been no change, in the position of older people. The circumstances of older people reflect a diversity of experiences and a persistence of inequality, but older people can no longer be conceived in general terms as "roleless," disengaged, or forced into dependency. In a similar fashion, the circumstances of those living in the third age may merely seem to be precursors of the decline and disability of those living to older ages or those living with greater restrictions, but it would be a mistake to bracket both sets of experiences into one generic concept of old age. The distinctiveness of both the third and the fourth ages means that individuals experiencing them often have different needs and different capacities from one another. Subsuming them under one label runs the risk of failing to address the circumstances of either, suggesting less autonomy to one group and too much agency to another.

The role of social gerontology is to study how old age is lived and how it can be improved. There will be different ways of viewing the problems of "old age" in the future as there have been in the past, but such developments result from the fact that aging and old age are undergoing constant change and will throw up new challenges. It is in this context that the vulnerability of some sections of the older population can be addressed and moves toward the improvements in their lives more firmly situated in the more positive conceptualization of later life established by many of those in the third age.

KEY POINTS

Social Gerontology

- Social gerontology is the study of the social contexts of old age.
- There are a number of different approaches to understanding the social experience of old age.
- Some approaches in social gerontology problematize the situation of older people within society and present accounts that focus on individual adjustment, disengagement, or poverty.
- Other approaches see the emergence of new possibilities of aging as increased life expectancy is often accompanied by good health, especially at younger ages. These positions have been characterized as the "third age" and can be connected to ideas of productive aging.
- An important dimension of aging is the study of inequalities, either between older groups and younger ones or between older people themselves.
- The overall balance of health and illness in the older population, and unequal resourcing of old age, means that social gerontology needs to accept the heterogeneity of later life as a necessary starting point.

INTRODUCTION

Productive aging is defined as the capacity of an individual or population to serve in the paid workforce and in volunteer activities, to assist in the family, and to maintain, to varying degrees, autonomy and independence for as long as possible. The concept was created primarily in response to stereotyped depictions of older persons as dependent and a burden to society. It served to draw attention to the fact that productivity does not stop when a person grows older, and that the older population is being underused by society. It reflected both the need for older persons to work longer in an older society, and the persistence and universality of prejudice against them in the workplace.¹ The concept of productive aging was also a reaction to the tendency of economists to omit the voluntary activities and informal contributions made by older adults when measuring a nation's gross domestic product (GDP).

The extent to which an older person can remain productive is determined by a variety of personal factors, including physical and emotional well-being, motivation, attitude, education, and experience, and by changing technologies and societal attitudes and structures. The interplay between personal issues and societal norms has an important influence on both paid and unpaid productive activities. Confirming the landmark study by the National Institute of Mental Health of healthy community-resident aged men conducted in the 1950s and 1960s, The MacArthur Study of Successful Aging in America found that engagement in meaningful activities contributes to good health, satisfaction with life, and longevity, along with providing a potentially effective means of reducing costs of physical and emotional illness in later life. Older persons who have goals and structure are more likely to live longer than people who lack motivation and purpose.

Paid work includes remunerative self-employment and work for others. For older employees, the central issue regarding participation in paid work is retirement. Many factors influence an individual's decision to retire, including health, economic status, the quality of the work environment, the structure of social security and private pension plans, the availability of part-time work and/or flexibility of work hours, and age discrimination. Other significant factors are education, marital status, and spouse's labor force participation. Race and gender may also influence a person's decision to retire.²

DEMOGRAPHY

Years are being added to both ends of the life course, and at the same time as the birth rate drops, there is also an unprecedented reduction in maternal, infant, childhood, and late life mortality and morbidity rates. Population projections from the Social Security Administration show a decline in the working age population (20 to 64) per capita after 2010.³ In 1950, the ratio of Americans ages 20 to 64 to those 65 and above was 16.5:1. In 2001 it was 3.3:1. By 2030, it will decline further to 2:1.⁴

Viewed another way, the world's population is growing at an annual rate of 1.7% but the population over 65 increases by 2.5% per year. In the United States, workers aged 55 through 64 have become the fastest growing segment of the workforce.⁵ Most developing countries as well are aging rapidly. In Latin America and most of Asia, the number of people over 60 will double by 2030 to 14% of the population. In China, that number will rise to 22%.

In Europe, projections indicate that by 2050 retirees will outnumber workers and some fear that nations will be unable to finance their public pension systems. There is concern that if older workers retire in large numbers, sometime after 2010 there will be fewer workers to support more retirees, with the consequent reduction of growth in material standards of living among many European nations. These fears stem in part from the inappropriate interpretation of the dependency ratio, which broadly applied compares the number of dependents in a population (children plus persons 65 and older) to the population of younger adults. However, given that not everyone between the ages of 18 and 64 is working, that fewer children are being born, and that many persons over 65 are economically independent, through continuing employment, savings, private pensions, and social security based on contributions they have made to society over the course of many years, a more accurate measure of dependency would compare the economically dependent population with the population that is economically active.⁶ Moreover, the cost of raising a child to age 18 is estimated conservatively at \$200,000 (\$300,000 if the child goes to college).

Thanks to the technology revolution, productivity is a more important measure of a nation's economic well-being than the size of its workforce. For example, food is far more plentiful now than it was a century ago, even though 37% of Americans in 1900 were engaged in agriculture compared with 2% today. As productivity grows in a variety of industries there will be less need for workers of any age, and the continuing low birth rates in the industrialized world will not pose significant problems.

It has been suggested that if it were possible to maintain a constant number of years in retirement, rather than automatically leaving the workforce after completing a constant number of years in paid employment, labor force participation rates of older workers would increase. Thus the reduced growth in labor supply would not by itself cause living standards to be lower than they were in 1997.

RETIREMENT

Juanita M. Kreps⁷ noted in 1977 that retirement was a relatively new life stage, and that it was quickly becoming a device for balancing the numbers of job seekers with the demand for workers. And in the 1950s, social gerontologists Eugene Friedmann and Robert Havighurst⁸ wrote ". . . retirement is not a rich man's luxury or an ill man's misfortune. It is increasingly the common lot of all kinds of people. Some find it a blessing; others, a curse. But it comes anyway,

whether blessing or curse, and it comes often in an arbitrary manner, at a set age, without direct reference to the productivity or the interest of the individual in his work."

Before the industrial revolution people worked until they died and retirement was virtually unknown. Following industrialization, in 1889, Germany's Chancellor Otto von Bismarck established the first national contributory pension program in the modern era. At the turn of the twentieth century, the rise of labor unions in industrialized countries created worker protection that included retirement benefits. During most of the twentieth century, early retirement was an important labor market tool, serving to balance the number of people looking for jobs with the demand for workers and in particular supporting the careers of younger workers. Between 1910 and 1998–99, there was a drop of 1.2 years per decade in the age at which men retired from paid employment, so that the average male retirement age fell from 74 years to 63. Since male life expectancy has increased about 0.8 year per decade in the same period of time as the retirement age fell, late twentieth century workers have spent an increasingly significant portion of their lives in retirement. It is estimated that for many, retirement will last longer than their lives from birth until their entrance into the workforce.⁹ Having said that, it must be noted that a trend toward later retirement appears to be developing, with baby boomers indicating their intention to work beyond the age of 65.

In today's labor market demographic trends that include a longer life expectancy and fewer younger people entering the workforce are at odds with benefit programs inherited from an era that provided incentives for early retirement for older workers. Traditional defined benefit pensions still in force include provisions that often discourage people from working past a certain age. For example, pensions are denied some workers who wish to remain on their jobs in a part-time capacity after formal retirement and employers' concerns about legal or tax ramifications can also work against flexible work options. There is a shift away from defined benefit pensions to defined contributions, and therefore this problem is diminishing. This can favor staying on the job with less expense to the employer. It also permits workers to take pensions with them if they move from job to job, which contributes to continuing productive aging.

Retirement trends vary between nations due to differences in the overall job markets, and in countries with higher unemployment, financial disincentives are still used to discourage the continued employment of older workers. A 1998 study of 24 OPEC countries showed that in 1950 the average retirement age was 65 or higher, but by 1995 there was a drop to age 62 in many of these nations. The decrease in the average retirement age of women has been even faster.¹⁰

In the 1950s the United States placed in the middle of countries surveyed for retirement ages, but by 1995 it had one of the highest, with only Iceland, Japan, Norway, and Switzerland having a higher male retirement age, and Iceland, Japan, Norway, Sweden, and Turkey having a higher female retirement age. In Europe since the 1960s there has been a marked decline in labor force participation, especially by men ages 60 to 64. It is below 20% in Belgium; 35% in Italy, France, and the Netherlands; 50% in Germany; and 40% in Spain. There have also been declines in employment between ages 45 and 59. The rates of

labor force participation between 55 and 64 are less than 50% for both men and women in Finland, France, and the Netherlands.¹¹

In the United States, Social Security is the main source of cash income of households headed by an individual age 65 or older. It provides slightly more than 40% of the total cash income received by this population. Social Security replaces about 42% of the final wages earned by a fully employed single worker who earns the average wage and begins collecting at 65, and 63% of the final wages of a worker with a nonworking dependent spouse. Until recently, a retirement means test was used to prevent older workers who collected Social Security from continuing to earn more than a certain amount annually in paid employment. Workers between 65 and 69 lost \$1 in benefits for every \$3 they earned in excess of \$17,000. In 2000 the United States passed the Senior Citizens' Freedom to Work Act, which eliminated earnings penalties of Social Security recipients aged 65 and older who were born before 1945, allowing potential retirees to receive full benefits regardless of other earnings. As a result, the number of older persons who rejoin the workforce on a part-time, seasonal, or full-time basis is expected to rise, adding an estimated \$19.5 billion to the gross domestic product by 2008. Furthermore, for every \$2 in annual earnings in excess of the designated limit (\$10,800), a worker between 62 and 65 loses \$1 in annual benefits.

Another step that might promote productive aging was passed by Congress in 1983, with implementation beginning in 2003. The age at which retirees can claim full Social Security benefits in the United States will gradually increase from 65, reaching 67 by 2027. Recommendations have been made to raise the retirement age to 70 by 2029 and as needed after that, in accordance with further increases in life expectancy. Many OECD nations are also gradually increasing the age at which workers become eligible for retirement benefits. Incentives are being considered to encourage people to delay retirement benefits or continue working while they receive benefits. For example, the United Kingdom has equalized retirement ages for men and women by raising the retirement age for women.

Increasing the average age of full pension entitlement and removing pension earnings rules and penalties for working past a certain age would allow healthy people to continue paid employment while increasing the length of time during which contributions are made to pension funds. However, it must be noted that at the same time as it extends years of salaried employment, it represents a cut in benefits to the beneficiary. Protection must also be made available to those unable to work for health reasons.

PAID EMPLOYMENT

Complete retirement is much less prevalent among older Americans than is commonly believed. At least 50% of all workers "partially retire" by taking part-time jobs toward the end of their working lives, and the chance that an individual will reenter the labor force after initial retirement is about one in four. Older workers employed in nontraditional paid work arrangements include independent contractors, on-call and temporary workers, and those engaged in home-based work, part-time work, and postcareer bridge jobs. In 2000, only about 13% of older Americans worked, but a recent

survey conducted by the AARP (formerly the American Association for Retired Persons) found that about 80% of baby boomers plan to continue working after retirement, 35% at least part time.

With the drop in fertility in most industrialized nations, their future labor force will grow slowly, requiring them to invest in physical capital that will reduce labor needs, establish continuous education programs, liberalize immigration policies, train physicians to appropriately care for people as they grow older so they can continue to be productive, and encourage more women with children and older workers to remain in the workforce. Removing disincentives and creating positive incentives for older workers to stay employed can contribute to sustaining growth in industrialized nations. Policies that encourage phased retirement would include changing federal tax and pension laws to allow for the collection of partial benefits. Such laws would stimulate valued employees to remain on the job in flexible work situations, while eliminating some of the costs associated with their employment. Flexible employment options include job sharing, which allows two workers to split the responsibilities of one position, part-time work and temporary employment. Another option is work from home. Large companies report that between 1995 and at the turn of the twenty-first century, the percentage of employees who share jobs overall rose by 70%, and the number who work from home climbed 81%. A 1999 survey of more than 500 large corporations found that 16% are experimenting with flexible hours for older workers, and early quantitative data indicate a positive impact on productivity. Finally, long-time employees could serve as consultants or mentors.

A German flexible retirement proposal offers employees incentives higher than those already established by law. Unions and employers in Baden-Württemberg established a plan that allowed 55-year-old workers to work half time and receive 82% of their salary. If the employer did not wish to participate, at age 61 the worker could opt to work half time on 70% of full salary. Whatever the decision, the pension contribution would continue at 95% of the full time rate.

AGEISM IN THE WORKPLACE

Ageism is discrimination based on age, and it creates official and societal acceptance of limits on the employment of older persons, contributing to later-life displacement. Financial disincentives, workplace discrimination, and inadequate retraining are factors which must be considered when discussing the continued paid employment of older persons. National surveys conducted in the United States in the 1980s suggest that 80% of Americans in general and 61% of employers in particular believe that most employers discriminate against older people and make it difficult for them to find work.¹² Until 1967, when the Age Discrimination in Employment Act was passed in the United States, approximately one half of private sector job openings were advertised as closed to applicants over 55, and one quarter were barred to workers over 45. Age discrimination is the complaint most often lodged against employers, according to the Equal Employment Opportunity Commission, and a study in 1994 for the AARP showed that discrimination against older workers was about the same as that against African Americans and Hispanics of all ages.¹³

Although the relationship between age and job performance is exceedingly weak, misconceptions are common. They include the belief that most older workers are limited by health conditions, less flexible on the job, less educated, that they possess skills that are technologically obsolete, and are difficult to retrain. In a research study to determine whether worker performance declines with age, the literature showed that the only jobs for which performance appeared to decline with age were jobs that required manual labor. No correlation was found between age and work quality for supervisors and professionals, and job performance in sales was shown to improve with age.

British economist Richard Disney notes that although it is true that a younger workforce may be more adaptable and quicker to learn, it is also true that they have less training and experience. Although some individuals in an older workforce may experience a degree of depreciation in skills and difficulty in retraining during periods of rapid technological change, overall, they have greater experience and maturity, are more dependable, and embody high productivity and less absenteeism. Of course, continuing educational opportunities would further increase the value of continuing employment of older workers.

The proportion of chronically disabled older Americans has fallen steadily in the past decades, and fewer older people are unable to work because of disability. According to the National Long-Term Care Survey, the prevalence of chronic disability in Americans age 65 and older fell from 26.5% in 1982 to 19% in 2004–2005.¹⁴ There can be some decline in mental and physical functioning, but in general, older workers remain productive in spite of these limitations, by finding ways to compensate for both functional conditions and chronic diseases. In fact, disabilities are more likely to involve hearing or eyesight problems than a complete inability to function. Employer accommodation can be relatively easy, for example, adjusting font sizes on computer monitors or being sensitive to an employee's need to take medications while at work.

Historically, a large number of the life-time contributions to scholarship, the arts and sciences were made by men and women in their later years. In fact, the period of life after age 50 accounts for the major portion of output in most scholarly and scientific fields. Ages 70 to 79 alone account for 20% of the output in the fields of scholarship and 15% in the sciences.¹⁵ Today, employers report that their older workers are as creative as younger employees, more dependable, and far more experienced. According to a Harris Poll of 774 corporate human resource directors, 80% agree that older workers had less turnover, and 71% said they had as much ability as younger workers to acquire new skills.

Industrialized nations are just beginning to take action against persistent ageism. For example, Australia's Council on Ageing (COTA) has begun to urge employers, businesses, trade unions, academics, and workers themselves to look for solutions to age-based discrimination.

Effective laws are needed to ensure that older workers receive equal opportunities for training to keep up with changing technology and to encourage lifelong learning. Reforms must be passed to ensure that job opportunities are available for older workers, and that they are equipped with the necessary skills and level of competence. Restructuring the job environment to accommodate older workers

and developing innovative ways to reorganize work for long-tenure employees can increase productivity and help skilled older employees remain competitive. For example, in Norway, the government has undertaken a major national lifelong learning initiative, which is known as Competence Reform. Employees who have been working at least 3 years and employed by the same employer for the last 2 years have the right to full-time or part-time study leave for up to 3 years. Its purpose is to raise the level of competence and provide the country with a highly skilled and flexible workforce, and one of its benefits will be to help older workers stay abreast of new technologies and remain competitive in the workplace.

It has become increasingly important that computer-related training, like training in general, be customized to physically accommodate older trainees (i.e., offering larger monitors, screen displays, and a keyboard and mouse that can accommodate a limited range of motion), in addition to research in new technology (i.e., perfecting a voice-activated computer that eliminates the need for keyboard and mouse). In a collaborative effort between the private and public sector, computer learning centers in the United States that accommodate older students, computer software companies and aging organizations have begun to work together to promote computer literacy among older adults.

UNPAID WORK

Free time was once the exclusive province of the well-to-do, especially women, but now millions of older persons have the time that younger persons lack. A 1999 survey¹⁶ reports that nearly half of all Americans age 55 or older engage in some form of unpaid work.

Unpaid work includes volunteer work performed through formal organizations, such as hospitals, churches, and schools; informal help to relatives and friends, including caregiving and home maintenance; and unpaid help in a family business.¹⁷ Formal volunteering in a community can be a substitute for paid labor, either producing services at a preexisting level, expanding the product of a community's public and private organizations, or creating a new service, such as volunteer service organizations. Examples include mentoring programs for inner city children, foster grandparent programs, and the recruitment of retired medical professionals in the development of free health clinics for the delivery of health care to the medically underserved.

Domestic activities include home maintenance and production of goods or services for home consumption. Older members add significantly to the nation's welfare in activities that include care of young, sick, or functionally limited family members and the transmission of values to younger generations.

Older people fill an important role as informal parent-surrogates to grandchildren. In 1998 this cohort was responsible for the care of nearly 4 million children, or 5.6% of all American children under the age of 18. Over 2.5 million maintained families with or without legal parents also in residence, and in more than 888,000 cases, they raised the children alone. Among families with preschoolers and employed mothers, 17% received primary child care from the child's grandparents. Family dynamics and financial constraints militate against adoption, and often lacking legal

status as guardians, they can experience financial difficulties maintaining themselves and their grandchildren.

Unpaid labor by family members, which reduces labor costs of a family enterprise, is predominantly the purview of older persons. Beyond economic considerations, their participation may have the positive effect of enriching family relationships and enhancing the older person's sense of self-worth.

JAPAN

Japan's population is aging much faster than in any other industrialized country. It has one of the lowest birthrates of any developed nation and the longest-living population. Employment opportunities for older persons in Japan are limited, and the **unemployment rate has increased**. In the mid 1970s, twice as many workers entered the job market as were retiring and the legal minimum age at which employees could retire and receive a pension was 55. But, as the twenty-first century unfolds, two workers will retire for every worker entering the job market. Sooner or later, industries will find it impossible to recruit enough young workers to the labor market to replace workers who have left.

In 1998, the legal minimum age of retirement in Japan was raised to 60, and it will gradually be raised to age 65 by 2013 for men and by 2018 for women. Thirty-seven percent of Japanese men work after age 60, in contrast to 10% of American men. Japanese employers retain some of their older workers at lower wages, and transfer some others to subsidiaries or related firms. Workers also can find jobs with their old firm's suppliers or customers.

With a view to encouraging even further employment of older workers, the Japanese government is beginning to offer companies a variety of incentives to encourage their older workers to remain in the workforce. Incentives include subsidies to businesses whose total workforce has more than 10% older workers and to employers who have eliminated mandatory retirement. Other incentives include partial coverage of expenses for employers who have adapted facilities and equipment in the workplace to make them better suited for older workers.

DEVELOPING NATIONS

The United Nations estimates that by 2025, more than 75% of the over 60-population will live in developing nations, including 70% of the world's 604 million women over age 60. Forty percent of older people in developing nations will live in the countryside, but very few studies of this population have been undertaken.

Traditionally, old people who lived in rural poverty could depend upon their adult children to care for them as they aged. Today, modern industries and opportunities for advancement draw the young to the cities, leaving the elders in the community to cope as best they can with limited resources. Since rural economies depend predominantly upon heavy manual labor, frail older persons are often left without visible means of support. Women especially lack the resources, skills, and social independence to cope with the changing social conditions. International nonprofit organizations, such as the United Nations Subcommittee on Aging, the International Women's Movement, and Help

Age International, among others, are in the early stages of addressing the problems of impoverished older women in developing countries.

Small loan programs in developing nations limit credit availability to older persons; however, there are notable exceptions. Since 1976, a Bangladeshi nonprofit organization, Grameen Bank, has made small, unsecured loans available to people of all ages to begin small businesses, which are known as “microenterprises.” Older women are particularly encouraged to participate in these entrepreneurial endeavors. Action for Welfare and Awakening in Rural Environment (AWARE), in Hyderabad, India, is one of several agencies that enable older workers to buy materials for individual work projects. In Colombia, Pro Vida, a nongovernmental agency, has developed programs to redirect or retrain the skills of older people (e.g., one town’s innovative program gives impoverished older persons a monopoly on employment in a recycling program). In Ecuador, bakeries employ older people, and in the Philippines, they are trained in car repair and encouraged to open their own businesses. Laundries, home repair services, general merchandise shops, equipment rentals, industrial sewing, child care, and hand-made crafts are other types of enterprises that have provided work for older persons in developing nations.¹⁸

CONCLUSION

In the twenty-first century, declining mortality and disability rates in early old age measure the improved health of older people. In some ways, retirement has been a twentieth-century phenomenon. It was required when the majority of people labored in mines, factories, and foundries, and it continues to be humane and necessary for individuals who have reasons to stop working after a lifetime of toil. Analyses of a variety of occupations and their physical requirements show that a much smaller proportion of jobs require strenuous physical effort, and a large percentage require only moderate or light physical exertion. They suggest that the physical demands of work are easier to meet than they were in the past.¹⁹

A social norm that is appropriate to the new longevity and to a world trend toward human rights would be one in which all people are considered individually and collectively as a resource to meet their own and society’s needs; one in which retirement remains a desired goal, as indeed it is, after a lifetime of work. At the same time, the new added life expectancy necessitates a commensurate increase in work expectancy, as long as there are jobs and people can work without age discrimination.

The responsibility for preserving one’s human capital ultimately rests with the individual. If older individuals can continue to develop their productive potential, whether in paid employment, service to family and community, or by

sharing artistic and avocational abilities, their lives will be enriched at the same time as they continue to benefit society. Late life productivity is multifaceted, encompassing altruism, citizenship, stewardship, creativity, and the search for faith. A study found that while older people think that older workers should not stand in the way of younger workers, they also believe that “life is not worth living if you cannot contribute to the well-being of others.”²⁰

KEY POINTS

Productive Aging

- Productive aging is the capacity of an individual or population to engage in paid work and in nonremunerative activities, such as volunteer service to the family and community. It is affected by both internal and external factors. Internal factors include physical and emotional health, motivation, attitude, and experience. External factors involve society’s willingness and ability to accommodate the special needs of older persons.
- Factors that encourage paid employment in later years include worker demand, educational level, changing technologies that may require retraining, and societal attitudes and structures. The age at which a country mandates or encourages its workers to retire influences the productive aging of its citizens.
- Ageism is discrimination based on age, and it creates official and societal acceptance of limits on the employment of older persons. Financial disincentives, workplace discrimination, and inadequate retraining are factors that have an impact on their continued employment.
- Some benefit programs discourage workers from remaining on their jobs and provide incentives for early retirement. This is at odds with the projected demographics of greater life expectancy and fewer younger people entering the workforce. Removing disincentives to retirement and creating incentives for older workers to stay employed and employers to retain them can contribute to sustained growth in industrialized nations. Incentives include retraining older workers in new technologies, making accommodations for disabilities that do not impact on their ability to do the job, and developing options for job-sharing and part-time employment.
- Means tests penalize older workers who receive pension benefits if they earn more than a specified amount. For example, in 2000 the United States eliminated earnings penalties of Social Security recipients aged 65 and older. Many OECD nations are also gradually increasing the age at which workers become eligible for retirement benefits.
- Older persons contribute significantly to a nation’s benefit in activities that contribute to the care of young, sick, or functionally limited family members and the transmission of values to younger generations. Unpaid labor by older family members can significantly reduce labor costs of a family enterprise.

People's lives are embedded in rich social contexts; many social factors impact on each of our lives every day. This is perhaps more noticeably so for older adults as declines in health and functional status may increase reliance on social supports and diminish opportunities for social engagement, even in the face of social circles dwindling due to declining health and function among peers.

This chapter will provide an overview of how social factors affect health in old age, through a discussion of the concept of *social vulnerability*. The association with health outcomes relevant to geriatric medicine (including function, mobility, cognition, mental health, self-assessed health, frailty, institutionalization, and death) will be the focus, with particular emphasis on the relationship between social vulnerability and frailty. Detailed discussion of social gerontology and of standardized instruments and measurement scales used in the social assessment of older people is beyond the scope of this chapter; interested readers are referred to the two chapters on these topics in this volume.

BACKGROUND AND DEFINITIONS

Many social factors influence health, including socioeconomic status, social support, social networks, social engagement, social capital, and social cohesion.¹⁻⁸ As such, the social context is key to a broad understanding of health and illness. Perhaps due in part to the numerous disciplines in which this line of inquiry has been investigated (including epidemiology, sociology, geography, political science, and international development, among others), terminology and methods of approach have differed. In some instances, the same terminology has been used to refer to different ideas, whereas in others, divergent terminology obscures underlying commonalities. There has also been debate surrounding the level, from individual to communal, at which some elements of the social context are relevant, and as such, how they can be measured.^{1,9,10} In the following section, the various terms and concepts will be defined and discussed, and each will be placed in context on the continuum from individual to group influence (Figure 33-1).

Socioeconomic status

Socioeconomic status (SES) is a broad concept that includes such factors as educational attainment, occupation, income, wealth, and deprivation. There are three broad theories of how socioeconomic status might relate to health.¹¹ The materialist theory states that gradients in *income and wealth* are associated with varying levels of deprivation, which in turn affects health status as those with fewer means have inferior access to health care and the necessities of life. Another view is that *education* influences health through lifestyle and health-related behaviors such as diet, substance use, and smoking. A third theory sees social status (often measured by *occupation*) and personal autonomy as key influences on health, particularly through the stresses that accompany

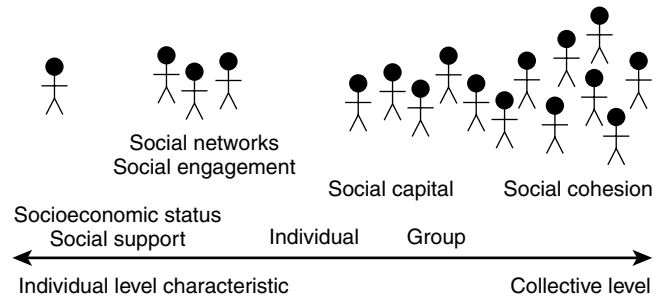

Figure 33-1. The continuum of social factors that influence health, acting from individual to group levels.

low social status and low autonomy.¹¹ Measurement of each of these elements of SES may present difficulties in the older adult population. Older persons are likely to be retired and older women may never have worked outside the home, making occupational assessments problematic. Income is associated with employment status, and many income supplements and benefits are available to those with disability and poor health raising problems of reverse causation.¹¹ Educational opportunities available to older cohorts may have been limited, creating a “floor effect” in which it is difficult to differentiate among the majority whose educational attainment is low.¹¹ Additionally, information may be missing when a proxy respondent has been used, depending on how well the proxy knows the subject. Socioeconomic status is a property of individuals; however, aggregates of such measures can be used to describe the social context in which people live. For example, average income, employment rates, or educational attainment may be useful descriptors when applied to groups of people living in relevant geographic areas such as housing facilities or neighborhoods, and may allow for study of contextual effects on health.¹²⁻¹⁸

Social support

Social support refers to the various sources of help and resources obtained through social relationships with family, friends, and other care providers. Types of social support include emotional (including the presence of a close confidante), instrumental (help with activities of daily living, provided through labor or financial support), appraisal (help with decision making), and informational (provision of information or advice).¹⁹ Various measures of social support have been studied, with some tending to be more “objective” (based on reports of actual use of services and tangible help received in the various domains) and others more “subjective,” based on the individual’s perception of the adequacy and richness of the supports to which they have access. Social support can also importantly be seen as a two-way transaction, with the older person receiving support in some areas while providing support in others. For example, within spousal relationships each spouse may have complementary strengths and weaknesses; between generations, older people may provide care for grandchildren and financial support for adult children, while receiving instrumental support.²⁰

Social networks

Social networks are the ties that link individuals and groups in social relationships. Various characteristics can be measured, including size, density, relationship quality, and composition.¹ Both social networks and social support are generally seen as individual-level resources, and are measured at an individual level.^{3,19,21} Through social networks, individuals can access social support, material resources, and various other forms of capital (cultural, economic, and social).²²

Social engagement

Social engagement represents an individual's participation in social, occupational, or group activities, which may include formal organized activities such as religious meetings, service groups, and clubs of all sorts. More informal activities such as card groups, trips to the bingo hall, and cultural outings to see concerts or galleries can also be considered as social engagement. Volunteerism is often considered separately,¹ but can also be seen as an important measure of social engagement.

Social capital

Social capital is a broad term which has been used inconsistently in the literature, and there is ongoing debate about its nature and measurement. For example, Bourdieu defines social capital as "the aggregate of the actual or potential resources which are linked to possession of a durable network of more or less institutionalized relationships."²² His definition is consistent with the idea that social capital is a resource that can be accessed and measured at an individual level, stating that "the volume of social capital possessed by a given agent thus depends on the size of the network of connections he can effectively mobilize and the volume of the capital ... possessed by each of those to whom he is connected."²² However, his definition is also consistent with the view that social capital is a *property* of the relationships within the network—if there are no connections between individuals, there would be no social capital. Coleman makes a similar argument, stating, "Unlike other forms of capital, social capital inheres in the structure of relations between actors and among actors. It is not lodged either in the actors themselves or in the physical implements of production."²³ He also sees social capital as a resource accessible by individuals, writing, "social capital constitutes a particular kind of resource available to an actor."²³

Putnam defines social capital as "the features in our community life that make us more productive—a high level of engagement, trust, and reciprocity"²⁴ and sees it as "simultaneously a 'private good' and a 'public good' "with both individual and collective aspects."²⁵ To access the "private good" benefits of social capital, an individual would need to be integrated into a network and have direct connections with other members. But the "public good" effects of social capital would accrue to everyone in the community, regardless of their personal connections to others. The "public good" concept of social capital is shared by others, including Kawachi et al, who see social capital as an ecologic level characteristic that can only properly be measured at a collective level, and state that "social capital inheres in the structure of social relationships; in other words it is an ecologic characteristic," which "should be properly considered a feature of the collective (neighborhood, community, society) to which an individual belongs."^{3,14,21,26}

Measures of social capital are as varied as its definitions, and include both structural elements (such as social networks, relationships, and group participation) and cognitive ones (such as trust in others, voting behavior, newspaper subscription, feelings of obligation, reciprocity and cooperation, and perceptions of neighborhood security).^{1,10,23}

Social cohesion

The concept of social cohesion implies collectivity of definition and measurement. Again, definitions vary, but generally relate to ideas of cooperation and ties that unite communities and societies. For example, Stansfeld defines social cohesion as "the existence of mutual trust and respect between different sections of society."²⁷ For Kawachi and Berkman, social cohesion relies on two key features of a society: absence of social conflict and presence of social bonds.³

Social isolation

Social isolation is another term that is encountered in the literature relating social circumstances and health. It is related to ideas of loneliness, reduced social and religious engagement, and reduced access to social supports. It may also incorporate properties of the older person's environment, such as difficulty with transportation. As with many other social factors, social isolation can be "subjective" (as perceived by the older person themselves, e.g., loneliness) or "objective" (based on outside measures or assessments by others).

Social vulnerability

The concept of social vulnerability addresses the understanding that the reason we are interested in the social environment is not merely as a descriptor, but to attempt to quantify an individual's relative vulnerability (or resilience/invulnerability) to perturbations in their environment, social circumstances, health, or functional status. Older people's social circumstances are complex, with multiple factors that may interact in potentially unforeseen ways. A global measure of social vulnerability would thus account for this complexity while providing descriptive and predictive value. A measure of social vulnerability should be broad enough to capture a rich description of the social deficits (or problems) that an individual has, be readily and practically measurable in population and clinical settings, be responsive to meaningful changes, and be predictive of important health outcomes.

HOW CAN WE STUDY SOCIAL INFLUENCES ON HEALTH?

Study of how social factors influence health requires careful consideration of analytic design in relation to the specific questions being asked (Table 33-1).

Possible approaches include traditional "one thing at a time" analyses in which a single social factor (for example, the social network) is related to the outcome of interest, ideally adjusting for possible confounders in a multivariable model. This approach has certain benefits, chief among them simplicity and clarity in execution and interpretation. For example, it allows for clear statements of important findings such as "An extensive social network seems to protect against dementia."²⁸ This approach can be done using single variables considered individually, a combination of variables relating to different aspects of the same theme (e.g., several

Table 33-1. Analytic Approaches for Studying Social Influences on Health

Analytic Approach	Benefits	Drawbacks
"One Thing at a Time" Single variables considered individually <i>(e.g., size of the social network)</i> Combination of variables relating to the same theme <i>(e.g., several variables describing social network)</i> Validated measurement instrument <i>(e.g., Lubben Social Network Scale)</i>	Simple and clear execution and interpretation Allows simultaneous investigation of several variables, adjusting for one another and for relevant confounders Use of standardized and validated instruments enhances reliability and validity	May result in overly simplistic understanding of associations <ul style="list-style-type: none"> • Validity considerations must be addressed • Models may become too complex with technical challenges (e.g., colinearity) • Lengthy administration time • Rigidity • Use may be limited with existing datasets if difficult to reconstruct faithfully
"Many Things at Once" Index approach: deficit accumulation <i>(e.g., social vulnerability index, frailty index)</i>	<ul style="list-style-type: none"> • Takes many aspects of social circumstances into account simultaneously • Does not rely on use of single variables, which may present measurement challenges in some older people • Related factors are not arbitrarily separated • Allows representation of gradations in exposure • Potential applicability to most datasets and clinical situations 	<ul style="list-style-type: none"> • Represents risk relating to composite social circumstance rather than single identifiable factors in isolation • Complex modeling based on novel techniques
Options for Studying the Social Context "Horizontal" analyses <i>(e.g., multivariable regression modeling)</i> "Vertical" analyses <i>(e.g., multilevel modeling, hierarchical linear modeling)</i>	Simple and clear execution and interpretation <ul style="list-style-type: none"> • Yields more detailed understanding of contextual effects • Preserves independence of observations • Avoids loss of meaning due to data aggregation 	<ul style="list-style-type: none"> • May not provide a full understanding of the social context • Technical problems for models: observations not really independent • Not all datasets lend themselves to these models; need sufficient numbers in groups with shared characteristics • Complex models

variables that relate to the size and quality of the social network), or set instruments that have been previously validated to measure the social factor of interest (e.g., the Berkman-Syme Social Network Index and the Lubben's Social Network Scale).²⁹ The standardized psychometric properties of such scales add to the reliability and validity of studies that employ them, but their use does have drawbacks including relative rigidity and lengthier administration time. Their use may also be limited or impossible with existing datasets due to challenges encountered in their faithful reconstruction.

Deficit accumulation offers another potential approach to the study of social influences on health. Akin to the frailty index, which readers will find described elsewhere in this volume, a *social vulnerability index*, operationalized as a count of deficits relating to many social factors, offers a means of considering an individual's broad social circumstance and the potential vulnerability of their health and functional status. The index has a number of benefits, including: (1) the potential to include many different categories of social factors (for example SES, social support, social engagement, social capital), (2) the commonly encountered difficulty of embodying social and socioeconomic characteristics using single variables in studies of older adults is alleviated by including consideration of multiple different factors, (3) related factors are not arbitrarily separated into distinct categories for separate analysis, and (4) representation of gradations in social vulnerability is improved compared with consideration of one or a few binary or ordinal social variables. This last point

is particularly important given that studies using the social vulnerability index in two cohorts of older adults have found that no one was completely free of social vulnerability (i.e., no individual had a "zero" score on the index).³⁰

In addition to these analytic considerations of how the social factor(s) of interest is/are measured, incorporating the social context into the analyses can be done in different ways. More traditional "horizontal" approaches might add a summary variable that describes the individual's social context (e.g., mean neighborhood income or educational attainment) as a variable/confounder attached to the individual in the multivariable model.^{16,17} This approach can yield useful findings and has the advantage of simplicity, but some might argue that it does not provide a full understanding of the importance of the contextual variable(s) and it presents statistical problems in terms of independence of observations (individuals are no longer truly independent if they share these important characteristics of the groups to which they belong). Multilevel (or "vertical") modeling (e.g., hierarchical linear modeling) is another option; here, the individual is nested within layers of group influence, with collective characteristics treated as attributes of the group rather than of the individual.³¹ This approach offers the advantage of allowing for more detailed understanding of the contextual effects, preserving the independence of observations, and not losing information as happens when data are aggregated.³¹

The consideration of contextual or group-level variables such as neighborhood and community characteristics is

particularly relevant to the study of how social factors affect health because many social factors are properties of the groups or communities in which individuals live and may be best measured on a group level. As we have seen, there is active debate about whether social capital is a property of individuals or of groups.^{1,9} Most theories of social capital are consistent with the idea that it is a property of relationships between individuals and within societies rather than residing within individuals *per se*. The heart of the issue that continues to divide theorists is whether social capital is a resource that an individual can be said to draw upon, and thus, in practical research terms, whether or not it can legitimately be measured at an individual level. This debate has clear implications for the design and interpretation of research studies that aim to investigate how social factors influence health; valid and useful findings can rest only on sound theoretical foundations. In this regard, a second distinction may be helpful: the answer may depend on whether the question applies to *where social capital exists* (is it a property of individuals or of relationships?) or to *how it is measured and accessed*.⁹ Practically speaking, measurement issues and data availability may strongly influence analytic design. The issue of how social factors should be studied in relation to older adults' health is therefore ideally guided by a balance of these theoretical considerations and analytic pragmatism.

SUCCESSFUL AGING

This concept has been the subject of numerous inquiries in both the academic literature and the popular press.³² Interested readers are referred to the comprehensive chapter by T. A. Glass in the sixth edition of this text.³³ Definitions of successful aging vary, but generally fall into psychosocial and biomedical camps. Psychosocial conceptualizations emphasize compensation and contentedness, where biomedical definitions are based on absence of disease and disability.³³ The concept of successful aging recognizes that the aging process is variable, and that how older people adapt to later life changes associated with aging influences how "successfully" they will age. Ideally, research into this area would identify potentially modifiable factors at play that help some age "better/more successfully" than others.

There is a potential downside to the idea of successful aging: if successful aging is applied as a value judgment, it may be at the cost of blaming and further marginalizing the "unsuccessful agers," those who are not so fortunate as to have the good health and functional status that might allow them to be doing aerobics at 102 or volunteering with "the old people" at 99.³² Such stereotypes, based on both rare aging successes and on the undercurrent of ageism that is common in our society, also influence portrayal of older people in the popular media. Both positive and negative stereotypes run the risk of perpetuating the marginalization of the most vulnerable older people, whether their "unsuccessful aging" is implied or emphasized.³²

Another way to think about successful aging is those individuals who overcome their expected trajectory in the natural history of decline for a given level of frailty. Work with the frailty index has shown that trajectories of decline are established early, and that such declines are well-predicted using mathematical models.^{34,35} However, there are some individuals who improve or transition to lower

levels of frailty (who are able to "jump the curve" from their own predicted course and outcomes to attain the outcomes that would be expected for people with a lower baseline level of frailty); this might be a useful subgroup in which to study predictors and correlates of this "successful aging."

ASSOCIATIONS WITH HEALTH

The various social factors discussed here have been associated with health outcomes that are important for the older population. Readers interested in broad-based discussions of how social circumstances relate to health (and to other attributes of societies) are referred to the works of Putnam, Wilkinson, and Marmot, who have each made strong and comprehensive cases that weak social cohesion and declines in social capital contribute to poor health,²⁵ and may explain associations between poor health and income inequalities³⁶ and social status inequalities.⁶ As in many areas of geriatric medicine, studies pertaining specifically to older adults are limited in number. These will be discussed here along with important findings from general population studies in relation to health outcomes that are important in geriatric medicine.

Survival

Numerous studies have found associations between social factors and survival. Perceived social support and social interaction were associated with lower 30-month mortality in a cohort of 331 community-dwelling adults aged 65 and older in Durham County, N.C.³⁷ In the Alameda County 1965 Human Population Laboratory study, those, including older adults, with a richer social network, more contact with friends and family, and church or other group membership (used to generate a social network index) had lower mortality over 9 years of follow-up.³⁸ Using 17-year follow-up data from the same study, social connectedness predicted better survival at all ages, including those aged 70 and older.⁵ Older individuals with few social ties also had reduced survival in a cohort study conducted in Evans County, Ga.² In another study, increased social ties predicted 5-year survival in two of three community-based cohorts.³⁹ The Whitehall studies of men employed in the British civil service identified an impressive gradient in survival across levels in the occupational hierarchy: in middle age, office workers in the lowest ranking jobs had four times the mortality of those in the highest ranking "administrators" category. This gradient persisted after retirement (though it diminished to twice the risk of mortality) in the oldest age group studied, age 70 to 89.^{6,7} High social vulnerability, as measured using a social vulnerability index, increased the risk of mortality over 5 and 8 years follow-up in two separate longitudinal studies of older Canadians: the Canadian Study of Health and Aging (CSHA) and the National Population Health Survey.³⁰ Ecologic (collective-level) analyses using multilevel modeling have also linked high social capital, defined by high trust and membership in voluntary associations, with reduced mortality at state¹⁸ and neighborhood¹⁴ levels in the United States.

Cognitive decline and dementia

In a study of 2812 older adults living in New Haven, Conn., social disengagement was associated with 3-, 6-, and 12-year incident cognitive decline defined as a transition to a lower category of performance on the 10-item Short

Portable Mental Status Questionnaire.⁴⁰ Greater emotional social support predicted better cognitive function measured by a battery of tests assessing language, abstraction, spatial ability, and recall over 7.5 years in the MacArthur Studies of Successful Aging.⁴¹ Among 2468 CSHA participants aged 70 and older, high social vulnerability was associated with a 35% increase in the odds of clinically meaningful cognitive decline (a decline of ≥ 5 points⁴² on the Modified Mini Mental State Examination [3MS]) over 5 years.⁴³ In a cohort of 1203 older adults in Kungsholmen, Sweden, those with a limited social network (including consideration of marital status, living arrangement, and contacts with friends and relatives) had a 60% increased risk of dementia over an average of 3 years of follow-up, whereas the incidence of dementia decreased in a stepwise fashion with increasing social connectedness.²⁸ The association of strong social networks and participation in mental and physical leisure activities with reduced incidence of dementia was also supported by a systematic review.⁴⁴ An American study of 9704 older women found that a richer social network (defined as the top two tertiles on the Lubben Social Network Scale) was associated with maintenance of optimal cognitive function (i.e., not experiencing age-related declines in cognition) over 15 years of follow-up.⁴⁵ Loneliness has also been associated with lower levels of baseline cognition in older people, more rapid cognitive decline, and double the risk of pathologically diagnosed Alzheimer dementia.⁴⁶ Social interaction and engagement reduced the probability of declines in orientation and memory in a 4-year study of community-dwelling Spanish older adults⁴⁷ and greater social resources (networks and engagement) were similarly associated with reductions in cognitive decline in old age.⁴⁸

Socioeconomic status has also been studied in relation to cognition and cognitive declines in late life. Low SES (as measured by education, income, and assets) was associated with cognitive decline (≥ 5 point decline in the 3MS over 4 years) independent of biomedical comorbidity in a cohort of 2574 older participants aged 70 to 79 in the Health, Aging, and Body Composition study.⁴⁹ In a study that measured performance on complex memory tasks and electroencephalography (EEG) recordings of event-related potentials, older women (aged 65 and older) of high socioeconomic status performed similarly to younger women in complex source memory tasks, and appeared to make use of neural compensation strategies not used by their lower SES counterparts and not required by the younger subjects.⁵⁰ In the Chicago Health and Aging project study of 6158 older people aged 65 and older, early life socioeconomic status (both of the individual's family and of their birth county) was associated with late life cognitive performance but not with subsequent rate of decline.⁵¹ A report from the English Longitudinal Study of Ageing (ELSA) found that neighborhood-level SES was associated with cognitive function independent of individual SES.¹⁶ Using hierarchical linear modeling, neighborhood-level educational attainment was associated with cognitive function of Americans aged 70 and older participating in the Study of Assets and Health Dynamics Among the Oldest Old (AHEAD). This was independent of individual factors including educational attainment and neighborhood measures of income, leading the authors to conclude that promoting educational attainment in the general population may help older residents to maintain cognitive function.⁵²

Functional decline and dependence

Low levels of social engagement among older adults have been associated with increased disability (measured as impairment in activities of daily living, mobility, and upper and lower extremity function) over 9 years of follow-up.⁴ Older adults (aged 72 and older) with dense social networks showed delayed onset of self-perceived disability over 8 years of follow-up in a panel study of 1000 residents of three retirement communities in Florida.⁵³ Social engagement through group participation, social support, and trust/reciprocity were each associated with reduced functional impairment in community-dwellers in a cross-sectional analysis of the Health Survey for England. The association between group participation and functional impairment was also statistically significant among residents of institutional care homes.⁵⁴

Mobility

Various social factors have been associated with risk of falls and of subsequent injury. For example, one Australian population-based study found that older people with lower SES, those living alone, and those needing repairs to their home were more likely to have fallen.⁵⁵ Another study identified protective factors for fall-related hip fractures that included being currently married, living in the same place for more than 5 years, having private health insurance, and engaging in social activities.⁵⁶ Neighborhood-level deprivation has been associated with incident self-reported mobility difficulties and measured impairment in gait speed independent of individual SES and health status in the English Longitudinal Study of Ageing (ELSA).¹⁷

Institutionalization

As most studies in this field have been done using surveys or cohorts with community-based sampling frames, there has been a paucity of research including residents of long-term care facilities. However, severe lack of social support has been associated with higher odds of care home residence,⁵⁴ and is a risk factor for care home placement.^{57,58} The issue of how social factors and social vulnerability affect the health of older residents of institutions requires further study. In a cross-sectional analysis of the Health Survey for England, where associations between social capital and health were found among care home residents, these associations were generally weaker than in the community setting, suggesting that the importance of social capital may vary according to living situation.⁵⁴

Mental health

Low perceived neighborhood social capital and high social disorganization were associated with both psychiatric and physical morbidity in a study of British adults.⁵⁹ Mental health has also been found to be associated with the strength and nature of social ties, although protective effects do not appear to be uniform across all population groups.⁶⁰ For example, a study of 1714 older Cubans found that social networks (particularly those centered on children and extended family) were associated with reduced depressive symptoms in women, whereas being married and not living alone were more important for men.⁶¹ Among community dwelling older adults, social support, group participation, and

trust/reciprocity were each associated with better mental health as measured by the General Health Questionnaire, an instrument that has been validated to detect mild psychiatric morbidity. Social support was also associated with reduced psychiatric morbidity among older adults who resided in care homes.⁵⁴ Lower neighborhood SES and higher population density were associated with depression and anxiety among people aged 75 and older in Britain, but in this study the effect of neighborhood SES was explained by individual SES and health factors.⁶²

Self-assessed health

Individual-level social capital, as defined by religious participation, trust, and having a helpful friend, was associated with better self-assessed health among Swedish-speaking adults in a bilingual region of Finland.⁶³ High community-level social trust and membership in voluntary associations were also associated with better self-assessed health among community-dwelling adults in multilevel analyses adjusting for individual-level influences on health in two large ($N = 167,259$ and $21,456$) American studies.^{13,15} Among 1677 community dwelling older adult participants in the Health Survey for England, higher levels of social support, group participation, and trust/reciprocity were associated with better self-assessed health.⁵⁴ At a neighborhood level, low SES (including poverty, unemployment, low education, and reliance on public assistance) was associated with poor self-assessed health of Americans aged 70 and older in the AHEAD study, independent of individual-level health and SES factors. This association with self-assessed health held even though the neighborhood-level attributes were not independently associated with cardiovascular disease and functional status.⁶⁴

Frailty

In two cohorts of older Canadians, social vulnerability was moderately correlated with frailty, but was distinct from it. Both frailty and social vulnerability contributed independently to the risk of mortality.³⁰ Several social determinants of frailty were identified in an elderly Chinese population aged 70 and older; these included low SES (occupational category and inadequate income), having few or little contact with relatives and neighbors, low participation in community/religious activities, and reporting low social support.⁶⁵

MECHANISMS

Various mechanisms have been proposed to explain how social factors might affect health. Broadly speaking, these can be broken down into four groups: biologic and physiologic, behavioral, material, and psychological. Study of neurophysiology and neuroanatomy may also contribute to understanding the relationship between social factors and health.

Physiological

Chronic and sustained stress responses exert powerful effects on health through complex hormonal regulatory systems, with myriad downstream effects on tissues and organs. Various animal studies have found effects on the

hypothalamic-pituitary-adrenal axis. Chronically elevated levels of glucocorticoids in socially isolated rats accelerate aging processes including hippocampal cell loss and cognitive impairment.¹⁹ Social support has also been linked to immune function in both humans and animals, with social isolation and loneliness compromising immunocompetence even among otherwise healthy medical students.¹⁹

Behavioral

Socioeconomic inequalities (including employment and educational opportunities) and the norms and influences exerted through social networks and communities may affect health-related behaviors such as diet, smoking, substance use, and exercise. This may partially explain social influences on health; however, many studies in which these behaviors are taken into account find that social circumstances exert additional independent effects on health.^{13,19,37,38}

Material

Socioeconomic status and social support networks clearly affect access to goods and services. This access accrues in three broad ways: through financial resources (what you have), social status (who you are), and social contacts (who you know). Those with financial means and high social status can afford to make healthy lifestyle choices (e.g., balanced diet, opportunities for exercise, avoiding smoking, and substance abuse) and access health care services that may be difficult to obtain without such resources. There are also strong systemic and societal factors that serve to maintain the social exclusion of marginalized individuals and groups. Those with strong social support resources can access financial and instrumental assistance in time of need.

Psychological

Self-efficacy and adaptive coping strategies are important for health, and are some of the potential psychological mechanisms through which social factors may influence health.¹⁹ Low self-efficacy (having low confidence in one's abilities) is associated with fear of falling, with important functional and mobility ramifications for older people.⁶⁶ Low self-efficacy has also been found to predict functional decline in older people with impaired physical performance.⁴ Social supports and engagement may bolster feelings of self-efficacy and self-confidence.

Neurophysiology and neuroanatomy

Study of patients with neurologic conditions has historically been a rich source of insight into the function of the brain and nervous system. Whereas the potential mechanisms discussed in the last few paragraphs attempt to explain how social circumstances themselves might influence health, here we consider the reverse, by studying people with neurologic conditions including dementia we may be able to learn more about how the brain influences social factors like engagement, participation in social networks, and perceptions of others such as trust and reciprocity that are important to the idea of social capital. For example, some individuals with dementia become socially withdrawn and apathetic, suspicious and less trusting, or have other personality changes that influence their social function. Study of the localization and function (e.g., with functional imaging techniques and more

traditional neuropathology) of such problems may add to the elucidation of the links between social function and social circumstances and health. This field is in its early stages, but as an example, "agreeableness" in frontotemporal dementia (which is often characterized by personality changes and problems with social function) has been shown to be positively correlated with the volume of the right orbitofrontal cortex and negatively correlated with left-sided orbitofrontal volume.⁶⁷ Animal studies may also contribute to this area of inquiry. For example, study of hyenas has shown that the four distinct species of hyenas can be placed on a continuum of increasing social complexity. Interestingly, the volume of the frontal cortex (as determined by internal measurements of their skulls) is directly proportional, with the hyenas that have the most complex social relationships having the greatest frontal lobe volumes.⁶⁸

FRAILITY, EXCLUSION, AND "SILENCE BY PROXY"

Older adults who are frail and/or cognitively impaired present a unique challenge for research in this field for many reasons. These include exclusion from research, reliance on proxy informants, problematic assessment of social situation and socioeconomic status, and controversy regarding informed consent.

Many frail older adults may be excluded from population-based research if the sampling frame excludes nursing homes (as is commonly the case) or if persons unable to answer for themselves are not included in surveys. Even if efforts are made to include these groups by using proxy respondents, subjective reports and personal historical details may be missing or unreliable.^{9,54}

This "silence by proxy" presents great challenges in research involving frail elderly people, as it is often hardest to gather information from those who are the most frail, particularly in institutions where family may be unavailable to fill in historical details. One might imagine that social support and social interactions could be more relevant to health in frail older people because they might be most reliant on family and friends for care and encouragement, and that benefits of social engagement could be greater in terms of mobility and optimizing function appropriate to their level of ability. As such, the associations found in studies from which they are excluded could be underestimated.

POLICY RAMIFICATIONS AND POTENTIAL FOR INTERVENTIONS

Although there are not many intervention studies in which social vulnerability is reduced and health outcomes studied, some studies do suggest hope in this regard. For example, there is evidence that participation in some types of voluntary groups may help to buffer the negative psychological effects of functional decline.⁶⁹ Intervention trials with so-called "befriending services," in which social support is offered by a volunteer visitor, have had mixed results, possibly due in part to limited uptake.⁷⁰ There is a large literature and clinical experience with structured peer support groups, for example, those provided through various disease-specific community organizations; discussion of these is beyond the scope of this chapter.

One area in which social interventions have the potential to improve health is in the design of seniors' housing. Given the mounting evidence that social engagement and interaction with neighbors improves health, these principles could be brought to bear as housing developments and facilities for older people are designed, built, and renovated. Cannuscio has described such senior housing strategies as a "promising mode of delivery of social capital to the aging population."²⁶ Long-term care facilities could be designed to encourage interaction among residents and with the wider community. Resident rooms spread out along long hallways, inaccessible to those with mobility impairment, might be replaced by rooms organized into pods around shared common areas.²⁷ "Planned care environments" in which a continuum of living arrangements from independent apartments to full nursing care exist within a single complex might foster neighborhood cohesion and reduce residential mobility, which has been shown to negatively impact the formation of social ties.^{12,26} Community planning on a larger scale may also help to address many of the challenges to mobility and community interaction faced by older people. Sidewalks and crosswalks wide enough and in good enough repair to allow the use of mobility aids, traffic lights with cycles long enough to allow safe crossing, accessible public transportation, and availability of services in local residential neighborhoods are strategies that benefit the health of people of all ages. As an example of taking such policy considerations to national and international levels, these issues are at the core of the World Health Organization's Age-Friendly Cities project.⁷¹

CONCLUSIONS

Although further research is required to clarify and contextualize the relationships between social circumstances and health in older adults, it is becoming increasingly clear that social factors exert great influence. Here, the various social factors that have been studied in relation to health have been reviewed, along with their relationship to the concept of overall social vulnerability. Specific associations with health outcomes that are important in geriatric medicine, including frailty, have been discussed.

The social vulnerability index approach has numerous advantages, including theoretical grounding in an understanding of the continuum of social influences on health and in relation to work on frailty, consideration of numerous different domains of social factors at once, and great potential for clinical applicability. From the point of view of clinical services providing care in geriatric medicine, the issue is not only which deficits an individual has, but how they add up to contribute to that person's vulnerability in ways that might predispose them to adverse outcomes. As such, a composite measure of social vulnerability may be a useful and potentially clinically relevant starting point to conceptualize the social circumstance of older adults whom we encounter in the course of clinical care. This points to the need for clinical operationalization and testing of such measures of social circumstances.

Presentation of Disease in Old Age

Sonja Rosen
Brandon Koretz
David B. Reuben

Not only are diseases more common in elderly people, they may be more difficult to diagnose accurately. Nonspecific symptoms, such as altered mental status, weight loss, fatigue, falls and dizziness may be the earliest or only manifestations in this age group. For example, many infections (e.g., pneumonia, urinary tract infection) may present with a change in mental status and fatigue, but few or no symptoms related to the source of the infection. Furthermore, classic presenting symptoms of common diseases may be absent. For example, older persons having myocardial infarction may not report having chest pain.

A number of possible explanations may account for such atypical presentations. Multiple comorbid conditions may alter the presentation of disease, and age-related physiologic changes may alter the perception of stimulus. For example, because of age-related changes in immunity, the febrile response may be absent in infected older persons.¹ Furthermore, cognitive impairment may prevent the patient from providing an accurate history. As a result, these atypical presentations may be more common than classic presentations. Moreover, an atypical presentation may predict a poor outcome for hospitalized elderly patients,² perhaps as a result of delays in diagnosis and initiation of appropriate therapy.

Because older patients may often have nonspecific symptoms and/or atypical symptoms for disease, we have chosen to present this material in two different formats. First, this chapter examines five nonspecific presentations of disease (altered mental status, weight loss, fatigue, dizziness, and falls and fever). Next, we review some common diseases, discussed by organ system, to explore the differences in disease presentation between younger and older patients.

NONSPECIFIC CLINICAL PRESENTATIONS OF DISEASE IN THE OLDER POPULATION

As noted in [Table 34-1](#), six nonspecific presentations may be due to diverse disorders. We review the major diseases responsible for these presentations and provide approaches to determining the causes.

Altered mental status

Altered mental status (AMS) may often be the only indicator of a serious underlying disease.³ Presenting symptoms can include disorientation, decreased or nonsensical verbalization, and somnolence or hyperactivity or a mixture of both. When altered mental status is of rapid onset accompanied by disturbed consciousness (especially decreased attention) and is due to a medical condition, it meets the criteria for delirium. Delirium can also be associated with sleep disturbances

and hallucinations. Delirium is a common presentation of disease in the elderly, and is the most common complication associated with inpatient hospital admission for older people.⁴ The symptoms of delirium may persist for months and are associated with adverse outcomes.⁵

The differential diagnosis of AMS in elderly patients is very broad, and encompasses many systems. The presence of a clinical history suggesting infection, low grade fever, or leukocytosis may suggest an infectious cause. As stated before, because of age-related changes in immunity, older persons may not necessarily mount a fever or leukocytosis.¹ The most common infectious causes of delirium include respiratory, urine, and skin infections. Another cause may be iatrogenic secondary to medications. Medications with a narrow therapeutic index and/or those that cross the blood-brain barrier are the most common culprits. These include anticholinergics and benzodiazepines. Alcohol intoxication or withdrawal should also be considered. Metabolic disorders include electrolyte imbalances, especially sodium disorders, dehydration, hypoglycemia, and hypoxia. Cardiovascular causes include heart failure and myocardial infarction.⁶ Central nervous system causes such as infections (e.g., meningitis and encephalitis,⁷ stroke, seizures, and subdural hematomas are less common. Finally, miscellaneous causes of altered mental status in the older population include urinary retention and fecal impaction.⁸

Altered mental status may also occur in the absence of delirium. For example, psychiatric causes, such as dementia with psychosis, psychotic depression, and bipolar disorder, may present with changes in mental status. Psychosis may be accompanied by delusions and hallucinations, and is one of the most common noncognitive symptoms associated with Alzheimer's dementia.⁹ The second most common cause of psychosis in the elderly is depression.¹⁰ Mania, though less commonly present in the elderly population, is characterized by hyperactivity, but patients should generally remain oriented.

When patients are too altered to give a reliable history, it is important to obtain a careful history and physical examination, which requires corroboration by family members, friends, caregivers, or health care workers, for patients who live in institutional settings. It is also important to review medications with a focus on recent changes and over-the-counter medications that may have anticholinergic properties (e.g., those containing diphenhydramine). For the most part, infection and other major medical causes can be identified with a set of simple laboratory studies, including a complete blood cell count with differential, comprehensive metabolic panel, urinalysis, chest x-ray, electrocardiogram, and, depending on patient's clinical status, cardiac enzymes.

Table 34-1. Nonspecific Clinical Presentations of Disease in the Older Population

Category	Disease Examples	Altered Mental Status	Weight Loss	Fatigue	Dizziness	Falls	Fever
Infection	Urosepsis	x	x	x	x	x	x
	Pneumonia	x		x		x	x
	Subacute endocarditis	x		x			x
	Cellulitis	x		x			x
	Meningoencephalitis	x					x
Metabolic disorders	Hypoxia	x	x	x	x	x	
	Dehydration	x		x	x	x	
	Hyponatremia	x		x	x	x	
	Hypoglycemia	x		x		x	
Cardiopulmonary	Heart failure		x	x			
	COPD		x	x			
Cancer			x	x			x
Psychiatric		x	x	x	x		
Cerebrovascular		x			x	x	
Rheumatologic	Pseudogout (CPPD)	x	x	x			x
	Rheumatoid arthritis	x		x			x
	Temporal arteritis	x		x			x
	Adult-onset Still disease			x			x
Endocrine	Hyperthyroidism	x	x	x			x
	Hypothyroidism	x		x			

If an infectious cause is suspected but no clear source can be found, a lumbar puncture may be warranted,¹¹ although a recent retrospective analysis of 232 hospitalized patients with fever and altered mental status demonstrated that lumbar punctures for suspected nosocomial meningitis in non-surgical patients have a low yield.¹² Though altered mental status is unusual in meningitis, it may be a sign of other central nervous system infection, particularly meningoencephalitis. Furthermore, older patients may not mount the typical immune-response associated with these infections, such as fever or leukocytosis. Finally, brain imaging is of value in ruling out stroke or subdural hematoma if there is clinical suspicion of either diagnosis, or if the evaluation of AMS is otherwise unrevealing. Finally, EEG is helpful in diagnosing occult seizures.

Weight Loss

Undernutrition is indicated by unintentional weight loss of more than 5% within a year.¹³ Unintentional weight loss occurs in up to 15% of community-dwelling older persons, between 20% to 65% of hospitalized patients, and 5% to 85% of institutionalized older persons.¹⁴

Unintentional weight loss is often a marker of severity of comorbidities or undiagnosed disease, and it may be divided into three causes: social, psychological, and medical.¹⁴ Social reasons include poverty, functional impairment, social isolation, poor nutritional knowledge, and elder abuse. Most surveys have shown that poverty is the single most important social cause of weight loss.¹⁵ Dependence in ADLs and IADLs, such as needing assistance with feeding, shopping, or food preparation, are also important factors. Psychological reasons include psychiatric problems such as depression, paranoia, and bereavement. Depression has been shown to be the major cause of weight loss in the outpatient setting.¹⁶ Ninety percent of older adults with depression have weight loss, compared with 60% of younger adults.¹⁷ It is also an important cause in institutionalized patients. Medical reasons include dementia; pulmonary and cardiac diseases; malignancy; medications; alcoholism; infectious diseases;

poor dentition; endocrine abnormalities, especially hyperthyroidism and diabetes; malabsorption; and dysphagia.

The first step in determining the cause is to assess whether patients have adequate dietary intake.¹⁸ If they have inadequate dietary intake, physiologic and psychosocial factors should be investigated. Physiologic factors include nausea, constipation, poor oral health, and functional dependence. Medication side effects also may contribute. For example, narcotics and anticholinergics may cause constipation, which in turn may cause bloating and poor appetite. Psychosocial factors including poverty, dementia, depression, and social isolation should be investigated. The use of geriatric screening instruments such as the Mini Mental State Examination¹⁹ and the PHQ-9²⁰ can help elucidate the etiology.

On the other hand, if patients have adequate dietary intake, a search must be undertaken for underlying disease by careful history and physical examination, with special attention paid to symptoms that may suggest malignancy (such as cough, constipation, or gastrointestinal bleeding), cardiac, or pulmonary disease. The physical examination should evaluate for lymphadenopathy, palpable masses, and breast or thyroid abnormalities. Initial laboratory testing should include pre-albumin, complete blood cell count with differential, comprehensive metabolic panel, thyroid-stimulating hormone, urinalysis, erythrocyte sedimentation rate (ESR), lactate dehydrogenase (LDH), and chest x-ray.²¹ Depending on the patient's clinical findings and laboratory results, consideration should be given to abdominal ultrasound or CT.

Fatigue

Fatigue can be defined as tiredness or decreased energy, and excessive daytime fatigue is not a normal process of aging.²² As the body protects its functional reserve, fatigue may be associated with generalized weakness that may occur if fatigue progresses.²³ Fatigue may be acute or chronic, the latter of which is the result of physical and/or psychological factors.

Physiologic causes of fatigue by body systems include hematologic/oncologic (e.g., anemia, cancer, and cancer-related therapy), cardiac (e.g., congestive heart failure),

renal or liver disease, endocrine (thyroid disease, diabetes), and pulmonary (sleep-related breathing disorders, severe obstructive or restrictive lung diseases). Fatigue is one of the most common side effects of cancer treatment, with 70% of cancer patients receiving radiation and chemotherapy experiencing this symptom and may also persist for years after treatment.²⁴ Fatigue is also the most common symptom of congestive heart failure (CHF), and is the initial presenting complaint in 10% to 20% of new CHF diagnoses.²⁵ Obstructive sleep apnea (OSA) is common in patients over 60 years, with a reported prevalence of 37.5% to 62%; daytime sleepiness is a prominent symptom.²⁶ Other sleep disorders, such as insomnia or disturbances in sleep-wake cycles that may occur with dementia, can also lead to daytime fatigue. Some chronic infections, such as subacute endocarditis, may also present with fatigue as a chief complaint. Medications are also a common culprit of fatigue in the elderly, particularly antihistamines, anticholinergic medications, sedatives or non-sedating hypnotics, and antihypertensive medications (especially beta-blockers at high doses). Finally, psychiatric illnesses, most commonly depression, can cause excessive fatigue.

The evaluation of fatigue begins with history, with focus on any symptoms concerning for malignancy (e.g., weight loss) or other body system diseases that may suggest a cause (e.g., dyspnea suggesting anemia, congestive heart failure, ischemia, or pulmonary disease; recent bereavement suggesting depression). A cognitive assessment with the Mini Mental State Examination¹⁹ should be performed to screen for cognitive impairment, and the PHQ-9²⁰ should be performed to screen for depression. Similarly, the physical examination should focus on any red flags (e.g., weight loss suggesting malignancy, edema suggesting congestive heart failure). A review of medications should focus on any potentially sedating medications, including over-the-counter medications such as antihistamines. The laboratory and diagnostic testing is then tailored toward identifying possible causes. In addition to basic labs (complete blood cell count, comprehensive metabolic panel, thyroid-stimulating hormone, urinalysis), additional diagnostic tests may be ordered based on history and physical findings (e.g., an electrocardiogram, echocardiogram, and BNP may be ordered in someone suspected of having CHF).

Dizziness

Dizziness occurs in more than 30% of the population over 60 years of age, and as many as 7% of elderly patients have this symptom.²⁷ Though common, dizziness is not a normal process of aging. It can be a vexing clinical problem, the cause of which is often difficult to both diagnose and treat. Most older patients who have dizziness have a benign cause, but dizziness may also be indicative of a more serious underlying medical condition. One study of patients older than 60 years of age having dizziness showed that 28% had a cardiovascular diagnosis and 14% had a central neurologic disorder. Of note, 22% had no attributable cause of symptoms identified.²⁸ Psychological disorders are rare as the primary cause of dizziness, but may be contributing or modulating factors in older persons with dizziness.²⁹ Furthermore, patients with dizziness may develop fear of falling, falls,³⁰ and subsequent disability in daily activities secondary to their symptoms.³¹

To determine the cause of dizziness, it is important to first determine the nature of the presenting symptoms. Dizziness can be classified into four symptom categories: vertigo, presyncope, dysequilibrium, and nonspecific dizziness.³² *Vertigo* is defined as a feeling that one's surroundings are moving, and can be episodic or continuous. Causes of vertigo include benign paroxysmal positional vertigo, acute labyrinthitis, Meniere's disease, vertebrobasilar insufficiency, brain stem stroke, tumors, and cervical vertigo. *Presyncope* is defined as a lightheaded feeling or impending faint. Presyncope is commonly due to orthostatic hypotension, vasovagal attacks, and decreased cardiac output, such as significant valvular lesions or arrhythmias. *Dysequilibrium* is defined as a sense of unsteadiness or imbalance where one feels as if one is going to fall, and is usually constant and occurs primarily while standing. Dysequilibrium is usually the result of vestibular loss (e.g., acoustic neuroma), proprioceptive (e.g., cervical osteoarthritis) and somatosensory loss (e.g., peripheral neuropathy), cerebellar or motor lesions (e.g., subcortical or cerebellar infarct, tumors) or multiple neurosensory impairments, such as those occurring in Parkinson disease. Finally, some nonspecific dizziness symptoms do not fit into any of the above categories. These may be described as mild lightheadedness, but also may be difficult for patients to describe. Infections (e.g., urinary tract infections), anxiety, or hyperventilation are commonly responsible for nonspecific dizziness.

The evaluation of the differential diagnosis begins with a history and physical examination, with a focus on the nature of the patient's symptomatology. A dizziness simulation battery can be performed to further delineate which type of dizziness the patient suffers from.³³ For example, reproduction of symptoms with nystagmus in response to the Barany or Dix-Hallpike maneuver is diagnostic for vertigo. Further vestibular concerns can be evaluated with audiometry, brain MRI, and/or referral to an otolaryngologist. Presyncope should be evaluated with screening laboratory tests, including complete blood cell count, comprehensive metabolic panel, urinalysis and thyroid function, electrocardiogram, and possible further cardiac (e.g., event monitor, echocardiogram) or neurologic (carotid ultrasound, brain MRI) testing, depending on clinical presentation and history. In addition, dysequilibrium may require a neurology evaluation and further neurologic testing. Non-specific dizziness should also be evaluated with basic screening laboratory tests as indicated earlier.

Falls

Over one third of the community dwelling persons over 65 fall each year, and more than 50% of these patients have recurrent falls.³⁴ Falls are responsible for two thirds of accidental deaths, which are the fifth leading cause of death in older adults.³⁵ One in 10 falls results in serious injury, including hip fracture and subdural hematomas.³⁴ Falls are also independently associated with functional and mobility decline. All patients over 65 should be screened for a history of falling in the last year, as patients who have fallen in the last year are at higher risk for falling again.³⁶

Though the cause of most falls is multifactorial in nature, it is useful to understand the separate entities that may be contributing factors or may independently cause falls. These include the following physiologic contributors: cardiac disease (e.g., orthostatic hypotension, arrhythmia, valvular lesions, ischemia); neurologic diseases (e.g., strokes, subdural

hematomas in recurrent fallers, peripheral neuropathy; cognitive impairment); musculoskeletal (e.g., osteoarthritis, leg asymmetry, muscle weakness); sensory impairment (visual and hearing impairment); iatrogenic (medications; physical restraints in institutionalized settings); and primary gait and balance impairments. There are also several other nonphysiologic factors that may cause or contribute to falls, including: incorrect use of walking aids; environmental hazards (e.g., loose carpets), performing several activities simultaneously, inappropriate footwear, and hazardous behavior.³⁷

If the physician learns that a patient has fallen in the last year, a multifactorial evaluation of the cause(s) should be undertaken. This begins with a history determining the circumstances surrounding the falls (e.g., loss of balance, tripping secondary to poor vision, or presyncopal symptoms). A review should be performed of both prescription and nonprescription medications that may be contributing to falls (e.g., sedatives, anticholinergics, non-sedating hypnotics). The physical examination should include orthostatic vital signs, visual acuity testing, and a gait and balance evaluation. The physician can most efficiently observe a patient's gait while the patient is entering and leaving the examination room. Simple tests of balance include observing the patient's ability to stand side-by-side, semitandem and full-tandem for 10 seconds; and stability during a 360-degree turn.³⁸ The neurologic examination should evaluate for any focal or generalized weakness, impaired cognition, signs of parkinsonism (e.g., rigidity, tremor) or poor proprioception. For patients who are found to have cognitive impairment or focal weakness, further evaluation may include brain imaging to assess for vascular disease. In addition, patients with focal weakness may require musculoskeletal imaging (e.g., to evaluate for osteoarthritis, spinal stenosis, mass lesions) and EMG studies to evaluate for possible peripheral neuropathy. The cardiovascular examination should include evaluation for valvular lesions, arrhythmias, or carotid lesions. An electrocardiogram should be performed with further cardiac testing if patients have presyncopal or syncopal symptoms (see Dizziness section). The musculoskeletal examination should focus on any muscle weakness or atrophy, joint abnormalities, foot deformities, or leg asymmetry. A complete blood count, basic metabolic panel, thyroid-stimulating hormone, and vitamin B₁₂ level may identify a specific or contributing cause.

Fever

Fever is the prototypical sign of many infections (most commonly urinary tract, infections, pneumonias, skin, and intra-abdominal infections; less commonly endocarditis and osteomyelitis), and some malignancies (e.g., lymphoma, renal cell carcinoma, and hepatic cell carcinoma) and rheumatologic diseases (e.g., calcium pyrophosphate dihydrate deposition disease, rheumatoid arthritis, temporal arteritis, and adult onset Still's disease). Other less common causes include drug reactions, hematomas, and thyroid storm.

The presence of fever serves as a warning sign for potentially life-threatening diseases.³⁹ But, as already mentioned, the febrile response may be absent in infected older patients. While errors in measurement may account for some of this variability,⁴⁰ older patients, on average, have a lower basal temperature than younger persons.⁴¹ To compensate for this, some have suggested that the use of change from basal temperature

might be more sensitive for the presence of infection than absolute temperature.⁴⁰ In elderly individuals, an oral temperature of greater than 99° F should be considered elevated.¹ One study examined the importance of fever in 470 consecutive elderly patients who were seen in an emergency room with temperatures of 100.0° F or greater.⁴² Three quarters of these patients were classified by the authors as seriously ill.

The fever workup should begin with a history focusing on evaluation for infection, malignancy, or rheumatologic disease. Physical examination should pay attention to cardiac (e.g., murmurs suspicious for endocarditis) and pulmonary examination (e.g., rhonchi indicating possible pneumonia), lymphadenopathy, skin findings, joint abnormalities, and gastrointestinal examination (e.g., pain, organomegaly or other masses). Laboratory evaluation should begin with complete blood cell count with differential, urinalysis, urine culture, and chest x-ray and ESR, the latter if there is clinical suspicion for osteomyelitis, endocarditis, temporal arteritis, or lymphoma. Further imaging may be warranted if there is clinical suspicion for occult disease, such as intraabdominal abscesses or neoplasm.

COMMON DISEASES AND THEIR ATYPICAL PRESENTATION IN THE OLDER POPULATION

As noted in [Table 34-2](#), common diseases may often have atypical presentations in the older population. In this section, we review some of these common diseases and discuss the differences in disease presentation between younger and older patients.

Gastroesophageal reflux disease

Symptoms of gastroesophageal reflux disease (GERD) are common among elderly patients. The typical symptom in the older population is postprandial substernal burning exacerbated by reclining. Among older persons referred for endoscopy, almost 20% have erosive or complicated esophagitis.⁴³ People in this subgroup are more likely to complain of dysphagia, respiratory symptoms (chronic cough, hoarseness, or wheezing), and vomiting than patients without severe esophagitis.

Peptic ulcer disease

Among patients with endoscopically diagnosed ulcers, elderly people are less likely to have abdominal pain.⁴⁴ Conversely, they are more likely to have bleeding, a shorter duration of symptoms, and other symptoms not typically considered to be associated with peptic ulcer disease (nausea, vomiting, anorexia, or abdominal pain not relieved by eating or drinking).⁴⁵

Appendicitis

Although appendicitis is more common in younger patients, its mortality is substantially higher among older persons.⁴⁶ The classic presentation is peri-umbilical pain that rapidly localizes to the right lower abdominal quadrant in association with peritoneal signs. Although this pattern may not be as common in elderly persons, most older patients will develop right lower quadrant pain at some time during the illness. Abdominal rigidity, decreased bowel sounds, and the presence of a mass appear to be more common in older

Table 34-2. Common Diseases and Their Atypical Presentations in the Older Population

Disease	Typical Presentation in Younger Persons	Atypical Presentation in Older Persons
GERD	Postprandial burning with reclining	Postprandial burning with reclining Dysphagia Chronic cough Hoarseness
PUD	Epigastric abdominal pain	Bleeding Nausea and vomiting Anorexia Abdominal pain not relieved by eating or drinking
Appendicitis	Peritoneal signs localizing to right lower quadrant Nausea/vomiting Leukocytosis	Abdominal rigidity Abdominal pain—generalized Decreased bowel sounds Nausea/vomiting Leukocytosis
Cholecystitis	Right upper quadrant pain Murphy sign Fever Nausea/vomiting Leukocytosis	Generalized abdominal pain Fever Nausea/vomiting
Myocardial infarction	Substernal chest pain radiating to left arm or jaw	Chest pain Dyspnea Vertigo Altered mental status Heart failure Weakness
Pneumonia	Fever Cough Chills Pleuritic chest pain	Tachypnea Altered mental status Decreased oral intake Fever Cough Chest pain
Gout	Male predominance Monoarticular	Indolent course Polyarticular
Rheumatoid arthritis	Indolent course	Acute onset Fever Weight loss
Urinary tract infection	Dysuria Fever	Fatigue Altered mental status Dizziness Nausea

patients.⁴⁷ Though variable, the frequency of nausea, vomiting, leukocytosis, and fever do not appear to be significantly different between older and younger patients.

Cholecystitis

The typical presentation of cholecystitis is right upper quadrant pain, fever, nausea, vomiting. Leukocytosis may not be present in elderly patients. In one retrospective cross-sectional study of 168 patients over the age of 65, 57% had nausea, 38% had vomiting, and 36% had back or flank pain radiation.⁴⁸ Surprisingly, 84% had neither epigastric or right upper quadrant pain, and 56% of patients were afebrile.

Myocardial infarction

Altered mental status, neurologic symptoms, weakness, and worsening heart failure are common presentations of an acute myocardial infarction in older persons.⁴⁹ Because pain perception decreases with aging, silent myocardial ischemia is more common. Even when older patients have the classic presentation of substernal discomfort, its intensity tends to be less severe.

Some studies have directly compared the presenting symptoms of MI in younger and older patients. In a Finnish study, typical presentations occurred more commonly in younger

patients, whereas older patients more commonly had dyspnea, vertigo, and loss of consciousness.⁵⁰ A second study found that chest pain became less common as a presenting symptom of MI as patients aged; however, most patients of all ages had chest pain accompanying their MI.⁵¹ The presence of syncope, stroke, and delirium as initial symptoms was also significantly associated with increased age.

Pneumonia

Pneumonia is the fifth leading cause of death among elderly people. Unlike the typical presentation of pneumonia consisting of fever, cough, chills, and pleuritic chest pain, atypical presentations occur more frequently in older persons.⁵² These atypical presentations include decreased oral intake, falling, or confusion, or an abrupt worsening of an underlying chronic medical condition (e.g., hemiplegia from a prior stroke). Tachypnea is common; three quarters or more of elderly patients with pneumonia may present with respiratory rates greater than 20/min,^{53,54} and may be one of the earliest signs of pneumonia, often occurring 24 to 48 hours before the clinical diagnosis.⁵⁵ Fever has been reported in 27% to 80% of older patients with pneumonia.^{54,56,57,58} A cough has been noted in 54% to 82% of elderly patients admitted to the hospital with community-acquired

pneumonia.^{59,60} Chills or rigors are noted in about one quarter of patients and a similar percentage had falls.⁴⁸ Chest pain may be present in one third.⁵² Delirium occurs in 15% to 47% of patients with pneumonia and seems to be more common among nursing-home patients (approximately 48%) than those who live independently.^{54,56,57,60}

Gout

The presentation of gout in the older person may follow a more indolent course and be more likely to be polyarticular.⁶¹ The male predominance noted in younger patients does not seem to be present among older persons.⁶² There is a strong association with long-term diuretic use; renal excretion of uric acid is inhibited because of volume contraction.^{63,64} For the same reason, tophaceous deposits are more likely to be present in elderly people.

Rheumatoid arthritis

Compared with younger persons, older patients who develop rheumatoid arthritis (RA) tend to have more constitutional symptoms (fever, weight loss, and fatigue), are more likely to have an acute onset of arthritis, have more shoulder involvement, and have a negative assay for rheumatoid factor.^{65–68} However, there are some concerns about the methodological rigor of the studies on which these conclusions are based.⁶⁹

Urinary tract infection and urosepsis

Bacteriuria becomes increasingly common with advancing age. In the absence of symptoms, its association with increased mortality is controversial.⁷⁰ It is clear, however, that the urinary tract is the most common source for bacteremia in elderly patients admitted to a hospital.⁵⁴ The typical symptoms associated with lower tract infections—dysuria, urgency, and suprapubic pain—are commonly absent in older patients with bacteriuria.⁷¹ Similarly, the flank pain, fevers, and chills that typically accompany upper urinary tract infections may be absent. The clinical picture of urinary

tract infections in older persons is variable. In one series of elderly patients with bacteremia from urinary sources, 30% had confusion, 29% had a cough, and 27% had dyspnea.⁷² Other studies suggest that the febrile response to urinary tract infection remains intact, but also suggest that confusion is a common presenting sign.⁷³

CONCLUSION

Many studies support the notion that common diseases present differently in the elderly population. What is less clear is whether it is appropriate to call these presentations atypical. In fact, when the atypical presentation is more common than the classic presentation described for younger persons, perhaps it should be termed the typical presentation in the older age group. Rather than using the 25-year-old as the reference standard for all age groups, practitioners should remain aware that diseases have different clinical features depending upon the age of the affected patient. Physicians should also be aware of common nonspecific presentations of illness, and their differential diagnosis and appropriate evaluation to help lead them to the right diagnosis.

KEY POINTS

Presentation of Disease

- Nonspecific presentations of disease may be the earliest or only manifestations of disease in older people.
- Six common nonspecific presentations of disease include altered mental status, weight loss, fatigue, falls, dizziness, and fever.
- Practitioners should remember that many common diseases may present differently in younger and older patients.

Multidimensional Geriatric Assessment

Laurence Z. Rubenstein

Lisa V. Rubenstein

Geriatric assessment is a multidimensional, usually interdisciplinary, diagnostic process intended to determine a frail elderly person's medical, psychosocial, and functional capabilities and problems with the objective of developing an overall plan for treatment and long-term follow-up. It differs from the standard medical evaluation in its concentration on frail elderly people with their complex problems, its emphasis on functional status and quality of life, and its frequent use of interdisciplinary teams and quantitative assessment scales.

The process of geriatric assessment can range in intensity from a limited assessment by primary care physicians or community health workers focused on identifying an older person's functional problems and disabilities (screening assessment), to more thorough evaluation of these problems by a geriatrician or multidisciplinary team (comprehensive geriatric assessment), often coupled with initiation of a therapeutic plan. This chapter discusses both limited geriatric assessment, such as can be performed by a single practitioner in an office setting, and comprehensive geriatric assessment, usually requiring a specialized geriatric setting.

Because the ultimate goal of geriatric assessment is to improve quality of life for elderly people, readers may find [Figure 35-1](#) helpful.¹ As diagrammed, quality of life includes health status and socioeconomic and environmental factors. Health status can be quantified both by measures of disease, such as signs, symptoms, and laboratory tests, and by measures of functional status. By functional status, we mean the individual's ability to participate fully in the physical, mental, and social activities of daily life. The ability to function fully in these arenas is strongly affected by an individual's physiologic health, and can often be used as a measure of the seriousness of a patient's multiple diseases. A comprehensive geriatric assessment should be able to evaluate and plan care for all these areas.

BRIEF HISTORY OF GERIATRIC ASSESSMENT

The basic concepts of geriatric assessment have evolved over the past 75 years by combining elements of the traditional medical history and physical examination, the social worker assessment, functional evaluation, and treatment methods derived from rehabilitation medicine, and psychometric methods derived from the social sciences. By incorporating the perspectives of many disciplines, geriatricians have created a practical means of viewing the "whole patient."

The first published reports of geriatric assessment programs came from the British geriatrician Marjory Warren, who initiated the concept of specialized geriatric assessment units during the late 1930s while in charge of a large London infirmary. This infirmary was filled primarily with chronically ill, bedfast, and largely neglected elderly patients who had not received proper medical diagnosis or rehabilitation and who were thought to be in need of lifelong institutionalization. Good

nursing care kept the patients alive, but the lack of diagnostic assessment and rehabilitation kept them disabled. Through evaluation, mobilization, and rehabilitation, Warren was able to get most of the long bedfast patients out of bed and often discharged home. As a result of her experiences, Warren advocated that every elderly patient receive comprehensive assessment and an attempt at rehabilitation before being admitted to a long-term care hospital or nursing home.²

Since Warren's work, geriatric assessment has evolved. As geriatric care systems have been developed throughout the world, geriatric assessment programs have been assigned central roles, usually as focal points for entry into the care systems.³ Geared to differing local needs and populations, geriatric assessment programs vary in intensity, structure, and function. They can be located in different settings, including acute hospital inpatient units and consultation teams, chronic and rehabilitation hospital units, outpatient and office-based programs, and home visit outreach programs. Despite diversity, they share many characteristics. Virtually all programs provide multidimensional assessment, using specific measurement instruments to quantify functional, psychological, and social parameters. Most use interdisciplinary teams to pool expertise and enthusiasm in working toward common goals. Additionally, most programs attempt to couple their assessments with an intervention, such as rehabilitation, counseling, or placement.

Today, geriatric assessment continues to evolve in response to increased pressures for cost containment, avoidance of institutional stays, and consumer demands for better care. Geriatric assessment can help achieve improved quality of care and plan cost-effective care. This has generally meant more emphasis on noninstitutional programs and shorter hospital stays. Geriatric assessment teams are well positioned to deliver effective care for elderly persons with limited resources. Geriatricians have long emphasized judicious use of technology, systematic preventive medicine activities, and less institutionalization and hospitalization.

STRUCTURE AND PROCESS OF GERIATRIC ASSESSMENT

Geriatric assessment begins with the identification of deteriorations in health status or the presence of risk factors for deterioration. These deteriorations include both worsening of disease and worsening of functional status. If disease alone has worsened, without affecting function, the patient should be able to be cared for in usual primary care settings. In addition, when functional status problems are mild and are not rapidly progressive, it is appropriate for a primary care practitioner to proceed with the assessment. However, because families and patients identify functional status problems early, and because internists and family practitioners often are unfamiliar with the concept of "treating" functional status impairment as a problem in its own right, patients often self-refer to geriatric care settings for these functional status problems when

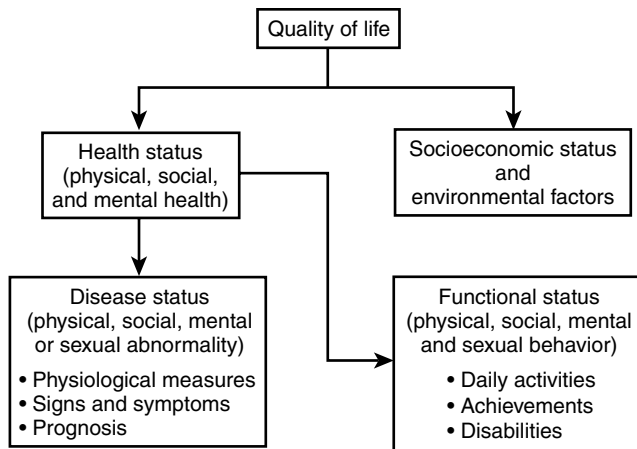

Figure 35-1. Conceptual components of quality of life—relationship to health and functional status. (Adapted from Rubenstein LV, Calkins DR, Greenfield S et al. Health status assessment for elderly patients: reports of the Society of General Internal Medicine task force on health assessment. *J Am Geriatr Soc* 1989;37:562–9, with permission of Blackwell Science, Inc.)

such settings are available. Patients who have new severe or progressive deficits should ideally receive comprehensive multidisciplinary geriatric assessment. Figure 35-2 outlines an approach for evaluating elderly outpatients with health status deterioration and deciding who should be referred to multidimensional geriatric assessment settings.

Using this approach, an elderly patient with a deteriorating health status of any kind, be it a markedly elevated blood glucose, a vertebral collapse, or a new inability to perform errands, should be evaluated briefly to determine the full extent of functional disabilities. Many experts believe that frail elderly people, defined generally as people over the age of 75, or over age 65 with chronic disease, should also be screened for functional disability or risk factors at regular intervals such as once a year, even when no known acute health insults have occurred.^{1,4–7} When a new disability or high-risk state is detected through screening, such patients may also be appropriate for a full geriatric assessment.

A typical geriatric assessment begins with a functional status “review of systems” that inventories the major domains of functioning. The major elements of this review of systems are captured in two commonly used functional status measures—basic activities of daily living (ADL) and instrumental activities of daily living (IADL). Several reliable and valid versions of these measures have been developed,^{8–12} perhaps the most widely used being those by Katz et al,¹³ Lawton and Brody,¹⁴ and Wade and Colin.¹⁵ These scales are used by clinicians to detect whether the patient has problems performing activities that people must be able to accomplish to survive without help in the community. Basic ADL include self-care activities, such as eating, dressing, bathing, transferring, and toileting. Patients unable to perform these activities will generally require 12- to 24-hour support by caregivers. Instrumental activities of daily living include heavier housework, going on errands, managing finances, and telephoning—activities that are required if the individual is to remain independent in a house or apartment.

To interpret the results of impairments in ADL and IADL, physicians will usually need additional information about the patient’s environment and social situation. For example, the

amount and type of caregiver support available, the strength of the patient’s social network, and the level of social activities in which the patient participates will all influence the clinical approach taken in managing deficits detected. This information could be obtained by an experienced nurse or social worker. A screen for mobility and fall risk is also extremely helpful in quantifying function and disability, and several observational scales are available.^{16,17} An assessment of nutritional status and risk for undernutrition is also important in understanding the extent of impairment and for planning care.¹⁸ Likewise, a screening assessment of vision and hearing will often detect crucial deficits that need to be treated or compensated for.

Two other key pieces of information must always be gathered in the face of functional disability in an elderly person. These are a screen for mental status (cognitive) impairment and a screen for depression. Of the several validated screening tests for cognitive function, the Folstein Mini Mental State Examination is one of the best because it efficiently tests the major aspects of cognitive functioning.¹⁹ Of the various screening tests for geriatric depression, the Yesavage Geriatric Depression Scale²⁰ and the PHQ-9 (depression screen of the Patient Health Questionnaire)²¹ are in wide use, and even shorter screening versions are available without significant loss of accuracy.²²

The major measurable dimensions of geriatric assessment, together with examples of commonly used health status screening scales, are listed in Table 35-1.^{7–36} The instruments listed are short, have been carefully tested for reliability and validity, and can be easily administered by virtually any staff person involved with the assessment process. Both observational instruments (e.g., physical examination) and self-report (completed by patient or proxy) are available. Components of them—such as watching a patient walk, turn around, and sit down—are routine parts of the geriatric physical examination. Many other kinds of assessment measures exist and can be useful in certain situations. For example, there are several disease-specific measures for stages and levels of dysfunction for patients with specific diseases such as arthritis,³⁰ dementia,³¹ and parkinsonism.³² There are also several brief global assessment instruments that attempt to quantify all dimensions of the assessment in a single form.^{33–36} These latter instruments can be useful in community surveys and some research settings but are not detailed enough to be useful in most clinical settings. More comprehensive lists of available instruments can be found by consulting published reviews of health status assessment.^{7–12,37}

A number of factors must be taken into account in deciding where an assessment should take place. These are outlined in Table 35-2. Mental and physical impairment make it difficult for patients to comply with recommendations and to navigate multiple appointments in multiple locations. Functionally impaired elders must depend on families and friends, who risk losing their jobs because of chronic and relentless demands on time and energy in their roles as caregivers, and who may be elderly themselves. Each separate medical appointment or intervention has a high time-cost to these caregivers. Patient fatigue during periods of increased illness may require the availability of a bed during the assessment process. Finally, enough physician time and expertise must be available to complete the assessment within the constraints of the setting.

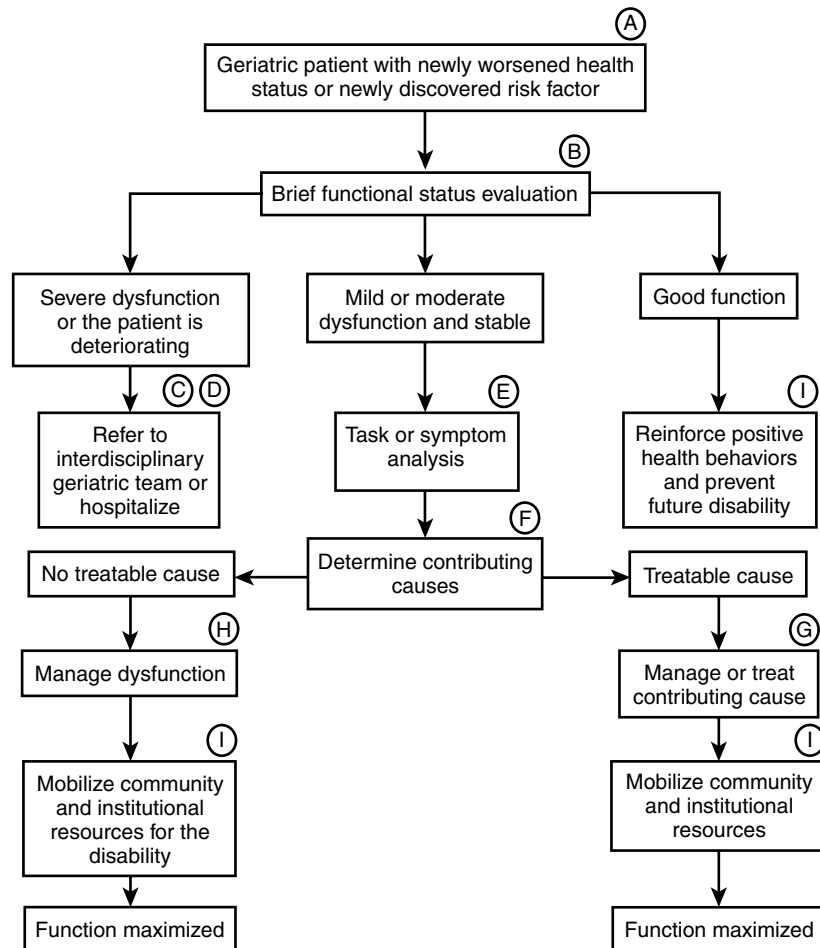

Figure 35-2. Evaluating and treating health status deterioration among geriatric outpatients.

A, Elderly patients with a new deterioration in health status or newly discovered risk factor(s) may need geriatric assessment. Examples of patients needing assessment include the following:

1. Frail elderly people with a new functional disability or risk factor for deterioration detected on routine screening
2. Elderly people with a new or worsened medical complaint or laboratory finding (e.g., "I fell last week" or the x-ray shows a new vertebral compression fracture)
3. Elderly people with a new or worsened functional disability complaint ("I can't go to church because of my health")

B, Brief functional status evaluation should include the following:

1. Activities of daily living (ADL)^{13-15,23}
2. Instrumental activities of daily living (IADL)^{14,23}
3. Mental status (e.g., Folstein Mini Mental State Examination)¹⁹
4. Affective status (e.g., Yesavage Geriatric Depression Scale)²⁰⁻²²

C, Full multidimensional geriatric assessment and/or hospitalization is necessary for elderly patients with new severe or progressive functional disability

D, Targeted assessment for patients in office practice is appropriate for the following:

1. Patients whose functional disabilities or medical problems are mild enough to make multiple appointment feasible
2. Patients whose disability is stable enough to permit assessment over weeks to months

E, To perform task or symptom analysis, select the patient's major symptom or disability or chief complaint (the one that bothers him/her the most, the disability upon which resolution of other health problems depends, or the one that is the most treatable). Then determine the exact maneuvers necessary to complete the task, or the exact components of the symptom (e.g., "difficulty getting dressed" due to difficulty putting on shoes because of inability to bend, or "difficulty with housework" because of failure to complete tasks despite adequate physical ability to perform them)

F, To determine contributing causes:

1. Perform a targeted history, guided by the functional disabilities detected and by the known common occult causes of disability in the elderly (see text)
2. Perform a targeted physical examination, always including postural blood pressure changes, vision and hearing screening, observations of gait (at least get up, walk 25 feet, turn around, sit down). Determine all specific physical disabilities, such as hip flexor weakness or poor hand mobility, that explain the observed functional disability.

G, Manage or treat contributing cause(s). Begin appropriate medical treatments and evaluations. Mobilize community and institutional resources as appropriate (low-vision resources for blindness; Alcoholics Anonymous for alcoholics, etc.). Identify key members of the multidisciplinary team and refer as needed (e.g., social worker for social isolation, physical therapist for gait disorder, or psychiatrist for depression).

H, When the disability cannot be reversed, maximize function using available services and behavioral or physical adaptation. For example, rearranging schedule to maximize activity, providing adaptive devices, or arranging for home support services might be indicated.

I, Always reinforce positive health behaviors.

Table 35-1. Measurable Dimensions of Geriatric Assessment With Examples of Specific Measures

Dimension	Basic Context	Specific Examples
Basic ADL ²³	Strengths and limitations in self-care, basic mobility, and incontinence	Katz (ADL) ¹³ ; Lawton Personal Self-Maintenance Scale ¹⁴ ; Barthel index ¹⁵
IADL ²³	Strengths and limitations in shopping, cooking, household activities, and finances	Lawton (IADL) ¹⁴ ; Older Americans Resources and Services, IADL Section ²⁷
Social activities and supports ²⁴	Strengths and limitations in social network and community activities	Lubben Social Network Scale ²⁸ ; Older Americans Resources and Services, Social Resources Section ²⁷
Mental health— <i>affective</i> ²⁶	The degree to which the person feels anxious, depressed, or generally happy	Yesavage Geriatric Depression Scale ^{20,22} ; PHQ-9 ²¹
Mental health— <i>cognitive</i> ²⁷	The degree to which the person is alert, oriented, and able to concentrate, and perform complex mental tasks	Folstein Mini-Mental State ¹⁹ ; Kahn Mental Status Questionnaire ²⁹
Mobility— <i>gait and balance</i> ^{9,11}	Quantitative scale of gait, balance, and risk of falls	Tinetti Performance Oriented Mobility Assessment ¹⁶ ; Get Up and Go Test ¹⁷
Nutritional adequacy ¹⁸	Current nutritional status and risk of malnutrition	Nutrition Screening Initiative Checklist ¹⁸ ; Mini Nutritional Assessment ²⁵

Abbreviations: ADL, activities of daily living; IADL, instrumental activities of daily living.

Table 35-2. Determining the Intensity and Location of the Geriatric Assessment

	Office Setting	Outpatient/Homecare Team	Inpatient Unit/Team
Level of disability	Low	Intermediate	High
Cognitive dysfunction	Mild	Mild to severe	Moderate to severe
Family support	Good	Good to fair	Good to poor
Acuity of illness	Mild	Mild to moderate	Moderate to severe
Complexity	Low	Intermediate	High
Transportation access	Good	Good	Good to poor

Most geriatric assessments do not require the full range of technology nor the intense monitoring found in the acute-care inpatient setting. Yet hospitalization becomes unavoidable if no outpatient setting provides sufficient resources to accomplish the assessment fast enough. A specialized geriatric setting outside an acute hospital ward, such as a day hospital or subacute inpatient geriatric evaluation unit, will provide the easy availability of an interdisciplinary team with the time and expertise to provide needed services efficiently, an adequate level of monitoring, and beds for patients unable to sit or stand for prolonged periods. Inpatient and day-hospital assessment programs have the advantages of intensity, rapidity, and ability to care for particularly frail or acutely ill patients. Outpatient and in-home programs are generally cheaper and avoid the necessity of an inpatient stay.

Assessment in the office practice setting

A streamlined approach is usually necessary in the office setting. An important first step is setting priorities among problems for initial evaluation and treatment. The “best” problem to work on first might be the problem that most bothers a patient or, alternatively, the problem upon which resolution of other problems depends (alcoholism or depression often fall into this category).

The second step in performing a geriatric assessment is to understand the exact nature of the disability through performing a task or symptom analysis. In a nonspecialized setting, or when the disability is mild or clear-cut, this may involve only taking a careful history. When the disability is more severe, more detailed assessments by a multidisciplinary or interdisciplinary team may be necessary. For example, a patient may have difficulty dressing. There are multiple tasks associated with dressing, any one of which might be the stumbling block (e.g., buying clothes, choosing appropriate

clothes to put on, remembering to complete the task, buttoning, stretching to put on shirts, or reaching downward to put on shoes). By identifying the exact areas of difficulty, further evaluation can be targeted toward solving the problem.

Once the history has revealed the nature of the disability, a systematic physical examination and ancillary laboratory tests are needed to clarify the cause of the problem. For example, difficulty dressing could be caused by mental status impairment, poor finger mobility, or dysfunction of shoulders, back, or hips. Evaluation by a physical or occupational therapist may be necessary to pinpoint the problem adequately, and evaluation by a social worker may be required to determine the extent of family dysfunction engendered by or contributing to the dependency. Radiologic and other laboratory testing may be necessary.

Each abnormality that could cause difficulty dressing suggests different treatments. By understanding the abnormalities that contribute most to the functional disability, the best treatment strategy can be undertaken. Often one disability leads to another. Impaired gait may lead to depression or decreased social functioning, and immobility of any cause, even after the cause has been removed, can lead to secondary impairments in performance of daily activities because of deconditioning and loss of musculoskeletal flexibility.

Almost any acute or chronic disease can reduce functioning. Common but easily overlooked causes of dysfunction in elderly people include impaired cognition, impaired special senses (vision, hearing, balance), unstable gait and mobility, poor health habits (alcohol, smoking, lack of exercise), poor nutrition, polypharmacy, incontinence, psychosocial stress, and depression. To identify contributing causes of the disability, the physician must look for worsening of the patient’s chronic diseases, occurrence of a new acute disease, or appearance of one of the common occult diseases listed

earlier. The physician does this through a refocused history guided by the functional disabilities detected and their differential diagnoses, and a focused physical examination. The physical examination always includes, in addition to usual evaluations of the heart, lungs, extremities, and neurologic function, postural blood pressure, vision and hearing screening, and careful observation of the patient's gait. The Mini Mental State Examination, already recommended as part of the initial functional status screen, may also determine what parts of the physical examination require particular attention as part of the evaluation of dementia or acute confusion. Finally, basic laboratory testing including a complete blood count, a blood chemistry panel, and tests indicated on the basis of specific findings from the history and physical examination, will generally be necessary.

Once the disability and its causes are understood, the best treatments or management strategies for it are often clear. When a reversible cause for the impairment is found, a simple treatment may eliminate or ameliorate the functional disability. When the disability is complex, the physician may need the support of a variety of community or hospital-based resources. In most cases, a strategy for long-term follow-up and often, formal case management should be developed to ensure that needs and services are appropriately matched up and followed through.

Comprehensive geriatric assessment

If referral to a specialized geriatric setting has been chosen, the process of assessment will probably be similar to that described above, except that the greater intensity of resources and the special training of all members of the interdisciplinary team in dealing with geriatric patients and their problems will facilitate carrying out the proposed assessment and plan more quickly, and in greater breadth and detail. In the usual geriatric assessment setting, key disciplines involved include, at a minimum, physicians, social workers, nurses, and physical and occupational therapists, and optimally may include other disciplines such as dietitians, pharmacists, ethicists, and home-care specialists. Special geriatric expertise among the interdisciplinary team members is crucial.

The interdisciplinary team conference, which takes place after most team members have completed their individual assessments, is critical. Most successful trials of geriatric assessment have included such a team conference. By bringing the perspectives of all disciplines together, the team conference generates new ideas, sets priorities, disseminates the full results of the assessment to all those involved in treating the patient, and avoids duplication or incongruity. Development of fully effective teams requires commitment, skill, and time as the interdisciplinary team evolves through the "forming, storming, and norming" phases to reach the fully developed "performing" stage.³⁸ Involvement of the patient (and caregiver, if appropriate) at some stage is important in maintaining the principle of choice.^{38,39}

EFFECTIVENESS OF GERIATRIC ASSESSMENT PROGRAMS

A large and still growing literature supports the effectiveness of geriatric assessment programs (GAPs) in a variety of settings. Early descriptive studies indicated a number of benefits

from GAPs, such as improved diagnostic accuracy, reduced discharges to nursing homes, increased functional status, and more appropriate medication prescribing. Because they were descriptive studies, without concurrent control patients, they were not able to distinguish the effects of the programs from simple improvement over time. Nor did these studies look at long-term, or many short-term, outcome benefits. Nonetheless, many of these early studies provided promising results.^{40–44}

Improved diagnostic accuracy was the most widely described effect of geriatric assessment, most often indicated by substantial numbers of important problems uncovered. Frequencies of new diagnoses found ranged from almost one to more than four per patient. Factors contributing to the improvement of diagnosis in GAPs include the validity of the assessment itself (the capability of a structured search for "geriatric problems" to find them), the extra measure of time and care taken in the evaluation of the patient (independent of the formal elements of "the assessment"), and a probable lack of diagnostic attention on the part of referring professionals.

Improved living location on discharge from a healthcare setting was demonstrated in several early studies, beginning with T. F. Williams' classic descriptive pre-post study of an outpatient assessment program in New York.⁴⁵ Of patients referred for nursing home placement in the county, the assessment program found that only 38% actually needed skilled nursing care, while 23% could return home, and 39% were appropriate for board and care or retirement facilities. Numerous subsequent studies have shown similar improvements in living location.^{46–59} Several studies that examined mental or physical functional status of patients before and after comprehensive geriatric assessment coupled with treatment and rehabilitation showed patient improvement on measures of function.^{46–50,52,56}

Beginning in the 1980s, controlled studies appeared that corroborated some of the earlier studies and documented additional benefits such as improved survival, reduced hospital and nursing home use, and, in some cases, reduced costs.^{46–67} These studies were by no means uniform in their results. Some showed a whole series of dramatic positive effects on function, survival, living location, and costs, whereas others showed relatively few if any benefits. However, the GAPs being studied were also very different from each other in terms of process of care offered and patient populations accepted. To this day, controlled trials of GAPs continue, and as results accumulate, we are able to understand which aspects contribute to their effectiveness and which do not.

One striking effect confirmed for many GAPs has been a positive impact on survival. Several controlled studies of different basic GAP models demonstrated significantly increased survival, reported in different ways and with varying periods of follow-up. Mortality was reduced for Sepulveda geriatric evaluation unit patients by 50% at 1 year, and the survival curves of the experimental and control groups still significantly favored the assessed group at 2 years.^{46,60,61} Survival was improved by 21% at 1 year in a Scottish trial of geriatric rehabilitation consultation.⁵⁶ Two Canadian consultation trials demonstrated significantly improved 6-month survival.^{52,53} Two Danish community-based trials of in-home geriatric assessment and follow-up demonstrated reduction in mortality,^{47,58} and two Welsh studies of in-home GAPs

had beneficial survival effects among patients assessed at home and followed for 2 years.^{49,50} On the other hand, several other studies of geriatric assessment found no statistically significant survival benefits.^{51,55,56}

Multiple studies followed patients longitudinally after the initial assessment and thus were able to examine the longer-term utilization and cost impacts of assessment and treatment. Some studies found an overall reduction in nursing home days.^{46,56,62} Hospital use was examined in several reports. For hospital-based GAPs, the length of hospitalization was obviously affected by the length of the assessment itself. Thus some programs appear to prolong initial length of stay,^{44,63,64} whereas others reduce initial stay.^{58,65} However, studies following patients for at least 1 year have usually shown reduction in use of acute-care hospital services, even in those programs with initially prolonged hospital stays.^{46,47,54}

Compensatory increases in use of community-based services or home-care agencies might be expected with declines in nursing home placements and use of other institutional services. These increases have been detected in several studies^{47,49,52,66} but not in others.^{46,54,59} Although increased use of formal community services may not always be indicated, it usually is a desirable goal. The fact that several studies did not detect increases in use of home and community services probably reflects the unavailability of community service or referral networks rather than that more of such services were not needed.

The effects of these programs on costs and utilization parameters have seldom been examined comprehensively, owing to methodological difficulties in gathering comprehensive utilization and cost data, and statistical limitations in comparing highly skewed distributions. The Sepulveda study found that total first-year direct health care costs had been reduced owing to overall reductions in nursing home and rehospitalization days, despite significantly longer initial hospital stays in the geriatric unit.⁴⁶ These savings continued through 3 years of follow-up.⁶⁰ Hendriksen's program⁴⁷ reduced the costs of medical care, apparently through successful early case-finding and referral for preventive intervention. Williams' outpatient GAP⁵⁴ detected reductions in medical care costs owing primarily to reductions in hospitalization. Although it would be reasonable to worry that prolonged survival of frail patients would lead to increased service use and charges—or, of perhaps greater concern, to worry about the quality of the prolonged life—these concerns may be without substance. Indeed, the Sepulveda study demonstrated that a GAP could improve not only survival but prolong high-function survival,^{46,60} while at the same time reducing use of institutional services and costs.

A 1993 meta-analysis attempted to resolve some of the discrepancies between study results, and tried to identify whether particular program elements were associated with particular benefits.^{68,69} This meta-analysis included published data from the 28 controlled trials completed as of that date involving nearly 10,000 patients, and was also able to include substantial amounts of unpublished data systematically retrieved from many of the studies. The meta-analysis identified five GAP types: hospital units (six studies), hospital consultation teams (eight studies), in-home assessment services (seven studies), outpatient assessment services (four studies), and "hospital- home assessment services" (three

studies), the latter of which performed in-home assessments on patients recently discharged from hospitals. The meta-analysis confirmed many of the major reported benefits for many of the individual program types. These statistically and clinically significant benefits included reduced risk of mortality (by 22% for hospital-based programs at 12 months, and by 14% for all programs combined at 12 months), improved likelihood of living at home (by 47% for hospital-based programs and by 26% for all programs combined at 12 months), reduced risk of hospital (re)admissions (by 12% for all programs at study end), greater chance of cognitive improvement (by 47% for all programs at study end), and greater chance of physical function improvement for patients on hospital units (by 72% for hospital units).

Clearly not all studies showed equivalent effects, and the meta-analysis was able to indicate a number of variables at both the program and patient levels that tended to distinguish trials with large effects from those with more limited ones. When examined on the program level, hospital units and home-visit assessment teams produced the most dramatic benefits, whereas no major significant benefits in office-based programs could be confirmed. Programs that provided hands-on clinical care and/or long-term follow-up were generally able to produce greater positive effects than purely consultative programs or ones that lacked follow-up. Another factor associated with greater demonstrated benefits, at least in hospital-based programs, was patient targeting; programs that selected patients who were at high risk for deterioration yet still had "rehabilitation potential" generally had stronger results than less selective programs.

The meta-analysis confirmed the importance of targeting criteria in producing beneficial outcomes. In particular, when use of explicit targeting criteria for patient selection was included as a covariate, increases in some program benefits were often found. For example, among the hospital-based GAP studies, positive effects on physical function and likelihood of living at home at 12 months were associated with studies that excluded patients who were relatively "too healthy." A similar effect on physical function was seen in the institutional studies that excluded persons with relatively poor prognoses. The reason for this effect of targeting on effect size no doubt lies in the ability of careful targeting to concentrate the intervention on patients who can benefit, without diluting the effect with persons too ill or too well to show a measurable improvement.

Studies performed after the 1993 meta-analysis have been largely corroborative. A more recent meta-analysis confirmed that inpatient GAPs for elderly hospital patients may reduce mortality, increase the chances of living at home in 1 year, and improve physical and cognitive function.⁷⁰ However, with principles of geriatric medicine becoming more diffused into usual care, particularly at places where controlled trials are being undertaken, differences between GAPs and control groups seem to be narrowing.^{71–76} For example, a 2002 study of inpatient and outpatient GAPs failed to demonstrate substantial benefits.⁷⁷ Other studies continue to reveal major benefits of inpatient programs.^{78,79} Effects of outpatient GAPs have been less impressive, with a 2004 meta-analysis showing no favorable effects on mortality outcome.⁸⁰ For cost reasons, growth of inpatient units has been slow, despite their proven effectiveness, whereas outpatient programs have increased, despite their less impressive

effect size in controlled trials. However, some newer trials of outpatient programs have shown significant benefits in areas not found in earlier outpatient studies, such as functional status, psychological parameters, and well-being, which may indicate improvement in the outpatient-care models being tested.^{72–76,79}

A 2002 meta-analysis of preventive home visits revealed that home visitation programs are consistently effective if they are based on multidimensional geriatric assessments, employ multiple follow-up visits, and are offered to elderly persons with relatively good function at baseline.⁸¹ The NNV (number needed to visit) to prevent one hospital admission in programs with frequent follow-up was shown to be about 40. An expanded 2008 meta-analysis of preventive home visits largely confirmed the earlier findings on the importance of multidimensional assessment and higher function, but not on multiple follow-up visits.⁸² It has also been recently confirmed that a key component of successful programs is a systematic approach for teaching primary care professionals. These results have important policy implications. In countries with existing national programs of preventive home visits, the process and organization of these visits should be reconsidered on the basis of the criteria identified in this meta-analysis. In addition, there are a variety of chronic disease management programs specifically addressing the care needs of older adults.⁸³ Engrafting the key concepts of home-based preventive care programs into these programs should be feasible and cost-effective as they continue to evolve. Identifying risks and dealing with them as an essential component of the care of elderly persons is central to reducing the emerging burden of disability and improving the quality of life for older adults.

A continuing challenge has been obtaining adequate financing to support adding geriatric assessment services to existing medical care. Despite GPs' many proven benefits, and their ability to reduce costs documented in controlled trials, health care financiers have been reluctant to fund geriatric assessment programs—presumably out of concern that the programs might be expanded too fast and that costs for extra diagnostic and therapeutic services might increase out of control. Many practitioners have found ways

to “unbundle” the geriatric assessment process into component services and receive adequate support to fund the entire process. In this continuing time of fiscal restraint, geriatric practitioners must remain constantly creative to reach the goal of optimal patient care.

CONCLUSION

Published studies of multidimensional geriatric assessment have confirmed its efficacy in many settings. Although there is no single optimal blueprint for geriatric assessment, the participation of the interdisciplinary functional status and quality of life as major clinical goals are common to all settings. Although the greatest benefits have been found in programs targeted to the frail subgroup of elderly people, a strong case can be made for a continuum of GAP-screening assessments performed periodically for all older persons and comprehensive assessment targeted to frail and high-risk patients. Clinicians interested in developing these services will do well to heed the experiences of the programs reviewed here in adapting the principles of geriatric assessment to local resources. Future research is still needed to determine the most effective and efficient methods for performing geriatric assessment and on developing strategies for best matching needs with services.

KEY POINTS

Geriatric Assessment

- Geriatric assessment is a systematic multidimensional approach to improving diagnostic accuracy and planning care for frail elderly people.
- Controlled trials have documented many benefits from geriatric assessment, including improved functional status and survival and reduced hospital and nursing-home admissions.

Laboratory Medicine in Geriatrics

Alexander Lapin

INTRODUCTION

The improvement of life style and health care, especially in industrialized countries created the phenomenon of the inverse demographic pyramid. As a result, the proportion of elderly within the general population is growing constantly. Many disciplines of geriatric medicine have become topics of growing interest. However, this is not the case in laboratory medicine where, besides an occasional stress on reference intervals for the elderly, a more fundamental discussion on consequences resulting from the actual demographic trend has not resulted until now. This chapter should provide some insights on this problem.

Objectivity as a basic principle of in vitro diagnosis

Since antiquity, in vitro diagnosis follows the same principle: A biologic sample (blood, urine) is drawn from the patient and subjected to analysis of its properties. The result is then interpreted in terms of clinical information concerning the health status of the patient. If such analysis is properly calibrated, the result can be expressed quantitatively (e.g., by numerals, not by words as is the case in other diagnostic disciplines, such as in pathology or radiology). Thereafter the result of a laboratory analysis is not an expertise, which results from the subjective experience of the operator, but is an objective measurement, which is always related to an *a-priori* postulated standard. Thus most of the results provided by laboratory investigations can be considered as data. In general, they are reproducible and comparable to each other and, as such, they represent a validated instrument of modern, evidence-based medicine.

To extend the principle of objectivity even on clinical interpretation, the laboratory report contains an indication of reference interval, which is stated aside from the numerical quotation of the result. It corresponds to the statistical distribution of the results that would be obtained when the analysis would be performed on a collective of healthy (not specifically diseased) individuals. Usually, such a reference group is taken as a demographic sample from the normal adult population while the term of normal is usually understood as a synonym for healthy.¹

However, since the reference interval is determined statistically, on the basis of calculation of the 95th percentile of gaussian normal distribution, 5% of results obtained from healthy individuals will be always situated outside the reference range and this without any pathologic correlation. This means that performing an increasing amount of laboratory tests in the same healthy individual, the probability that one of the results would be outside of the reference interval increases constantly. Ironically the more one performs laboratory investigations, the probability that the individual will be found as not normal increases.¹

This consideration illustrates the limits of the statistically based reference concept,² emphasizing the fact that a human

being is first of all an unrepeatable personality, not just an anonymous element of a collective. And even this insight does not reveal the specificity of the problem of the geriatric laboratory medicine.

Geriatric individuality

From the sociologic point of view, the question of whether an older person is healthy or sick cannot be answered by productivity in his or her job, nor by fact that he or she brought a notification of illness to the employer, but actually by his or her subjective feeling, which is an aspect of his or her quality of life.

But there is another aspect which should be considered in geriatric laboratory medicine. It is a continuous decline of physiologic functions. Age-dependent impairment of renal and pulmonary function, progression of osteoporosis, decrease of various endocrine functions, and weakening of immunity at an older age are some such examples.³⁻⁶ In view of this, and in an analogy to pediatrics, attempts have been made to establish—even for geriatrics—age-related reference intervals. Nevertheless, these intentions failed because of individuality and variability of the senescent process from both a clinical and a biologic point of view.

In pediatrics as in adult medicine, the majority of population is healthy and patients have usually one, but rarely several, causes for their illness. The primary aim of medicine here is to detect and to cure the disease as efficiently as possible to protect the future life chances of the individual and to return him or her as fast as possible back to normal (working) life. In geriatrics it is different. Here, since an old person has reached the last part of life, clinical history must be more complex than in previous phases of life. Passed crises, emergency situations, but also periods of prosperity and affluence, all had influence on the actual health state. Various diseases and trauma, which randomly occur in the course of life, have left more or less relevant aftereffects, which at the older age, contribute to the specificity of the clinical status of each aged person. Moreover, with advancing age, the probability of manifestation of a genetically or secondarily predisposed disease increases progressively. All together these inputs can be characterized by the term multimorbidity, which is a very important notion of clinical geriatrics. It characterizes the occurrence of several diseases or pathologic processes in one patient, which proceed often in an oligosymptomatic and atypical ways.

Of course, different involutive processes can be considered more or less as physiologic processes of older age, but they all can occur with individual accentuation and can be triggered by different random events at different moments of the life. In this context it becomes more and more difficult to define unequivocally the term of biologic age.⁷ And finally, one has to accept that death itself is often a result of one or more diseases breaking out during the ultimate period of life (Figure 36-1).

Figure 36-1. The course of life (horizontal axis) and randomly occurring diseases and traumas (—), and their aftereffects (---): At the end of life, they are contributing in an additive way to the final clinical status. (From Lapin A, Böhmar F. Laboratory diagnosis and geriatrics: more than just reference intervals for elderly ... *Wien Med Wochenschr* 2005;155:1–2, :30–5.)

In sum, when speaking about normality in geriatrics, one has to state that in age the perfectly healthy individual is a biologic rarity rather than the normal case.⁸

From screening to monitoring

The opinion that geriatric reference intervals can be estimated by large scale studies seems to be spurious even from a theoretical point of view. According to the publication of Harris,⁹ the width of the reference interval is determined by three kinds of variation, which can be characterized by appropriated coefficients of variation C_V :

- C_{VA} – analytical variation – which is due to the imprecision of an analytical method
- C_{VB} – biologic variation – which concerns variations within one individual
- C_{VC} – interindividual variation – which is due to differences between several individuals

The total variation (C_{VTOT}) results from the geometric sum of these three variations:

$$C_{VTOT} = \sqrt{C_{VA}^2 + C_{VB}^2 + C_{VC}^2}$$

In practice, it can be assumed that the analytical variation (C_{VA}) is almost negligible because of a high technical standard of the analytical method and that the total reference interval (C_{VTOT}) is determined by two other kinds of variation: the biologic (C_{VB}) and the interindividual (C_{VC}) one. Therefore two extreme constellations can be considered:

1. In the first case, the reference interval of the parameter is almost identical with the biologic variation (C_{VB}), which is nearly the same in all healthy individuals ($C_{VC} \rightarrow 0$) (this is, for example the case with glucose). Now, when in one particular individual a disease breaks out, the probability that the corresponding value will be shifted out of the reference range is increased. Thereafter, using such a test, the "pathology" would be detected early and the probability to obtain a result outside the reference interval will be increased by repeated measurement (Figure 36-2).
2. By contrast, another situation is given when the parameter shows narrow biologic variation ($C_{VB} \rightarrow 0$),

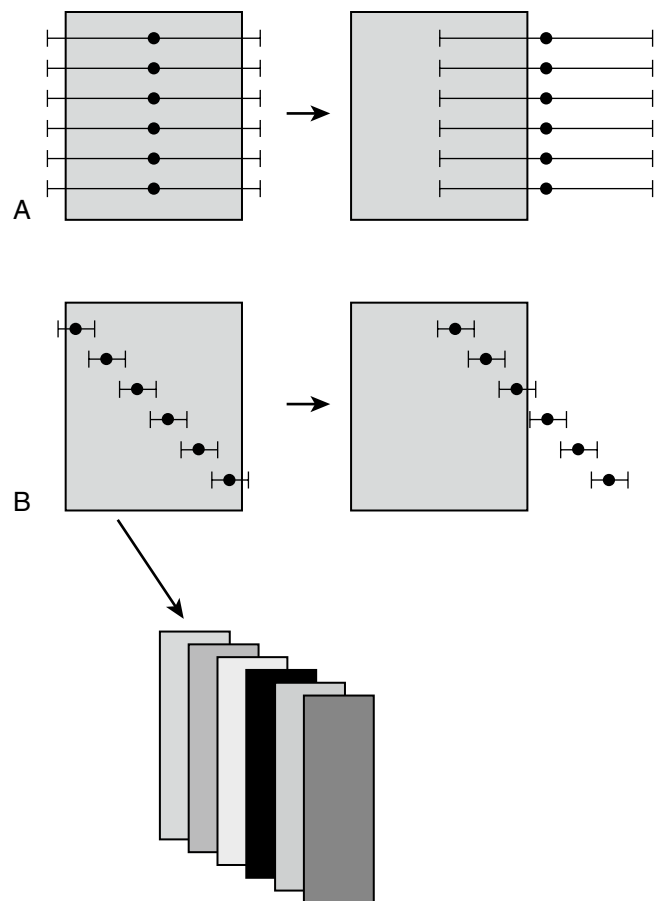

Figure 36-2. Influence of illness on two kinds of laboratory investigations (according to Harris EK 1974⁹). A, The width of the reference interval is determined by biologic factors (e.g., intraindividual variation [C_{VB}]). Due to an illness, all values are shifted out from the reference interval. B, The width of the reference interval is determined by intraindividual variation (C_{VC}), whereas intraindividual variation is negligible ($C_{VB} \rightarrow 0$). An illness would shift the values only in a segment of individuals of the considered collective. To improve the diagnostic relevance of this test, stratification (e.g., redefinition of the subreference intervals) has to be performed.)

but mean values (or medians) of this variation are different from individual to individual (this is, for example, the case with uric acid). In this case, the reference interval results preferentially from the distribution of mean values (medians) of such

Modified from Lapin A, Böhmer F. What are "normal" laboratory parameters in elderly patients when examined on first admission to a geriatric hospital? A pilot study. *Eur J Geriatr* 2003;5(2):86-93.

individual variations (C_{VC}). Strictly speaking, such a test is less suitable for the diagnostic use, especially for early detection of a disease. A minor pathologic change, which occurs in one individual, would provide a shift merely out of his or her individual interval of biologic variation, but not necessarily outside the reference interval as determined for all considered individuals of the whole collective (C_{TOT}). Evidently, such a pathologic change can remain undetected, even despite a repeated measurement.

To increase the diagnostic significance of such a test, it is necessary to perform stratification of the reference collective (e.g., to determine separately the reference intervals in different subpopulations, which in turn should be defined according to more specific criteria such as gender, age, other demographic parameters [Table 36-1]).

But for geriatrics it is not enough. The stratification also should consider other criteria, such as physical constitution, nutritional status, mobility, cognitive activity, predominant disease, and others.

By pushing stratification to the extreme, it becomes more and more difficult to find statistically relevant reference groups of individuals with the same characteristics. This is a major problem in establishing an age-dependent reference interval in geriatrics.^{10,11}

On the other hand, the ultimate stratification may be when the actual result (measured value) is referred uniquely to the previous results of the same person. And here, parameters of narrow biologic variation but of wide interindividual differences are not useful for screening (e.g., to detect a new disease), but they are well suited for monitoring dynamic changes in the individual clinical status of a concrete patient. However, a basic condition for the realization of such "long-term monitoring" is the assessment of the long-time stability and quality of the applied laboratory tests. Unfortunately, especially in geriatrics, this can be sometimes put in question.

The monitoring in geriatrics

One of the actual trends of today's laboratory medicine is consolidation of laboratories, which is imposed by the improvement of economic efficiency of laboratory testing. Usually this means the concentration of medical laboratories in large semiindustrial diagnostic institutions.¹²

The outsourcing of laboratory medicine from clinical institutions entails a depersonalization of the communication between clinicians and laboratory specialists.^{13,14} Consequently, certain aspects which have been theoretically known to affect the diagnostic significance of laboratory testing gain an unexpected actuality. One of these concerns the preanalytics.

Due to reduced physiologic reserves, many elderly patients who show larger biologic variation have to be considered for a number of laboratory parameters. Such pre-analytical effects include orthostatic effects (especially in patients with edema), effects related to impaired mobility and/or nutritional status, and seasonal influences.¹⁵ Moreover, poor venous status of some elderly patients can cause difficulties in the phlebotomy and blood collection, which is then responsible for hemolytic sera and inadequately small sample volume for an optimal analytical process.

The fact that the number of samples provided by geriatric practitioners is far inferior to those of an acute wards' can induce negligence and sloppiness resulting in the bad habit that geriatric samples are treated with less interest and without priority. Well known is the situation when, in a nursing home, the lab courier is missed and collected samples have to be left for the next day or for the later analysis batch. The increased turnaround time is always disadvantageous. For the stability of analytes*¹⁵ and for the actuality of diagnostic information that has been submitted to the clinician.

But the consolidation of laboratory medicine has induced another trend, which can be characterized as point-of-care testing (POCT). Using small testing devices mostly based on dry-chemistry principle, analyses can be performed close to the patient and therefore in a shorter and easier manner

*Analyte: substance, enzymatic activity, or other subject of chemical analysis.

Table 36-2. Examples of Possible Alteration of Clinical Significance of Some Laboratory Parameters When Used in Geriatrics

	Usual Significance in Adults	Possible Alternative Significance in Elderly
BUN	Renal insufficiency	Acute catabolism (often reversible)*
Albumin	Renal or hepatic insufficiency	Biologic age, [†] malnutrition, frailty
Cholesterol	Risk of atherosclerosis (high cholesterol)	Malnutrition, [‡] marker of fatal prognosis [§] (low cholesterol)
Gamma-GT	Alcoholism, cholestasis, hepatitis	Liver congestion (e.g., by heart insufficiency)
Amylase	Pancreatitis	Parotitis (often during summer season); macroamylase
LDH	Parenchymal damages, hemolysis	Phlebotomy problem
Total protein (normal)	Chronic inflammation	Exsiccation, myeloma
CRP	Inflammation, acute phase	Infection, necrosis (sometimes unique conclusive marker)
ESR	Chronic inflammation	Occult neoplasm
PTT	Heparin, hemophilia	Lupus inhibitor
Haemoglobin	Bleeding	Anemia of the elderly, myelodysplastic syndrome
MCV (normal)	Alcohol abuse	Vitamin B ₁₂ or folate deficiency

*For example, after an accidental episode of acute dehydration.

than by using a distant laboratory.¹⁶ For geriatrics, the POCT is of particular interest, not the least because of the growing scope of available tests. Although the use of POCT has become a generally accepted procedure, some disadvantages such as calibration, documentation, and especially uncontrolled performance by untrained personnel represents a subject of many discussions in different meetings of the laboratory medicine.

Nevertheless, a serious problem can arise when laboratory data, provided by different sources (e.g., diagnostic institutions and by different POCT-devices), are clinically evaluated in the same patient's history.¹⁷ Such a situation is quite frequent in geriatrics since aged patients can be treated within a short period by several medical providers: In a doctor's office, in a nursing home as a resident, and in a hospital as an emergency patient.

Medical significance of laboratory results in the aged

Finally there is the issue of medical significance of laboratory analyses in the context of clinical geriatrics. This can be different from adult medicine and not only in physiologic parameters, but also in demographic changes, life expectancy, and clinical consequences (Table 36-2).

An example for change in diagnostic significance in the course of life can be seen in the case of cholesterol (Figure 36-3). Usually the mean level of cholesterol in serum correlates with cardiovascular risk and increases with the age. However, from the sixth decade, this increase stops and the cholesterol level begins to decrease. This behavior is due to successive demographic change of the cohort. Individuals, which at their adult age revealed a high level of cholesterol, become now at the older age victims of their own increased risk being now continuously excluded from the higher-age cohort as a result of mortality.¹⁸ At the same time, cholesterol also becomes a marker for nutritional status: its decrease correlates with malnutrition.¹⁹ And finally, on the end of this age-dependent correlation, the sudden decrease of the cholesterol level can indicate a worsening life expectancy prognosis.²⁰

Figure 36-3. Age-dependent course of cholesterol (according to the author's data). (From Lapin A, Böhmer F. *Laboratory diagnosis and geriatrics: more than just reference intervals for elderly...* *Wien Med Wochenschr* 2005;155:1–2, 30–5.)

Due to the symptomatic, supportive and palliative therapy, which is in geriatrics more important than in adult medicine, the geriatrician is sometimes forced to undergo therapeutic compromises; for example, using corticosteroids in patients with diabetes mellitus. In this situation, to optimize the individual therapeutic strategy, it is not enough to monitor the clinical status; more important can be the estimation of the still remaining functional capacity of different organs and systems. For example, it is useful to monitor renal function by measuring serum creatinine, but more conclusive can be to estimate the creatinine clearance to know which proportion of renal functional reserve remains intact. In other words, parameters, which enable the estimation of still remaining functional capacity and/or which provide prognostic information, are of particular importance for geriatrics. A good example of such parameters is natriuretic peptide (known as BNP), whose blood level provides quantitative information about the degree of cardiac insufficiency in sense of congestive heart failure.

Another important feature of geriatrics is the frequent presence of multimorbidity. In this context, Fairweather and Campbell demonstrate, that in the elderly, "failing to make diagnosis when the disease is present or making a diagnosis when a disease is not present is likely to occur twice as often as in younger patients."²⁰ In the same way, an actual autopsy study showed that the accuracy rate of the clinical diagnosis of the immediate cause of death is no higher than roughly 50%.²¹

In this sense it is meaningful to differentiate between multipathology and multi-etiology. Since multipathology can be seen as a complex of several impairments of the organism, the term of multi-etiology is a more complicated one. It characterizes several dynamic pathologic processes, often convoluted in each other. Often, pathologic conditions such as infections, cardiovascular diseases, acute abdomen, hyperthyroidism, and depression occur in the elderly in an atypical and nonspecific way and with correspondingly atypical symptoms, physical findings, and laboratory results.²² But more difficult can be the adequate estimation of multiple etiological factors that are contributing to the current status of the patient. Often due to the propensity to think in terms of a single disease, it can be difficult for the clinician to decide which of the actual factors are important and will benefit the patient if treated. At the same time, the underestimation of multi-etiology together with the progressive decline of the cognitive and physical status of the patient can aggravate the problem of the degradation of the diagnostic information.²³ However, especially in view of the prognosis of the patient, there can be a growing discrepancy between the necessity of a diagnostic and therapeutic intervention and the need for conservation patient care into appropriate dignity. In this case, even laboratory medicine faces ethical limits.

CONCLUSION

With the growing of the elderly population in industrialized countries, the role of geriatric medicine will grow steadily. This in turn will create corresponding requirements for better efficiency in laboratory diagnoses. More than elsewhere in medicine, in geriatrics one has to deal with individuals rather than with collectives, and it can be expected that geriatric laboratory medicine will be subjected to a change of paradigms. Not only the statistically revealed evidence, as

obtained from studies of a large number of individuals, but also the consideration of the individual patient, with his or her clinical individuality, status, predispositions, physiologic reserves, and prognosis, will need another, probably an alternative insight. It will not be sufficient to consider health solely from the deterministic point of view, observing differences between physiology and pathology of laboratory findings, but likewise it will be important to consider the clinical individuality as a relative risk in the dimension of time for the rest of the patient's life.²⁴

From the practical point of view, it would be necessary to pay more attention to limits of the diagnostic significance of laboratory testing of the elderly. This should be considered especially for education programs of specialists in geriatric medicine. Research in geriatrics should be concentrated on new diagnostic parameters that would enable a better estimation of the clinical risk to the patients.

KEY POINTS

Laboratory Medicine in Geriatrics

- **Normality in geriatrics:** The perfectly healthy individual is a biologic rarity rather than the normal case. In geriatrics, it is a problem to postulate generally applicable references.¹
- **Multimorbidity:** By approaching the end of life, the sum of after-effects of previous diseases and the probability of manifestation of predisposed diseases increases. The individuality of a person increases by his or her life itinerary.
- **To keep the best possible quality of life** requires monitoring of individual clinical status, rather than screening for potentially occurring diseases, with the aim of a complete cure.
- **Laboratory parameters** that provide information about still available physiologic reserves are especially valuable. Clinical interpretation of some laboratory tests can be modified by life expectancy of the patient.
- **Laboratory medicine in geriatrics** should be performed with long-time quality assessment, professional logistics, and with special consideration of preanalytics.

¹other terms used more or less correctly for the same purpose: reference range, normal values

Social Assessment of Geriatric Patients

Rosalie A. Kane

Social functioning is a broad concept, embracing all human relationships and activities. Social functioning therefore is multidimensional and cannot be measured meaningfully in a single scale. Physicians caring for older people will need routinely to assess at least some aspects of the social functioning of their patients. In some instances, physicians will also need to understand and use assessments done by the social worker on his or her own hospital teams, by local authority social workers (in the United Kingdom), or by case managers in community long-term care programs (in the United States). For these purposes, it is useful to consider the nature of available assessment technology, the particular aspects of social functioning that should be assessed, and the usefulness of the information derived for the actual planning of care.

SOCIAL ASSESSMENT AS PART OF COMPREHENSIVE ASSESSMENT

Particularly in the United States, but also in other developed countries, frail elderly persons often receive their first general, multidimensional assessment from a social worker or nurse who is defined as a case manager or care coordinator.¹⁻² Such assessments are typically performed in the patient's own home, but they may also be performed in the hospital before the patient's discharge. The assessor uses a structured information-gathering schedule (often contained in a rather long booklet) to pose questions directly to the older person or (if the older person is incapable of participating) to a surrogate informant. Such assessments can take an hour or more to complete. They do not involve a physical examination or laboratory tests.

Multidimensional assessment used by case managers will typically include the following components:

- Factual information about the older person's marital status, household composition, housing situation, and income.
- Assessment of physical health based on some combination of the following checklist: symptoms; diseases the respondent believes he or she has; reports of overall use of hospitals, physicians, and other health care; reports of days sick; reports of medications used; summary of deficits in hearing, vision, speech, and dentition; and a self-reported estimate of the patient's health.
- Assessment of the ability to perform basic activities of daily living using a standardized scale. Such scales, at a minimum, measure independence in bathing, dressing, toileting, transferring out of bed or chair, and feeding, but may also include information about mobility, hand control, continence, and endurance.
- Ability to perform more complex social skills associated with independent living, sometimes called IADL (instrumental activities of daily living). Items that may or may not be scored on such a scale include cooking, cleaning, doing laundry, shopping, using transportation, communicating by telephone, managing money, and taking medications.
- Direct screening for cognitive impairment (to determine whether the respondent is reliable).
- Direct assessment of depressive affect and other possible psychological disturbances.
- Assessment of the social functioning of the older person in terms of the range of activities and relationships that the person pursues, the help available to or used by him or her, the presence of a confidante, and perhaps the subjective satisfaction of the older person with social interactions.
- Enumeration of the help the older person is receiving from family members and friends, from social programs, and from privately paid helpers directly employed by the older person and family.

Such batteries of questions are common in the United States, where they are in wide use in public programs. Many are derived from an assessment protocol developed at the Older Americans Research and Service (OARS) program at Duke University, commonly called the OARS methodology,³ which has had extensive work done on its psychometric properties⁴ and which has been extensively adapted. Another multidimensional tool that has had substantial work is the CARE (Comprehensive Assessment and Referral Evaluation) interview, developed by Gurland et al⁵ for a collaborative study done in the United States and the United Kingdom and later refined by the development of scales.⁵⁻⁹ But the protocols in actual use for case management programs vary enormously in the way they combine questions and scales.

Some general points can be made about these multidimensional assessment tools and their use by social workers and case managers with geriatric patients.

DESCRIPTIVE OVERVIEW

The batteries usually attempt a descriptive overview of physical and psychiatric functioning, but make no claims to diagnostic capability. Rather, in the context of an overall social assessment, the questions on physical and psychological health are designed to point out when fuller geriatric or psychogeriatric assessments should be sought. Thus the presence of questions about health status, health use, and medications are designed not to encroach on physicians' diagnostic prerogatives, but to identify persons needing medical attention and to take medical conditions into account in planning care.

SCORES

Scores may be derived for various subsections of the assessment, but the assessments seldom can generate an overall well-being score that has clinical significance.

COMPREHENSIVE ASSESSMENT PROTOCOLS

These vary in the extent to which the information is based on queries made directly to the older person versus judgments of the assessor on the enumerated items. Unless careful instruction and training accompanies the assessment instrument, it is likely that the resultant information will not distinguish well between the older person's responses and the assessor's judgments.

FUNCTIONAL ABILITIES

These are at the heart of the assessment, but are difficult to standardize and interpret. Although substantial agreement has been achieved on items for inclusion on ADL and IADL scales, variations occur in detail and approach to measurement. Sometimes, for example, the information about functioning is based on observation and sometimes on the older person's report. Sometimes the individuals are queried about what activities they are able to perform, and sometimes about activities they actually do perform. Sometimes the score is based on demonstration under test conditions, and sometimes professionals rate performance based on their observations. Widely varying time frames may be used (e.g., the last few weeks, the last few months, right now). There is also variation in the standard for adequate performance and the extent to which pain and discomfort of the older person, or elapsed time to complete a task, are taken into account. Recent work has been done to combine ADL and IADL items in a general scale. Rather than using the conventional but arbitrary system of according equal points for each item, Finch et al¹⁰ did empirical work to develop a scale where items are weighted according to their overall importance in functional capacity.

SERVICE PROVISION

When used by case managers or social workers, the assessment protocol is meant to inform decisions about the services that should be arranged and the priority the particular older person's needs should get. However, there is seldom a clear set of rules to guide the assessor in translating the information from the assessment into guidelines for a service plan. Glass shows the intimate relationship between social factors and ADL functioning.¹¹ Taking advantage of a data set where respondents were asked about functioning in terms both of what they thought they could do and what they did do, he identified "underachievers" who failed to perform to their perceived capacity and, oddly enough, "overachievers" who claimed to do what they believed they were incapable of doing. Further inspection showed remarkable resourcefulness and creativity among the overachievers, and a variety of social and psychological factors (lack of wish to do the function, lack of transportation, lack of opportunity, lack of money, family factors) among the underachievers.¹¹

ASPECTS OF SOCIAL FUNCTIONING

The multidimensional, comprehensive batteries described above are composed of constituent parts, designed to measure various aspects of functioning. The groundwork for measuring those dimensions is often laid in earlier research with the particular set of questions or scales. Let us now consider what aspects of social functioning should be measured.

All behavior of human beings might be termed social. But many aspects of social functioning hardly need be measured in detail for geriatric care. In a multivolume review of measures pertaining to old people, Mangen and Peterson¹² devote chapters to measurement of dimensions such as religiosity, interspousal relationships, and filial relationships. Relevant social dimensions for geriatric care constitute a shorter list, which has been summarized in a number of review works.^{13,14} Suggested below is the information on social functioning that is needed, excluding health use and basic performance of ADL, which are important components but are covered elsewhere in this volume. Note, however, that ADL and IADL performance will be enhanced or impeded by social factors, and, conversely, social factors can influence the repercussions of ADL or IADL impairment. To deal with the latter, Allen and Mor¹⁵ elaborated on functional measures by incorporating follow-up questions designed to assess any deleterious consequences of insufficient help (e.g., "Have there been times in the past month when you were not able to bathe as often as you would have liked because no one was available to help you?" or "Have there been times in the past month when you were unable to eat when you were hungry because no one was available to help you?"). They refer to these as indices of unmet need.

First, the ability to perform social roles, sometimes called social skills, is relevant. For younger people, such measures usually encompass their performance as employees, family members, and citizens.¹⁶ For older people, perhaps shortsightedly, the measurement of role performance is usually limited to ability to perform the so-called instrumental ADL (cooking, cleaning, laundry), which are, in turn, related to household management and independent living.

Second, information about social relationships (their frequency, context, and quality), social activities (again their frequency, nature, and quality), social resources (including income, housing, and environmental conditions) is useful to geriatric providers. Third, social support is a salient concept to examine; it may include the help the patient is receiving and can expect to continue to receive from others in the environment, and the degree to which this help is perceived as supportive. Fourth, subjective social well-being can be measured more generally.

A fifth area of social function—family burden or family stress—has come into prominence in the last decade.¹⁷ Although highly relevant to geriatric care, this measure pertains to family caregivers rather than to the older person receiving the care. The idea is that an understanding of the type and degree of burden that caregiving creates for the relative primarily responsible will help determine whether the arrangement is realistic, humane, and fair, and the extent to which relief for the family member is necessary.

A sixth emerging area concerns personal autonomy, values, and preferences. In recent years, there has been much interest in personal autonomy and values of older persons receiving long-term care.¹⁸ This is fueled by growing social science literature that suggests that older people who perceive that they have lost control and choice over their lives experience adverse health outcomes, including depression, increased morbidity, and even increased mortality.^{19–21} Some attempts have been made to estimate a measure of autonomy, although these measures are not ordinarily incorporated into everyday clinical practice. A related effort entails assessing

the values and preferences that may be important to geriatric patients.²²

Finally, substantial work has been done to seek a satisfactory approach to assessing the older person's satisfaction with the care and help received. Before briefly discussing each of these areas, some general comments about the problems of measuring social functioning are warranted.

Problems in assessing social functioning

First, social concepts such as social isolation, social support, or social well-being are value-laden abstract constructs, subject to interpretation. Thus several scales containing different items may purport to measure the same thing, whereas scales that seem to be similar in content carry different labels.¹² It is important not to be deceived by the name of the scale, but to examine its contents.

Second, most social variables have both an objective and a subjective component. For example, one can measure social support by quantifying the support network and its activities, or by asking whether the older people view themselves as supported in various ways. Similarly, one can examine the burden of caregivers by quantifying their objective tasks with the patient and their other obligations, or one can measure the extent to which they feel burdened. Both approaches may be important.

Third, adequate social functioning can be achieved through diverse patterns. One seldom finds clear norms for interpreting the results of social information. A person who states that he or she has 10 friends is not necessarily twice as well befriended as a person with five, nor can one say that a person who spends much time playing cards is better off than one who spends the same amount of time fishing. Growing out of this observation are two important points in interpreting social information: (1) a change in social functioning may be as important as the actual value on a scale; and (2) information about adequate thresholds of functioning is needed. Regarding the latter, the objective of social measurements for geriatric caregivers is not to achieve a perfectly scaled measure of a social property such as isolation or social support; rather, it is to determine whether these dimensions have fallen below some threshold that means that the patient is at risk.

Fourth, social role expectations for the elderly are unclear at best and vary according to ethnic groups and over time. Nobody seems to know what constitutes adequate role performance for a retiree, a grandparent, or an elderly widow or widower, and establishing these norms is more complicated because of their likely sensitivity to cultural differences.

Finally, much social functioning involves people in interaction with others. They fill social roles, cope with stress, receive help from family members, and so on. How well a particular older person functions socially is, in part, dependent on the behavior of others, which complicates the assessment process. Glass et al²³ have pioneered in expanding the range of social functioning examined in older people. In studies underway at Yale and later at Harvard, the team has attempted to develop better measures of social functioning related to productive aging in social and economic roles, incorporating housework, yard work, childcare, and other family roles, paid work, and volunteer work.

Social relationships, activities, and resources

The aggregated social relationships of a client, viewed descriptively, are sometimes called the social network. "Social network" refers to the web of social relationships and contacts that an individual may have. Although difficult because of the amount of data collection needed, objective properties of social networks can be described using terms such as size (how many people are in the network), density (the number of people who know each other in the network), homogeneity (similarity of network members on various characteristics), multiplexity (the number of different types of interactions exchanged), and reciprocity (the balance or imbalance between perception of giving and receiving support).²⁴ Researchers point out that "social network" is a static concept referring to relationships across the life span; the term "social convoy" has been suggested as a more dynamic concept.²⁵ Measures in this area have been extensively reviewed by Levin.²⁶

Although social networks have properties—such as size, density, frequency, and intensity of contact, permeability, and directionality^{24–29}—from the viewpoint of geriatric care, the large number of properties that can be elaborated upon for social research can be reduced to an interest in the frequency and nature of the patient's human contacts in the course of a day, week, or month. One approach, often incorporated into assessment, involves querying the patient about the frequency of contacts in person, by telephone, or by mail by categories of people (adult children, other relatives, friends, others), using a metric such as "frequently, occasionally, seldom, or never," or attempting more exact quantification (less than once a week, and so on). Such questions are sometimes followed up by asking the person whether he or she has contact with these people more than desired, about the right amount, or less than desired. The OARS methodology, a multidimensional assessment tool described earlier,⁵ contains an often-used measure of social contacts.

Some efforts have been made to combine social contacts and social activities in brief social network scales, designed to predict the individual's well-being and need for service. The Berkman Social Network Scale,³⁰ developed in a general population, and the Lubben Social Network Scale,³¹ developed for the elderly, are examples. Typically, marital status, membership in formal groups, and religious participation are included with other brief measures of social contact to form a short scale.

To assess social resources, well-planned, consistently asked questions are better than scales. Each assessment of social functioning does well to contain straightforward questions about household income and assets, and income and assets of the older person with the disability. It is also important to determine the composition of the household and the nature and adequacy of the housing. In some social contexts, access to a car and transportation is also an important social resource. Depending on the political context, information about insurance coverage, veteran status, and specific disability status may provide a key to resources that could be available for the person. Other information that is important in developing a plan and coming to know the individual includes information about the individual's occupation or former occupation, and interests; typically such items are overlooked.

Social support

A description of the social network does not automatically translate into an understanding of how well the patient's needs are met, nor does it permit a prediction of how well the needs may continue to be met in the future. Being enmeshed in a large network of family and friends may, depending on the network, be reassuring or stressful, helpful or harmful, informative or misleading. Social support is the positive tangible and intangible assistance drawn from the social network.³² A social network or convoy has multiple functions, which also can be measured.^{26,27} These include giving informational support, such as facts and advice; affective support, such as comfort, encouragement, and love; social support and stimulation, such as companionship; and tangible help, such as money or physical assistance. It is obvious that the geriatric team has an interest in knowing whether a given patient has a network that can or does provide such support. The social network is the potential vehicle for social support, but may be associated with negative and positive effects. Social scientists have studied the complex stress process that involves interaction of life events, chronic life strains, self-concepts, coping skills, and social supporters.³³

If the geriatric patient already has tangible needs for physical help from others, one measure of social support is a straightforward tabulation of the kinds of help received and their frequency. Assessment tools usually attempt, however, to go beyond this simple count to an estimation of the likelihood that the help can continue into the future, and the prospects for a replacement, if the person giving most of the help cannot continue. Research suggests that often the patient's social support in terms of physical help depends on one person whose own health may be fragile, or who cannot continue indefinitely because of competing demands.³⁴ In such cases, planning can begin to broaden the base of social support. In other instances, additional relatives and friends are available to help, but the primary family caregiver assumes that nobody else is capable or willing. If the patient has not previously needed physical help, then an estimation of the likelihood of this help is needed. A few key questions can assist in making this prediction; for example: "If necessary, is there someone who could come and help you during the day?" or "Is there someone who could stay overnight with you if necessary?" Social support measures are also summarized in Levin's recent review.²⁶

Subjective well-being

An overall measure of the patient's well-being is sometimes sought in a comprehensive assessment tool. Such measures are also often used to evaluate the worth of long-term care programs.^{35,36} The two most frequently used measures in this regard are Lawton's Philadelphia Geriatric Center Morale Scale³⁷ and the Life Satisfaction Index (LSI-A) of Neugarten, Havighurst, and Tobin.^{38,39} Both these scales are relatively brief and simple to administer, both have developed an extensive use history, and both measure elements of life satisfaction by asking clients to consider the extent to which their expectations in life were met. At the same time, both also measure aspects of existential well-being or happiness.

Although these two scales are often used for program evaluation, it is unclear how much these measures should change as a result of a worthwhile program. For example, a meal

program may be performing an important and appreciated function, and yet the answer to the question "Overall, have I achieved most of my goals in life?" would remain the same. In general, it seems best to measure satisfaction with a program directly, through questions that specifically ask about satisfaction with various elements of the program itself.¹³

Caregiver burden

In both the United States and in Europe, social services authorities for the elderly recognize that their programs would be inadequate to meet the needs for care were it not for the volunteer efforts of family members. Indeed, unpaid family members give most of the personal care and house-keeping help that is received by community-dwelling older people. In the United States, almost 80% of in-home services for elderly people are given by family members. It has become a widespread program principle that social services should supplement and enhance family care, when appropriate, but should not replace it.

Given this situation, it becomes important to assess the well-being of family caregivers to estimate (1) how long such care may be expected to continue, and (2) legitimate needs for relief. Somewhat unfortunately because of its negative connotations, this area of measurement is often called measurement of "family burden." Many scales have been developed in the last decade to assess family caregiver burden.⁴⁰⁻⁴⁵ These scales are often themselves multidimensional (including, for example, physical burden, emotional burden, social burden, and financial burden), and they may concentrate on subjective burden or objective burden, or both. Other scales designed especially to examine the stress-engendering aspects of family care for persons with dementia specifically measure the presence and frequency of a range of troublesome behavior. Pearlin et al⁴⁶ have contributed a careful conceptual model of the stress process related to family caregiving, complete with brief measures of the relevant aspects of the phenomenon (including problematic behavior, overload, relational deprivation, family conflict, job-caregiving conflict, economic strain, role captivity, loss of self, caregiving competence, personal gain, management of situation, management of meaning, and management of distress). This series of measures is designed for research rather than clinical practice, yet it reminds us that the concept of caregiver burden is by no means straightforward. In general, it has been well documented that objective needs of the older person and objectively defined tasks occasion varying degrees of burden. The Caregiving Hassles Scale⁴⁷ can be used to measure the extent to which care of an elderly relative causes small daily tribulations or, in the vernacular, "hassles." Some authorities believe that the daily hassles produce more stress than dramatic life crises. Less attention has been given to the positive aspects of caregiving, sometimes called "uplifts," though these, too, have been measured and studied.⁴⁸

The stress or burden of family caregivers, balanced against positive aspects of the role, should be part of a comprehensive assessment of an older person. However, the social worker or case manager must then be prepared to interpret and use the information to decide when and how much relief should be offered to family members. It is important also to understand the information collected according to the relationship of the family caregiver to the patient (spouse, adult offspring, other relative) and the competing obligations of

that family caregiver (which could include employment, care of younger children, care of another disabled or elderly relative, or even dealing with their own failing strength).

In addition to applying specific measures that generate scores, clinical teams can benefit by consulting a practical reference work by Lustbader and Hooyman,⁴⁹ which lists sets of assessment questions that are useful for specific caregiving situations. For example, when a spouse is a caregiver, they suggest that one ask about the length of the marriage before the illness; the health of the caregiving spouse; the predisability marital patterns; the timing of onset relative to the couple's retirement plans; the impact of the illness on the couple's financial resources; the impact on their sexual functioning; and the availability of backup help from other family and friends. If siblings are sharing caregiving, the assessment might include these questions: Is there concern about a potential inheritance straining sibling relationships? Is there financial disparity among siblings? Is there a natural leader, a parental favorite? Is there a health care professional among them? Are there stepsiblings among them? What have been the adult siblings relationships to each other? And what obligations must each sibling meet in addition to parental care?

Personal autonomy, preferences, and values

In the last decade in the United States, there has been an attempt to record older people's preferences regarding life-sustaining medical treatment.^{50–53} Such information is desired partly for legal reasons, to prevent liability, and partly to guide clinicians in giving good care. If taken seriously, however, assessment of such preferences is notoriously difficult. The validity of the data depends on whether accurate information has been adequately disclosed to the respondent and has been understood by the respondent. Some work has been undertaken to construct and study such measures, though in practice many assessment batteries merely contain a notation of the older person's preference for such services as cardiopulmonary resuscitation, artificial hydration, or respirators, and their preferences about who they want to act in their stead if they become temporarily or permanently unable to make decisions without any assurance that the questions were asked or comprehended in any consistent way.

Others have sought to assess values of geriatric patients directly, a pursuit that is fraught with conceptual and methodological difficulties.⁵⁴ Using a tool that is meant to be an exercise in self-discovery rather than precise measurement, Gibson, a philosopher, and her colleagues^{55,56} developed a values history, which they recommend for distribution to clients to complete at their leisure and with discussion among families. At the other extreme, Doukas and McCullough⁵⁷ have developed an approach that uses a few true-false questions to tap into values about risk, life and death, and spirituality.

Work has been done to assess systematically the ordinary values and preferences of older people that might be related to their care. Although not amenable to generating an overall scale, it is feasible to incorporate a list of topics that the patient rates in terms of importance, providing descriptive detail. Using a stem that relates the topic to care that they might need now or in the future, the instrument developed asks the person to rate the importance of the following: performing everyday routines in a particular way; participating

in certain activities at home or away from home; personal privacy; specific events or milestones being anticipated or projects being completed; freedom from pain; taking risks as opposed to being protected but less free; involving or not involving family in their care; qualities desired in a helper; and qualities desired in a place to live. Older clients were willing to respond to such questions, revealing differences in the importance these issues hold and in the content of what they deemed important. However, clinicians were often somewhat reluctant to enter into such discussions, partly because of the time involved (about 20 minutes) and partly because of a sense of being intrusive or being unable to act on the preferences expressed.^{22,58}

Although considerable hubris is involved in attempting to assess values and preferences, and assessors doing so must guard against believing that they have encapsulated the essence of another human being in a few simple items, it seems equally improper to ignore this arena. In fact, systematic efforts to assess the patient's values and preferences are likely to restructure the encounter between social workers and geriatric patients in important ways. Moreover, insights into the values and preferences of the older persons served may be the best safeguard against inappropriate or paternalistic decision making about their lives.

Satisfaction

Although the technical quality of care procedures may be assessed by professionals using objective criteria, increasing emphasis has been given to seeking a reliable way to elicit the patient's perspective, particularly with reference to home help and personal assistance. It is argued that the intimacy of care and its close connections to daily life requires that professionals have a way of determining how patients view that care. Indeed, evidence suggests that older people are often reluctant to accept the help suggested, and speculation has been that this reaction is related to dislike of the way services are offered. Geron^{59,60} conducted focus groups with older home care clientele from varying ethnic backgrounds to identify the elements of quality important to consumers. With great consistency across ethnicity, older people identified the following elements of good care: humaneness (helpers who were likable, pleasant, courteous, caring), competence, dependability, continuity (i.e., if the previous two criteria were met, consumers preferred consistency rather than change), adequacy in terms of amount of help, and choice in the type and timing of help received. They then developed and tested a satisfaction tool. It is noteworthy, however, that such tools are quite specific to the service context.

Satisfaction has come to be seen as a measure of experience mediated by expectations. As such, it is bedeviled by the propensity of people to adjust their expectations downwards or to hold low expectations in the first place. Measurement of satisfaction is also rendered technically difficult if those whose reports are sought are dependent on the services or, worse, feel intimidated—the latter being a possibility for those living in group residential settings. Nonetheless, substantial progress has been made in measuring satisfaction.⁶¹

Social functioning of people with dementia

A large number of scales have been developed for rating or assessing the social functioning of persons with dementia in terms of presence of appropriate behavior and absence

of behaviors considered disruptive.^{62,63} Initially these instruments relied on ratings by professional caregivers or family caregivers. More recently, observational and even physiologic tools have been used to measure social stress and social well-being on the part of those who cannot communicate.⁶⁴ In the late 1990s, several tools were developed and tested that depend on self-report from the person with dementia. Notably Brod et al⁶⁵ developed a short set of Likert type of quality of life ratings called the DqoL, and Logsdon et al⁶⁶ developed an even shorter set of 13 dichotomous questions for self-report of quality of life. Both these tools have reported good reliability. Teri and Logsdon⁶⁷ developed the Pleasant Events Schedule-AD, which is used either with the person with dementia or a proxy observer, to zero in on the existential experience of the person with dementia.

An emerging concern is the discordance found between the rating of the older person and that of a family or staff proxy when paired ratings are available. This has called proxy ratings into question without presenting any substitute to measure social well-being in those persons whose dementia is too advanced for self-report. It would seem prudent to use proxies most when highly objective information about social functioning is sought, and to provide clear definitions of the behavior being observed, an approach taken in the multidimensional observational scale for older adults (MOSES).⁶⁸

Social assessment within congregate group settings

Assessments of social functioning and social well-being within the context of a nursing home or board-and-care home need to take into account the nature of the setting. Although elaborate approaches to examine how the individual fits into the community have been made for research purposes,⁶⁹ this area of assessment is in its infancy in terms of scale development to be applied to residents. Sometimes this work is lumped with satisfaction measures that are tailored to specific residential programs. A large ongoing project funded by the U.S. Department of Health and Human Services concentrates on measuring quality-of-life outcomes for nursing home residents and has developed short scales to tap 11 dimensions of quality of life: meaningful activity, individuality, dignity, privacy, enjoyment, relationships, comfort, functional competence, spiritual well-being, sense of security and order, and autonomy.⁷⁰ These measures largely deal with social as opposed to physical functioning, and choice or systematic attention, although elaborate measures of environmental climates have been made for research purposes.

EMERGING AREAS OF SOCIAL ASSESSMENT

Other areas of social assessment are amenable to measurement and may be important in specific situations, but measurement approaches are just evolving. Also some new themes are getting attention. The following are some examples:

- Measures of housing environments and housing satisfaction. This is an underdeveloped arena.⁷¹ Some

work has recently been done to separate factors related to assisted living environments (often called "housing with services"). One such study identified personal care services, general services, apartment, control/choice, and housekeeping/dining as separate constructs.⁷²

- Assessment of formal support in the form of help from personnel from health care and social service organizations. Such a measure of assistance may or may not be thought of as part of the social assessment; but, however classified, it is necessary. It is often helpful to divide "formal care" into types of tasks: nursing tasks, such as help with medicines or procedures; personal care, such as help with bathing, toileting, eating, and transferring; housekeeping tasks, such as laundry, cooking, cleaning; help with transportation; help with business matters; and help with arranging for services, such as case management. Assessments usually develop indicators of frequency (days/visits per month, week, or day) and intensity (total hours of help of each type in a given period).
- Assessment of the specific tasks performed by family caregivers. Some assessment tools develop parallel questions to use in inquiring about the type of tasks and the frequency and intensity provided by both formal and informal sources. It is only by comparing formal and informal help received with needs for assistance that an estimation of unmet need is developed. Typically, care plans developed by social workers are designed to meet unmet needs.
- Assessing social well-being across cultures. Attention is now being given in general to the extent to which assessments of elderly people cross cultural lines. Cultural relativity would be particularly important for

KEY POINTS

Social Assessment

- Social functioning is a multidimensional construct that cannot be well measured in a single scale.
- Relevant domains of social functioning with available measures include: ability to perform social roles; social relationships; social support; family caregiver well-being; autonomy; values and preferences; and satisfaction.
- Measurement strategies for social functioning must take into account that most domains have an objective and subjective component; that normative social role definitions in old age are lacking; that there appear to be multiple ways to achieve satisfactory social functioning; and that research is needed to establish thresholds with clinical significance.
- Advances have been made in conceptualizing quality of life for persons with dementia and for eliciting reliable direct responses from those with substantial cognitive impairment. Observational approaches have been developed for those who cannot be interviewed.
- Measures of social well-being need to be modified or augmented for people who live in congregate group settings to receive care.
- Topics highlighted for developmental work include: housing environments and housing satisfaction; assessment of help from paid individuals and organizations; the type and intensity of care activities performed by family caregivers; and cross-cultural measures of social functioning.

making normative judgments about social well-being. This topic was flagged in an issue of the *Journal of Mental Health and Aging*, where both methodological and content considerations are reviewed.⁷²

ASSEMBLING THE ASSESSMENT PROTOCOL

As this chapter has suggested, assessment of social functioning can be as detailed as the geriatric team desires, touching on many or few dimensions of social functioning. The assessment may also vary in its mix of scales, single items, clinical ratings, and reliance on open-ended, unstructured approaches. This chapter recommends a consistent and standardized approach to assessing aspects of social functioning. Commitment to consistency and routine approaches is

probably more important than which particular instrument is selected. Initial parsimony is also suggested, followed by more detailed assessment as necessary. It is highly likely that there will be an inverse relationship between the amount of information collected and the reliability and validity of the assessment interview.

A social worker is highly accepted as a member of a geriatric team. However, the importance of social information—whether collected specifically by a social worker or collected by a generalist who is gathering information to be used by all professionals on the team—has been insufficiently appreciated.

Surgery and Anesthesia in Old Age

D. Gwyn Seymour

This chapter provides a general overview of surgery and anesthesia in old age, but lays particular stress on those areas of the subject that are changing most rapidly and/or are attracting most clinical and research interest. After a brief introduction dealing with epidemiologic trends, the elderly surgical patient is evaluated from a predominantly medical viewpoint. It is not possible to go into details of anesthetic or surgical technique here, but these have been considered at length elsewhere.¹⁻⁴

Rehabilitation of the elderly orthopedic patient, important though it is, is also not dealt with here because it is discussed elsewhere in this textbook.

TRENDS IN SURGERY AND ANESTHESIA IN OLD AGE

The surgical treatment of elderly patients is not a late twentieth century invention. Of 100 cases of strangulated hernia operated on by van Assen in Amsterdam between 1903 and 1906, 18 persons were between 50 and 70 years of age, 17 were between 70 and 80 years, and 3 were over 80.⁵ Inhalational anesthesia was used in one third of the cases, with local anesthesia in the others. There were only two deaths, but one of those was a patient aged 81.

In the last 30 years, however, the increase in surgical activity in patients aged 65 and over has been much greater than would have been expected from demographic trends alone.⁶ This increase has not just been in life-saving procedures, but has also been seen in procedures such as cataract surgery or total hip replacement, which are predominantly aimed at increasing the quality of life. Surgery for cataract and total hip replacement for osteoarthritis are two prime examples of high-technology approaches to a surgical problem that have had a major impact on the quality of life of elderly patients. They neatly refute the simplistic assumption that high-technology "cures" are for the young, and low-technology "care" is for the old—a policy which is ethically dubious, and often financially unsound, because of the high costs of long-term care.⁷ As Grimley Evans puts it, in many circumstances, "curing is caring."⁸ In recent years, some of the increased surgical activity in young and old alike has been because of technological advances such as minimally invasive surgery. These techniques have had a major impact in urology, gynecology, general surgery,^{1,4,6,9} and even in cardiac surgery.^{10,11,12}

Some of the changes in surgical activity in different age groups have followed naturally from changes in the incidence or prevalence of disease or the availability of effective nonsurgical therapy.⁶ Thus surgery for peptic ulceration has become much less common in the last 30 years, but on the other hand there has been a marked increase in the number of hip fractures, partly due to demographic change but probably due to underlying changes in osteoporosis prevalence as well.¹³ In an ideal world, we would first assess medical and surgical needs in the community and then provide the appropriate services to meet those needs. A number of

reviews edited by Stephens and Raftery¹⁴ are of interest in this respect, particularly those dealing with colorectal cancer, total hip replacement, total knee replacement, cataract surgery, hernia repair, varicose vein treatment, prostatectomy, peripheral vascular disease, and adult intensive care.

AGE, SURGERY, AND OUTCOME

The association between age, surgery, and postoperative outcome is a complicated one.

1. Many surgically treatable diseases become more common with age. For example, the incidence of colorectal cancer increases almost exponentially after the age of 40.¹⁴
2. Age may have an effect on surgical presentation; for instance, an acute abdomen in some older people may have less dramatic signs and symptoms.¹⁵
3. Ageist attitudes may influence patients and professionals in decisions as to whether elective surgical referral is indicated. Whereas overall attitudes are changing, older patients in higher socioeconomic groups may have very different elective referral rates from older people who are socioeconomically deprived.¹⁶
4. The incidence of nonelective presentation of surgical disease tends to rise sharply with age¹⁷ probably from a mixture of the above factors, and nonelective surgical procedures have much higher rates of morbidity and mortality than elective procedures.¹⁷⁻¹⁹
5. Elderly surgical patients often have one or more coexisting medical conditions.²⁰ When these involve major organs, such as the heart, lung, or kidney, then the risks of surgery and anesthesia tend to increase.^{17,21}
6. Even in the absence of coexisting medical disease, gerontologic studies point to a diminution in homeostatic reserve with age, a condition that has been termed "homeostenosis."²² Under conditions of extreme stress (such as severe burns or trauma), the fit elderly patient has less chance of survival than the fit young patient²³⁻²⁵ but vigorous intensive therapy can improve survival rates at all ages.^{25,26}
7. The increasingly common "league table" approach, by which the surgical mortality rates of individual institutions are widely publicized, may have a detrimental effect on the care of high-risk elderly surgical patients. There might be managerial pressures to avoid surgery because of the "detrimental" effect that a postoperative death would have on the league table. Case-mix stratification is a theoretical way around this problem, but is very difficult to achieve in practice.²⁷

How can all these effects be disentangled? A fair summary of the available evidence is that it appears to be age-associated illness rather than the aging process itself that is

the main reason for the increase in morbidity and mortality following surgery and anesthesia in old age.^{28,29} Lines of evidence to support this assertion include:

- The APACHE III system, which looks at risk factors predicting mortality in intensive care unit patients, has indicated that almost 50% of the variability in mortality is a result of the intensity of the acute illness, whereas only 3% is because of chronologic age.³⁰
- While univariate analyses in which age is the only predictor variable tend to show a strong relationship between old age and adverse outcome in general surgical patients, multivariable analyses relating several preoperative risk factors to postoperative outcome have usually shown age by itself to be less important as an independent predictor.^{31–33}

Thus attempts to set upper age limits for certain operations are suspect not simply from an ethical point of view,⁷ but are technically suspect because age by itself is such a poor predictor of adverse postoperative outcome in an individual elderly person. Even in groups of older people there are no distinct cut-off points.^{30,34} Each person with a surgical problem—whatever his or her age—needs and deserves an individual assessment. In each case there is a need to estimate, on an individual basis, whether the potential benefits of a surgical operation outweigh the potential risks.^{29,35}

ANESTHETIC FACTORS

For a more detailed account of anesthesia in old age, specialist texts should be consulted,^{1–3} but the following section considers topics of general interest to the referring physician.

Morbidity and mortality following anesthesia

In some elderly individuals, factors such as the extent and type of surgical pathology and the presence of serious coexistent medical disease may suggest that the potential risks of surgical intervention outweigh the potential benefits. Under such circumstances, the nonanesthetist should resist the temptation to pronounce the patient “not fit for an anesthetic,” as postoperative deaths occurring solely because of anesthesia are very rare at any age, and in any case, it should be the anesthetist who estimates anesthetic risk.³⁵ In Pedersen’s¹⁷ series of patients of all ages, nonfatal complications directly attributable to anesthesia occurred in 1 patient in 170, whereas the overall rate of postoperative cardiopulmonary complications was as high as 1 in 11. For complications directly attributable to anesthesia, there was no correlation with age. For problems not directly attributable to anesthesia, in-hospital mortality and cardiorespiratory complications were rare below the age of 50, but there was a steady increase in incidence of these postoperative problems for age groups 50 to 69, 70 to 79, and 80 and over. The total in-hospital postoperative mortality in Pedersen’s series was 1.2%, but it was difficult to judge whether or not anesthesia contributed to individual deaths, many of which occurred in elderly patients having major surgery for malignant disease. Difficulties in attributing the relative contribution to postoperative mortality of multiple factors such as urgency of presentation, extent of medical and surgical pathology, type of surgical procedure, and anesthetic technique is a recurring problem in surgical audit.^{38,39}

Anesthetic drugs in elderly patients

Dodds⁴⁰ has described anesthesia as “applied clinical pharmacology with enough pathophysiology to confuse the picture.” The scope for confusion of the picture is greatly increased in old age, particularly if preexisting polypharmacy is present. The review of anesthetic drugs in the elderly population by Dodds,⁴⁰ and a shorter account in a recent handbook⁴¹ are recommended as a concise guide to an enormous subject. However, nine key points from that review are highlighted here, with the permission of the author.

1. The minimum alveolar concentration (MAC) is that concentration of an anesthetic gas that suppresses movement in response to a surgical stimulus in 50% of subjects. MACs tend to fall with age; in one study, halothane had a MAC of 1.08% in children but 0.64% at age 81.
2. With increasing age, there is a tendency for increased shunting in the lungs and decreased cardiac output. These pathophysiologic changes have complex effects on the uptake of volatile gases, as a low cardiac output favors rapid uptake, whereas a decreased lung function produces the opposite effect.
3. Where there is preexisting ischemic heart disease, the patient may be vulnerable to the cardiac depressant effects of some anesthetics and there is also the theoretical risk that isoflurane, enflurane, sevoflurane, and desflurane might “steal” blood from ischemic myocardium through vasodilation of normal vessels.
4. Hepatic metabolism and/or clearance of drugs tends to be affected by age, but there is considerable variability. Insoluble anesthetic agents that require no hepatic metabolism should be safer than soluble agents. Some agents such as halothane also have potentially hepatotoxic metabolites, and this agent may also produce a fall in protein synthesis.
5. Hepatic metabolism releases inorganic fluoride from some hydrocarbon anesthetics, and nephrotoxicity could theoretically occur.
6. Because of reduced neuronal density and a reduced metabolic rate, the elderly may be more sensitive to a given amount of anesthetic drug. Additionally, in patients with a delayed circulation time, there is a danger of overdosage when intravenous agents are given too fast because a delayed response may be mistaken for a lack of therapeutic effect. Smaller doses, slower rates of infusion, or repeated small boluses are recommended in elderly people.
7. Neuromuscular blocking agents can be classified into depolarizing and nondepolarizing types. The latter are usually favored in old age and atracurium has attractions because it is not dependent on renal and hepatic metabolism for its clearance.⁴²
8. Elderly people appear to have an increased sensitivity to opiates.
9. Nonsteroidal anti-inflammatory agents (NSAIDs) are commonly used for analgesia in younger patients, but may present increased hazards in the elderly population because of nephrotoxicity, fluid retention, and tendency to gastric irritation.

Long-term medications

Although not exclusively an “anesthetic” topic, it is convenient at this point to mention that a number of long-term medications that the patient is taking may have important implications for anesthesia and surgery. The main preoperative role of the physician is to gather information about current prescribed and over-the-counter drugs and to inform the surgical/anesthetic team. Most cardiovascular drugs will need to be continued, and sudden withdrawal of β -blockers and statins may present particular problems.⁴³

ACE inhibitors will usually be omitted on the day of surgery, but this needs to be discussed with the surgical/anesthetic team. Decisions on the continuation of warfarin will depend on the surgical procedure and the reason the drug is being given, but will usually be guided by local protocols. Of other antithrombotic drugs, clopidogrel may have persistent effects for 10 days after cessation and recent use of this drug should be drawn to the attention of surgeons and anesthesiologists. Local protocols for patients with diabetes are usually readily available. Patients with Parkinson’s disease may present difficult anesthetic and perioperative problems and require special attention.⁴⁴ The physician should be aware that “nil-by-mouth” regimens may permit the administration of essential oral drugs, but details are best left to the anesthetic/surgical team.

Prophylactic preoperative β -blockade

On theoretical grounds, preoperative initiation of β -blockers might be expected to have a beneficial effect on postoperative cardiovascular complications. In 2007, an influential report, while acknowledging that the evidence base was incomplete, favored the use of β -blockers in patients undergoing vascular surgery if myocardial ischemia had been demonstrated on formal cardiac testing.⁴³ However, a recent editorial⁴⁵ advised caution in the use of both prophylactic β -blockers and statins, at least until the ongoing POISE and DECREASE IV trials had reported. The POISE results appeared in May 2008,⁴⁶ and came to the worrying conclusion that, in patients undergoing noncardiac surgery, extended-release metoprolol succinate significantly increased the rate of mortality and strokes postoperatively, even though the number of cardiac events was decreased. Thus while other studies raise the theoretical possibility that lower doses of long-acting β -blocker titrated 7 days in advance could be beneficial,⁴⁷ the administration of higher-dose β -blocker therapy in the perioperative period might well be associated with greater risk than benefit.

STRATEGIES OF PREOPERATIVE ASSESSMENT

What should be the preoperative role of the physician?

The anesthesiologist is the person best qualified to assess anesthetic risk, and is also the person responsible for deciding whether or not a patient is fit for anesthesia.³⁵ However, an authoritative document on perioperative care in older people²⁹ has concluded that preoperative cross-specialty advice involving anesthesiologists, surgeons, and physicians is beneficial in the preoperative assessment, particularly in patients aged 80 and over. Although some of the “physician advice” may

be provided by organ specialists, such as cardiologists or respiratory physicians, a frail older person is likely to need a comprehensive geriatric assessment (CGA), which is the domain of specialists in old age medicine (i.e., geriatricians) and their associated multidisciplinary teams.

Although geriatricians and their teams have commonly been involved in the postoperative (and sometimes the preoperative) care of orthopedic patients,⁴⁸ formal structures leading to preoperative and postoperative involvement with older general surgical patients has been rare. The POPS (Proactive care of Older People undergoing Surgery) program is an interesting exception, and in the first POPS publication, Harari et al⁴⁹ describe how they targeted elective high-risk surgical patients aged 65 and over, hypothesizing that preoperative CGA and preoperative and postoperative monitoring and interventions would reduce postoperative complications and length of stay. The published results to date have not had randomized concomitant controls, and a formal randomized control trial is underway, but it appears that the POPS approach can have a favorable effect on postoperative morbidity (pain, pneumonia, delirium, wound infection, and pressure sores), speed of mobilization, mean lengths of stay, and rates of delayed discharge.⁴⁹ The current criteria for considering patients for a POPS assessment are shown in Table 38-1.

Another innovative system that incorporates elements of CGA with other assessments is PACE (Pre-operative Assessment of Cancer care in the Elderly).⁵⁰ Following an extensive survey of preoperative status and postoperative outcome, the PACE researchers have published details of the preoperative characteristics of their patient group, and a publication linking preoperative factors with postoperative outcome is awaited.⁵¹

General strategy of preoperative assessment

In their recent handbook, Dodds et al² list eight key points that need to be considered when assessing an older patient in whom major surgery is being planned. These are shown in Table 38-2. Focusing down, Dodds et al² propose a four-point approach to preassessment, along broadly traditional lines.

1. The **history**, to identify past and present medical and surgical problems, allergies, medication usage, and past anesthetic and surgical procedures.
2. A review of **organ systems**

Table 38-1. Referral Guidance for the POPS (Proactive care of Older People undergoing Surgery) Program, for Patients Aged 65 and Over Awaiting Surgery⁴⁹

Cardiovascular: MI in past 2 years, or unstable angina, or treated heart failure, or untreated BP >160/90
Poorly controlled DM
Previous stroke
On warfarin
Chronic lung disease (if thought to put patient at risk)
Poor nutrition (BMI <20, wt loss >5 kg in last 6 months)
Two or more falls from standing in past year
Memory problems, or history of confusion, or known dementia
ADL: Needing help with getting to toilet, bed to chair, standing, dressing, walking
Likely to need a complex discharge package

Table 38-2. Key Points for Preoperative Assessment and Preparation of Elderly Patients Undergoing Major Surgery

- Age as such is not a good predictor of surgical risk.
- Physiologic age-related changes increase the risks of surgery and anesthesia.
- Comorbidities increase with age.
- Anesthetic planning for surgery in elderly people is a challenge.
- Aim of assessment is to identify within the composite elderly patient what integrated responses are critically reduced, or have failed, and then to systematically review individual organ systems for functional reserve.
 - o Incidence of ischemic heart disease and valve disease increases with age and is associated with increased morbidity and mortality.
 - o Chest disease is common in the elderly, and pulmonary complications are more common in the postoperative period.
 - o Presence of interval delirium or confusion indicates a very high risk of postoperative cognitive impairment and general anesthetic or sedation should be avoided.
 - o Hepatic insufficiency usually results in a poor surgical outcome.
 - o Renal insufficiency associated with uremia increases risk.
- Before emergency surgery, there may not be time for complete evaluation and correction of risk factors.
- Life-saving treatment can proceed without consent.
- Advance directives before surgery should be documented, and the name of the patient's surrogate should be recorded.

Reproduced from Dodds C, Chandra MK, Servin F. *Anaesthesia for the Elderly Patient*. Oxford, UK: Oxford University Press; 2007.

3. Estimates of **functional reserve** of various organs, especially the heart, lungs, and kidneys
4. **Investigations**, paying particular attention to symptoms and signs indicating a severe and/or evolving clinical problem

The implications of abnormalities in the major organ systems are considered later in this chapter, but the topics of functional reserve and "routine" preoperative testing will be considered at this point.

Estimating functional reserve

Numerous studies have demonstrated a mild decrease in *basal function* of many organ systems in apparently healthy older people, but have pointed to a much more marked decrease when *reserve capacity* systems are put under stress. For example, when the case of cardiac output, the differences between young and old subjects are much more notable on exercise than they are at rest.⁵² When pathology is added to "normal" aging the loss of reserve capacity may be considerable, but the degree of deficit might become apparent only when the system is stressed by surgical disease, anesthesia, and/or a surgical procedure. It has been calculated² that major surgery and its associated systemic inflammatory response may see a rise of oxygen requirements from an average of 110 mL/min/m² to an average of 170 mL/min/m².

It is not practicable to carry out direct measurements of preoperative cardiorespiratory reserve in all older people undergoing moderate or major surgery, and the best indicator that further specialized investigation might be indicated is likely to be the history supplemented by observation of usual activities. An approximate quantification of cardiorespiratory reserve can be based on the number of Metabolic Equivalents (METs) a patient can achieve. One MET is broadly defined as the energy it takes to sit quietly, and is defined as 3.5 mL/kg/min based on the resting oxygen

Table 38-3. Classification of Functional Capacity^{43,53}

Estimated energy requirements in metabolic equivalents (METs) of various activities:

1-4 METS:

- Can take care of self—eat, dress, use the toilet
- Can walk indoors around the house
- Can walk a block or two on level ground at 2-3 miles/hr
- Can do light housework, such as dusting or washing dishes

4-10 METS:

- Can climb a flight of stairs or walk up a hill
- Can walk on level ground at 4 miles/hr
- Can run a short distance
- Can do heavy housework (e.g., scrubbing floors/lifting furniture)
- Can play golf, go bowling, go dancing, play doubles tennis, throw a baseball

>10 METS:

- Can do strenuous sports (swimming, singles tennis, football, basketball, skiing)

requirement of a 70-kg male aged 40.² Typical METs for a number of standard activities are shown in [Table 38-3](#). The basic research work on METs dates back 40 years or more, but the concept was brought to a wider audience by the 1996 ACC/AHA (American College of Cardiology and American Heart Association) guidelines of perioperative examination for noncardiac surgery, subsequently updated in 2002 and 2007.⁴³ The ACC/AHA guidelines regard the attainment of 7 METs as "excellent," 4 to 7 METs as "moderate," and less than 4 METs as "poor." An ability to climb two flights of stairs without stopping is equivalent to about 4 METs and is a criterion commonly employed by British anesthetists.²

According to the ACC/AHA guidelines, patients who require further cardiac testing (using criteria referred to later in this chapter) should undergo treadmill exercise ECG or pharmacologic stress testing. A possible alternative is to estimate the "anaerobic threshold" by means of a bicycle ergometer, as part of a general strategy of "hemodynamic optimization." This technique is now available in a number of U.K. hospitals.^{54,55}

"Routine" preoperative testing

What tests (such as blood tests, electrocardiograms, and chest x-rays) are required "routinely" in asymptomatic patients who are about to undergo surgery? Over the years this has been a subject of a large amount of debate and a modest amount of research. Various guidelines have not always been concordant in their advice and much of their content has needed to be based on expert consensus opinion. The National Institute for Health and Clinical Excellence (NICE) guidelines on preoperative testing are pertinent to the present discussion because they give separate recommendations for adults aged 60 and over,⁵⁶ although NICE acknowledges that consensus among their expert advisers was hard to achieve.

In deciding to carry out a test preoperatively (or, for that matter, in any clinical situation) it is useful to reflect on the five possible functions of a test, as listed by Garcia-Miguel et al⁵⁷:

1. To assess a preexisting health problem
2. To identify unexpected conditions

3. To predict preoperative or postoperative complications
4. To act as a baseline for later comparisons
5. To be an opportunistic screening for unconnected conditions

RESPIRATORY PROBLEMS IN THE OLDER SURGICAL PATIENT

Incidence of postoperative respiratory complications

Respiratory complications are common after surgery in elderly patients, and while the majority of such patients survive, deaths from respiratory causes still rank alongside cardiac and thromboembolic deaths as major potentially preventable causes of postoperative mortality. Sprung et al⁵⁸ estimate that 40% of perioperative deaths in people aged 65 and over have a respiratory cause.

The reported incidence of postoperative respiratory problems depends on the exact definitions used. In general surgical patients assessed prospectively in Cardiff (Wales), postoperative respiratory problems were found in 33% of those aged 65 to 74, and in 50% of those aged 75 and over; but these percentages became 20% and 24%, respectively, when uncomplicated atelectasis was disregarded.⁵⁹ The risk of postoperative respiratory complications in these patients was increased in the presence of preexisting lung disease, smoking, volume depletion, and incisions near the diaphragm.⁶⁰ Similarly, Brooks-Brunn⁶¹ reported six risk factors to be independently associated with postoperative respiratory complications in adults aged 18 and over undergoing abdominal surgery. These were: age 60 or over; impaired preoperative cognitive function; smoking in the previous 8 weeks; body mass index 27 or more; history of cancer; and incision involving the upper abdomen (or upper and lower abdomen together). Pedersen et al⁶² found that age, major abdominal surgery, emergency operation, preexisting chronic lung disease, prolonged anesthesia, and the presence of pancreatitis were all positively associated with an increased risk of postoperative respiratory problems. Much more recently, Qaseem et al⁶³ estimated that, relative to age less than 60, the odds ratios for postoperative respiratory complications were 2.09 for those aged 60 to 69 and 3.04 for those aged 70 to 79.

Pathophysiology of respiratory problems in elderly surgical patients

Lung abnormalities are common in older people even in the absence of smoking or known lung disease, although it is difficult to be sure how much of the abnormality is due to aging and how much to other factors such as recurrent respiratory infections or pollution. Pulford and Connolly⁶⁴ have pointed to an increased closing volume (i.e., the lung volume at which basal airways begin to collapse) as one of the most consistent abnormal respiratory findings in old age, and this appears to be important in the cause of many postoperative respiratory complications.⁶⁵ Because closing volumes tend to lie within the range of tidal ventilation when normal individuals aged 65 and over are sitting quietly, postoperative atelectasis is a constant threat in old age, especially in patients who are not mobilized promptly.² Sprung et al⁵⁸ recently

focused on those age-related respiratory changes that were most likely to be adversely affected by anesthesia and surgery. These were reduced lung static recoil, increased chest wall stiffening, and reduced alveolar surface area, combining to cause a decrease in vital capacity and expiratory flow rates, and an increase in residual volume and ventilation-perfusion mismatch.

Simple atelectasis may produce only minor signs and a low-grade hypoxemia but becomes clinically important when the lungs are already compromised and/or where the atelectasis develops into frank pneumonia. It should be noted, however, that in the majority of postoperative patients, atelectasis is thought to be initiated not by retained secretions but by basal airways collapse.^{21,65} In this situation, classic "expiratory" methods of percussion and encouragement of coughing may do more harm than good.⁶⁶

Estimation of respiratory risk and possible preventive strategies

In thoracic surgery, there is a large amount of literature on the role of preoperative respiratory function testing as an aid to decision making.⁶⁷⁻⁶⁹ A recent guideline from the American College of Physicians (ACP) is an important milestone in developing an evidence-based approach to respiratory assessment in adults undergoing nonthoracic surgery. The ACP guidelines deserve to be read in full,^{63,70,71} but an abbreviated summary is given in Table 38-4. Drawing on the same material, Cartin-Ceba et al⁷³ have produced a strategy particularly aimed at older patients, which has separate schedules of recommendations for the preoperative, intraoperative, and postoperative period.

Late postoperative hypoxemia

In the early postoperative period, prompt detection of possible respiratory complications and/or hypoxemia has been greatly aided by the development of pulse oximetry (although the need for direct measurement of blood gases has not been removed entirely, as pulse oximeters indicate oxygen saturation rather than absolute oxygen tensions and give no indication as to carbon dioxide levels⁷⁴). Pulse oximeters have also had a major role in identifying brief episodes of profound hypoxemia in some individuals 2, 3, 4, or even more days following surgery.⁷⁵ The basic underlying mechanisms for episodic hypoxemia are reasonably well understood, although the conventional explanation offered here is probably an oversimplification.⁶⁵ In some cases, a patient who has had little or no hypoxemia for the first 1 or 2 postoperative days starts to develop episodes of profound hypoxemia (perhaps going below 60% saturation of oxygen), during the second, third, or fourth postoperative night. These desaturations often coincide with the presence of rapid-eye-movement (REM) sleep, which causes a disturbance of the respiratory mechanism similar to obstructive sleep apnea. The stress of surgery and, in particular, the use of opiates at the time of operation appear to suppress REM sleep for 2 to 3 days after major surgery, and it is when the REM sleep reappears that the episodes of desaturation occur.⁷⁶ Initially, the suppression of REM sleep was blamed entirely on opiates, but the phenomenon also occurs in patients who have not been given opiates.

Table 38-4. Brief Summary of American College of Physicians Recommendations on "Risk Assessment for and Strategies to Reduce Perioperative Pulmonary Complications for Patients Undergoing Noncardiothoracic Surgery"^{63,70-72}

- A. In order to initiate appropriate preoperative and postoperative interventions:
- Evaluate preoperatively the following risk factors:
 - Chronic obstructive airways disease
 - Age over 60
 - Congestive cardiac failure
 - ASA class of II or more (i.e., the presence of even minimal impairment)
 - Impairment in activities of daily living
 - Smoking (but note that a smoking history shows only a modest correlation with increased postoperative chest complications once respiratory disease has been allowed for, and evidence suggests that smoking cessation probably needs to take place at least 2 months before surgery)
 - obesity and mild or moderate asthma are not proven risk factors for postoperative pulmonary complications.
 - Recognize the following higher risk procedures, with concomitant risk factors:
 - Operations lasting >3 hr
 - Abdominal surgery
 - Thoracic surgery
 - Vascular surgery
 - Aortic aneurysm repair
 - Emergency surgery
 - General (as opposed to regional) anesthesia
 - Note that a serum albumin of less than 35 g/L is a powerful marker for postoperative pulmonary complications
- B. In those judged at higher risk, recommended procedures to reduce postoperative pulmonary complications are:
- Deep breathing exercises or incentive spirometry
 - Selective use of nasogastric tube
- C. Preoperative spirometry and chest radiography is not recommended routinely, but might be indicative for patients with previous diagnosis of chronic obstructive airways disease or asthma.
- D. The following should not be used "solely for reducing postoperative pulmonary complication risk:"
- Right heart catheterization
 - Total parenteral or enteral nutrition (for those who are malnourished or have low serum albumin levels).

Hypoxemia would be expected to cause arrhythmias and it is tempting to conclude that some unexplained postoperative deaths around the third postoperative day are because of the cardiac effects of unrecognized hypoxemia.⁷⁷⁻⁸⁰ However, it has been difficult to demonstrate a one-to-one relationship between episodes of hypoxemia and cardiac disturbance,⁸¹ and other factors such as carbon dioxide levels might be important as well. Hypoxemia would also be expected to have a detrimental effect on wound healing and cerebral function^{82,83} but again, there is need for further research.

Episodes of late postoperative hypoxemia can be prevented almost entirely by giving continuous oxygen by nasal cannulae for several days after surgery.⁸⁴ Common regimens are "three days and five nights." However, there are practical difficulties in identifying the patients who will be at risk from hypoxemia, and there is a balance to be struck between trying to monitor large numbers of patients with pulse oximeters and the alternative strategy of giving oxygen to a high proportion of patients even though some may not need it.

CARDIAC PROBLEMS IN THE ELDERLY SURGICAL PATIENT

Incidence of postoperative cardiac complications

Clinical evidence of postoperative myocardial infarction has been reported in 1% to 4% of unselected general surgical patients aged 65 and over.²¹ In patients aged 75 and over, and in populations of patients with known ischemic heart disease, the incidence is at least twice as high. The association between increasing age and postoperative myocardial infarction is likely to be due in part to a secondary association between age and preoperative ischemic heart disease. Additional risk factors repeatedly reported to increase the chance of postoperative myocardial infarction include myocardial infarction within the previous 6 months and active congestive cardiac failure.⁸⁵ Other risk factors for postoperative myocardial infarction and/or cardiac failure include age, angina, hypertension, diabetes, arrhythmias, peripheral vascular disease, valvular heart disease, smoking, and previous cardiac surgery.⁸⁵

More extensive electrocardiographic monitoring in the perioperative period has revealed that many elderly patients have repeated episodes of subclinical myocardial ischemia that might be amenable to treatment. As mentioned above, some of these episodes might be precipitated by episodes of profound hypoxemia that are respiratory rather than cardiac in origin.

Diagnosis of myocardial infarction in the postoperative period is difficult because the symptoms may be masked by analgesia or anesthesia, and the expected cardiac enzyme changes (such as a rise in creatinine kinase) may be mimicked by surgical trauma to muscle. However, more specific enzyme tests such as troponin I and troponin C have allowed more precise diagnosis and enabled smaller infarcts to be detected.⁸⁶ Once clear clinical signs and symptoms of postoperative myocardial infarction are present, the death rate has been reported to be as high as 50%.^{17,21} However, in the study by Badner et al,⁸⁷ which used troponin estimations as part of the diagnostic process, there were only three deaths out of the 18 patients with a postoperative myocardial infarction.

Cardiac assessment of the noncardiac surgical patient

It has been estimated that for every patient with heart disease undergoing cardiac surgery, there are about 10 patients with heart disease, recognized or unrecognized, undergoing noncardiac surgery.⁸⁵ Many such patients are elderly. A large amount of literature has therefore grown up on the "cardiac assessment of the noncardiac surgical patient."^{88,89} Even though extensive use of high-technology screening of cardiac and respiratory function might in theory be able to predict many postoperative complications,^{90,91} the large number of patients undergoing surgery every day would make such a policy impractical. Apart from the practical and economic implications, there are also scientific objections to high technology mass screening. Some of the cardiac tests are not without risk, and, in addition, widespread preoperative cardiac screening in relatively low-risk patients would inevitably throw up large numbers of false positive results, which could result in the unnecessary postponement of much-needed surgery.

Are there "low-technology" strategies based on simple clinical assessment that would increase our chances of predicting postoperative cardiac complications? The earliest studies looked at risk factors one at a time (univariate analysis).⁸⁵ Subsequently, Goldman et al⁹² in 1977 produced the first multifactorial index of cardiac risk in general surgical patients aged 40 and over. The problem with any clinical risk index is that it tends to perform well on the dataset from which it was constructed (i.e., the training dataset) but usually performs less well on subsequent datasets (test datasets).⁶⁰ Attempts to validate the Goldman index in other datasets gave variable results, particularly in patients undergoing vascular surgery.²¹ A modification of the Goldman index by Detsky in 1986⁹³ attempted to increase predictive power by taking into account the underlying surgical illness, but these early risk indices have now been largely superseded by other approaches, as is described later.

These newer approaches have employed a stepwise approach to risk prediction, with initial screening tests leading, where appropriate, to more complicated investigations.^{88,89} The ACC/AHA guidelines, first published in 1996 and later updated in 2002 and 2007,⁴³ deserve close reading, but are briefly described in the section that follows. First, however, a more general point about risk prediction needs to be made, which has applications outside the field of cardiac assessment and also applies to medical and surgical situations. A major concept that is incorporated into the ACC/AHA guidelines is the principle that more complex evaluation of risk, by means of noninvasive or invasive investigations, is best applied in those patients whose risk has already been judged as being *neither very high nor very low*. The mathematical justification for this comes from Bayes' theorem and is related to the concept of prior probability. In essence this states that, because most medical tests are neither very good nor very bad but something in-between, they are most likely to influence decision making when the prior estimation of risk is neither very high nor very low.^{88,89} Where the prior probability of disease is very low, then the available noninvasive tests do not usually have a sufficiently high sensitivity and specificity to "lift" the patient into the "moderate risk" group and so do not alter the clinical assessment. On the other hand, when the prior probability of heart disease is very high, say 90%, then even if the noninvasive tests are negative, this is not enough to "demote" the patient to a low-risk category, and so the tests again do not alter management.

The ACC/AHA guidelines⁴³

The ACC/AHA guidelines of 1996, 2002, and 2007 have many features in common, with the latest guidelines being summarized in Table 38-5. With the exception of patients whose surgical problems are so urgent that they need to go for surgery straight away, the guidelines recommend one of four courses of action depending on patient circumstances:

1. Proceed to surgery without further investigations.
2. Perform noninvasive cardiovascular investigations to define risk with more precision (further management depending on the results of these investigations).
3. Do invasive cardiovascular testing straight away.
4. Delay or cancel surgery, or perform a lesser procedure, because the estimated cardiac risk is very high.

The broad basis of classifying patients is shown in Table 38-5. It can be seen that three types of risk factor are considered:

1. The nature and extent of the surgery being planned
2. Clinical predictors for increased perioperative cardiovascular risk
3. The functional capacity of the individual patient. (The method of estimating functional capacity has been described above and in Table 38-3. The ACC/AHA recommendation is that patients with a maximal functional capacity of 4 METS or less should be considered at high risk)

At the center of the ACC/AHA document is an algorithm which, on the basis of the three types of risk factor, recommends which of the four courses of action should be pursued. The original papers or Web site⁴³ should be

Table 38-5. ACC/AHA Guidelines⁴³ for Perioperative Cardiovascular Evaluation before Noncardiac Surgery

<p>Consider three factors:</p> <ol style="list-style-type: none"> 1. The nature and extent of the surgery being planned: <ul style="list-style-type: none"> • Vascular surgery (reported cardiac risk >5%) such as aortic and other major vascular surgery, and peripheral vascular surgery. (This category was referred to as "high surgical risk" in previous guidelines.) • Intermediate surgical risk (reported cardiac risk 1% to 5%), such as intraperitoneal and intrathoracic surgery, carotid endarterectomy, head and neck surgery, orthopedic surgery, and prostate surgery. • Low surgical risk (such as endoscopic procedures, superficial procedures, cataract surgery, breast surgery, ambulatory surgery) 2. Clinical predictors for increased perioperative cardiovascular risk: <ul style="list-style-type: none"> • "Active cardiac conditions" (referred to as "major risk" in earlier guidelines), such as unstable coronary syndromes (unstable or severe angina, acute [<7 days] or recent [<1 month] myocardial infarction), decompensated heart failure, significant arrhythmias, and severe valvular disease. • Clinical factors from the Revised Cardiac Risk Index (replacing the "intermediate" category referred to in earlier guidelines) including history of <ul style="list-style-type: none"> o Heart disease (including previous myocardial infarction) o Compensated or prior heart failure o Cerebrovascular disease o Diabetes mellitus o Renal insufficiency • Minor, including <ul style="list-style-type: none"> o Age over 70 o Uncontrolled hypertension o Rhythm other than sinus o ECG abnormalities (LV hypertrophy, left bundle branch block, ST-T abnormalities) 3. Functional capacity, based on MET levels of <4 or ≥ 4 (as described previously). An algorithm incorporating information from these three elements (see reference 43) indicates who should: <ol style="list-style-type: none"> 1. Proceed to surgery without further investigations 2. Undergo further noninvasive cardiovascular investigations 3. Undergo invasive cardiovascular investigations 4. Be considered for a cancellation or delay of surgery, or performance of a lesser surgical procedure

From Fleisher LA, Beckman JA, Brown KA, et al. ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: a report of the American College of Cardiology/American Heart Association Task force on practice guidelines (writing committee to revise the 2002 guidelines on perioperative cardiovascular evaluation for noncardiac surgery). *J Am Coll Cardiol* 2007;50(17):1707-32 (executive summary) and e159-e241 (full report).

consulted by those intending to use the algorithm in clinical practice.

While the ACC/AHA guidelines draw as far as possible on research evidence, many of their recommendations are not fully "evidence-based," with expert opinion being used to fill shortfalls in the published literature. It is therefore to be expected that refinements and alterations will be required as more research information becomes available. It should also be recognized that, as currently formulated, the ACC/AHA guidelines would lead to practical problems for many clinicians and health care administrators. For example, as peripheral vascular disease is classified as having a "high" surgical risk, the guidelines would indicate that all such patients should routinely undergo noninvasive cardiac testing before surgery. In most U.K. centers, this is not current common practice and would present considerable logistical problems.

A final point to make about all predictive systems is that they are only part of the process of risk reduction. While a broad stratification of preoperative risk is a reasonable aim (not least as a means of allowing the patient an informed choice as to whether he or she wants surgery), risk reduction also demands that a significant effort should be directed into the peri- and postoperative care of *all* patients. Such care requires careful monitoring at a level appropriate to the patient's condition, with adequate provision of high-dependency units and intensive-therapy units if clinically indicated. Within a U.K. setting, there is concern that existing facilities are not always sufficient to provide optimal levels of postoperative care, with the result that older, frailer patients who are being monitored extremely closely during the period of their operation may rapidly find themselves back on a general surgical ward soon afterwards.³⁷⁻³⁹

Cardiac surgery

Paradoxically, the prediction of risk in patients who are undergoing cardiac as opposed to noncardiac surgery is less of a problem, as most cardiac patients will have had sophisticated and invasive preoperative cardiac testing. Even more importantly, such patients are routinely monitored postoperatively, usually in an intensive therapy unit. A decade ago, in leading centers, the mortality rate following cardiac surgery in patients aged 70 and over was only of the order of 5%, compared with a rate of about 2.5% in patients under 69, and a quarter of all patients were over 70.^{94,95} However, outside specialist teaching centers there has been concern that referral practices and cardiac surgical rates in older patients are suboptimal.⁹⁶⁻⁹⁸ Research has shown that quality of life and functional improvement after successful cardiac surgery is at least as good after the age of 70 as it is for younger patients.⁹⁹⁻¹⁰⁰ Such studies add weight to the argument that procedures such as angioplasty, and operations such as coronary artery bypass grafting and aortic valve replacement, should be more widely available in elderly people.

Another growth area of potential benefit to older surgical patients is "minimally invasive cardiac surgery." To those outside the field, minimally invasive cardiac surgery appears to be a contradiction in terms, but there is a growing interest in techniques such as "beating heart anastomoses," which can avoid the problems of cardiac bypass.^{10,12,101} For anatomic reasons, minimally invasive techniques cannot replace

all conventional coronary artery bypass procedures, but they could take their place alongside conventional surgery and percutaneous coronary angioplasty as one of a basket of techniques that could benefit elderly people.

UNDERNUTRITION

Poor nutrition has been reported to have adverse effects on immune response, wound healing, and gastrointestinal, cardiovascular, and respiratory function,¹⁰² and undernutrition in adults with medical and surgical problems is at long last attracting significant clinical and research interest. Nutritional assessment should therefore be part of the routine evaluation of older patients who are being considered for surgical treatment, even if this policy requires extra training of doctors and health workers.¹⁰³

Research interest in undernutrition in adult surgical patients in hospitals was prompted by studies such as that of Bistrian et al¹⁰⁴ in the 1970s. Although the accuracy of some of the early estimates of prevalence has been challenged,¹⁰⁵ such studies were important in drawing general attention to the existence of malnutrition in hospitals. One of the valid criticisms of the early studies was overreliance on the serum albumin as a purely nutritional marker, whereas in recent years, it has become clear that it is better to regard it as a general indicator of illness severity.^{106,107} For instance, in a surgical patient with a low serum albumin and an intra-abdominal abscess, it is more likely that the inflammatory response is causing the low albumin than it is that malnutrition is causing the sepsis.

The review by Corish¹⁰² indicated that the nutrition of older patients coming into surgical wards is often suboptimal and that this is clinically relevant to their management. Once within hospital, the older patient may not be nutritionally safe. Corish points to studies which indicate that elderly hospital inpatients who are "eating normally" have a dietary intake well below their estimated energy requirements, and observations of food wastage indicate that as little as 60% of the food that is served to older patients is actually consumed. A deterioration in nutritional status following admission is therefore quite common, and is compounded by "nil by mouth" episodes as the result of illness, investigations, or surgical procedures.

At a practical clinical level, how should we assess nutritional status in elderly patients on a busy surgical ward? Corish¹⁰² discusses individual methods that could be used but points out that none has been developed specifically for the elderly surgical patient and comments that "all the traditional markers in nutrition lose their specificity in the sick adult." For a broad assessment of nutritional status, Corish highlights the American Society for Parenteral and Enteral Nutrition (ASPEN) guidelines. Risk factors for undernutrition and adverse outcomes listed by ASPEN include: involuntary loss or gain before hospital admission of more than 10% of usual body weight within 6 months (or 5% in 1 month); a weight of 20% over or under ideal body weight; the presence of chronic disease; increased metabolic requirements; alterations to the normal diet as a result of recent surgery, illness, or trauma; and an inadequate nutritional intake for greater than 7 days.

Along with the criteria listed above, different rules of thumb have been suggested for the detection of "clinically

significant" weight loss in the elderly population. These include 4.5 kg over 2 years, 2 kg per year, 4% or 5% over 1 year and 7.5% over 6 months. Although there is a dispute about exact criteria, Corish points out that a loss of 20% of body weight is almost invariably associated with physiologic impairment, and that older people may well be less tolerant of weight loss than the young.

Additional nutritional indicators that have been used in some studies include anthropometry, various serum proteins, creatinine/height index, functional status, immunologic competence, and bioelectrical impedance.¹⁰² Anthropometric methods of assessing nutrition may appear to be more "scientific" than other methods, but there are often practical problems in applying them to older people in general, and old surgical patients in particular. Anthropometric measurements that can potentially be used in routine clinical practice are weight, height, body mass index (BMI) (weight in kilograms divided by the square of the height in meters), triceps skinfold thickness, midarm circumference, midarm muscle circumference, hand-grip strength, and measured weight change. McWhirter and Pennington¹⁰⁸ remind us that the BMI by itself is not a sensitive indicator of protein-energy malnutrition in adults because it does not distinguish between depletion of fat or muscle. There are added problems in assessing BMI in older people, who may lose height as the result of osteoporosis. Some researchers substitute knee height or arm demispan for body height, but then, as for all the other anthropometric measurements, it is necessary to establish age- and sex-matched norms in a comparable general population.¹⁰⁸ Furthermore, in acutely ill surgical patients, even the measurement of body weight presents practical problems.

Multi-item nutrition risk indices reviewed by Corish include the Nutritional Risk Index, Nutritional Risk Score, Subjective Global Assessment, Mini Nutritional Assessment, Prognostic Nutritional Index, Likelihood of Malnutrition Index, and the Instant Nutritional Assessment.¹⁰² All have strengths and weaknesses with the usual tradeoff between sensitivity and specificity and a varying requirement for specialized laboratory tests.

In an effort to improve nutritional assessment in all hospitalized patients, the British Society for Enteral and Parenteral Nutrition (BAPEN) has been promoting the use of "MUST" (Malnutrition Universal Screening Tool).¹⁰⁹ MUST-type information is designed to be easy to collect and includes height, weight (past, present, and including a % estimate of recent weight loss), and BMI (calculated using arm width span or knee height if there is severe kyphosis) and estimates of severity of illness and likely future intake of nutrition. It would seem to be good practice for the referring physician to include such information when referring patients for possible surgery and anesthesia. The recording of serum albumin would also be a reasonable routine strategy, provided that it is realized that it is primarily a marker of poor health. Routine recording of the BMI will also identify patients with a high BMI, who will present different anesthetic and surgical problems (see later discussion). MUST is intended to be a pragmatic tool for clinical use rather than a precise instrument for use by specialist researchers, but it incorporates two important principles from the early surgical work of Windsor and Hill, namely that recent weight loss may be more important than the absolute weight, and that patients who have a

reduction in function alongside signs of undernutrition are much more at risk than those who do not.^{106,110,111}

Nutritional supplementation

Although there is ample evidence that malnutrition is statistically associated with a range of problems in medical and surgical patients,¹¹² this does not necessarily prove that the relationship is one of cause and effect. Still less does it prove that nutritional enhancement will improve postoperative outcome. The only way to assess the benefits or otherwise of nutritional supplementation in undernourished elderly patients is to carry out randomized controlled trials.¹⁰² Such trials are not easy to do, and two recent reviews of nutritional supplementation in the elderly population have commented on the poor quality of many of the trials.^{113,114} The systematic review of Milne et al¹¹³ looked at 49 randomized controlled trials of protein and energy supplementation involving a total of 4790 elderly people at risk of malnutrition. Twenty of the trials took place with hospital patients, of which eight involved hip fracture patients but only two involved general surgical patients. The overall conclusion, when all the studies were combined, was that nutritional supplementation produced demonstrable weight gain, and probably a reduction in mortality, although beneficial effects on complications and functional status could not be consistently demonstrated.

The systematic review of Avenell and Handoll¹¹⁴ confined its attention to postoperative nutritional supplementation in elderly patients following hip fractures. Twenty-one randomized trials published before February 2006 were included, involving 1727 participants. Again, it was difficult to draw firm conclusions. The eight trials providing additional oral feeding (with a variety of feeds containing energy, protein, and some vitamins and minerals) were consistent with a beneficial effect provided that a combined endpoint of "mortality plus complications" was used in the statistical analyses. The four trials involving nasogastric feeding provided only limited data but did not show a convincing effect on mortality, and, moreover, tubes were poorly tolerated. Only five of the studies overall, and only two of the nasogastric tube studies specifically examined the effect of supplementation on malnourished patients. This might well have been an important omission because following nasogastric feeding in the classic early study by Bastow et al,¹¹⁵ the hospital mortality in the "very thin" category of patients was reduced relative to the "thin" group (relative risk 0.37 vs. 1.12). However, the confidence intervals were very wide owing to small patient numbers, and so the results were not statistically significant. Similarly, when morbidity was the outcome measured by Bastow, it was the "very thin" group who appeared to benefit most. If the evidence that nutritional support is most likely to be of benefit when targeted on very malnourished patients is borne out by future research, this will be good news for both patients and health service managers. For instance, the study by McWhirter and Pennington¹⁰⁸ indicated that 27% of general surgical patients, 39% of orthopedic surgery patients, and 43% of medical elderly patients were "undernourished." However, when only severe malnutrition was considered, the figures became more manageable, being 1%, 6%, and 19%, respectively.

From a purely academic standpoint, we might conclude that the existing randomized controlled trials do not as

Table 38-6. ESPEN Guidelines on Enteral Nutrition for Surgery¹¹⁶

1. Enteral nutrition (by mouth, or if necessary, by tube) is indicated without delay, even in the absence of obvious undernutrition, if:
 - It is anticipated that the patient will be unable to eat for more than 7 days perioperatively, or
 - The patient cannot maintain oral intake above 60% of recommended intake for more than 10 days
2. Where patients are at "severe nutritional risk," a delay for preoperative enteral nutrition is recommended. Severe nutritional risk is defined by the presence of at least one of:
 - Weight loss >10%–15% within 6 months
 - BMI <18.5 kg/m²
 - Subjective Global Assessment Grade C
 - Serum albumin <30 g/L (with no evidence of hepatic or renal dysfunction).
3. Finally, it is important to start enteral nutrition therapy as soon as a nutritional risk becomes apparent, rather than waiting until severe undernutrition has developed.

yet permit the construction of authoritative guidelines. However, in the meantime, we need to offer the best nutritional advice that we can for our older surgical patients. Combining information from many sources, ESPEN (the European Society for Parenteral and Enteral Nutrition) has recently issued guidelines on enteral nutrition in surgery¹¹⁶ that cover both the preoperative and postoperative period. The main preoperative recommendations are shown in Table 38-6.

OBESITY

The pathophysiology of obesity has been discussed by Bray,¹¹⁷ who divides patients into five categories: individuals who are not obese (class 0) have BMIs of 20 to 25 kg/m², whereas the BMIs of individuals in class I (low risk from obesity), II (moderate risk), III (high risk), and IV (very high risk) are 25 to 30, 30 to 35, 35 to 40, and greater than 40 kg/m², respectively. In reviewing anesthetic risks, Wilson and Reilly¹¹⁸ take 35 kg/m² or more as their definition of obesity, and discussed the physiologic and anatomic implications. However, even in patients with severe obesity it has been difficult to demonstrate an increase in postoperative mortality; the main excess risk appears to be postoperative wound infections, with some studies also reporting an increase in thromboembolic complications.¹¹⁸

Studies of postoperative outcome in mild or moderately obese patients are surprisingly uncommon in the literature.¹¹⁸ Garrow et al¹¹⁹ prospectively studied 469 patients undergoing abdominal surgery of whom 73 were classified as obese (defined as the top 15% of BMIs for men and women). The obese group had significantly more wound infections, but no differences were found in respect of deep venous thrombosis, pulmonary embolism, chest infections, urinary infections, and unexplained fever. Postoperative deaths (one in the obese group and six in the nonobese group) were too few for statistical analysis.

Garrow's series¹¹⁹ was not confined to elderly people, but in a much earlier survey of general surgical patients aged 65 and over, patients above the 75th percentile of triceps thickness had twice the rate of postoperative wound infections, but no increase in postoperative chest infections or

in-hospital mortality.¹²⁰ In a more recent study of elderly general surgical patients,¹⁹ patients were classed as being underweight or overweight by simple visual inspection. It was the underweight group that had the worst in-hospital mortality¹⁹ and 5-year mortality (Seymour et al, unpublished observations). This is of interest because there is evidence from population studies that, as a broad generalization, once a patient has achieved old age (often despite their obesity), it is being underweight rather than being overweight that tends to be associated with worse long-term survival.^{121–123}

Looking at in-hospital events in more detail, a retrospective study of perioperative morbidity following primary knee and hip replacement defined obesity as 20% above ideal weight for height, based on life insurance tables.¹²⁴ On this criterion, 103 out of 154 patients were classified as obese (joint replacement patients with osteoarthritis tend to be overweight, in contrast to hip fracture patients who tend to be underweight). Although the obese patients had longer operative times, their stay in the hospital, number of days with a fever, number of transfusions, and analgesic use were no different from the nonobese.¹²⁴ In a retrospective study of coronary artery bypass graft patients aged between 60 and 86, obesity was significantly related to length of hospital stay, but was less important as a predictor than congestive cardiac failure, renal impairment, and being aged 75 years and over.¹²⁵ A detailed discussion of the technical problems that obesity presents to the anesthetist and intensivist is provided by Adams and Murphy.¹²⁶

FLUID AND ELECTROLYTE IMBALANCE

Reports from NCEPOD (National Confidential Enquiry Into Perioperative Deaths)³⁷ have stressed the critical importance of fluid balance in elderly surgical patients. In the 1999 review,³⁸ which concentrated on patients aged 90 and over, examples of overadministration and underadministration of fluid were encountered. In regard to perioperative fluid management, the following six key points were made:

1. Fluid imbalance can contribute to serious postoperative morbidity and mortality.
2. Fluid imbalance is more likely in elderly people as they tend to have renal impairment or other comorbidity.
3. Accurate monitoring, early recognition, and appropriate treatment of fluid imbalance is essential.
4. Fluid balance should be accorded the same status as drug prescription.
5. Training in fluid management, for medical and nursing staff, is required to increase awareness and spread good practice.
6. There is a fundamental need for improved postoperative care facilities.

However, the assessment and treatment of fluid and electrolyte disturbance in surgical patients is difficult, particularly for emergency patients where the deficits are likely to be most severe. There is no simple "cookbook" approach that will guarantee perfect fluid balance every time, and the best strategy usually is to make an initial broad assessment, to start treatment on that basis, and to monitor progress constantly thereafter. If cookbook rules are difficult to formulate for young surgical patients, then they are even more difficult

to draw up for older patients; here, the increased prevalence of preexisting renal disease and homeostatic impairment in the cardiovascular system and renal system¹²⁷ produces a need for tighter control, at the same time the signs and symptoms of salt and/or water depletion are more difficult to interpret.^{21,128}

Assessment of fluid and electrolyte status

The standard surgical strategy when assessing perioperative fluid and electrolyte requirements in patients of any age is (1) to assess preexisting deficits, (2) to estimate maintenance needs, and (3) to allow for continuing losses.^{21,129}

The assessment of preexisting fluid and electrolyte deficits is more difficult in elderly patients because many of the classic signs of water and salt depletion such as reduced skin turgor and postural hypotension are neither sensitive nor specific in old age. For example, postural hypotension or lax skin tone may exist in elderly patients who are not volume-depleted, whereas a compensatory tachycardia may fail to develop in elderly people who are.^{21,128,130} There is a need not just to examine the patient but to look at the whole clinical context over the previous few days. For instance, a patient who has been vomiting for 2 days is likely to be depleted of both salt and water even if the clinical signs are equivocal.

Water depletion

Another basic principle of electrolyte/fluid balance is to try to estimate the type of fluid that has been lost and to identify the main body compartment that has been affected. It is helpful to remember that depletion of water alone has a very different effect from losses of salt plus water.^{21,129,130} Pure water depletion primarily affects the intracellular compartment, and the initial symptoms and signs are nonspecific, being drowsiness, irritability, and perhaps low grade fever.^{21,128} In healthy younger patients, thirst is a reliable indicator of water depletion, but this may not be true in a proportion of healthy older patients,^{127,130} and the symptom may in any case be impossible to elicit in acutely ill surgical patients. The main fact to remember about water depletion is that hypernatremia tends to develop, and Lye¹³¹ has estimated that 90% of cases of hypernatremia in geriatric clinical practice are a result of water depletion.

Salt and saline depletion

Loss of salt (or saline, as salt loss is usually associated with water loss as well) has its predominant effect on the extracellular compartment, which includes the vascular compartment.^{21,129,130} Middle-aged patients with this type of depletion classically develop postural hypotension and tachycardia, but the presence or absence of these signs may be difficult to interpret in older patients where postural hypotension from other causes may occur in one quarter of patients, and where autonomic reflexes are often blunted.¹³⁰

The patient with severe saline depletion will eventually develop circulatory collapse and poor peripheral circulation, but these are late signs. A low jugular venous pressure (obtained by lying the patient flat and observing the neck) is a test of volume depletion that is underused.²¹ In severe cases, more invasive methods such as central venous

pressure monitoring may be needed and noninvasive means of estimating intravascular volume are being developed.^{132,133} Whereas a high serum sodium can be used to diagnose water depletion, a low serum sodium is unfortunately not a good sign of salt depletion because hyponatremia can occur in a variety of clinical conditions, including congestive cardiac failure, where total body stores of sodium tend to be high, and where intravenous administration of saline might lead to clinical disaster.

In a younger patient with salt and water depletion, the appropriate kidney response is to produce a urine that is concentrated and low in salt. If a young patient develops oliguria, and the urine has these features, then a "prerenal" deficit can be presumed and fluid challenge can be given. In the elderly patient, where a degree of coincidental renal impairment is common, oliguria may develop as a result of prerenal causes, but the urine may be misleading because the preexisting renal damage does not allow for salt and water conservation. Again, there is the need to take into account the whole clinical situation and not one set of biochemical results. If the clinical signs and history point to a likely volume depletion, then the correct course of action is to treat cautiously and monitor closely.

Defining dehydration

Strictly the word *dehydration* should apply to water depletion on its own.¹³⁴ However, in general usage, dehydration is often taken to mean a deficit of water or salt or both, and the classic signs of dehydration under this usage are actually signs of salt depletion such as postural hypotension. An otherwise very useful review of salt and water depletion in elderly medical patients¹³⁰ appears to use the term dehydration in this more general sense. As the signs, symptoms, and treatment of saline depletion on the one hand, and water depletion on the other, are different, it is therefore unfortunate that the word dehydration is often used in a nonspecific sense to smudge both of these together. The best course of action is probably to avoid the word altogether and to try to specify the nature and amount of the fluid that has been lost, and which body compartment is primarily affected.

Practical aspects of fluid and electrolyte therapy

Some broad rules of thumb that have been suggested when treating fluid/electrolyte disturbance in elderly surgical patients are as follows:

1. A water loss of 2 kg or more is probably significant in an elderly patient.¹³¹
2. In younger adults, Shires and Canizaro¹³⁵ suggest that a saline loss of 4% of the body weight is "mild," 6% to 8% is "moderate," and 10% is "severe." Elderly patients are probably at more risk from a given percentage of saline depletion because of their more limited homeostatic reserve.
3. It has been estimated that, in the younger surgical patient, 4 L of saline are lost before signs of depletion appear, and 4 L of saline are gained before edema develops.¹³⁶ There appear to be no comparable estimates for older patients.

4. The recommended rate of fluid administration depends on the type of fluid that has been lost.

In cases of water depletion, rapid replacement may be hazardous, as cerebral edema can result. Van Zee and Lowry¹²⁹ recommended that only one half of the calculated water deficit should be administered over the first day, with the remainder being replaced over the next 1 to 2 days. Water repletion can be achieved by 5% dextrose infusions intravenously or subcutaneously. Water by the oral or nasogastric route is an alternative.

In cases of volume depletion, rapid replacement is usually desirable. In young patients with severe volume depletion, Shires and Canizaro¹³⁵ recommend an initial infusion rate of 2 L/hr, but state that this rate should be halved as soon as signs of improvement appear. Even then, when rates of infusion are above 1 L/hr, they recommend that a physician be in constant attendance. For older patients with severe volume depletion, Shires and Canizaro point out that the benefits of rapid repletion may be partly offset by the risks of fluid overload, and they state that monitoring by central venous line or a pulmonary artery catheter is desirable.

Wet, dry, or something else?

"Wet, dry or something else" is the title of a recent editorial by Bellamy,¹³⁷ which refers to the "great fluid debate" raging among anesthetists as to whether a patient should be given a liberal or a restricted fluid regimen over the perioperative period. This is of particular relevance to older patients because of their tendency to "homeostenosis," as described at the beginning of this chapter. Bellamy suggests that the wet and dry schools of thought can best be reconciled by individualizing the amount and timing of fluid administration depending on the measured cardiovascular status of the individual patient who is being treated. The key concept is circulatory "optimization," so that fluids are given to those who are depleted while being withheld from those who are fluid overloaded. With the increasing availability to the anesthetist of noninvasive or minimally invasive monitoring devices,¹³⁸ the concept of optimization has passed from a theoretical concept to a practical prospect, and although this is an area of more immediate interest to the anesthetist and intensivist than the referring physician, an awareness of such concepts will assist mutual understanding and has a general applicability outside the fields of surgery and intensive care. A related concept, which also merits a wider readership is that of ERAS (enhanced recovery after surgery). The central idea¹³⁹ of ERAS is to question the conventional approach to perioperative metabolic care, which accepts that a stress response to major surgery (with all its potential adverse effects in patients with homeostenosis) is inevitable. Fearon et al¹³⁹ describe how an ERAS group was set up in 2001 bringing together departments of surgery from Scotland, Sweden, Denmark, Norway, and the Netherlands, around the key concept that "a substantial element of the stress response can be avoided with the appropriate application of modern anesthetic, analgesic, and metabolic support techniques."¹³⁹ Early mobilization and a reduced postoperative stay in the hospital is also a key feature of ERAS, which has attractions for patients and hospital managers alike.

CENTRAL NERVOUS SYSTEM

Postoperative stroke

Postoperative stroke is a relatively rare complication following general surgery, although the incidence rises with age, being around 1% in those over 65 and 3% in the over 80 age group. Although age, cardiac disease, peripheral vascular disease, hypertension, smoking, and previous cerebrovascular events all appear to be risk factors, risk prediction in individual patients is difficult.¹⁴⁰ However, procedures on the carotid arteries, and coronary artery bypass procedures, carry a higher stroke risk than general surgical procedures. In the case of carotid endarterectomy for symptomatic stenosis, the balance of risks and benefits has been worked out in two controlled clinical trials, but the place of surgery in asymptomatic stenosis is still a matter for debate.¹⁴¹⁻¹⁴³

The risk of stroke after open heart surgery appears to be falling but still remains higher than that for general surgery.¹⁴⁴ The improvement in outcome in cardiac bypass patients has usually been attributed to better techniques of extracorporeal circulation, but two studies of postoperative cardiac patients have claimed that the main risk of postoperative stroke is to be found in a small subset of patients with preexisting cerebrovascular or carotid disease.^{145,146}

Postoperative delirium

Postoperative mental impairment following surgery has been a topic of interest for many years. A proportion of older patients will develop acute postoperative delirium. This has an incidence of 10% to 40% depending on the type of operation, on the exact definition of delirium employed, and on whether the study was prospective or retrospective.^{59,147} Many of the precipitants of delirium in the postoperative situation are the same as those causing delirium in the medical patient;¹⁴⁸ they include acute illness (particularly infection), the effects of drugs, and withdrawal from alcohol or psychoactive drugs such as tranquilizers. However, delirium may also be due to premedication (especially with anticholinergics), anesthetic drugs, associated surgical complications, and episodes of late hypoxemia. Diagnosis of the cause of delirium may also be more difficult postoperatively. For instance, delirium tremens developing postoperatively in an emergency surgical patient who has been unwilling or unable to give a history of heavy alcohol intake before admission may be attributed to "surgical" causes.

A painstaking prospective study of the risk factors for postoperative delirium has been carried out.¹⁴⁹ Independent predictors of delirium were: an age of 70 or over; self-reported alcohol abuse; poor cognitive status; poor functional status; markedly abnormal preoperative sodium, potassium, or glucose; noncardiac thoracic surgery; and aortic aneurysm surgery. Although it is sometimes stated that delirium is less common after regional as opposed to general anesthesia, in a large randomized controlled study of patients undergoing elective total knee replacement, Williams-Russo et al¹⁵⁰ found no statistical difference between the incidence of postoperative delirium in patients following general anesthesia (12 of 128, or 9.4%) and that following epidural anesthesia (16 of 134, or 12%).

Although it is good practice to try to minimize risk factors that might cause delirium in elderly surgical patients, and

minimal use of premedication in older surgical patients is one way of doing this, the main clinical requirement is probably to recognize delirium when it occurs and to treat the cause vigorously. However, as detailed in a number of recent reviews,^{151–154} randomized trials of strategies aimed at reducing the incidence of delirium in older people in a variety of clinical situations are now being reported.¹⁵⁵ In a randomized controlled study of hip fracture patients, it was reported that daily visits from a geriatrician reduced the overall incidence of postoperative delirium.¹⁵⁶ Another recent study of hip fracture patients used a nurse-led intervention program, and although the incidence of delirium was not reduced, the duration of delirium episodes was shortened.¹⁵⁷

Although there are still many unanswered questions, the preoperative cognitive status is an important piece of information for the referring physician to pass on to the surgical/anesthetic team, and anesthesiologists are becoming increasingly familiar with cognitive assessment scales such as the Abbreviated Mental Test or the Mini Mental State Examination.² Reasons for recording preoperative cognitive status include:

1. Considerations about whether the patient has the capacity to consent to a surgical procedure¹⁵⁸
2. The fact that preexisting dementia is a major predisposing risk factor for delirium^{151,152} and the need to identify patients who might benefit from intervention^{152–154}
3. The practical consideration that postoperative delirium is easier to diagnose if there is a preoperative baseline

Postoperative dementia

The more difficult question in regard to postoperative mental status is whether dementia ever occurs as a primary event following uneventful surgery and anesthesia. There has been argument about this in the literature for 50 years following pioneering studies that attempted to identify patients who had "never been the same since their operation."^{159,160} Many of the early studies in this area were uncontrolled and did not have a baseline mental assessment measurement.¹⁶¹ Some were also associated with emergency surgical procedures where a number of factors such as hypotension or sepsis might have had a permanent effect on cerebral function that was not directly due to surgery or the anesthetic process.¹⁶¹

In recent years there have been attempts to carry out properly controlled trials, with detailed psychological testing before and after surgery.¹⁶¹ An inevitable limitation of such trials is that the need to make precise preoperative psychological assessments tends to limit them to elective patients who are undergoing anesthesia under carefully controlled conditions and so the risk of postoperative complications of any type is likely to be small. Such formal trials have not demonstrated objectively that anesthesia, whether general or regional, has a permanent effect on cognitive functioning. For instance, in the study of Jones et al,¹⁶² average scores on objective tests of cognitive function before surgery were not statistically significantly different from those obtained 3 months after surgery, although there was a group of 21 out of the 129 patients who reported some subjective changes. It is not clear whether these patients had real but subtle changes in cognitive function that could not be picked up by the

standard tests, or whether they had other conditions such as depression or postoperative fatigue that were not primary dementing processes. A subsequent prospective randomized study of local versus general anesthesia for cataract surgery in patients aged 65 to 98 years found no cognitive decline at 3 months after surgery, and no difference between the two anesthetic groups.¹⁶³

Subsequently, Williams-Russo et al found no long-term (6-month) difference in cognitive functioning between elderly patients undergoing elective orthopedic surgery under regional anesthesia and those undergoing general anesthesia.¹⁵⁰ However, the cognitive function of 12 out of the 231 patients (7 of 114 of those having an epidural anesthetic and 5 of 117 having a general anesthetic) was worse at 6 months than it had been preoperatively. In the absence of long-term follow-up information of nonoperative patients using the same cognitive assessment protocols, it is difficult to assess whether a decline of this amount would have occurred even in the absence of surgery.

Many of the earliest studies could be criticized because they had no controls and/or because preoperative psychological testing was limited or absent. However, the first ISPOCD (International Study of Post-Operative Cognitive Dysfunction) study was specifically designed with these criticisms in mind, and still came to the worrying conclusion that 25.8% of all patients had POCD (postoperative cognitive dysfunction) 7 days after surgery and that 9.9% of patients still had evidence of POCD on the repeat neuropsychological tests carried out at 3 months (with corresponding values for controls being 3.4% and 2.8%).¹⁶⁴ Contrary to expectations, no correlation was found between perioperative hypoxemia and/or hypotension and the subsequent development of early or late POCD. Indeed, despite analyses of the effects of more than 25 other clinical parameters, only age showed a statistically significant correlation with late POCD. Because the first ISPOCD study did not provide definitive guidance with regard to the prevention or treatment of POCD, ISPOCD2 was embarked upon,¹⁶⁵ but many of the key questions remain unanswered.¹⁶⁶

So what should we advise an older patient who is concerned about the risk of cognitive impairment following an elective surgical procedure? This remains a difficult question, and in a recent review of central nervous system dysfunction after noncardiac surgery in old age, led by a senior ISPOCD researcher, no definitive answers were offered.¹⁶⁷ Rather, the following five points were made:

First, CNS dysfunction after anesthesia and surgery is predominantly a problem of old age. Second, postoperative delirium is an established clinical entity, although more research is required into the cause, prevention, and management. Third, POCD cannot yet be regarded as a single defined syndrome. Although there appear to be some older patients who show persistent cognitive dysfunction after an apparently uneventful surgery and anesthesia, the occurrence of cognitive problems in hospitalized nonsurgical patients makes it difficult to determine whether the link between surgery and/or anesthesia is causative. Fourth, more follow-up studies of patients with mild cognitive impairment are needed. Fifth, postoperative CNS dysfunction is a public health problem worthy of a large amount of future study.

ONLINE COMPUTERIZED RISK ASSESSMENT AND GUIDANCE

An interesting technical development in the last decade has been the growth and refinement of multivariable risk assessment tools that are intended to give estimates of surgical risk. Many of these tools are available online, raising the possibility that they might be used during or after a consultation with an older patient contemplating surgery, or perhaps directly by older people themselves. Although there are the usual technical problems in devising tools that can produce accurate predictions in groups of patients, let alone individuals, this is a development of great potential interest to patients, physicians, anesthetists, and surgeons. Two of the better known systems are the group of instruments bearing the POSSUM label, and the EUROSCORE system.

POSSUM stands for Physiological and Operative Severity Score for the enUmeration of Mortality and morbidity. The original POSSUM publication¹⁶⁸ established the principle of building a combined risk score from: (1) "physiologic" risk (based in more recent POSSUM versions on nonsurgical factors such as age, cardiac function, systolic blood pressure, pulse, urea and hemoglobin) and (2) "operative severity" (incorporating information about the procedure, urgency, stage of carcinoma if present, and degree of peritoneal soiling). Since then, a whole POSSUM family has arisen, including P-POSSUM (using updated coefficients from the initial POSSUM tool) O-POSSUM (esophageal procedures), AAA-POSSUM (abdominal aortic aneurysm) and CR-POSSUM (colorectal procedures). CR-POSSUM is of particular interest because colorectal cancer is a common surgical problem in old age with a good chance of surgical cure, but the operation is associated with significant morbidity and mortality. Tekkis and Smith have produced an excellent Web site¹⁶⁹ that not only provides updates of the latest POSSUM instruments (and other risk prediction instruments), but also carries out risk calculations on line. A new index for predicting postoperative mortality in patients aged 80 and over with colorectal cancer has also recently been proposed by Heriot et al.¹⁷⁰

EUROSCORE is a multivariable risk prediction system with a focus on risk prediction after cardiac surgery. The calculations are based on (1) patient-related factors (including age), (2) cardiac-related factors, (3) operation-related factors, and, like POSSUM, the system is housed on an excellent Web site that allows individual patient details to be entered and estimated risks to be calculated.¹⁷¹

There are also a number of Web sites that give more general information about topics of relevance to the older surgical patient. Two such sites are those of the Age Anaesthesia Association (AAA)¹⁷² based in the United Kingdom and the Society for the Advancement of Geriatric Anaesthesia (SAGA)¹⁷³ based in the United States.

SURGICAL AND ANESTHETIC AUDITS

Audit is a process that has been well established for many years among surgeons and anesthetists, and physicians have much to learn from their colleagues in these specialties. A major advance in Britain has been the establishment of a National Confidential Enquiry into Perioperative Deaths (NCE-POD) for the United Kingdom, excluding Scotland, and

the corresponding Scottish Audit of Surgical Mortality (SASM).^{37–39} Annual reports publish illustrative cases where deaths of individual surgical patients might have been avoided, and because about two thirds of all the deaths occurred in patients over the age of 70, they are particularly relevant to the present discussion. Recurrent themes over the years have been the necessity for nonelective patients to be treated in units with appropriate facilities and by staff with the appropriate levels of experience. In some of the individual case reports, potentially preventable factors have included a lack of medical stabilization of patients before surgery. It must be acknowledged, however, that this is a difficult judgment to make because excessive delay before surgery is also associated with increased complication rates in many conditions, including hip fractures. Audits such as NCEPOD and SASM have also stressed the importance of having appropriate organizational structures in place to deal with high-risk groups such as the elderly emergency surgical patient.^{37–39}

KEY POINTS

Surgery and Anesthesia

- The association between age, surgery, and postoperative outcome is a complex one. However, there are scientific and ethical reasons to argue that age by itself should not be a barrier to surgery. Each patient, whatever his or her age, needs an individual assessment so that the potential benefits and risk of surgery and anesthesia can be identified.
- Respiratory problems are a common cause of postoperative morbidity, and an important cause of postoperative mortality. Research into the mechanism of postoperative respiratory complications has allowed a more logical approach to prevention and treatment and helpful guidelines are now emerging, but further research is required to define an optimal set of strategies. Pulse oximetry has made it easier to monitor and treat hypoxemia, but research is still going on into the underlying mechanisms.
- "Cardiac assessment of the noncardiac surgical patient" has been an area of research activity for many years. Guidelines issued by the American College of Cardiology and the American Heart Association (ACC/AHA) in 1996, 2002, and 2007 provide a coherent approach to the management of surgical patients who have coincidental cardiac disease. However, while there is a considerable evidence base supporting these guidelines, further research is needed.
- Undernutrition in middle-aged and elderly surgical patients has only recently attracted the research attention that it deserves. Broad guidelines for identifying older surgical patients at risk and for designing nutritional interventions are available, but the evidence base is still patchy.
- The ERAS (enhanced recovery after surgery) approach is an important development in perioperative care, which is based on the concept that a "substantial element of the stress response can be avoided with the appropriate application of modern anesthetic, analgesic, and metabolic support techniques." Developments in minimally invasive monitoring and therapeutic technologies are complementary to the ERAS approach.
- The causes of acute delirium in surgical patients are similar to the causes in elderly nonsurgical patients. A major and continuing concern over the years, however, has been whether permanent cognitive dysfunction can occur simply as a result of an uneventful anesthetic. The first International Study of Postoperative Cognitive Dysfunction (ISPOCD1) was designed to answer these questions once and for all, but doubts remain.

The establishment of audit, the general acceptance of well-designed guidelines for patient management, and evidence-based approach are examples of general measures that are likely to improve postoperative outcome of all elderly surgical patients. This approach is complementary to the more usually discussed method of risk reduction, which is to target high-risk patients before surgery and to put in maximum effort at this point. It is becoming clear, however, that perfect targeting of patients is unlikely ever to be achieved and that a combined approach involving selective targeting, perioperative and postoperative monitoring, and close attention to the general environment, structure, and interprofessional links of the surgical service is needed.^{26,29} A wider look at the subject might also consider the process of referral in the first place, and would also examine the attitudes of society to high-technology treatment in old age.^{7,8,16,174}

FUTURE TRENDS

Factors increasing the number of surgical procedures in old age

It is highly likely that the technical developments in surgery and anesthesia that have occurred in the recent past will continue in the future and will allow potentially beneficial surgery to be extended to ever older and frailer patients. Such developments are also likely to lead to more favorable attitudes to surgery in old age, so that more patients will be referred. Even if attitudes and techniques were not to change, demographic changes would lead to an increase in surgery in the old and the very old in the next two decades.

Factors decreasing surgical procedures in old age

It is to be hoped that preventive medicine or novel forms of medical therapy will reduce the need for surgical intervention in many conditions. This has already been seen in

regard to modern medical therapy for peptic ulceration. An increase in minimally invasive techniques might also lead to a reduction in the number of major surgical operations being performed. For instance, gallbladder surgery is increasingly being performed by laparoscopic techniques rather than via a laparotomy.⁹

A reduction in surgical activity in some conditions because of better medical therapies or the substitution of less invasive procedures is obviously to be applauded. Much more sinister, however, is the tendency for politicians and health planners to contemplate that some forms of potentially beneficial surgery should be rationed on the basis of age, even though there is very poor evidence that age by itself has any significant effect on the ability of a patient to benefit from a given surgical procedure.

If elderly patients are denied surgery simply on the basis of their age, this is by definition *agist* and such practices need to be challenged vigorously.^{16,34} However, more subtle forms of discrimination might occur because of reduced equity of access of older people to medical and surgical services, and a U.K. Medical Research Council review concluded that "research is needed to examine the extent of differences in access to the NHS according to age group."¹⁷⁵ Although detection of inequity of access is difficult for both medical and surgical conditions, the research is technically simpler in the surgical situation because interventions and endpoints tend to be more clearly defined. Preliminary investigations by Seymour and Garthwaite¹⁶ suggested that inequity of access for surgical patients on the basis of age does exist, but that this interacts with inequity based on patient deprivation. Age-related inequity is probably decreasing with time, but inequity on the basis of deprivation might be more resistant to change.

Measuring Outcomes of Multidimensional Interventions

Paul Stolee

Although frailty in older persons may be associated with an underlying loss of complexity in many physiologic systems,¹ the clinical conditions and geriatric syndromes² that are commonly present in frail older persons are often highly complex. This clinical complexity, including the multiple interacting medical and social concerns, is the challenge and also the joy^{3,4} of geriatrics.

Geriatric services respond to this complexity with comprehensive approaches to assessment, multidisciplinary teams, and multidimensional interventions. Although there may be widespread agreement on the need for comprehensive, multidisciplinary, and multicomponent approaches, there is less agreement on the specific elements of these approaches. It is also not always clear which specific interventions or aspects of care (or combinations thereof) “make the difference” for an individual patient or for groups of patients—hence the references to the “black box” of geriatrics.^{5,6} Clinical complexity and comorbidity have often meant that frail older persons are excluded from many clinical trials.⁷ This is problematic both in terms of the interventions being tested—interventions targeting single diseases often have limited efficacy for the constituency of geriatric medicine patient⁸—and in terms of the results of these studies—which are not generalizable to many frail older patients.^{8,9} Multicomponent interventions have been found to be more effective than single component interventions for frail older patients,¹⁰ but these types of programs are much more difficult to evaluate in the context of clinical trials.⁸ Allore and colleagues¹¹ make a distinction between statistical/analytical considerations and clinical considerations in the design of such trials. Statistical or analysis considerations would suggest one specific intervention should target a single outcome or risk factor (the basis on which power calculations are generally undertaken).⁷ Clinically, however, it makes sense for interventions to target more than one outcome or risk factor, and many interventions are likely to have overlapping effects.¹¹ For studies of interventions for frail older patients, clinical and analytical considerations are particularly at odds.

Given the heterogeneity of the patient population, and the heterogeneity of clinical interventions, it is not surprising that evidence for the effectiveness of geriatric interventions has been hard to establish. Rubenstein and Rubenstein¹² have closely observed this literature over the years, and have pointed out a number of factors associated with an increased likelihood of demonstrating their effectiveness. These include appropriate targeting, more intensive interventions, control over longer-term management, and a usual care control group. To this list, it is suggested here that an additional consideration be added: the selection of meaningful and responsive outcome measures. The selection of appropriate outcome measures for geriatric interventions is not straightforward and has been identified as a priority for research.^{13,14} In the early 1990s, a working group of the American Geriatrics Society achieved a

consensus on measures appropriate for measuring outcomes of geriatric evaluation and management units.¹⁵ The consensus statement recommended 12 physical outcomes, three psychological and social functioning outcomes, and 17 outcomes related to health care utilization and cost (reflecting concerns about future implementation and funding). The number and variety of these measures reflect the multidimensional nature of geriatric care and its potential system impact. While all of these measures may have relevance to specialized geriatric interventions, few, if any, of these measures would be relevant for all patients. The question therefore becomes how to achieve nonarbitrary dimensionality reduction from multidimensional interventions with multidimensional outcomes.

Some of the challenges associated with measuring outcomes of multidimensional geriatric interventions can be gauged by reviewing the outcome measures used in randomized controlled trials of these interventions. Relevant studies were identified from selected major systematic reviews and meta-analyses, beginning with the seminal meta-analysis of comprehensive geriatric assessment services published by Stuck and colleagues in 1993.¹⁶ Other reviews included a review of studies specifically focused on outpatient geriatric assessment,¹⁷ two reviews of studies focused on preventive home visits,^{18,19} and one review that specifically targeted multi-component interventions.¹¹ Collectively, these reviews reported results from 56 randomized controlled trials (Appendix Table 1). Outcome measures were categorized into mortality; self-rated health; health care utilize; three assessment domains—physical function, cognitive function, and psychosocial outcomes; and an “other” category. In these 56 studies (Appendix Table 2),

- Physical function was measured in 54 studies, using 32 different measures, of which 23 were statistically significant.
- Cognitive function was measured in 33 studies, using 11 different measures, of which 6 were statistically significant.
- Psychosocial function was measured in 36 studies, using 29 different measures, of which 12 were statistically significant.
- Self-rated health was measured in 18 studies, using 8 different approaches, of which 4 were statistically significant.
- Health care use outcomes were measured in 45 studies, using 19 different measures, of which 24 were statistically significant.
- Other outcomes were measured in 32 studies, using 16 different measures, producing statistically significant results in 13 studies.

The collective data illustrate several points. Geriatric services were associated with statistically significant benefits in

each category of outcome measure in at least some studies, but no category of outcome was significantly improved in all studies. None of the studies reported significant improvement in all of the outcomes measured. The review also highlights the range of outcomes considered meaningful, and plausible, for geriatric services. Death is a clear end point, and mortality is amenable to summation and comparison in meta-analyses but is not necessarily the most meaningful parameter for programs serving a frail clientele for whom life expectancy is limited.⁷ Indicators related to health care use are of great relevance to the health system and while they may relate to an older person's quality of life (for example, for some older persons, quality of life may be higher in community settings than in a long-term care home), these are at best indirect measures of quality of life from a patient's perspective. Within each of the other domains, there is further evidence of heterogeneity—each domain has multiple aspects, and a large variety of instruments and approaches have been used to measure these. Even within the "other" category, an outcome such as "falls" is itself a multifactorial syndrome.¹¹

Geriatric assessment outcomes and quality of life measures

The assessment domains commonly measured in geriatric intervention studies can be seen as major components of quality of life. If outcomes commonly targeted by multidimensional geriatric interventions can be considered collectively as a reflection of quality of life as the overarching domain of importance, then a sufficiently comprehensive quality of life measure could be a good choice as an outcome measure for common use in geriatric intervention studies. A candidate measure is the Medical Outcomes Study 36-Item Short Form General Health Survey (SF-36),²⁰ which has been very widely used as a health-related measure of quality of life.²¹ Unfortunately, testing of its use with older persons has not been extensive,⁷ and results of these studies suggest the utility of this measure in geriatrics may be limited.²² The development of a measure that could achieve wide acceptance has been hindered by the lack of a common conceptual or theoretical understanding of the meaning of quality of life and by lack of agreement on its constituent elements.²³ Walter Spitzer has argued, however, that the development of a "gold standard" measure is possible even for a subjective construct such as quality of life: "We fail to have a Gold Standard...because no one has made it his or her primary objective to develop a Gold Standard either for measures of health status or for measures of quality of life...I believe Marilyn Bergner and her co-workers have a sufficiently long head start that they deserve support from all the rest of us."²⁴ Although Spitzer pointed to the work of Marilyn Bergner on the Sickness Impact Profile²⁵ as the best candidate for further development as a gold standard quality of life measure, Bergner turned out not to share this view: "The bitter truth is that there is no gold standard, there is unlikely ever to be one, and it is unlikely to be desirable to have one."²⁶

Standardized assessment systems

Another approach that aims at providing a comprehensive assessment of health and social functioning is the use of a standardized assessment system, of which the interRAI Minimum Data Set (RAI/MDS) assessment systems are the most prominent. The interRAI instruments are a comprehensive

assessment and problem identification system developed by an international consortium of researchers.²⁷ The original interRAI assessment was developed for long-term care homes (MDS 2.0) in response to U.S. government regulations (OBRA) aimed at improving nursing home quality.²⁸ The interRAI Home Care assessment instrument (RAI-HC, or MDS-HC),²⁹ has been developed for home care settings. Other versions have been developed for use in mental health,³⁰ acute care,³¹ palliative care,³² and other settings. RAI assessment items include personal items, referral information, cognition, communication and hearing, vision, mood, behavior, physical functioning, continence, disease diagnoses, preventive health measures, nutrition status, oral health, skin condition, environmental assessment, and formal and informal service use. Specific scales have been derived from RAI assessment items, including measures of activities of daily living (ADLs),³³ cognitive impairment,³⁴ depression,³⁵ and pain.³⁶ Application of the RAI system has been linked with reduced institutionalization and functional decline.³⁷ The approach to data collection is one of "best available information." This may be done by interview or observation of the older person, by interview of the caregiver (paid or unpaid), or through chart review. While this approach may suggest the possibility of inconsistent data collection, it should be noted that there is growing support for outcome measurement that incorporates a variety of perspectives, including self-report, proxy, and objective measures.^{7,38}

An important advantage of the interRAI system is that it allows for consistency in data collection across sites and also across types of care settings—the various versions of the RAI instruments use similar questions and data collection approaches. This advantage is particularly strong when contrasted with the alternative practice of trying to achieve consensus on the "battery" of measures that should be used in clinical practice and outcome evaluation. Even if a particular group achieves consensus on a set of tools (e.g., Dickinson, 1993),³⁹ another group is likely to agree on a different set (e.g., Pepersack, 2008),⁴⁰ and it is unlikely that all members of either group will be consistent in their use of the prescribed measures.

A limitation of the interRAI assessment systems is the same as for other approaches aiming to achieve a comprehensive, multidimensional assessment: not all of the assessment areas will point to relevant clinical outcomes for all patients, and it would still be necessary to identify the specific outcomes of interest for a specific intervention or for a specific patient. In the interRAI system, this is addressed to some extent through the use of "triggers" that are used to identify issues warranting further investigation, referred to as resident assessment protocols (RAPs)⁴¹ or clinical assessment protocols (CAPs).⁴²

The inadequacies of outcome measures have often been suggested as a possible explanation for negative or ambiguous results of intervention trials. This is illustrated in the following comments from several studies:

"The fact that we observed no significant differences in the prevention of decline in activities of daily living or cognitive function in our study may be explained in several ways ... (including) ... insensitivity of our outcome measures to improvements that did occur."⁴³

"There might, however, have been positive effects which we could not detect. Our measurements on the health state may not have been sensitive enough to show relevant effects."⁴⁴

"The outcome variables may have been wrongly chosen to measure the effects of this kind of program."⁴⁵

"Common measures of disability may be insensitive to change in the outpatient setting of the day hospital."⁴⁶

"For most of the published programs, efficacy was tested on questionable indicators (e.g., mortality, health services use), on a crude proxy for functional decline (e.g., admission to a nursing home), or using a global unresponsive measure of functional autonomy."⁴⁷

"It is possible that the measures we used to evaluate health related quality of life lacked sufficient sensitivity."⁴⁸

A point made clear in the appendix is the lack of consensus and consistency in the selection of outcome measures for geriatric interventions. The heterogeneous and individualized nature of both geriatric programs and their patients makes such a consensus unlikely. Williams has argued strongly for the individualized nature of geriatric care:

"It is clear, first, that there are immense individual differences among older people, more than at any earlier age, in virtually all types of characteristics—physical, mental, health, and socioeconomic. Thus when we consider what quality of life means to an older person and what features of quality of care may contribute to that quality of life, we *must* arrive at highly individualized conclusions. This principle is of course recommended for all ages, but it may not be so essential in some aspects of earlier life as it is in the lives of older people."⁴⁹

Individualized outcome assessment

One attempt to reflect the individualized nature of older persons in outcome measurement is the use of clinical judgment, with such measures as the Clinical Global Impression⁵⁰ or Clinician Interview-Based Impression.⁵¹ These approaches allow a clinically experienced rater to reflect individual characteristics and health concerns in an overall assessment of improvement. These measures provide a role for informed clinical judgment in outcome assessment, but do not provide details on the specific aspects of a patient's health or quality of life that may have been improved as a result of an intervention.

The individualized nature of geriatric care can also be addressed through individualized outcome measures. Individualized outcome measures allow for specific measurement domains to be selected that are most relevant for individual patients. Individualized measures can be used to generate clinical insights into the nature of the effects of geriatric interventions, and particularly into understanding the effects of Alzheimer's disease treatment.⁵²

"To the extent that standard measures do not record ways in which important improvements or deteriorations occur, they miss an opportunity to enhance our understanding of what Alzheimer's disease looks like when it gets better, and to provide clinical correlates of supposed pharmacologic changes. In this regard, I believe that the developments of individualized outcome measures may provide some useful insights into patterns of clinically important changes and heterogeneous disease conditions."⁵³

A number of fully or semiindividualized measures have been developed for use in a variety of settings.⁵⁴ The most widely known of these is likely goal attainment scaling (GAS), which was proposed by Kiresuk and Sherman in the 1960s as a tool for evaluating human service and mental

health programs.⁵⁵ GAS is an individualized goal-setting and measurement approach that enables users to individualize goals to the needs, concerns, and wishes of a specific patient, and also to individualize the scale on which attainment of these goals is measured. GAS accommodates multiple individualized goals, and also permits calculation of an overall score that enables comparisons between individuals or between groups of patients. GAS differs from other individualized measures in two important respects. First, GAS allows for the individualization of the scales on which goals are measured and the goals. Second, GAS requires a judgment to be made at the beginning of treatment on the level of goal attainment that will be considered to be a successful outcome (rather than, for example, subjectively rating achievement of outcome on 10-point scales, as in the Canadian Occupational Performance Measure).⁵⁶

Individual goals are scaled on a five-point rating scale of expected outcomes, from -2: much less than expected; -1: somewhat less than expected; 0: expected level (program goal); +1: somewhat better than expected; +2 much better than expected. The steps to construct a GAS "follow-up guide" are detailed in Table 39-1. An example follow-up guide is provided in Table 39-2. Goals can be weighted in terms of their relative importance, although equally weighted goals are generally recommended.⁵⁷ A summary goal attainment score (T score) allows comparison of outcomes for different

Table 39-1. Developing a Goal Attainment Scaling (GAS) Follow-up Guide

1. Identify the issues that will be the focus of treatment.
 - Focus on problems that are important to the client and that the intervention is expected to change.
2. Translate the selected problems into goals—aim for at least three.
 - It must be possible to observe or elicit the client's level of attainment on these goals at the time of follow-up.
3. Choose a brief title for each goal.
4. Select an indicator for each goal.
 - The indicator is the behavior or state that clearly represents the goal, and can be used to indicate progress in meeting the goal.
5. Specify the expected level of outcome for the goal.
 - Predict the status of the client on the selected goal at the end of treatment or at a prespecified follow-up time.
6. Describe the client's current status in relation to the goal indicator.
 - Typically this is at the "somewhat less" or "much less" level. This is usually designated with a "checkmark" on the guide.
7. Specify the remaining "somewhat better" and "somewhat less" than expected levels of outcome for the goal.
 - These are more or less likely but still realistically attainable outcomes.
8. Specify the remaining "much better" and "much less" than expected levels of outcome.
 - Achievable, still realistic limits of the indicator.
 - Represent outcomes that might be expected 5%–10% of the time.
9. Repeat scaling steps for each of the goals.
 - Try not to skip any of the five levels for each goal.
10. Although GAS is an individualized approach, descriptors, items, or scores from standardized measures may be useful in scaling some GAS goals.
11. On follow-up, rate the level for each goal that best reflects the client's current state. This is usually designated with an asterisk on the guide.
12. Determine the GAS follow-up score.

patients or for groups of patients. GAS scores for a large group of patients are expected to have a mean of 50 and a standard deviation of 10. The GAS score can be calculated using a formula⁵⁵ or looked up in a table (e.g., Zaza, et al, 1999)⁵⁸ if goals are unweighted. A standardized menu approach has been proposed as a means to facilitate goal setting.⁵⁹

The first published use of GAS in geriatrics was in 1992.⁶⁰ Since then, the measurement properties of GAS in geriatric settings have been tested in a number of studies.⁶¹ GAS has been found to have good interrater reliability (intraclass correlation coefficients of 0.87 to 0.93)^{60,62,63} and to correlate with standardized measures such as the Barthel Index and with global ratings.⁶³ Of particular significance for outcome

measurement in geriatrics is that GAS has consistently been found to be very responsive to change. This has been demonstrated in before and after studies^{3,62-65} and in the context of a randomized controlled trial.⁶⁶ GAS has been used as an outcome measure in randomized trials of a geriatric assessment team⁶⁷ and of an antedementia medication.^{68,69} In both cases, GAS measured statistically significant benefits of the intervention. The clinical utility of GAS in geriatrics has been assessed using qualitative methods.⁷⁰

GAS is a measure that seems to be a particularly strong fit for the measurement needs and constraints of geriatric interventions. It has potential both as a research measure and as a clinical tool. Although goal priorities may differ among patients, caregivers, and clinicians,^{71,72} involving diverse perspectives can generate rich insights into the interventions that will most benefit older patients, and into the effects of these interventions.

CONCLUSION

Measuring the outcomes of multidimensional geriatric interventions presents significant challenges. These challenges have resulted in frail older patients often being excluded

from studies of interventions from which they might benefit, and in potential benefits of geriatric interventions not being detected by the measures used. After a quarter century of controlled trials in geriatrics, it seems unlikely or perhaps even inappropriate that consensus will be achieved on a set of standardized measures that will have wide applicability. For consistency of data collection and to provide comprehensive assessment information, there is a strong rationale to move toward standardized health information systems such as the interRAI. In measuring outcomes, Goal Attainment Scaling is an effective and clinically useful approach to addressing the challenges of outcome measures for heterogeneous, frail older patients.

ACKNOWLEDGMENTS

The author is grateful to Sarah Meyer for assistance in reviewing background literature for the development of this paper.

Table 39-2. Goal Attainment Scaling Follow-up Guide

Attainment Levels	Mobility	Activities of Daily Living (ADLs)	Future Care Arrangements
Much better than expected +2	>200 yards with walker, or independent with cane	Independent in ADLs and instrumental ADLs	Home with no need for home support
Somewhat better than expected +1	independent with walker (100-200 yards)*	Independent in ADLs and instrumental ADLs, except outside activities	Home with weekly home support
Expected level (program goal) 0	independent with walker, limited distance (< 100 yards)	Independent with ADLs, needs help with meal preparation, housework, and transportation*	Home with home support 2-3 times/week*
Somewhat less than expected -1	Walker with assistance ✓	Dependent in ADLs, except dressing ✓	Discharged to nursing home
Much less than expected -2	Bedfast	Dependent in ADLs, including dressing	On rehabilitation unit >7 weeks ✓
Comments			Patient does not wish nursing home placement

OUTCOME MEASURES									
Study	Setting	Study Description	Physical Function	Cognitive Function	Psychosocial	Self-Rated Health	Mortality	Health Care Utilization	Other
Counsell et al, 2000 ⁴⁸	GEMU USA	3 years N = 1531 Tested whether a multicomponent intervention called Acute Care for Elders improved functional outcomes and the process of care in hospitalized elderly patients	Mobility index, ⁴⁹ Physical Performance and Mobility Examination (PPME), ⁵⁰ Charlson comorbidity score, ⁵¹ IADLs, ³¹ Katz Index ² decline at 12 months favoured intervention group ($P = .037$); fewer intervention patients experienced the composite outcome of either ADL decline from baseline or nursing home placement at discharge ($P = .027$); persisted at 1 year follow-up ($P = .022$)	Pfeiffer Short Portable Mental Status Questionnaire ⁵²	CES-D (short form), ⁵³ physicians more often recognized depression in intervention group than controls ($P = .02$), patient satisfaction with hospitalization ⁵⁴ was higher in intervention group ($P = .001$), along with caregiver satisfaction ($P < .05$)	Overall health status, APACHE II ²⁰		Reason for hospitalization, time from admission to initiation of discharge planning, social work consultations, orders for bed rest, physical therapy consults, application of physical restraints, length of stay, costs, intervention, physicians significantly reported no difficulty getting treatment plans carried out ($P = .010$), and noted that they were often informed of useful information on discharge plans ($P = .015$), additionally, intervention nurses reported higher satisfaction with extent of care ($P = .001$) and extent to which issues were discussed ($P = .001$)	Medications
Epstein et al, 1990 ⁵⁵	HAS USA	1 year N = 600 Studied the effectiveness of consultative geriatric assessment and follow-up for ambulatory patients	Physical examination, new diagnoses, functional impact of patient diagnosis, Katz Index, ² OARS (IADLs), ⁵⁶ SIP ⁵⁷	MMSE ¹⁹ showed significantly better cognitive function at 3 months than controls ($P < .05$) and those over 80 years improved more than those who were younger ($P < .05$)	Social support, social activities, ⁵⁸ coping style, emotional health adapted from RAND Health Insurance Study, ⁵⁹ satisfaction ⁶⁰ showed significant benefits for those that were in the lowest quintile of functional health at 1 year ($P < .05$)	Changes in health status, overall perceived health with adapted RAND ⁶¹	No significant difference	Nursing home placement, incidence of hospitalization, costs, length of stay, office visits, use of diagnostic tests	Medications, nutrition, economic issues, environmental issues
Fabacher et al, 1994 ⁶²	HAS USA	1 year N = 254 Examined the effectiveness of preventive home visits in improving health and function in older adults	Physical examination, health behaviour inventory, gait and balance assessment, ⁶³ Katz Index, ⁶⁴ IADLs ³¹ were significantly higher in intervention group at 1 year ($P < .05$)	MMSE ¹⁹	GDS ²⁸			Intervention group had significantly increased likelihood of having a primary care physician at 1 year ($P < .05$)	Environmental hazards, falls, immunization rates significantly improved in intervention group at 1 year ($P < .05$), non-prescription drug use increased significantly for control group at 1 year ($P < .05$)
Fretwell et al, 1990 ⁶⁵	IGCS USA	6 months N = 436 Assessed whether early interdisciplinary geriatric assessment could prevent mental, physical and emotional decline without increasing hospital stay or costs	Katz Index ⁶⁶	MMSE ⁶⁷	Zung Self-Rating Depression Scale (SDS), ⁶⁸ treatment groups emotional function improved ($P = .045$) at 6 weeks		No significant difference	Costs, number of days in institution	
Gayton et al, 1987 ⁶⁹	IGCS Canada	6 months N = 222 Evaluated the effects of a interdisciplinary geriatric consultation team in an acute care hospital	Barthel Index, ⁷⁰ Level of Rehabilitation Scale (LORS) ⁷¹	Pfeiffer Short Portable Mental Status Questionnaire ⁴			No significant difference	Health care utilization, number of days in institution, place of residence at discharge	
Gilchrist et al, 1988 ⁷²	GEMU UK	22 months N = 222 Tested the efficacy of an orthopaedic geriatric unit in managing elderly women with proximal femoral fractures	General medical assessment, hip and chest X-ray, more patients in study group were found to have new medical disorders than those in control (95% CI = 3.4 to 28.5, $P < .025$)	Mental function ^{73,74}			No significant difference	Placement of patients, length of hospital stay	
Gunner-Svensson et al, 1984 ⁷⁵	IGCS Denmark	11 years N = 343 Assessed whether social medical intervention would help to avoid relocation in nursing homes	Unspecified questions on somatic symptoms, functions, activities	Unspecified questions on mental condition with emphasis on dementia	Unspecified questions on communication		No significant difference	Housing, medical contact, help in illness, relocations significantly differed in favour of the intervention group for women over 80 years old ($P < .05$)	Diet, demographic information (age, sex, and marital status)

OUTCOME MEASURES									
Study	Setting	Study Description	Physical Function	Cognitive Function	Psychosocial	Self-Rated Health	Mortality	Health Care Utilization	Other
Hall et al, 1992 ⁷⁶	HAS Canada	3 years N = 167 Evaluated a local health program (long-term care program of the B.C. Ministry of Health) to assist frail elderly persons living at home	ADLs, chronic disease		Memorial University Happiness Scale, ⁷⁷ UCLA Loneliness Scale, ⁷⁸ Social Readjustment Rating Scale, ⁷⁹ social support	MacMillan Health Opinion Index, ⁸⁰ Health Locus of Control (HLC) ⁸¹	Significantly higher survival rates for those in the treatment group at 3 years ($P = .054$)	At 2 years, significantly more of the treatment group remained at home ($P = .02$), and at 3 years ($P = .04$)	Smoking, alcohol consumption, nutrition, number of prescription medications
Hansen et al, 1992 ⁸²	HHAS Denmark	1 year N = 344 Evaluated a nurse and physician led follow-up model of home visits to elderly patients after discharge from hospital	General medical data		Unspecified social data		No significant difference	Number of days in institutions, number of readmissions to the hospital, intervention patients were admitted to a nursing home significantly less than controls ($P < .05$) at 1 year follow-up	
Harris et al, 1991 ⁸³	GEMU Australia	1 year N = 267 Aimed at testing the differences in medical management and clinical outcome between a designated geriatric assessment unit and two general medical units.	ADLs, ⁸⁴ radiology and pathology tests, discharge diagnosis	MMSE ¹⁹			No significant difference	Accommodation prior to hospitalization, length of admission, accommodations at discharge	Procedures performed, medications on admission and discharge showed that patients in the geriatric assessment unit were discharged on fewer drugs ($P < .04$)
Hebert et al, 2001 ⁸⁵	HAS Canada	1 year N = 503 Tested the efficacy of a multidimensional program aimed at functional decline of elderly people	Functional Autonomy Measurement System (SMAF), ⁸⁶ hearing		General Well-being Schedule, ^{87, 88} Social Provisions Scale ⁸⁹		No significant difference	Admissions, use of health services	Medications, risk of falls
Hendrikson et al, 1984 ⁹⁰	HAS Denmark	3 years N = 285 Measured the effects of preventative community measures for elderly people living at home					Significantly more deaths in control group than in intervention group ($P < .05$)	Contact with general practitioners, or primary care practitioners, significantly more medical calls registered to control group ($P < .05$), significant reduction in hospital admissions in intervention group ($P < .05$), admissions into nursing home significantly larger in control group ($P < .05$)	
Hjort Sorensen & Sivertsen, 1988 ⁹¹	HAS Denmark	3 years N = 585 Tested the effectiveness of a socio-medical intervention aimed at relieving unmet medical and social needs of elderly people	ADLs and IADLS ⁹²		Quality of life	Self-rated health	No significant difference	Practical help received, need for more help, number of institutionalizations	
Hogan et al, 1990 ⁹³	IGCS Canada	1 year N = 132 Conducted a trial of a GCS in an acute care setting	Improved Barthel Index ⁹⁴ at 1 year in intervention group ($P < .01$)	Mental Status Scale ⁹⁵			Intervention had improved 6 month survival ($P < .05$) at 4 months	Number of days in institution, living arrangements post discharge	
Hogan et al, 1987 ⁹⁶	IGCS Canada	1 year N = 113 Assessed the effectiveness of a GCS on outcomes related to hospital stay	Barthel Index ⁹⁴ .	Improvement in Metal Status Score ⁹⁵ in intervention group ($P < .01$)			Lower short-term death rates in intervention group ($P < .05$)	Costs, number of days in institution, number of referrals to community services at discharge higher in intervention group ($P < .005$)	Falls, treatment group received fewer medications at discharge ($P = .05$)
Inouye et al, 1999 ⁹⁷	GEMU USA	2 years N = 852 Evaluated a multicomponent strategy for the prevention of delirium in hospitalized older patients	Katz Index, ² Jaeger vision test, whisper test, ⁹⁸ APACHE II ²⁰	Confusion Assessment Method, ⁹⁹ MMSE, ¹⁹ Digit Span Test, ¹⁰⁰ modified Blessed Dementia Rating Scale ^{101, 102} showed significantly less incidence of dementia ($P = .02$) and low total number days of delirium ($P = .02$) and total number of episodes ($P = .03$) in intervention group					Adherence to intervention

OUTCOME MEASURES									
Study	Setting	Study Description	Physical Function	Cognitive Function	Psychosocial	Self-Rated Health	Mortality	Health Care Utilization	Other
Jensen et al, 2003 ¹⁰³	ICGS Sweden	34 weeks N = 362 Assessed the effectiveness of a multifactorial program for the prevention of falls and injury on elderly with high and low levels of cognition	Hearing and vision, Barthel ADL Index, ^{70, 104} Mobility Interaction Fall Chart, ¹⁰⁵ DiffTUG (measures ability to walk and carry a glass of water) ¹⁰⁶	MMSE ¹⁹					Environmental hazards, medications, falls (number of residents suspected of falling, number of falls, and time to occurrence of first fall significantly longer in high MMSE intervention group ($P < .001$)), fall related injuries using Abbreviated Injury Scale ¹⁰⁷ showed increased injuries in low MMSE control group ($P = .006$)
Kennie et al, 1988 ¹⁰⁸	IGCS UK	18 months N = 144 Assessed whether prospective management could reduce various outcome measures in females with femoral fractures	Katz Index, ² ADLs significantly better in treatment group ($P = .005$)	Pfeiffer Short Portable Mental State Questionnaire ⁴				Significantly fewer discharges of patients in treatment group to NHS or private nursing care ($P = .03$)	
McEwen et al, 1990 ¹⁰⁹	HAS UK	20 months N = 296 Tested the effectiveness of a nurse-run screening program	McMaster health index, ¹¹⁰ functional and problem evaluation interview ¹¹¹		Nottingham health profile, ¹¹² Philadelphia Morale Scale, ¹¹³ significantly better in test group with respect to attitude in own ageing ($P < .01$) and loneliness ($P < .05$) at 20 month follow-up, emotional reaction ($P < .05$) and isolation ($P < .01$) perceived to be worse in control group at 20 month follow-up.		No significant difference	Contact with health and social services	Compliance with medication
Melin et al, 1992 ¹¹⁴	HHAS Sweden	6 months N = 249 Assessed the impact of a primary home care intervention program on patient outcomes after discharge from a short-stay hospital	Katz Index, ^{17, 66, 115, 116} IADLs ^{117, 118} improved at follow-up in study group ($P = .04$), medical disorders declined in the study group at 6-month follow-up ($P < .001$)	MMSE ^{19, 119}	Social function ratings on activities attended, contacts made during preceding week was significantly higher in study group ($P = .01$) at 6 month follow-up			Number of admissions to short term care and rehabilitative care hospitals, number of inpatient care days and outpatient care days showed that study group spent more days in home care than controls ($P < .001$) but fewer days in long-term hospital care than controls ($P < .001$)	Number of medications increased in control group at 6 month follow-up ($P = .02$)
Newbury et al, 2001 ¹²⁰	HAS Australia	2 years N = 100 Measured the effectiveness of a nurse-led health assessment of elderly people living independently at home	Hearing and vision, physical condition, Barthel Index, ⁷⁰ mobility	MMSE ¹⁹	Unspecified social factors, SF-36 Quality of Life Questionnaire ¹²¹ and GDS-15 ¹³ showed significant improvement in intervention group at 1 year ($P = .032$ and $P = .05$, respectively)	Self-rated health	No significant difference	Housing, admission to institutions	Medication, compliance, vaccinations, alcohol and tobacco use, nutrition, number of problems in each group, number of participants with problems, number of self-reported falls showed significant improvement in intervention group ($P = .033$)
Pathy et al, 1992 ¹²²	HAS UK	3 years N = 725 Evaluation of a case finding and surveillance program of elderly patients at home	General health status, Townsend Score ¹²³		Nottingham health profile Life Satisfaction index ¹²⁴	Self-rated overall health significantly higher in intervention group ($P < .05$)	Significantly lower in intervention group ($P < .05$)	Use of services (domiciliary visits, contact with general practitioner, chiropody and attendance allowance), questions about Meals on Wheels and home help, hospital admissions did not differ but duration of stay was shorter in intervention group ($P < .01$)

Appendix Table 1. Randomized Controlled Trials of Geriatric Interventions and Associated Outcome Measures—Cont'd

OUTCOME MEASURES									
Study	Setting	Study Description	Physical Function	Cognitive Function	Psychosocial	Self-Rated Health	Mortality	Health Care Utilization	Other
Powell & Montgomery, 1990 ¹²⁵	GEMU Canada	3 months N = 203 Studied the effectiveness of an inpatient geriatric unit at a hospital	Functional activity	Cognitive function improved between discharge and home visit in intervention group* *No p-value given	Depression, life satisfaction		Fewer patients died in intervention group* * No p-value given	Duration of stay longer in intervention group but overall admissions were lower* * No p-value given	
Reuben et al, 1999 ¹²⁶	OAS USA	15 months N = 363 Tested the effectiveness of outpatient CGA coupled with an adherence intervention	NIA lower extremity battery, ¹²⁷ Functional Status Questionnaire, ¹²⁸ MOS SF-36 ^{129, 130} showed change scores for treatment group in physical functioning ($P = .021$), RAS and BDD ¹³¹ significantly lower in treatment group ($P = .006$), Physical Performance Test ⁴⁷ showed treatment effect ($P = .019$)	MMSE, ¹⁹ mental health summaries showed significant treatment effect ($P = .006$)	Patient Satisfaction Questionnaire, ¹³² Perceived Efficacy in Patient-Physician Interaction scale, ¹³³ treatment group benefited on social functioning scale ($P = .01$), and emotional well being ($P = .016$) at 15 months	Treatment group reported less pain ¹²⁹ than control group ($P = .043$)	No significant difference		Falls
Rubenstein et al, 1984 ¹³⁴	GEMU USA	2 years N = 123 Assessed the effectiveness of a geriatric evaluation unit in improving patient outcomes	IADLs, ³¹ Personal self-maintenance scale ³¹ showed significant improvement in study patients ($P < .01$), almost 5 times as many new diagnoses were made in study group than controls ($P < .001$)	Kahn-Goldfarb Mental Status Questionnaire ¹²	Philadelphia Geriatric Morale Scale ¹¹³ showed significant improvement at 1 year follow-up for study patients ($P < .05$)		Mortality rate was significantly higher in control group at 1 year follow-up ($P < .005$)	Utilization costs, initial placement at discharge; significantly higher study patients were discharged to their home than controls ($P < .05$), more than twice as many controls were discharged to a nursing home ($P < .05$), study patients underwent more specialized screening examinations and consultations than controls ($P < .001$), at 1 year follow-up controls averaged more than twice as many nursing home days ($P < .05$)	Medications
Rubin et al, 1992 ¹³⁵	HHAS USA	1 year N = 200 Studied the effectiveness of a GEM program on health care charges and Medicare	Medical history, Katz Index, ⁶⁶ IADLs	Sensory and communication abilities, ¹³⁶ MMSE ⁵⁶	Social history, affective and behavioural status ¹³⁶			Experimental group was significantly more likely to receive home health care than control group ($P < .01$), control group had significantly greater inpatient charges ($P < .03$) and Medicare reimbursement ($P < .005$)	Medications
Rubin et al, 1993 ¹³⁷	OAS USA	1 year N = 200 Assessed the effect of outpatient GEM on physical function, mental status and well-being	Katz Index, ⁶⁶ IADLs ⁴⁶ showed greater improvement and less decline in treatment group at 1 year ($P = .038$)	MMSE ⁵²	Life Satisfaction Index-Z (LSI-Z) ¹³⁸	Self-perception of health status (OARS) ⁵⁶ was significantly higher for the treatment group ($P = .006$); perceived less decline in health ($P = .007$) and fewer activity limitations ($P = .024$)	No significant difference	No significant differences between groups on long-term nursing placements	
Shaw et al, 2003 ¹³⁹	IGCS UK	1 year N = 274 Determined the effectiveness of multifactorial intervention after falls in older patients with cognitive impairments and dementia	General medical examination, mobility assessment, ¹⁴⁰ assessment of walking aids, feet and footwear ¹⁴¹				No significant difference	Fall related attendance at accident or emergency department, fall related hospital admissions	Number of falls, time to first fall, injury rates, medications, environmental hazards ¹⁴²
Silverman et al, 1995 ¹⁴³	OAS USA	1 year N = 442 Studied the process and outcome of outpatient CGA	ADLs, ^{3,144} Barthel Index, ⁹⁴ urinary and bowel incontinence identified significantly more often in study group ($P < .0001$)	MMSE, ¹⁹ Clinical Dementia Rating Scale (CDR), ¹⁴⁵ cognitive impairment identified significantly more often in study group ($P < .0001$)	Measures of social support, patient satisfaction with care, ¹⁴⁶ clinical depression and anxiety sections of Diagnostic Interview Schedule (DIS) ^{147, 148} showed significantly lessened anxiety in study group at 1 year ($P = .036$), depression identified significantly more often in study group ($P = .0004$)	Self-perceived health status		Nursing home institutionalizations	Changes in participant status, caregiver stress ¹⁴⁹ was significantly less at 1 year in study group ($P = .002$)

Appendix Table 1. Randomized Controlled Trials of Geriatric Interventions and Associated Outcome Measures—Cont'd

OUTCOME MEASURES									
Study	Setting	Study Description	Physical Function	Cognitive Function	Psychosocial	Self-Rated Health	Mortality	Health Care Utilization	Other
Strandberg et al, 2001 ¹⁵⁰	OAS Finland	5 years N = 400 Determined the effectiveness of a multifactorial prevention program for composite major cardiovascular events in the elderly with atherosclerotic disease	General medical examination, cardiovascular tests (blood pressure, heart rate and 12-lead resting electrocardiogram), blood tests, physical function, ¹⁵¹ clinical events	Consortium to Establish a Registry for Alzheimer's Disease tool (CERAD) ¹⁵²	Health related quality of life using the 15D, ^{153, 154} Zung Questionnaire		No significant difference	Health care resource utilization, hospitalizations, permanent institutionalization	
Stuck et al, 1995 ¹⁵⁵	HAS USA	3 years N = 414 Evaluated the effect of in-home CGA and follow-up of elderly people	Geriatric Oral Health Assessment Index, ⁸ balance and gait, ¹⁵⁶ vision and hearing, ⁹ treatment group required less assistance in basic ADLs ¹¹ ($P = .02$) at 3 years	Kahn-Goldfarb Mental Status Questionnaire ¹²	GDS, ¹³ extent of social network and quality of social support ¹⁵⁷			Costs, significantly more visits to general practitioner among intervention group patients ($P = .007$), nursing home admission higher among control group patients ($P = .02$)	Medications, environmental hazards, percentage of ideal body weight ¹⁵⁸
Stuck et al, 2000 ¹⁵⁹	OAS Switzerland	3 years N = 791 Examined the effects that preventive home visits with annual multidimensional assessments have on functional status and institutionalization between high- and low-risk older persons	Gait and balance performance, ⁶³ ADLs and IADLs ¹¹ ; intervention group at low baseline were less dependent in IADLs (95% CI = 0.3 to 1.0, $P = .04$)	MMSE ¹⁹	GDS ¹³	Self perceived general health, ¹⁶⁰ self reported chronic conditions		Nursing home admission was higher in high-risk intervention group ($P = .02$)	Medication use ¹⁵
Teasdale et al, 1983 ¹⁶¹	GEMU USA	1 year N = 124 Assessed whether a geriatric assessment unit using a multidisciplinary team approach impacted patient placement outcomes					No significant difference	Source of admission, placement at discharge, location 6 months post admission, location of patient after discharge, mean duration of stay was significantly longer in intervention group ($P < .001$)	
Thomas et al, 1993 ¹⁶²	IGCS USA	1 year N = 120 Tested the effectiveness of a inpatient geriatric consultation team	Functional Assessment Inventory (FAI) ¹⁶³ : physical and activities scales, Katz Index ²		FAI: psychological and social scale ¹⁶³		Significantly more patients died in control group at 6 months ($P = .01$)	Referrals to community service, number of post discharge general practitioner visits, discharge destination, number of days in institution, control group had significantly more readmissions ($P = .02$)	FAI: economic scale ¹⁶³
Timonen et al, 2002 ¹⁶⁴	OAS Finland	9 months N = 68 Studied the effects of a multi-component training program focused on strength training after hospitalization	Diseases, strength and physical performance tests, strength of knee extension significantly better after intervention in study group at 3 and 9 months ($P = .004$ and $P = .009$, respectively), isometric hip abduction strength significantly improved in intervention group at 3 months ($P = .004$), maximum walking speed improved significantly at 3 and 9 months in study group ($P = .004$ and $P = .022$, respectively), Berg Balance Scale ¹⁶⁵ significantly better in study group at 3 and 9 months ($P = .004$ and $P = .001$, respectively)						Medication
Tinetti et al, 1994 ¹⁶⁶	HAS USA	1 year N = 301 Evaluated the effect of multiple-risk-factor reduction on incidence of falls	Presence of chronic disease, ADLs, ³¹ vision ¹⁶⁷ and hearing, ¹⁶⁸ Sickness Impact Profile (ambulation and mobility subscales), ²⁷ risk factor for balance impairment reduced in intervention group at 1 year ($P = .001$), impairment in toilet transfers reduced ($P = .05$)		Depressive symptoms ¹⁶⁹			Costs	Room-by-room number of hazards for falling, Falls Efficacy Scale, ¹⁷⁰ at 1 year, control group fell significantly more ($P = .04$), intervention group significantly reduced number of medications ($P = .009$)

Appendix Table 1. Randomized Controlled Trials of Geriatric Interventions and Associated Outcome Measures—Cont'd

OUTCOME MEASURES										
Study	Setting	Study Description	Physical Function	Cognitive Function	Psychosocial	Self-Rated Health	Mortality	Health Care Utilization	Other	
Toseland et al, 1997 ¹⁷¹	OAS USA	2 years N = 160 Investigated the effectiveness of an outpatient GEM team by examining changes in health status, health care utilization and costs	SF-20, ¹⁷² Functional Independence Measure (FIM) ¹⁷³⁻¹⁷⁵					No significant difference	Outpatient utilization (visitation of UPC/GEM clinic, medicine clinic, surgery clinic, emergency room, and total clinic visits), inpatient utilization (number of hospital admissions, hospital days of care, nursing home admissions and nursing home days of care); GEM patients used significantly fewer emergency room services ($P < .05$), GEM patients used significantly more total outpatient clinic services ($P < .01$), Costs (total inpatient costs, total outpatient costs, nursing home costs, institutional costs, total health care costs); significantly more outpatient cost in GEM patients over 2 years ($P < .05$)	
Tucker et al, 1984 ¹⁷⁶	OAS New Zealand	5 months N = 120 Assessed the effectiveness of a day hospital in the geriatric service	Significant increase in Northwick Park ADL Index ¹⁷⁷ at 6 weeks for intervention group ($P = .002$)	Cognitive function ¹⁷⁸	Zung Index, ⁶⁸ intervention group showed improved mood at 5 months ($P = .011$)				Domiciliary services, day hospital costs 1/3 greater than alternative	
Tulloch & Moore, 1979 ¹⁷⁹	OAS UK	2 years N = 295 Evaluated the effects of a geriatric screening and surveillance program on health status of elderly people	Screening for medical disorders found significantly greater incidence in the study group compared to controls ($P < .01$); greater proportion of medical problems unrecognized in control group ($P < .001$)						Rate of hospital admission, outpatient referrals was significantly higher in study group ($P < .01$), time spent in hospital was less for the study group than controls ($P < .01$)	Socio-economic problems
van Haastregt et al, 2000 ¹⁸⁰	HAS Netherlands	18 months N = 316 Assessed whether a multifactorial program of home visits reduces falls and mobility impairments in the elderly	Physical health, mobility, control scale and mobility range scale of SIP68, ^{181, 182} number of physical complaints, Frenchay daily activities ^{183, 184}	Mental health section of RAND-36 ^{10, 15}	Social functioning, ¹⁸⁵ psychosocial functioning	Perceived health by RAND-36, ^{186, 187} perceived gait problems				Falls efficacy scale, ^{170, 188} falls, medications, environmental hazards ¹⁹⁰
van Rossum et al, 1993 ¹⁹⁰	HAS Netherlands	3 years N = 580 Tested the effectiveness of preventive home visits to elderly people	Self-rated functional state, hearing and vision problems	Memory disturbances ¹⁷⁸	Self-rated well-being, ¹⁹¹ loneliness, ¹⁹² modified Zung Index ⁶⁸	Self-rated health	No significant difference	Costs, use of community and institutional care		
Vetter et al, 1984 ¹⁹³	HAS UK	2 years N = 1286 Evaluated the effectiveness of health visitors on elderly population of an urban (Gwent) and a rural (Powys) town	Townsend Score ¹²³		Mental disability, ^{194, 195} use of social contacts, self-rated quality of life		Significantly more deaths in Powys ($P < .01$)	Use of medical and social services, Gwent intervention group used chiropody significantly more than Powys ($P = .02$), significantly more home visits from Gwent intervention group ($P = .005$)	Availability of caregiver, composition of household, type and quality of housing, participants in Gwent attended more lunch clubs than Powys ($P < .05$)	
Vetter et al, 1992 ¹⁹⁶	HAS UK	4 years N = 674 Assessed whether health visitors reduced the incidence of fractures in the elderly	Townsend Score, ¹²³ medical condition, assessment and improvement of general muscle tone						Falls and fractures, nutrition, medications, environmental hazards

OUTCOME MEASURES									
Study	Setting	Study Description	Physical Function	Cognitive Function	Psychosocial	Self-Rated Health	Mortality	Health Care Utilization	Other
Wagner et al, 1994 ¹⁹⁷	HAS USA	2 years N = 1559 Tested a multicomponent program to prevent disability and falls in older adults	Fitness test, physical limitations scale, ¹⁹⁸ hearing and vision, control group worsened in RAS ($P < .05$), BBD ¹³¹ ($P < .01$) and MOS ^{199, 200} ($P = .05$) at 1 year follow-up			Self-rated health and practices questionnaire			Environmental hazards, alcohol consumption, medications, significantly fewer members of intervention group reported falling than of control group (difference = 9.3%, 95% CI = 4.1 to 14.5%) at 1 year follow-up
Williams et al, 1987 ²⁰¹	OAS USA	1 year N = 117 Evaluated whether team-oriented assessment can improve traditional health care approaches	Functional status and medical diagnoses ^{202, 203}		Social supports ^{202, 203}			Health care utilization, degree of client satisfaction with evaluation, health service utilization behaviours	
Winograd et al, 1991 ²⁰⁴	IGCS USA	1 year N = 197 Studied the effect of an inpatient multidisciplinary GCS on health care utilization, functional and mental status	Physical Self-Maintenance Scale, ADLs, IADLs	MMSE ¹⁹	Philadelphia Geriatric Morale Scale ¹¹³			Health care utilization	
Yeo et al, 1987 ²⁰⁵	OAS USA	18 months N = 205 Compared the effects of two models of outpatient care on functional health and subjective well-being	SIP ⁵⁷ showed significantly less functional decline in intervention patients ($P = .029$) and its physical dimension ($P = .011$)		Zung Self-Rating Depression Scale (SDS), ^{68, 206} Life Satisfaction Index A (LSI), ²⁰⁷ Affect Balance Scale (ABS), ²⁰⁸ psychosocial dimension of SIP ⁵⁷	Self-rated health measure ^{209, 210}	No significant difference		

GEMU, geriatric and evaluation management unit, HAS, home assessment service, HHAS, hospital home assessment service, IGCS, inpatient geriatric consultation service, OAS, outpatient assessment service.

Appendix Table 2. Summary of Outcome Measures Used in Randomized Controlled Trials of Geriatric Interventions

Conclusions	Of 56 studies described, 54 measured physical function, using 32 different measures, and of which 23 studies reported statistical significance.	Of 56 studies described, 33 measured cognitive function, using 11 different measures, and of which 6 studies reported statistical significance.	Of 56 studies described, 37 measures psychosocial function, using 29 different measures, and of which 12 studies reported statistical significance.	Of 56 studies described, 18 measured self-rated health, using 8 different measures, and of which 4 studies reported statistical significance.	Of 56 studies described, 35 measured mortality, and of which 9 studies reported statistical significance.	Of 56 studies described, 45 measured health care utilization, using 19 different measures, and of which 24 studies reported statistical significance.	Of 56 studies described, 32 measured "other" outcomes, using 16 different measures, and of which 13 studies reported statistical significance.	

*Numbers in bold denote the frequency of instruments used within the collective studies.

**Instruments categorized in terms of reported use within each study (e.g. SF-36 may be used as a measure of physical function, self-rated health or quality of life)

Cardiac failure increases in both prevalence and incidence with age.¹ It is a disease of middle and old age, although the underlying causes differ considerably with age.² In younger patients with cardiac failure, the cause is frequently coronary artery disease, whereas in the older patient valvular disease and hypertension are more often implicated. Most epidemiologic studies are based on symptoms and signs of cardiac failure, but more recent data include objective assessments of ventricular function, which is more sensitive.³

The prevalence of heart failure continues to rise as more patients survive myocardial infarction as a result of fibrinolytic therapy. In addition, patients with hypertension are surviving longer as a result of continued improvements in the prevention of strokes.⁴ Fortunately, it appears that the effective treatment of hypertension may in fact prevent the onset of heart failure even in the very old.⁵ The HYVET study of nearly 4000 hypertensive patients aged 80 and over showed a significant reduction in any cardiovascular event, including the development of any heart failure, in the group treated for hypertension.

When considering the epidemiology of heart failure, note that it is defined as the presence of symptoms and signs of cardiac decompensation, together with objective evidence of underlying structural heart disease. These are the definitions used by the European Society of Cardiology⁶ and the American Heart Association⁷ who have recently independently reached a consensus on the diagnosis of heart failure. This is an important step because it has resulted in a more focused approach when considering precisely what disease entity is being treated in individual patients. Heart failure is of major economic significance; in the United Kingdom it accounts for up to 5% of hospital admissions,⁸ and in the rest of Europe hospitalization for heart failure is a significant financial burden for a number of countries.⁹ Many older adults with heart failure also have multiple pathologies and coexistent diseases, including cognitive impairment, which make the diagnosis more difficult to confirm.¹⁰

EPIDEMIOLOGY

Relatively few studies report the incidence and prevalence of heart failure in the older patient population. Much of the epidemiologic data comes from Scandinavia¹¹ and the Framingham study,¹² although recently new data have come from the United Kingdom from a relatively young population.³ The early data collected from studies were predominantly from medical record analysis and patient questionnaires. This type of data collection has its limitations.

In a West London study,¹³ the prevalence of heart failure in those aged under 65 was reported as 0.06%, compared with 2.8% in those over 65. This study likely underestimated the severity of the problem as only patients who had been prescribed as diuretic were included; others with relatively mild disease might have been missed. Many earlier epidemiologic studies were performed on populations that were inadequately described and give no information

on the population at risk. The precise prevalence of left ventricular dysfunction in the whole population has been obscure until recent years. Studies in the late 1950s revealed a prevalence of 0.2% in the 45 to 64 year age group¹⁴ and 1.9% in those over the age of 65. Another U.S. study demonstrated prevalence rates of 1% and 6.5% in corresponding age groups.¹⁵

The criteria for heart failure used in the Framingham Heart Study population¹² were more strictly defined and the baseline prevalence was 0.3% of the population aged 62 or less. However, over a 34-year follow-up period the prevalence rate was 0.8% in ages 50 to 59 and 9.1% in the over 80s age group.¹⁶ By contrast, more recent estimates from North Glasgow, Scotland, estimated the prevalence of left ventricular systolic dysfunction based on echocardiographic criteria to be about 2.9%.³ This figure was obtained from a population of 1640 patients between the ages of 25 and 74. The systolic dysfunction was symptomatic in 1.5% of patients and asymptomatic in 1.4%. In this study it therefore appears that systolic dysfunction was at least twice as common as symptomatic heart failure defined by clinical criteria.

The longitudinal Framingham study suggested that prevalence rates doubled every decade and reached approximately 10% for people in their 80s.

Prescribing data also highlight the extent of the problem; in the United States, up to 1 in 5 elderly patients were being treated for chronic cardiac failure.¹⁷ In the United Kingdom, echocardiographic data in patients over 75 years of age suggest that prevalence may be around 10% of patients being managed in the community.¹⁸

Information on the incidence of heart failure also reveals a sharp increase over the age of 75 years. The best available incidence data are from the Framingham Heart Study¹⁹ and the study of men born in 1913.²⁰ In the Framingham study, 5200 individuals have been followed since 1948 and the incidence rises markedly with age. The annual incidence was 2% per thousand in men and 1% per thousand in women under the age of 54, and 14% per thousand in men and 13% per thousand in women between the ages of 75 and 84. The Framingham study data probably underestimate the incidence because the entry criteria did not include the milder forms of heart failure.

In the Scandinavian study of men born in 1913, the annual incidence for those in the 50 to 54 year age group was 1.5 per thousand per year, which increased to 10.2 per thousand per year at ages 61 to 67.

The Hillingdon Heart Failure Study²¹ was a population-based surveillance system in which patients first developing heart failure were identified. Over a 20-month period, 220 patients fulfilled the criteria for heart failure and the incidence of the condition increased steeply with age and was higher in men than in women at all ages. Newer studies using echocardiography show not just that many patients have asymptomatic left ventricular dysfunction, but that heart failure with normal systolic function is increasingly recognized.²²

Hospitalizations for chronic heart failure are frequent, but this may relate mainly to approaches to treatment and assessment, together with awareness of the condition, rather than being a reflection of the incidence or prevalence. The number of hospital discharges where a diagnosis of heart failure has been coded has increased in recent years both in Holland²³ and in Scotland.²⁴ In the United States in 1991, congestive heart failure was the primary discharge diagnosis in around 790,000 hospitalizations.²⁵

DISEASE COURSE AND PROGNOSIS

Heart failure has a variable disease progress but in general, patients with impaired left ventricular systolic function have a poorer prognosis, whereas patients with normal systolic function heart failure tend to fare better. These patients are more likely to be hypertensive, have mild coronary artery disease, and be prone to deterioration in renal function during hospitalization.²⁶ Among older adults hospitalized with heart failure, mean survival time is about 2.5 years. However, there is considerable heterogeneity in survival.²⁷ In one study, the presence of chronic heart failure in older patients resulted in an approximate 50% reduction in life expectancy.

The increased numbers of patients hospitalized for heart failure may reflect improved survival following myocardial infarction, but also an improvement in heart failure management. As a result patients with heart failure are living longer, with more episodes of decompensation requiring hospital admission. Data from North America suggest that there is a high rate of readmission in heart failure patients.²⁸ Evidence suggests that a multidisciplinary approach to the treatment of heart failure may reduce the need for hospitalization in elderly patients with the condition.²⁹ Such an approach is crucial in the older patient where issues such as adherence, cognition, and continence figure prominently in the clinical decision-making process.

The prognosis for heart failure, although improved in recent years by drug treatment, is nevertheless still poor. The majority of patients with New York Heart Association Class IV disease (Table 40-1) will be unlikely to survive a year.

A study of elderly men admitted as inpatients with heart failure revealed that the 1-year mortality was in the region of 50%.³⁰ It is thus clear that heart failure is a relatively malignant condition and, although newer treatments have been shown to improve the prognosis for many patients, alleviation of symptoms and improved morbidity is as important as any potential mortality benefits in the older patient.³¹

PATHOPHYSIOLOGY

As noted, the pathophysiology of heart failure is multifactorial, especially in older patients in whom hypertensive heart disease and valvular heart disease are more common. There

may be structural abnormalities within the heart together with overcompensatory mechanisms in the renin-angiotensin system, the sympathetic nervous system, and the peripheral vasculature. Although there are specific changes in the cardiovascular system with age, (see Chapter 14) such as increased calcification, increased myocardial fibrosis, and reduced ventricular compliance,³² most elderly patients with heart failure have additional pathology to explain their symptoms. In patients with heart failure due to ischemia, remodeling can result in alterations in the shape and morphology of the left ventricle with ultimate left ventricular dilatation and a large end-diastolic volume.³³ In addition to changes in the structure of the left ventricle, many elderly patients have associated calcific degeneration of both the aortic and mitral valves, with functional and hemodynamically significant consequences.³⁴ The cardiomyopathies³⁵ are also a small but significant cause of heart failure in older patients, although the widely seen asymmetrical septal hypertrophy itself is not of great significance.³⁶ In hypertensive patients with left ventricular hypertrophy, the increase in collagen content of the ventricular wall and associated myocardial fibrosis may lead to diastolic filling abnormalities,³⁷ which may contribute to the symptoms of heart failure, and represent a major pathophysiologic substrate for the phenomenon of heart failure with preserved systolic function (HPSF). In addition, loss of atrial contraction can result in significant hemodynamic deteriorations as atrial systole has an increased importance in the older patients when left ventricular wall stiffness is increased.³⁸

In a healthy person, cardiac output is influenced directly by stroke volume and heart rate. In the failing heart, stroke volume is maintained by increasing the left ventricular end-diastolic pressure and volume, which is the basis of Starling's law of the heart. However, eventually at very high left ventricular end-diastolic volumes there will be no subsequent compensatory increase in cardiac output. One of the aims of heart failure treatment is to minimize increases in left ventricular end-diastolic pressure, so that cardiac output can be maintained and so that subsequent tissue oxygenation is adequate for perfusion of the vital organs.

The autonomic nervous system and the neuroendocrine systems initially support the failing heart, but ultimately the compensatory mechanisms may themselves prove harmful. Activation of the renin-angiotensin-aldosterone system can result in increased levels of angiotensin and aldosterone in the heart, kidney, brain, and vascular system, with undesirable consequences.³⁹ Furthermore, the associated high levels of plasma adrenaline and noradrenaline (epinephrine and norepinephrine) are associated with a poor prognosis due to deleterious effects on myocardial function, autonomic balance, and peripheral vascular function.⁴⁰

Much of the fluid overload and edema in heart failure is a result of the effects of the renin-angiotensin system on the kidney, and reduced bradykinin may be associated with increased vasoconstriction. Changes in the morphology of skeletal muscle may explain the fatigability seen in heart failure patients over and above that expected with reduced tissue blood supply.⁴¹ Disruption of the microvasculature is also seen with impaired endothelial function.⁴² These changes are usually consequences of the disease process

Table 40-1. New York Heart Association Classification of Heart Failure

Class I	No symptoms
Class II	Symptoms with ordinary activity
Class III	Symptoms with less than ordinary activity
Class IV	Symptoms at rest

and not merely related to age, although in extremely old patients with mild symptoms of cardiac failure, true pathologic processes and age-related processes may be difficult to differentiate.

Such age-related changes include a reduction of cardiac output on exercise, an increase in end-systolic volume, a decrease in ejection fraction with exercise, and a reduced heart rate with exercise.⁴³ It is important to note, however, that heart failure is a disease with systemic effects; derangements of immune function cause a proinflammatory response that may in itself be cardiotoxic and contributes to the development of anemia; circulating cytokines may also help to drive the prominent skeletal myopathy that accompanies heart failure and is in fact the major cause of tiredness and breathlessness in heart failure patients. This skeletal myopathy in turn causes abnormalities of ergoreceptor function that drive further sympathetic nervous system activation. Disturbance of lung architecture and gas exchange are seen in the lungs of heart failure patients even in the absence of overt fluid overload—a further contributor to the symptoms of heart failure.

Most of the established treatments for heart failure are in patients with systolic dysfunction. Even so, there are many elderly patients with normal systolic function who have symptoms and signs compatible with heart failure. Conversely, many elderly patients have these “diastolic abnormalities” on echocardiography but no symptoms of heart failure. The relative clinical significance of the diastolic abnormalities in these patients is unclear. They may go on to develop subsequent heart failure as a result of atrial fibrillation or systolic dysfunction, or may have intermittent episodes of mild cardiac decompensation possibly as a result of silent myocardial ischemia. Furthermore, echocardiographically determined measures of diastolic dysfunction are critically dependent on the degree of activation of the sympathetic nervous system. Such variables include transmitral flow velocities (the E to A ratio), the isovolumic relaxation time.⁴⁴ Further work is needed to establish the clinical usefulness of these measures and newer echocardiographic indices such as measures of longitudinal systolic function.

THE ETIOLOGY OF HEART FAILURE

Heart failure has been described as a syndrome rather than a diagnosis or disease, and the underlying cause must always be sought in patients having the syndrome. The most frequent cause of heart failure is left ventricular systolic dysfunction, usually as a consequence of ischemic heart disease, especially myocardial infarction. However, in elderly patients, valvular heart disease frequently contributes to the symptoms.

Less frequently, heart failure in the older patient may be caused by one of the cardiomyopathies, amyloidosis, storage diseases (e.g., hemochromatosis), secondary to chemotherapy or vitamin B deficiencies. In the over-80s, aortic or mitral valve disease frequently contributes to heart failure and many elderly patients in long-term care have background cardiac valvular disease.⁴⁵ Furthermore, as already noted, it is increasingly recognized that many patients have symptoms associated with heart failure in the presence of normal systolic function and no evident valvular disease.

This is often called diastolic heart failure or more commonly heart failure with preserved systolic function (HPSF). HPSF may be responsible for as much as 30% to 50% of heart failure in the elderly population.⁴⁶ The etiology of this heart failure is unclear, but it is more likely to be present in patients with hypertension and left ventricular hypertrophy. It is less clear how these patients should be managed, as most of the major studies have addressed patients with left ventricular systolic dysfunction as a cause of their heart failure.^{47–50}

Patients in heart failure with systolic dysfunction have a poorer prognosis than those with normal systolic function. It is also well established that patients with an increased left ventricular end-diastolic volume secondary to myocardial dilatation have a poor prognosis.⁵¹ Not infrequently heart failure will be precipitated by anemia, alcohol, and a number of other factors⁵² (Table 40-2).

DIAGNOSIS OF HEART FAILURE

It is fairly easy to recognize heart failure in its more severe versions when the patient has pronounced symptoms and signs accompanied by echocardiographic evidence of left ventricular dysfunction.⁵³ Even so, diagnostic difficulties arise in its milder forms.

The European Society of Cardiology (ESC) has developed guidelines for the diagnosis of heart failure⁶ (Table 40-3). However, with any guidelines there is a degree of vagueness, and in particular there is no specific definition of precisely what is meant by cardiac dysfunction. An example to highlight some of the difficulties is the case of the elderly lady whose echocardiogram shows preserved systolic function and who has swollen ankles with no breathlessness and mild fatigue. Does this type of patient have heart failure? Nonetheless, the ESC guidelines have generally clarified the situation even if there are still a few areas of ambiguity.

Table 40-2. Factors Which May Precipitate Heart Failure in the Elderly Person

Anemia
Alcohol
Intercurrent infection, including endocarditis
Fluid overload (often postoperatively)
Thyrotoxicosis
Drugs (e.g., NSAIDs)
Atrial fibrillation
Altered drug compliance
Pulmonary emboli

Table 40-3. European Society of Cardiology Guidelines for the Diagnosis of Heart Failure

Essential Features
• Symptoms of heart failure (for example, breathlessness, fatigue, ankle swelling)
• Objective evidence of cardiac dysfunction (at rest)
Nonessential Features
In cases where the diagnosis is in doubt, there is a response to treatment directed toward heart failure.

Table 40-4. Symptoms of Heart Failure in Elderly Patients, and Differential Diagnoses

Classic Symptoms	Atypical Features	Differential Diagnoses
Dyspnea	Lethargy	Anemia
Orthopnea	Confusion	COPD
Peripheral edema	Falls	Depression or anxiety
	Dizziness	Hypothyroidism
	Syncope	Hypoalbuminemia
	Immobility	Malnutrition
		Renal disease
		Neoplasm
		Lymphedema

COPD, chronic obstructive pulmonary disease.

For the clinician who is faced with an elderly patient with suspected heart failure, two questions should be considered before further assessment:

1. Are the patient's symptoms at least partly cardiac in origin?
2. If so, what kind of cardiac disease is producing these symptoms?⁵⁴

Table 40-4 lists the typical and atypical symptoms in the elderly patient with suspected heart failure and potential differential diagnoses.

The diagnosis of heart failure is especially difficult because it is not defined by an absolute level of any one parameter, as is the case with a number of other diseases. Consequently the diagnosis is a judgment based on a careful history and examination, chest radiology, electrocardiography, echocardiography, and other routine baseline investigations, such as full blood count, serum biochemistry, and thyroid function.

Clinical history

The most classic symptom of heart failure is exertional breathlessness. However, this is a common symptom and is often a result of chronic obstructive pulmonary disease (COPD), deconditioning, obesity, or interstitial lung disease.⁵⁵ Most people will experience some breathlessness with moderate exertion and, during exercise, the stage at which breathlessness is experienced depends on the overall level of fitness.

Anemia and obesity are confounding factors that make exertional dyspnea a very nonspecific symptom. Orthopnea is a more specific symptom that does not occur in normal patients and is not usually a feature in respiratory disease. However, the disease process has to be relatively advanced before orthopnea occurs; and even if it is present, diuretics have often been instituted by the patient's general practitioner to relieve this symptom. Likewise, paroxysmal dyspnea (PND) is a more extreme version of dyspnea and is a result of fluid redistribution which increases the left ventricular end-diastolic pressure. Again, PND is specific but an insensitive symptom because it signifies fairly severe heart failure, which should have been noted and previously treated.

Fatigue and lethargy are other common problems in heart failure, but they are probably even harder to define and assess than dyspnea, particularly in elderly patients. Fatigue

is common in people who are ill and more common still in older adults who are frail.

Ankle edema is a common presenting feature, but again there are many alternative causes, such as cor pulmonale, deep venous thrombosis, dependent edema, or hypoalbuminemia. Elderly women often have ankle edema, which is not caused by heart failure. Its precise cause is unknown, although venous insufficiency accompanied by pelvic obstruction to venous blood flow are commonly blamed. Indeed, it is elderly women with swollen ankles who most commonly cause false positives for heart failure when assessed subsequently by echocardiography.

Probably the best indication of underlying heart failure comes from the history, with a history of previous myocardial infarction or hypertension being useful indicators.⁵⁶ It should be remembered, however, that many elderly patients have silent myocardial ischemia or infarctions. In addition, many are unsure whether a previous hospitalization for chest pain was for a myocardial infarction or angina. Additional features that may suggest the diagnosis of heart failure include excessive alcohol intake, a history of rheumatic fever, and the use of drugs such as nonsteroidals, which might precipitate heart failure. Note too, however, that heart failure is associated with cognitive impairment, including memory impairment and frontal systems dysfunction that often manifests with slowness and decreased initiative.¹⁰ In consequence, it is easy in a busy clinical practice to be misled by incomplete or seemingly vague answers; both false-positive and false-negative responses can put the history off track.

Physical signs

Many of the physical signs of heart failure are nonspecific and of relatively low predictive value. These include tachycardia, pulmonary crepitations, and peripheral edema. Equally, many of the physical signs that are specific to heart failure are insensitive because they occur only once the heart failure has become severe. These include elevation of the jugular venous pressure, a gallop rhythm, and displacement of the cardiac apex beat. The situation is further compounded by the variable ability of doctors to detect these clinical signs.⁵⁷ As a result, few of the symptoms and signs are of any value on their own. The probability of the diagnosis of heart failure is weighed up by the individual clinician making full use of clinical judgment together with the findings on examination and careful history taking.⁵⁸

Investigations

The SIGN guidelines used in Scotland⁵⁹ for the diagnosis and treatment of heart failure due to left ventricular systolic dysfunction, although not specifically written for the elderly patient, provide a useful framework for investigations.

CHEST X-RAY

Chest x-ray is performed routinely and can produce useful information for patients with suspected heart failure. Cardiac enlargement (cardiothoracic ratio greater than 50%) implies cardiomegaly, and if present is a good guide to heart failure.⁶⁰ However, many heart failure patients do not

exhibit cardiomegaly, so it tends to be a specific but insensitive test which identifies severe heart failure only. Other helpful chest x-ray findings are pulmonary edema, upper lobe diversion, fluid in the horizontal fissure, and Kerly-B-lines in the costophrenic angles. In extreme cases, pleural effusions may be present, although clearly there are alternative explanations for them such as bronchial carcinoma, pneumonia, or pulmonary emboli. In a meta-analysis of 29 studies,⁶¹ Bayesian analysis found that chest radiography can only exclude heart failure (posttest probability less than 5%) and a decreased ejection fraction in patients who are asymptomatic can never confirm heart failure (posttest probability greater than 95%). However, it is likely that cardiomegaly represents underlying structural cardiac disease and in many patients heart failure will develop at some stage.

A chest x-ray can reveal other clues as to noncardiac disease that might be causing breathlessness. A lung tumor might be obvious, and emphysema may also be present. Nevertheless, the chest x-ray should be seen as a whole. For example, the finding of cardiomegaly plus bilateral pleural effusions with no other parenchymal lung disease makes heart failure extremely likely (although the presence of structural heart disease should still be confirmed by echocardiography).

ELECTROCARDIOGRAM

The 12-lead electrocardiogram (ECG) should be performed routinely. Left ventricular systolic dysfunction is rare in the presence of a completely normal 12-lead ECG, making it a useful "rule out" test. Recent data⁶² suggest that an abnormal resting ECG is sensitive (94%) with excellent negative predictive value (98%) but is much less specific (61%) and has poor positive predictive value (35%). Most studies suggest that this is the case; where there is doubt, an echocardiogram should be performed.

Other abnormalities on the ECG may be useful in the assessment of patients. For example, the presence of atrial fibrillation may be useful in concluding whether the patient should receive additional anticoagulation.

ECHOCARDIOGRAPHY

The optimum investigation in the elderly patient with suspected heart failure is echocardiography.⁶³ Both qualitative and quantitative assessment can be useful. However, the degree of left ventricular systolic dysfunction can be assessed by a number of indices. Fractional shortening is usually sufficient in most instances.⁶⁴ Left ventricular ejection fraction,⁶⁵ and more recently a regional motion index,⁶⁶ have been shown to provide accurate assessments of left ventricular systolic function; global assessment of function by an experienced operator is another valid approach, which correlates well with measured ejection fraction.⁶⁷ Echocardiography can clearly distinguish whether the left ventricle is dilated or not; this approach to assessing left ventricular dimensions is preferable to chest x-ray. Left ventricular dilatation and left ventricular systolic dysfunction usually accompany each other, but occasionally the left ventricle is dilated despite the presence of normal systolic function. Nevertheless, left ventricular dilatation implies impending

left ventricular systolic dysfunction and should probably be treated as such.

Echocardiography can also identify patients with mitral valve disease or aortic stenosis who may benefit from surgery. It can also assess diastolic dysfunction, although there is some controversy over this.⁶⁸ The problem relates to the fact that the left ventricle becomes stiffer as it ages, and it is difficult to define consistently when the stiff ventricle constitutes diastolic dysfunction. At the time of this writing, no echocardiographic criteria are fully accepted as measures of diastolic dysfunction.

However, there is one extreme version of diastolic dysfunction that can cause severe pulmonary edema. This occurs when the left ventricle is so stiff that left atrial pressure increases and leads to fast atrial fibrillation with profound breathlessness. In the short term, treatment is to reverse the abnormal rhythm, but longer-term strategies are required to prevent LV stiffness, which leads to atrial fibrillation. Echocardiography also provides information about left ventricular hypertrophy if present; such a finding provides evidence of structural heart disease to support a diagnosis of heart failure even if LV systolic function is normal.

Figure 40-1 suggests an approach for diagnosing heart failure in practice.

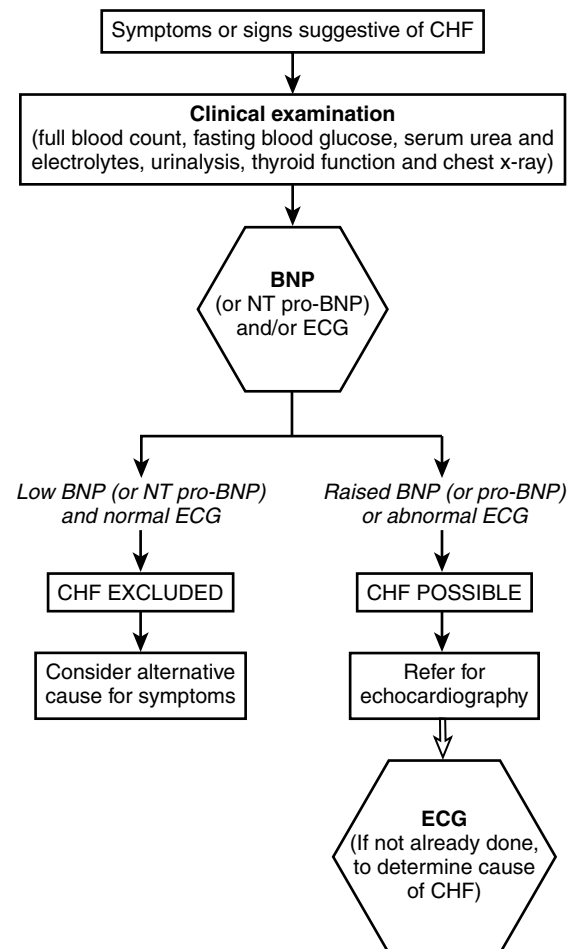

Figure 40-1. Diagnostic algorithm for patients with suspected chronic heart failure (CHF).

Natriuretic peptides

The natriuretic peptides (NPs) that are released from the atrium and ventricles have a variety of cellular effects, act as vasodilators, and cause a natriuresis. They have been shown to reflect left ventricular function, and levels correlate reasonably well with quantitative assessments of left ventricular function.⁶⁹ There is emerging evidence that the natriuretic peptides—and in particular BNP—have a role in identifying patients with left ventricular systolic dysfunction.^{70,71} These agents may have a role in the preselection of patients for echocardiography when it is not always available. In patients following myocardial infarction, it appears that the levels of B-type natriuretic peptide closely relate to ejection fraction.⁷² It has also been shown that in patients with acute dyspnea, plasma levels of BNP reflect left ventricular function.⁷¹ Testing is now possible with newer patient tests comparable to stick testing for blood sugar. In a community study, natriuretic peptides were effective in detecting patients with left ventricular systolic dysfunction.⁷³ Many other studies also demonstrate the role of BNP and ANP in the assessment of patients with heart disease, including their potentially prognostic role. One of the major challenges is now to make these tests more routinely available in clinical practice. **Figure 40-1** shows a diagnostic algorithm for patients with suspected chronic heart failure.

In summary, the diagnosis of heart failure is a sequential one which relies on a clear clinical history and examination followed by either electrocardiography, chest radiology, or echocardiography. Echocardiography is desirable in all cases although it may not be always available, particularly in older patients.⁷⁴ Nevertheless, it is probably more important in the elderly patient to obtain an echocardiogram before instigating treatment because structural abnormalities are more common and optimum treatment requires as accurate a diagnosis as possible so that adverse effects may be kept to a minimum.

When echocardiography proves to be technically difficult, objective assessments of left ventricular function may be made by radionuclide ventriculography. In the older patient, functional capacity can be assessed by performing a 6-minute walking test.⁷⁵ This can provide useful prognostic information.

TREATMENT OF HEART FAILURE

General issues

Since the 1960s, when loop diuretics were introduced,⁷⁶ treatments for heart failure have diversified. As the pathophysiology of heart failure has become clearer, treatment options have broadened and a number of agents, including ACE inhibitors and β -blockers, have been shown to improve prognosis. It is now known that the impairments in left ventricular function and the peripheral circulation can be treated, with consequent hemodynamic improvement. Neurohumoral activation can be blocked and left ventricular remodeling can be reduced.⁷⁷ These adverse consequences of heart failure are the targets of drug treatment. As a result, patients may require multiple-drug treatment and priorities need to be established. It is important that patients and their caregivers understand the implications of their treatment.

In the frail elderly patient, quality of life and alleviation of symptoms are especially important. The major clinical trials of heart failure have generally excluded older patients, so that most patients enrolled in studies are in the age range 50 to 70 years, favoring single system and single cause disease. Frail patients, by contrast, typically have many active illnesses resulting in co-morbidity which may require management itself.

Such complex patients require multidimensional evaluation and management both in hospital and in the community.⁷⁸ This ensures that a full picture of the patient's abilities, needs, and wishes is obtained, so that the goals of treatment are fully aligned with what the patient requires. It is clearly of little use to treat heart failure with all of the recommended therapies but to further impair function and quality of life through intolerable side effects.

It is worth remembering and reemphasizing that the different treatments are mediated by different mechanisms. Diuretics relieve the symptoms of fluid retention, and there is now evidence from a meta-analysis showing reduced rates of hospitalization and a mortality benefit.⁷⁹

ACE inhibitors improve symptoms and exercise tolerance as well as prognosis in patients with heart failure.^{47–49} This should be contrasted with β -blockers,^{50,80–82} where symptomatic benefit may be mild and even deleterious in the early stages of treatment. It is therefore important to carefully guide a patient through treatment, making sure that he or she understands the process of the disease. The key point is that, in the long term, β -blockers slow progression and improve prognosis dramatically. More recently the angiotensin antagonists have been shown to be tolerated^{83–85} and improve symptoms in patients with heart failure already taking diuretic treatment; there is good evidence that they are a useful substitute for ACE inhibitors in some patients, but they may not improve outcomes when added to ACE inhibitors.^{86–89} In the last few years digoxin⁹⁰ has been shown convincingly to improve symptoms and reduce hospitalizations in patients with severe heart failure refractory to standard treatments, although it appears that it does not alter mortality in patients who are in sinus rhythm with heart failure and carries significant risks of cardiac toxicity and confusion.

Nonpharmacologic management of the patient is particularly important, but also susceptible to problems with adherence, particularly in older people with cognitive impairment. Where possible, patients should be given advice about monitoring their weight, about the nature and relevance of their symptoms, and about the dosages of their drugs and the opportunity for flexible dosing dependent on symptoms. In general, patients should be advised to perform moderate exercise and stop smoking. Patients who drink alcohol to excess should be advised to cut back. Often patient caregivers have a vital role to play in the successful management of heart failure.

As with all medication use in older people, a drug should be started at a low dose and titrated in relation to the response, especially since patients may be taking over-the-counter preparations and the potential for drug interactions is considerable.⁹¹ Each of the aforementioned drug classes will be considered in more detail; but in addition to the main therapeutic options, mention will be made of drugs that have less proven efficacy.

Summary of Treatment Options

Chronic Heart Failure

Diuretics

- For symptoms of fluid overload and edema.
- Loop diuretic (furosemide or bumetanide) at appropriate dose. Also consider thiazide.

ACE inhibitor

- Symptomatic and mortality benefit for systolic dysfunction following confirmation of diagnosis by echocardiography.
- Options include enalapril, lisinopril, captopril, perindopril, ramipril. Dose should be titrated.

β-Blocker

- Should be considered for symptomatic and mortality benefit in mild, moderate, and even severe heart failure under close hospital supervision.
- Beneficial effects may not be immediate.
- Options include carvedilol, metoprolol, bisoprolol. Dose should be titrated.

Spironolactone

- Adjunctive treatment with a mortality benefit.

Digoxin

- As adjunctive treatment for symptomatic benefit and control of atrial fibrillation. Also provides symptomatic improvement in sinus rhythm but no clear mortality benefit.

Nitrates

- As adjunctive treatment for symptomatic benefit and control of associated angina.

Other options

- Amlodipine, ferrous sulfate, erythropoietin, warfarin, and amiodarone.

Nonpharmacologic

- Weight loss; low-salt diet; cessation of smoking; exercise; compliance aids.
- Multidisciplinary management.

Diuretics

Diuretics are fundamental to the treatment of chronic heart failure. The loop diuretics introduced in the 1960s were shown to be very effective in reducing symptoms associated with fluid retention and they had a clear hemodynamic benefit. Studies have shown deterioration in symptomatic heart failure when diuretics are withdrawn, and diuretics have been shown to reduce mortality and hospitalization in chronic heart failure.⁹²

The loop diuretics (which include furosemide and bumetanide) block the sodium-potassium-chloride transport exchange in the ascending limb of the loop of Henle.⁹³ Thiazides have a different site of action and work in the distal convoluted tubule.⁹⁴ Spironolactone has a yet different mode of action, antagonizing the aldosterone-mediated sodium exchange with potassium and hydrogen in the collecting ducts.⁹⁵ In older patients with heart failure, the rate of absorption of loop diuretics and time to peak plasma concentration are reduced as renal function is often impaired. High doses of diuretics may need to be used to produce a diuresis as the coexisting relative acidosis results

in increased competition for the organic acid transport pathway at the proximal tubule. The bioavailability of furosemide can be very variable, from 20% to 80%, but is more consistent with bumetanide.⁹⁶ Most of the loop diuretics have a fairly short half-life, in the region of 1 to 2 hours. In contrast, the thiazide and potassium-sparing diuretics have longer half-lives, which allow once-daily doses. Tolerance can occur to diuretics and this has clinical relevance. The natriuretic response diminishes after the first dose, but this can be reversed by restoring intravascular volume. Long-term administration of a loop diuretic can also result in tolerance, which can be combated by combining loop and thiazide diuretics together.⁹⁷

In patients with acute left ventricular failure, intravenous furosemide is effective, but prolonged use can result in a reduction in right-sided heart pressure with a consequent fall in cardiac output and increase in peripheral vascular resistance.⁹⁸ This can often be combated by treatment with a concomitant vasodilator such as a nitrate.⁹⁹ When furosemide is given to patients with severe acutely decompensating heart failure, high doses should be used until symptoms and signs of fluid overload have been controlled. An intravenous dose of 40 to 50 mg is often sufficient to control the symptoms, but when resistance to loop diuretics occurs, up to 250 to 500 mg per day may be required. In resistant cases, furosemide can be given by a continuous infusion of up to 4 g per day.

Metolazone¹⁰⁰ is a thiazide that can be used for resistant edema and heart failure. It blocks sodium reabsorption in the proximal convoluted tubule along with having thiazide effects on the distal convoluted tubule. It is given orally at a dose between 1.25 mg and 10 mg per day. It can result in a profound diuresis and postural hypotension may be significant. Close monitoring of electrolytes is essential.

When patients with heart failure are being treated with a diuretic, it is essential to monitor plasma biochemistry regularly. Particular electrolyte disturbances include hypokalemia,¹⁰¹ which may precipitate cardiac arrhythmias; hyponatremia,¹⁰² which may cause drowsiness and fits; and hypomagnesemia,¹⁰³ which may cause a number of cellular effects including muscle weakness and arrhythmias. Hypokalemia may be alleviated by the concomitant use of potassium-sparing diuretics such as spironolactone or by using an ACE inhibitor (see later discussion). Diuretic treatment can also result in disturbances of lipid metabolism, glucose intolerance, and hyperuricemia.¹⁰⁴

In addition to the above diuretic side effects, older patients are prone to difficulties with urinary incontinence, immobility, postural hypotension, dehydration, and confusion. These problems should be prominent in the prescriber's mind when instigating treatment in an individual patient. It is also important not to administer intravenous furosemide rapidly as this may precipitate an irreversible hearing loss.¹⁰⁵

A Dutch study of older adults¹⁰⁶ assessed the impact of discontinuing diuretic therapy for relatively mild symptoms of heart failure (patients with severe symptoms and acute heart failure, and those requiring intravenous diuretics, were excluded). In the follow-up period, diuretic therapy had to be reintroduced in half of the patients in whom it had been withdrawn, owing to symptomatic deterioration. Even though the patients in whom diuretic therapy had to be restarted were relatively well, this study highlights the

likelihood of a recurrence of symptoms if diuretics are discontinued in an elderly population.

Angiotensin-converting enzyme inhibitors

Angiotensin-converting enzyme (ACE) inhibitors have been available since the early 1980s, and evidence accumulated since then confirms their considerable efficacy in the treatment of heart failure. ACE inhibitors block overactivity of the renin-angiotensin system and the sympathetic nervous system.¹⁰⁷ In addition to these effects, ACE inhibitors seem to enhance the bradykinin-nitric oxide system in the vascular endothelium.¹⁰⁸ They may also have an influence outside the circulation in various tissues.¹⁰⁹ In patients with mild to moderate heart failure and even asymptomatic left ventricular dysfunction, they reduce morbidity and mortality.^{47–49} Mechanistically, ACE inhibitors are vasodilators with subsequent reduction in cardiac preload and afterload, resulting in hemodynamic and symptomatic improvement for patients with heart failure. In addition to reducing the overcompensatory activity of the renin-angiotensin system together with beneficial effects on the endothelium, ACE inhibitors may also have anti-ischemic effects¹¹⁰ and have an influence on the deleterious effects of the remodeling of the left ventricle following myocardial infarction.

The first study that demonstrated a benefit was in patients with severe heart failure (New York Heart Association class IV). In the CONSENSUS study,⁴⁷ patients were randomized to treatment with enalapril 2.5 mg titrated to 10 mg twice daily if tolerated, or a placebo. At 1-year follow-up, mortality was 52% in the placebo group and 36% in the enalapril group. There were also significant reductions in hospital admissions in the treatment group. In the SOLVD study,⁴⁸ patients with mild to moderate heart failure treated with enalapril 10 mg twice daily obtained a mortality benefit. This benefit also extended to patients in a prevention group of the SOLVD study as well as those in the treatment group. The trials not only demonstrated a mortality and symptomatic benefit, but also confirmed that, in general, treatment was well tolerated. The patients in these studies were middle-aged, so it may not be possible to extrapolate the findings directly to frail elderly patients. Nonetheless, most physicians would probably treat the older patient who had systolic dysfunction with an ACE inhibitor. Treatment with an ACE inhibitor also reduces the likelihood of myocardial ischemic events. In the SAVE study,⁴⁹ patients with asymptomatic left ventricular dysfunction (LVEF <40%) following myocardial infarction were treated with titrated doses of captopril up to 50 mg three times daily. There was a risk reduction of 19% in mortality compared with patients treated by placebo.

Further evidence for the efficacy of ACE inhibitors in patients with heart failure following myocardial infarction was obtained by the AIRE study.¹¹¹ Patients were randomized to treatment with ramipril 2.5 mg twice daily, increased to 5 mg twice daily if tolerated. In the 15-month follow-up the mortality rate in those treated with ramipril was 17%, compared with 23% in the placebo group.

As a result of the findings of all these trials, the use of ACE inhibitors has become increasingly widespread in patients with left ventricular systolic dysfunction. Subgroup analysis from large trials suggests that ACE inhibitors reduce mortality in older and younger patients, and even very old heart

failure patients tolerate ACE inhibitors well and show an improvement in exercise capacity relative to a placebo.¹¹² Care is still required to ensure that renal dysfunction and orthostatic hypotension do not result from ACE inhibitor use in older patients.¹¹³

The main contraindications to treatment with ACE inhibitors are obstructive valvular disease and renal impairment. Patients who are volume-depleted, particularly those with hyponatremia, are more likely to experience hypotension with initial dosage. However, this may be less marked with some ACE inhibitors than others.¹¹⁴ Treatment should be gradually titrated in divided doses until the maximum achievable dose is obtained. In general terms the optimal benefit is obtained at the top end of the dose range. The recent ATLAS study¹¹⁵ compared low and high doses of lisinopril in heart failure and patients with higher dosages fared better. Ideally, the diuretic dose should be reduced or curtailed to optimize intravascular volume at the time of initiation of therapy. This reduces the likelihood of hypotension. Renal function and electrolytes should be monitored at regular intervals, initially every few days or weekly and then every 3 to 6 months. It may be possible to reduce the dose of maintenance diuretic therapy once the patient has been established on ACE inhibition.

The effects of ACE inhibitors on heart failure appear to be a class effect. Individual drugs currently used include captopril, enalapril, lisinopril, perindopril, and quinapril. The main side effects of ACE inhibitors include cough, hypotension, hyperkalemia, and, rarely, angioneurotic edema. The occurrence of a cough with ACE inhibitors should prompt a switch to an angiotensin receptor blocker (ARB).

The role of ACE inhibition in patients in heart failure with normal systolic function is less clear. The recent PEP-CHF study¹¹⁶ compared perindopril with a placebo in older patients with preserved systolic function heart failure. There was no significant reduction in mortality, but symptoms and hospitalization were improved in the perindopril group. In practice, many older people with heart failure and preserved systolic function will require an ACE inhibitor for another indication, such as myocardial infarction, angina, hypertension, or stroke disease.

β -Blockers

It has become increasingly clear in the last few years that β -blockade is beneficial for patients with left ventricular systolic dysfunction and heart failure. A role for β -blockers was suggested as far back as the early 1970s.¹¹⁷ Part of the rationale behind their use relates to reducing the adverse consequences of overstimulation of the sympathetic nervous system in patients with heart failure.

The main historical concerns relate to the negative inotropic effects of β -blockers with the potential for hypotension, fatigue, and acute worsening of decompensated heart failure. However, the results of randomized trials now suggest that, after mild intolerance associated with starting treatment in some patients, the benefits of longer-term therapy are significant and worth pursuing. Improved understanding of the pathophysiology of heart failure has highlighted the potential role for β -blockers in reducing the effects of vasoconstriction and fluid retention associated with heart failure. Indeed it is the case that blockade of the sympathetic nervous system by β -blockers complements the beneficial effects

of ACE inhibitors on the renin-angiotensin system. Beta-blockers also have an antiarrhythmic effect and additionally facilitate coronary blood flow by prolonging diastole. Blockade of the adrenergic system may reduce both adrenaline (epinephrine)-mediated myocyte cell loss and myocyte dysfunction, thus reducing associated left ventricular systolic dysfunction.¹¹⁸ Furthermore, the promotion of cellular growth and ventricular remodeling which is mediated by noradrenaline (norepinephrine) is blocked by β -blockers. It also appears that β -blockade may reduce some of the uncoupling of the B-receptors from their G protein at a cellular level, preventing further deterioration in systolic function.¹¹⁹

In the last few years it has been confirmed that treatment with β -blockade initially in small dosages, with a number of agents, can result in significant mortality benefits for patients with heart failure.^{79–81} It is important that the dose be carefully titrated, with a close evaluation following each up-titration in order to detect worsening heart failure or associated hypotension. Up-titration of the dose should occur only when the patient is stable. Although most patients will show some improvement in their clinical condition and the progression of heart failure is reduced, exercise capacity may be only partially improved by treatment. However, hospital admissions for decompensated heart failure are overall less frequent.

Although the evidence for the use of β -blockade in heart failure is strengthening, some earlier studies in the late 1980s and early 1990s showed only a mild benefit following treatment.¹²⁰ It is only with the MERIT Heart Failure study,⁸³ the CIBIS II,⁸⁴ and the US COPERNICUS Heart Failure study⁵⁰ that the evidence base for the use of β -blockers in heart failure has become robust.

- In the MERIT study, nearly 4000 patients with New York Heart Association class II-IV heart failure were treated with long-acting metoprolol in divided and increasing doses. The treatment group started on a dose between 12.5 and 25 mg daily which was titrated to a target dose of 200 mg daily. Those patients treated had a reduced mortality rate of 34% in the 1-year follow-up period, the absolute mortality rate being reduced from 11% to 7.2%. Deaths from worsening heart failure and sudden deaths were both reduced significantly.
- In the CIBIS II study, the findings are similar with patients in New York Association class III-IV on standard treatment with diuretics and ACE inhibitors deriving additional benefit by treatment with bisoprolol, a β_1 selective adrenoceptor blocker. The dose of bisoprolol was titrated up to 10 mg daily, with the mortality rate being reduced from 13.2% to 8.8% in the treatment group. Carvedilol is a nonselective β -blocker with antioxidant, β -blocking, and vasodilator activity.¹²¹ Following treatment with titrated doses of carvedilol, patients with chronic heart failure, including those with severe heart failure, derived benefit following a 6.5-month follow-up period.
- In the COPERNICUS trial,⁵⁰ a 35% reduction in analyzed mortality was obtained in patients treated with carvedilol compared to placebo. The benefit was also significant in patients with NYHA class IV heart failure, with an annual mortality rate of 18.5% in the placebo group compared with 11.4% in the carvedilol group.

These landmark trials have convincingly demonstrated that β -blockers improve mortality in patients with chronic heart failure. The precise role of β -blockers in frailer older patients with associated cognitive impairment and more frequent postural hypotension and comorbidity is unclear. However, there is a compelling case for β -blockade in patients with no contraindications, especially for those beta-blockers that do not cross the blood-brain barrier.

Contraindications include bradycardia, AV block, hypotension, asthma, or chronic obstructive pulmonary disease with significant reversibility; it is worth noting that many patients with COPD can tolerate β -blockade, and such patients were successfully enrolled in the CIBIS II trial of bisoprolol in heart failure. Problems with tolerability may be accentuated if the patient is taking other cardioactive medications. Patients with peripheral vascular disease may also find β -blockers difficult to tolerate.

Until recently, data on the tolerability of β -blockade in older heart failure patients was lacking. Recent studies have suggested that β -blockers are tolerated by a majority of older heart failure patients,¹²² and the recent SENIORS trial¹²³ specifically evaluated a cohort of older patients with heart failure, mean age 76. In this study nebulol had a significant effect on reducing hospital admissions, although the impact on all-cause mortality did not reach significance, and the effects in patients aged over 75 appeared less than in the younger old. Also of note was the fact that a significant proportion of patients in the SENIORS study had preserved left ventricular function, suggesting that β -blockade may provide some benefits in this understudied group of heart failure patients.

Spironolactone

In the RALES study,¹²⁴ the effectiveness of spironolactone added to an ACE inhibitor and a loop diuretic for severe chronic heart failure was assessed. This was a randomized double-blind placebo-controlled trial in which 1633 patients with New York Heart Association class III-IV heart failure, and ejection fraction of less than 30% and established on full ACE inhibitor and diuretic therapy with or without digoxin, were included. Small doses of spironolactone (25 to 50 mg/day) were well tolerated and reduced total mortality by 30% in the treatment group. Deaths from progressive heart failure and sudden deaths were reduced equally, and the incidence of severe hyperkalemia was low in both arms of the study.

Clinical experience of spironolactone in older people with heart failure suggests the need for great caution, however. The incidence of renal dysfunction and hyperkalemia in practice is up to 10 times that seen in the RALES trial and inappropriate use of spironolactone outside the indications used in the RALES trial may lead to a high incidence of side effects.¹²⁵

Digoxin

Digoxin has been used in the treatment of heart failure for over 200 years. It is a positive inotrope and the effects of digoxin are mediated by inhibition of the Na^+ , K^+ -ATPase, which influences intracellular sodium with resultant influences on sodium/calcium exchange across the sarcolemmal membrane.¹²⁶ It has a relatively narrow therapeutic window, with the result that side effects are common, particularly in the elderly with renal impairment and hypokalemia.

In addition to its effects on the myocardium, digoxin is a weak diuretic and can cause gastric irritation¹²⁷ and has

a mild estrogenic effect.¹²⁸ Digoxin improves the cardiac output and the stroke volume index with a resultant improvement in hemodynamic status in heart failure patients. The side effects of digoxin are more pronounced in patients with hypokalemia because potassium competes for the binding site at the site of action.

Until recently there has been considerable controversy over the role of digoxin in patients with heart failure. Its role in patients with sinus rhythm was particularly unclear. In the DIG trial,⁹⁰ nearly 8000 patients were assessed in over 300 centers. Patients were randomized to digoxin or placebo and followed for an average of 3 years. The patients had clinical heart failure but were in sinus rhythm. In the majority of patients, the cause of heart failure was ischemic heart disease and the average ejection fraction was 32%. Total mortality was no different between the digoxin and placebo groups. Heart failure deaths were reduced in the digoxin group, but there was a trend toward an increase in deaths because of arrhythmias or myocardial infarction. Hospital admissions were significantly reduced. Thus digoxin can now be recommended to patients with heart failure and sinus rhythm who remain symptomatic despite the use of diuretics and ACE inhibitors, and β -blockers.

Clearly in older patients close monitoring of therapy is essential. Two relatively recent withdrawal studies^{129,130} indicate that digoxin is a useful adjunct to treatment in patients on ACE inhibitors and diuretics. With impaired renal function and reduced clearance of the drug, symptomatic nausea and fatigue are probably the most frequent complication together with bradycardia. A number of therapeutically important drug interactions also exist with digoxin, particularly with quinidine and amiodarone.¹³¹ It is also sometimes difficult to distinguish between digoxin toxicity and the underlying symptoms of cardiac failure; digoxin is also capable of worsening confusion in older people. Digoxin is the third most commonly implicated drug in admissions precipitated by medication side effects; the balance between potential benefits for patients with refractory heart failure must always be carefully weighed against this side effect profile.

Digoxin remains useful in controlling ventricular rate in patients with fast atrial fibrillation and decompensated heart failure. The recent Scottish Intercollegiate Guideline Network has suggested that patients with heart failure and atrial fibrillation who need control of their ventricular rate should be considered for treatment with digoxin. Others to be considered include patients with moderately severe or severely symptomatic heart failure; those who remain symptomatic despite diuretic and ACE inhibitor therapy; those who have had more than one hospital admission for heart failure; and those who have had poor left ventricular systolic function and persisting cardiomegaly.

The maintenance dose of digoxin in heart failure should be in the region of 125 $\mu\text{g}/\text{day}$, but smaller doses may be necessary in some patients. Although additional therapeutic benefit may be obtained at higher doses, toxicity becomes increasingly likely.

Angiotensin antagonists

Attention recently has been directed toward angiotensin receptor blockade as a means of modifying the symptoms of heart failure. It appears that there are at least two angiotensin receptors: AT I and AT II. Stimulation of the former

results in vasoconstriction, whereas stimulation of the latter results in vasodilatation. Angiotensin I receptor antagonists are effective in hypertension and their use is becoming more widespread.

The effects of these agents in elderly patients with heart failure were clarified in the ELITE, CHARM and Val HeFT^{85–89} studies. In the first, where mortality was the primary endpoint, no mortality difference was seen between patients treated with losartan or captopril. In the Val HeFT study, there appeared to be no improvement in mortality in patients with heart failure treated with valsartan on top of an ACE inhibitor. However, symptomatic improvement was demonstrated and the need for hospital admission was reduced by valsartan on top of an ACE inhibitor.

These agents are generally well tolerated and should certainly be used in patients who are intolerant of ACE inhibition because of cough. They are, however, licensed in the United Kingdom currently only as a treatment for hypertension. The most recent data are presented in the CHARM studies, which evaluated candesartan in three different groupings of patients. In the CHARM "alternative" study, comparing candesartan with a placebo in patients intolerant of ACE inhibitors, there was a significant reduction in hospital admission and cardiovascular death for those patients treated with candesartan. In the CHARM "preserved" study, which compared candesartan with a placebo in patients with heart failure and preserved LV systolic function, addition of candesartan to standard treatments reduced hospital admissions but had no impact on mortality. In the CHARM "added" study, candesartan further reduced death and hospitalization for patients already taking an ACE inhibitor when compared with a placebo. Concern exists, however, that multiple blockade of the renin-angiotensin system may lead to an increased incidence of side effects, particularly renal impairment, which may limit the usefulness of this approach in older people with heart failure.

Other pharmacologic agents

Nitrates have a well-established role in the treatment of angina, but they also have a role in the management of cardiac failure. They act predominantly through stimulation of intracellular guanylate cyclase with subsequent sequestration of intracellular calcium and resultant vasodilatation. Beneficial hemodynamic effects include a reduction in blood pressure together with decreased pulmonary artery wedge pressure.¹³² These favor an increase in cardiac output by reducing the preload on the left ventricle.¹³³ Tolerance to nitrate therapy is well recognized, but this can be reduced by nitrate-free periods.

A study of intravenous nitrate therapy showed that this treatment is effective in the treatment of acute pulmonary edema with reduction in symptoms of breathlessness and discomfort.¹³⁴ In one trial of acute left ventricular failure, intravenous isosorbide dinitrate appeared better than intravenous furosemide as a first-line therapy.¹³⁵

In the first Veterans Administration Cooperative Heart Failure trial (V-HeFT 1), isosorbide dinitrate and hydralazine¹³⁶ were compared with prazosin and placebo in patients with New York Heart Association class II-III heart failure. There was a mild improvement in mortality in the nitrate and hydralazine group and ejection fraction and exercise performance also improved. The most notable effect was

seen in patients of African extraction, and these findings were confirmed in patients with severe heart failure in the more recent A-HeFT study.¹³⁷ This highlights the potential value of nitrates and hydralazine as an intervention for patients unable to tolerate ACE inhibition who remain severely symptomatic. In addition to nitrates, other vasodilators such as calcium antagonists may have a role in heart failure. However, the PRAISE trial¹³⁸ showed that amlodipine has a neutral effect on mortality, which means that amlodipine can be used for its anti-ischemic effect in heart failure patients without worsening their heart failure.

Other agents have been evaluated in patients with cardiac failure but the above-mentioned drugs are currently the conventional treatment. In general terms, positive inotropes have been largely unhelpful and phosphodiesterase inhibitors have merely increased mortality.^{139,140} Flosequinan is also associated with increased mortality.¹⁴¹ Short-term use of intravenous positive inotropes may be useful in occasional patients, but their overall benefit is limited. Other simple measures may be useful. In a patient with a mild anemia, treatment of the anemia may improve tissue oxygenation and subsequent cardiac performance. This may require ferrous sulfate given intravenously, erythropoietin, or both. In patients with nutritional deficiencies, vitamin B supplementation may also be useful. There has been some recent concern that treatment with aspirin may negate the beneficial effects of ACE inhibitors in patients with left ventricular systolic dysfunction.¹⁴² The evidence for this is not strong and such patients with left ventricular systolic dysfunction should still be treated with an ACE inhibitor where possible. There is currently no strong evidence that anticoagulation for patients with heart failure in sinus rhythm is of any benefit. Patients with atrial fibrillation should receive treatment with warfarin if not contraindicated.

Cardiac arrhythmias are relatively common in patients with heart failure. Patients with atrial fibrillation should be managed with anticoagulation where possible, although it should be remembered that the risks of hemorrhagic side effects are likely to be greater in the older patient and tight control of the INR is mandatory. Anticoagulation should be avoided in patients who are frequent fallers. Rapid ventricular rates associated with fast atrial fibrillation can be controlled by digoxin and/or β -blockers. Conversion to sinus rhythm can prove difficult as often the atrial fibrillation is longstanding. However, as atrial systole has increased importance in the older patient, attempts to maintain sinus rhythm should be made if symptoms are severe, either electrically or pharmacologically with β -blockers or amiodarone. Recent studies have suggested that there is little prognostic benefit in cardioversion to sinus rhythm compared with a rate control strategy for patients with an ejection fraction of 35% or less, symptoms of congestive heart failure and a history of atrial fibrillation.¹⁴³ Ventricular arrhythmias are also relatively common in patients with heart failure. These ventricular arrhythmias may cause considerable hypotension and may even be fatal. Amiodarone is often used in the context of symptomatic ventricular arrhythmias, but it has a number of noncardiac side effects including pulmonary fibrosis, liver function abnormalities, thyroid dysfunction, and peripheral neuropathy. In a trial in South America,¹⁴⁴ 500 patients with heart failure were randomized to amiodarone or placebo at a relatively low

dose and followed up at 13 months. The mortality in the amiodarone group was 33.5%, compared with 41.4% in the placebo group—a risk reduction of 28%. In the CHF-STAT trial,¹⁴⁵ a higher dosage of amiodarone was used in a similar number of patients. At the higher dose, no mortality benefit was seen, although there was a reduced mortality trend in patients with a nonischemic cause. These studies would tend to suggest that amiodarone should be the antiarrhythmic of choice in patients with heart failure and symptomatic ventricular arrhythmias, but there is no role for widespread use of prophylactic amiodarone.

Drug interactions are frequently a problem in the elderly population and there are a number of significant interactions with amiodarone. The most significant of these is with warfarin and treatment should be carefully monitored. Patients with heart failure who have associated angina and myocardial ischemia should be treated for their ischemic heart disease by conventional means. Patients may require treatment with aspirin, β -blockade, statins, oral nitrates, calcium antagonists or other, nondrug, measures.

In patients with ischemic heart disease and mild to moderate impairment of left ventricular systolic functions, left ventricular performance may be improved by coronary bypass surgery. Such patients may have a hibernating area of myocardium, which could potentially be salvaged following bypass surgery.

Role of the heart failure nurse

Heart failure nurses have a critical role to play in coordinating heart failure care, monitoring patients symptoms, educating patients and caregivers, and up-titrating medications. They are therefore a pivotal member of the multidisciplinary team. Older heart failure patients, with their complex care needs, are particularly well placed to benefit from the skills that the heart failure nurse brings to bear. Trial evidence confirms that heart failure nurse intervention leads to lower levels of death and readmission in heart failure patients.¹⁴⁶

Multidisciplinary team interventions

Similarly, there is evidence to support multidisciplinary intervention in older heart failure patients; the combination of nurse specialist intervention, pharmacist medication review, and education plus physician intervention led to reduced hospitalization and improved symptom control and quality of life in a U.S. trial.²⁹

Both clinic-based and home-based MDT models have been used successfully; the addition of telemonitoring—for example, of weight and symptoms—or using more sophisticated invasive measures of hemodynamic function, is a potentially exciting adjunct to these models of care. Trials will be required in older, frail individuals to see whether such telemonitoring approaches are feasible and add to the quality of care.

Exercise in CHF

There is good evidence that at least for younger heart failure patients, regular submaximal aerobic or resistance exercise training leads to important improvements in symptoms, quality of life, reduces hospitalizations, and leads to a reduction in mortality.¹⁴⁷ There are few studies in older heart failure patients to guide the type, duration, and intensity of exercise intervention best suited to older heart failure patients.

In younger old patients, group circuit exercise in cardiac rehabilitation classes¹⁴⁸ appears successful, but in older, frailer patients, gentle seated exercise does not appear efficacious and a more vigorous alternative may be needed.¹⁴⁹

Patients with uncontrolled atrial fibrillation, active sepsis, decompensated fluid overload, severe aortic stenosis, or malignant ventricular arrhythmias (unless an implantable cardioverter defibrillator [ICD] is fitted) should probably not participate in exercise, but for other patients, exercise appears remarkably safe. An exercise intensity of up to 80% of maximal should be the aim; in practical terms this is a level at which patients can still talk. The optimal session frequency and length have yet to be determined, but will depend on symptoms and the practicalities such as a suitable venue and transportation. It is important to note that exercise training needs to be continued for sustained benefit; improvements in exercise capacity are lost rapidly on cessation of exercise. Exercise programs should therefore be capable of being continued at home unsupervised rather than being confined to supervised sessions in hospital or outpatient settings.

Smoking

Smoking increases the chance of further myocardial ischemic events, and directly worsens tissue oxygenation. Smoking should always be actively discouraged in patients with heart failure, however old. Counseling remains the cornerstone of intervention for those prepared to quit; nicotine replacement may be used with care in patients with stable coronary artery disease and no history of malignant ventricular arrhythmias, and bupropion may be useful in carefully selected patients without other contraindications.

Alcohol

Alcohol has depressant effects on the myocardium, and also interacts with common comorbid diseases, particularly urinary incontinence, where the excess of fluid and decreased sensation caused by alcohol may worsen incontinence. Consumption in older people should therefore be limited to one or two units per day. Patients with alcoholic cardiomyopathy should be strongly encouraged to abstain totally.

Diet

Surprisingly little data exist to guide practice regarding diet in heart failure. Many older people with heart failure are overweight, and although obesity may reduce exercise tolerance still further, cohort studies suggest that overweight heart failure patients survive longer than patients of normal weight. The value of calorie restriction in heart failure has not been subjected to randomized controlled trials, and caution thus seems appropriate in recommending this, even in obese patients.

Cardiac cachexia is less common in heart failure, but is associated with advanced disease and a particularly poor prognosis. Dietary approaches to reversing cardiac cachexia have not been subjected to randomized trials; nevertheless, a pragmatic approach to dietetic intervention in underweight heart failure patients is probably merited, given the overlap with other chronic causes of frailty and undernutrition seen in older people.

Although salt and fluid restriction has long been promoted as beneficial in controlling symptoms in heart failure, practical issues limit the applicability of this advice. Efforts should be made to avoid excessive fluid consumption, but salt restriction below the recommended 6 g/day limit is often difficult in older patients who may have deeply ingrained cooking habits, a reliance on preprepared foods, and for whom the flavor-enhancing properties of salt are important in stimulating appetite and food intake.

PROBLEMATIC DISEASE INTERACTIONS — COPD, INCONTINENCE, COGNITIVE IMPAIRMENT, DEPRESSION

Heart failure in older people never exists in isolation, and the art of good care of older people with heart failure is to balance the management of their heart failure with management of their comorbid diseases, taking into account their physical and psychological state, quality of life, and treatment preferences. The following comorbid conditions often give rise to particular problems in patients with heart failure.

COPD

As smoking is a risk factor for both heart failure and COPD, the syndromes often coexist. This may make diagnosis more challenging; in older people experiencing breathlessness, it is often necessary to investigate for both syndromes. Severe COPD may also lead to right heart dysfunction as the underlying cause of the heart failure syndrome.

Management of heart failure in the presence of COPD still involves ACE inhibitors and diuretics; overdiuresis may cause a precipitous drop in cardiac output and blood pressure if the right ventricle is impaired because the impaired ventricle requires high filling pressures. B-blockers can be used in many patients with COPD unless significant reversible airway obstruction is present. There are theoretical advantages to using β_1 -selective agents. In many patients, only an empirical trial of β -blockers will show if they are tolerated.

Exercise, in the form of pulmonary rehabilitation, is an important component of therapy for COPD, and exercise training should thus be encouraged when both conditions exist. Smoking, needless to say, should be firmly discouraged.

Urinary incontinence

Incontinence, always a prevalent problem in older people, is a particular problem in patients with heart failure. Reduced mobility and exercise capacity mean that reaching a toilet in time may be difficult, and the use of diuretics may lead to large urine volumes accumulating with little warning. This in turn leads to activity restriction because patients are worried about leaving the house after taking diuretics, or worse, patients deliberately miss diuretics, leading to decompensation of heart failure. Nocturia may also be a problem in patients with heart failure; lying flat causes excess fluid to redistribute from the lower extremities, increasing renal blood flow and urine excretion.

Careful adjustment of the dose and timing of diuretics is needed to circumvent these problems. Dividing doses, avoiding diuretics late in the day, or using diuretics with a slower onset of action such as torsemide¹⁵⁰ may all help. Use of interventions such as ACE inhibitors and exercise may help to improve exercise capacity, thus allowing patients to reach the toilet more easily.

Cognitive impairment

Cognitive impairment is common in older patients with heart failure, almost certainly a result of the two major causes of cognitive impairment sharing vascular risk factors with heart failure.¹⁰ The presence of marked cognitive impairment may cause problems with adherence to medication, the ability to undertake self-monitoring (e.g., weight), and the ability to understand and retain information about the illness, medications, and prognosis.

Such problems should be anticipated, and strategies to manage medication (e.g., dosette boxes), close involvement of caregivers in education, fluid management, meal preparation, and medication administration are vital. Heart failure itself is not necessarily a contraindication to anticholinesterase inhibitor therapies, but care is needed to ensure that there is no evidence of underlying AV or SA node disease or that other rate-limiting drugs do not cause heart block.

Depression

Depression is common in heart failure patients, as is the case in many older people with chronic disease. Debate continues as to whether depression is truly an independent risk factor for death in heart failure, but there is no doubt that it exacerbates symptoms and worsens an already poor quality of life.

As with all unwell older people, depression should be sought whenever a comprehensive assessment is performed, preferably using a screening tool such as the Geriatric Depression Score or the Hospital Anxiety and Depression Scale. Psychological interventions remain the cornerstone of treatment for mild to moderate depression; more severe depression may require drug treatment. Although there are no randomized controlled trials to guide treatment of depression in heart failure, the known cardiotoxic side effects of tricyclic antidepressants mean that this class should be avoided. Anecdotal evidence suggests that SSRIs and related classes are relatively safe for use in heart failure.

Rationalizing the drug burden

Heart failure as a disease entity often entails a large number of extra medications. Added to the medications that patients often need to take for their comorbid diseases, this presents a substantial burden (including financial) to patients, increases the chances of drug interactions, and makes adherence to therapy less likely.¹⁵¹

It is possible to use heart failure treatments for multiple indications, especially for multiple vascular diseases, which may help to reduce the burden of therapy. ACE inhibitors will help to treat hypertension and reduce the risk of myocardial infarction; β -blockers can be used for rate control in AF, reducing blood pressure and treating angina. If further antianginals are needed, using nitrates can have further beneficial effects on blood pressure and heart failure. Such approaches may provide a way of reducing the number of vascularly active medications that a patient takes. In some patients, sodium restriction and use of ACE inhibitors may even allow diuretics to be withdrawn, with consequent improvement in urinary continence and urge symptoms. Such an approach may then allow other medications aimed at the urinary tract to be reduced or stopped.

Device therapy

Two major advances in device therapy for heart failure have become commonplace in recent years: implantable cardioverter-defibrillators (ICDs) and cardiac resynchronization therapy (CRT), also known as a biventricular pacemaker. The two devices can also be combined into a single unit (ICD-CRT).

In patients with significantly impaired ejection fractions, ICDs are known to reduce death rates by providing timely treatment of ventricular arrhythmias.¹⁵² However, considerable discussion is required before using such devices in older heart failure patients with multiple comorbid diseases; such devices do not improve physical function or quality of life, may cause significant psychological distress—not to mention physical discomfort from defibrillation shocks—and will not prolong life in the face of the multiple system failures that are the hallmark of frailty.

Cardiac resynchronization on the other hand may dramatically improve cardiac function, exercise capacity, symptoms, and quality of life in carefully selected patients with advanced heart failure and significant dyssynchrony between the left ventricular septum and free wall.¹⁵³ Such devices may additionally allow sufficient hemodynamic improvement for other medications, such as ACE inhibitors and β -blockers, to be tolerated.

Palliative care for CHF

For patients with end-stage heart failure, there is good evidence to suggest that control of symptoms can be effectively managed by palliative care teams. The emphasis of most medical efforts in heart failure is directed to extending the duration of life, and sadly there are many patients with heart failure who do not have the opportunity to die a good death.

Communication is key; patients need to appreciate the prognosis in heart failure, which is worse than for breast and colorectal cancer. As the illness advances, sensitive discussions should take place to explore whether patients wish for life-prolonging therapy, including hospital admission, intubation, and inotropic support during exacerbations, and whether they wish to undergo cardiopulmonary resuscitation in the event of cardiac arrest. Involvement of caregivers as wished by patients, together with meticulous documentation of such discussions, can go a long way toward preparing the patients and their loved ones for the day when further efforts to prolong life become futile.

Near the end of life, some medications may be withdrawn if they are not contributing to symptom management. Intractable breathlessness may be alleviated by small doses of opiates; older patients with end-stage heart failure commonly also have pain, which is underreported.¹⁵⁴ Good palliative care involves the provision of support for all the patient's needs, including psychosocial and spiritual, and thus the narrow medical model used to manage heart failure or other chronic disease early in the course of the disease becomes less and less relevant as the illness progresses.¹⁵⁵

CONCLUSIONS

Chronic heart failure is a major cause of morbidity and mortality in older patients. Optimum treatment requires an accurate diagnosis. In the older patient, the cause of heart failure

is often heterogeneous and the clinical and examination findings should be confirmed by more objective assessments including chest radiology, electrocardiography, and particularly echocardiography. Elderly patients often have limited access to echocardiography, but it is essential given the high prevalence of background valvular disease and structural heart disease.

Once an accurate diagnosis has been established, treatment of left ventricular systolic dysfunction should follow the recent guidelines of the European Society of Cardiology and the American Heart Association where possible, with consideration of the specific requirements of the individual patient. Close supervision of treatment is mandatory particularly with ACE inhibitors and β -blockers where the possibility of short-term side effects is significant. Specific drug interventions should be tailored to individual patients, with cognitive impairment and additional pathology restricting the choice of agents available.

The prognosis for chronic heart failure is poor and at all times when treating the older patient emphasis should be on improving the patient's quality of life and symptom control, rather than merely delaying death.

Many of the major multicenter clinical trials have excluded older patients from analysis, but evidence should emerge about drug tolerability in patients over the age of 75. However, when there is evidence of fluid retention patients should be treated with a diuretic, and once evidence of left ventricular systolic dysfunction is confirmed they should be treated with an ACE inhibitor. Strong consideration should be given to treatment with a β -blocker. If the patient has severe heart failure, spironolactone (25 mg/day) should be added to the furosemide, ACE inhibitor, and β -blocker, but it is crucial to monitor the serum electrolytes carefully in the first month of therapy. If the patient is in atrial fibrillation and control of the ventricular rate is an issue, digoxin should be used. Other agents should be chosen in the light of contraindications to these major treatments. Digoxin and nitrates improve symptoms, and spironolactone may improve mortality. As in any illness, the response to treatment should be carefully monitored by the physician.

Multidisciplinary care is crucial, as with all older patients, and staff skilled in the care of older people should be closely involved in teams caring for heart failure patients. Exercise training, smoking cessation, and avoidance of excessive fluid and salt are important adjuncts to pharmacologic therapy.

In carefully selected patients, device therapy such as cardiac resynchronization therapy may provide additional significant improvements.

KEY POINTS

Chronic Cardiac Failure

- Chronic heart failure is a major cause of morbidity and mortality in elderly patients.
- The optimum treatment requires an accurate diagnosis. In the older patient, the cause of heart failure is often heterogeneous, so the clinical and examination findings should be confirmed by more objective assessments, including chest radiology, electrocardiography, and, particularly, echocardiography.
- Once an accurate diagnosis has been established, treatment of left ventricular systolic dysfunction should follow the recent guidelines of the European Society of Cardiology and the American Heart Association where possible, with consideration of the specific requirements of the individual patient.
- Close supervision of treatment is mandatory, particularly with ACE inhibitors and β -blockers, where the possibility of short-term side effects is significant.
- The prognosis for chronic heart failure is poor. Emphasis should be on improving the patient's quality of life and symptom control, although new treatments may also improve mortality.
- Many of the major multicenter clinical trials have excluded older patients from analysis, but evidence should emerge in the next few years about drug tolerability in patients over the age of 75.
- When there is evidence of fluid retention, patients should be treated with a diuretic. Once evidence of left ventricular systolic dysfunction is confirmed, they should be treated with an ACE inhibitor.
- Strong consideration should be given to treatment with a β -blocker. If the patient has severe heart failure, spironolactone (25 mg/day) should be added to the furosemide.
- If the patient is in atrial fibrillation and control of the ventricular rate is an issue, digoxin should be used.
- Other agents should be chosen in the light of contraindications to these major treatments. Digoxin and nitrates improve symptoms and spironolactone may improve mortality.

Diagnosis and Management of Coronary Artery Disease

Wilbert S. Aronow

The most common cause of death in elderly persons is coronary artery disease (CAD). Coronary atherosclerosis is very common in the elderly, with autopsy studies demonstrating a prevalence of at least 70% in persons older than 70 years. The prevalence of CAD is similar in elderly women and men.¹ In one study, clinical CAD was present in 502 of 1160 men (43%), mean age 80 years, and in 1019 of 2,464 women (41%), mean age 81 years.¹ At 46-month follow-up, the incidence of new coronary events (myocardial infarction or sudden cardiac death) was 46% in the elderly men and 44% in the elderly women.¹

CAD is diagnosed in elderly persons if they have either coronary angiographic evidence of significant CAD, a documented myocardial infarction (MI), a typical history of angina pectoris with myocardial ischemia diagnosed by stress testing, or sudden cardiac death. The incidence of sudden cardiac death as the first clinical manifestation of CAD increases with age.

CLINICAL MANIFESTATIONS

Dyspnea on exertion is a more common clinical manifestation of CAD in elderly persons than is the typical chest pain of angina pectoris. The dyspnea is usually exertional and is related to a transient rise in left ventricular (LV) end-diastolic pressure caused by ischemia superimposed on reduced LV compliance. Because elderly persons are more limited in their activities, angina pectoris in elderly persons is less often associated with exertion. Elderly persons with angina pectoris are less likely to have substernal chest pain, and they describe their anginal pain as less severe and of shorter duration than do younger persons. Angina pectoris in elderly persons may occur as a burning postprandial epigastric pain or as pain in the back or shoulders. Acute pulmonary edema unassociated with an acute MI may be a clinical manifestation of unstable angina pectoris due to extensive CAD in elderly persons.²

Myocardial ischemia, appearing as shoulder or back pain in elderly persons, may be misdiagnosed as degenerative joint disease. Myocardial ischemia, appearing as epigastric pain, may be misdiagnosed as peptic ulcer disease. Nocturnal or postprandial epigastric discomfort that is burning in quality may be misdiagnosed as hiatus hernia or esophageal reflux instead of myocardial ischemia because of CAD. The presence of comorbid conditions in elderly persons may also lead to misdiagnosis of symptoms as a result of myocardial ischemia.

Elderly persons with CAD may have silent or asymptomatic myocardial ischemia.³⁻⁵ In a prospective study, 133 of 195 men (68%), mean age 80 years, with CAD and 256 of 771 women (33%), mean age 81 years, with CAD had silent myocardial ischemia detected by 24-hour ambulatory electrocardiograms (ECGs).⁵ At 45-month follow-up, the incidence of new coronary events in elderly men with CAD was 90% in those with silent myocardial ischemia versus 44% in men without silent ischemia.⁵ At 47-month follow-up, the

incidence of new coronary events in elderly women with CAD was 88% in those with silent ischemia versus 43% in women without silent ischemia.⁵

The reason for the frequent absence of chest pain in elderly patients with CAD is unclear.

RECOGNIZED AND UNRECOGNIZED MI

Pathy⁶ reported that in 387 elderly patients with acute MI, 19% had chest pain, 56% had dyspnea or neurologic symptoms or gastrointestinal symptoms, 8% had sudden death, and 17% had other symptoms. Another study showed that in 110 elderly patients with acute MI, 21% had no symptoms, 22% had chest pain, 35% had dyspnea, 18% had neurologic symptoms, and 4% had gastrointestinal symptoms (Table 41-1).⁷ Other studies have also shown a high prevalence of dyspnea and neurologic symptoms in elderly patients with acute MI.⁸⁻¹⁰ In these studies, dyspnea was present in 22% of 87 patients,⁸ in 42% of 777 patients,⁹ and in 57% of 96 patients.¹⁰ Neurologic symptoms were present in 16% of 87 patients,⁸ 30% of 777 patients,⁹ and 34% of 96 patients.¹⁰

As with myocardial ischemia, some patients with acute MI may be completely asymptomatic or the symptoms may be so vague that they are unrecognized by the patient or physician as an acute MI. Studies have reported that 21% to 68% of MIs in elderly patients are unrecognized or silent.^{7,11-17} These studies also found that the incidence of new coronary events including recurrent myocardial infarction, ventricular fibrillation, and sudden death in patients with unrecognized MI is similar to^{11,14-16,18} or higher¹⁹ than in patients with recognized MI.

Elderly patients with acute MI have a higher prevalence of non-ST-segment elevation MI (NSTEMI) with absence of pathologic Q-waves than ST-segment elevation MI (STEMI) with pathologic Q-waves.^{20,21} Of 91 consecutive patients aged 70 years and older, mean age 78 years with acute MI, 61 (75%) had NSTEMI.²¹

DIAGNOSTIC TECHNIQUES

Resting ECG

In addition to diagnosing recent or prior MI, the resting ECG may show ischemic ST-segment depression, arrhythmias, conduction defects, and LV hypertrophy that are

Table 41-1. Presenting Symptoms in 110 Elderly Patients with Acute Myocardial Infarction

Dyspnea was present in 35% of patients
Chest pain was present in 22% of patients
Neurologic symptoms were present in 18% of patients
Gastrointestinal symptoms were present in 4% of patients
No symptoms were present in 21% of patients

Adapted from Aronow WS. Prevalence of presenting symptoms of recognized acute myocardial infarction and of unrecognized healed myocardial infarction in elderly patients. *Am J Cardiol* 1987;60:1182.

related to subsequent coronary events. At 37-month mean follow-up, elderly patients with ischemic ST-segment depression 1 mm or greater on the resting ECG were 3.1 times more likely to develop new coronary events than were elderly patients with no significant ST-segment depression.²² Elderly patients with ischemic ST-segment depression 0.5 to 0.9 mm on the resting ECG were 1.9 times more likely to develop new coronary events during 37-month follow-up than were elderly patients with no significant ST-segment depression.²² At 45-month mean follow-up, pacemaker rhythm, atrial fibrillation, premature ventricular complexes, left bundle branch block, intraventricular conduction defect, and type II second-degree atrioventricular block were associated with a higher incidence of new coronary events in elderly patients.²³ Numerous studies have also demonstrated that elderly patients with ECG LV hypertrophy have an increased incidence of new coronary events.^{24–26}

Numerous studies have found that complex ventricular arrhythmias in elderly persons with CAD are associated with an increased incidence of new coronary events including sudden cardiac death.^{27–30} The incidence of new coronary events is especially increased in elderly persons with complex ventricular arrhythmias and abnormal LV ejection fraction²⁷ or LV hypertrophy.²⁸ At 45-month follow-up of 395 men, mean age 80 years, with CAD, complex ventricular arrhythmias detected by 24-hour ambulatory ECGs significantly increased the incidence of new coronary events 2.4 times.²⁹ At 47-month follow-up of 771 women, mean age 81 years, with CAD, complex ventricular arrhythmias detected by 24-hour ambulatory ECGs significantly increased the incidence of new coronary events 2.5 times.²⁹

Exercise stress testing

Hlatky et al³¹ found the exercise ECG to have a sensitivity of 84% and a specificity of 70% for the diagnosis of CAD in persons older than 60 years of age. Newman and Phillips³² found a sensitivity of 85%, a specificity of 56%, and a positive predictive value of 86% for the exercise ECG in diagnosing CAD. The increased sensitivity of the exercise ECG with increasing age found in these two treadmill exercise studies was probably due to the increased prevalence and severity of CAD in elderly persons.

Exercise stress testing also has prognostic value in elderly patients with CAD.^{33–35} Deckers et al³⁵ demonstrated that the 1-year mortality was 4% for 48 patients 65 years of age or older who were able to do an exercise stress test after acute MI and 37% for the 63 elderly patients unable to do the exercise stress test after acute MI.

Exercise stress testing using thallium perfusion scintigraphy, radionuclide ventriculography, and echocardiography is also useful in the diagnosis and prognosis of CAD.^{36–38} Iskandirian et al³⁶ showed that exercise thallium-201 imaging can be used for risk stratification of elderly patients with CAD. The risk for cardiac death or nonfatal MI at 25-month follow-up in 449 patients 60 years of age or older was less than 1% in patients with normal images, 5% in patients with single-vessel thallium-201 abnormality, and 13% in patients with multivessel thallium-201 abnormality.

Pharmacologic stress testing

Intravenous dipyridamole-thallium imaging may be used to determine the presence of CAD in elderly patients who are unable to undergo treadmill or bicycle exercise stress testing.³⁹ In patients 70 years of age or older, the sensitivity of intravenous dipyridamole-thallium imaging for diagnosing significant CAD was 86%, and the specificity was 75%.³⁹ In 120 patients older than 70 years, adenosine echocardiography had a 66% sensitivity and a 90% specificity in diagnosing CAD.⁴⁰ An abnormal adenosine echocardiogram predicted a threefold risk of future coronary events, independent of coronary risk factors.⁴⁰ In 120 patients older than 70 years, dobutamine echocardiography had a 87% sensitivity and a 84% specificity in diagnosing CAD.⁴⁰ An abnormal dobutamine echocardiogram predicted a 7.3-fold risk of future coronary events.⁴⁰

Ambulatory electrocardiography

Ambulatory ECGs performed for 24 hours is also useful in detecting myocardial ischemia in elderly persons with suspected CAD who cannot perform treadmill or bicycle exercise stress testing because of advanced age, intermittent claudication, musculoskeletal disorders, heart failure, or pulmonary disease. Ischemic ST-segment changes demonstrated on 24-hour ambulatory ECGs correlate with transient abnormalities in myocardial perfusion and LV systolic dysfunction. The changes may be associated with symptoms, or symptoms may be completely absent, which is referred to as silent myocardial ischemia. Silent myocardial ischemia is predictive of future coronary events, including cardiovascular mortality in elderly persons with CAD.^{3–5,30,41–43} The incidence of new coronary events is especially increased in elderly persons with silent myocardial ischemia plus complex ventricular arrhythmias,³⁰ abnormal LV ejection fraction,⁴¹ or echocardiographic LV hypertrophy.⁴³

Signal-averaged electrocardiography

Signal-averaged electrocardiography (SAECG) was performed in 121 elderly postinfarction patients with asymptomatic complex ventricular arrhythmias detected by 24-hour ambulatory ECGs and a LV ejection fraction of 40% or higher.⁴⁴ At 29-month follow-up, the sensitivity, specificity, positive predictive value, and negative predictive value for predicting sudden cardiac death were 52%, 68%, 32%, and 83%, respectively, for a positive SAECG; 63%, 70%, 38%, and 87%, respectively, for nonsustained ventricular tachycardia; and 26%, 89%, 41%, and 81%, respectively, for a positive SAECG plus nonsustained ventricular tachycardia.⁴⁴

Multislice computed tomography and magnetic resonance imaging

A direct comparison of multislice computed tomography angiography (MSCTA) with magnetic resonance imaging (MRI) for noninvasive coronary arteriography was performed in 129 patients, mean age 64 years, with suspected CAD.⁴⁵ Sensitivity for coronary stenoses greater than 50% of luminal diameter was 82% for MSCTA versus 54% for MRI; the respective specificities were 90% and 87%. The negative predictive value was slightly higher for MSCTA (95% versus 90%). In this study, 74% of patients preferred MSCTA

over MRI. The greater diagnostic accuracy of MSCTA over MRI in this study is consistent with meta-analyses of both tests.^{46,47}

64-MSCTA and coronary angiography were performed in 145 patients, mean age 67 years, and stress testing in 47 of these patients to determine the sensitivity, specificity, positive predictive value, and negative predictive value of these tests in diagnosing obstructive CAD in patients with suspected CAD.⁴⁸ Of 145 patients, 64-MSCTA had a 98% sensitivity, a 74% specificity, a 90% positive predictive value, and a 94% negative predictive value in diagnosing obstructive CAD. Of 47 patients, stress testing had a 69% sensitivity, a 36% specificity, a 78% positive predictive value, and a 27% negative predictive value for diagnosing obstructive CAD, whereas 64-MSCTA had a 100% sensitivity, a 73% specificity, a 92% positive predictive value, and a 100% negative predictive value for diagnosing obstructive CAD. 64-MSCTA has a better sensitivity, specificity, positive predictive value, and negative predictive value than stress testing in diagnosing obstructive CAD.⁴⁸

CORONARY RISK FACTORS

Cigarette smoking

The Cardiovascular Health Study demonstrated in 5201 men and women 65 years of age or older that greater than 50 pack-years of smoking increased 5-year mortality 1.6 times.⁴⁹ The Systolic Hypertension in the Elderly Program pilot project showed that smoking was a predictor of first cardiovascular event and MI/sudden death.⁵⁰ At 5-year follow-up of 7178 persons 65 years of age or older in three communities, the relative risk for cardiovascular disease mortality was 2.0 for male smokers and 1.6 for female smokers.⁵¹ The incidence of cardiovascular disease mortality in former smokers was similar to that in those who had never smoked.⁵¹ At 40-month follow-up of 664 men, mean age 80 years, and at 48-month follow-up of 1488 women, mean age 82 years, current cigarette smoking increased the relative risk of new coronary events 2.2 times in men and 2.0 times in women.⁵² At 6-year follow-up of older men and women in the Coronary Artery Surgery Study registry, the relative risk of MI or death was 1.5 for persons 65 to 69 years of age and 2.9 for persons 70 years of age and older who continued smoking compared with quitters during the year before study enrollment.⁵³

Elderly men and women who smoke cigarettes should be strongly encouraged to stop smoking to reduce the development of CAD and other cardiovascular diseases. Smoking cessation will decrease mortality from CAD, other cardiovascular diseases, and all-cause mortality in elderly men and women. A smoking cessation program should be instituted.⁵⁴

Hypertension

Systolic hypertension in elderly persons is diagnosed if the systolic blood pressure is 140 mm Hg or higher from two or more readings on two or more visits.⁵⁵ Diastolic hypertension in elderly persons is similarly diagnosed if the diastolic blood pressure is 90 mm Hg or higher.⁵⁵ In a study of 1819 persons, mean age 80 years, living in the community, the prevalence of hypertension was 71% in elderly African Americans, 64% in elderly Asians, 62% in elderly Hispanics, and 52% in elderly whites.⁵⁶

Isolated systolic hypertension in elderly persons is diagnosed if the systolic blood pressure is 140 mm Hg or higher with a diastolic blood pressure of less than 90 mm Hg.⁵⁵ Approximately two thirds of elderly persons with hypertension have isolated systolic hypertension.⁵⁶

Isolated systolic hypertension and diastolic hypertension are both associated with increased CAD morbidity and mortality in elderly persons.⁵⁷ Increased systolic blood pressure is a greater risk factor for CAD morbidity and mortality than is increased diastolic blood pressure.⁵⁷ The higher the systolic or diastolic blood pressure, the greater the morbidity and mortality from CAD in elderly women and men. The Cardiovascular Health Study demonstrated in 5202 elderly men and women that a brachial systolic blood pressure greater than 169 mm Hg was associated with a 2.4-fold greater 5-year mortality.⁴⁹

At 30-year follow-up of persons 65 years of age and older in the Framingham Heart Study, systolic hypertension was related to a greater incidence of CAD in elderly men and women.⁵⁸ Diastolic hypertension correlated with the incidence of CAD in elderly men but not in elderly women.⁵⁸ At 40-month follow-up of 664 elderly men and 48-month follow-up of 1488 elderly women, systolic or diastolic hypertension was associated with a relative risk of new coronary events of 2.0 in men and 1.6 in women.⁵² Recent data from Framingham also suggest the importance of increased pulse pressure, a measure of large artery stiffness. Among 1924 men and women aged 50 to 79 years, at any given level of systolic blood pressure of 120 mm Hg or greater, the risk of CAD over 20 years rose with lower diastolic blood pressure, suggesting that higher pulse pressure was an important component of risk.⁵⁹ Among 1061 men and women aged 60 to 79 years in the Framingham Heart Study, the strongest predictor of CAD risk was pulse pressure (hazard ratio = 1.24).⁶⁰

Elderly persons with hypertension should be treated with salt restriction, weight reduction if necessary, cessation of drugs that increase blood pressure, avoidance of alcohol and tobacco, increase in physical activity, decrease of dietary saturated fat and cholesterol, and maintenance of adequate dietary potassium, calcium, and magnesium intake. In addition, antihypertensive drugs have been shown to reduce CAD events in elderly men and in elderly women with hypertension.^{61–69}

The Hypertension in the Very Elderly Trial (HYVET) randomized 3845 patients aged 80 years and older, mean age 84 years, with a sitting mean blood pressure of 173/90 mm Hg to indapamide plus perindopril if needed versus a double-blind placebo.⁶⁹ The study was prematurely stopped at 2 years (median follow-up was 1.8 years) because antihypertensive drug therapy reduced fatal or nonfatal stroke by 30%, fatal stroke by 39%, all-cause mortality by 21%, death from cardiovascular causes by 23%, and heart failure by 64%.⁶⁹

Elderly persons with CAD should have their blood pressure reduced to less than 135/85 mm Hg and to less than 130/80 mm Hg if diabetes mellitus or chronic renal disease is present.⁵⁵ JNC 7 pointed out that most patients with hypertension will require two or more antihypertensive drugs to achieve this blood pressure goal.⁵⁵ The drugs of choice for treating CAD with hypertension are β -blockers and angiotensin-converting enzyme (ACE) inhibitors.^{55,70} If a third

antihypertensive drug is needed, a thiazide diuretic should be administered.⁵⁵

Left ventricular hypertrophy

Elderly men and women with ECG LV hypertrophy^{24–26} and echocardiographic LV hypertrophy^{25,26,28,71} have an increased risk of developing new coronary events. At 4-year follow-up of 406 elderly men and 735 elderly women in the Framingham study, echocardiographic LV hypertrophy was 15.3 times more sensitive in predicting new coronary events in elderly men and 4.3 times more sensitive in predicting new coronary events in elderly women than was electrocardiographic LV hypertrophy.⁷¹ At 37-month follow-up of 360 men and women, mean age 82 years, with hypertension or CAD, echocardiographic LV hypertrophy was 4.3 times more sensitive in predicting new coronary events than was electrocardiographic LV hypertrophy.²⁵

Physicians should try to prevent LV hypertrophy from developing or progressing in elderly men and women with CAD. A meta-analysis of 109 treatment studies found that ACE inhibitors were more effective than other antihypertensive drugs in decreasing LV mass.⁷²

Dyslipidemia

Numerous studies have demonstrated that a high serum total cholesterol is a risk factor for new or recurrent coronary events in elderly men and women.^{52,73–75} At 40-month follow-up of 664 elderly men and at 48-month follow-up of 1488 elderly women, an increment of 10 mg/dL of serum total cholesterol was associated with an increase in the relative risk of 1.12 for new coronary events in both men and in women.⁵²

A low-serum high-density lipoprotein (HDL) cholesterol is a risk factor for new coronary events in elderly men and women.^{52,73,76–78} In the Framingham study,⁷³ in the Established Populations for Epidemiologic Studies of the Elderly study,⁷⁶ and in a large cohort of nursing home patients,⁵² a low serum HDL cholesterol was a more powerful predictor of new coronary events than was serum total cholesterol. At 40-month follow-up of 664 elderly men and at 48-month follow-up of 1488 elderly women, a decrement of 10 mg/dL of serum HDL cholesterol increased the relative risk of new coronary events 1.70 times in men and 1.95 times in women.⁵²

Hypertriglyceridemia is a risk factor for new coronary events in elderly women but not in elderly men.^{52,73} At 40-month follow-up of elderly men and at 48-month follow-up of elderly women, the level of serum triglycerides was not a risk factor for new coronary events in men and was a very weak risk factor for new coronary events in women.⁴¹

Numerous studies have demonstrated that statins reduce new coronary events in elderly men and in elderly women with CAD.^{79–92} The absolute reduction in new coronary events in these studies is greater for elderly persons than for younger persons. In an observational prospective study of 488 men and 922 women, mean age 81 years, with prior MI and a serum low-density lipoprotein (LDL) cholesterol of 125 mg/dL or higher, 48% of persons were treated with statins.⁸³ At 3-year follow-up, statins reduced new coronary events by 50%.⁸³ The lower the LDL cholesterol level achieved in this study, the greater the reduction in new coronary events.⁸³

In the 1263 persons aged 75 to 80 years at study entry and 80 to 85 years at follow-up in the Heart Protection Study,

any major vascular event was significantly reduced 28% by simvastatin. Lowering serum LDL cholesterol from less than 116 mg/dL to less than 77 mg/dL by simvastatin caused a 25% significant reduction in vascular events.⁸²

In the Heart Protection Study, 3500 persons had initial serum LDL cholesterol levels less than 100 mg/dL.⁸² Decrease of serum LDL cholesterol from 97 mg/dL to 65 mg/dL by simvastatin in these persons caused a similar decrease in risk as did treating patients with higher serum LDL cholesterol levels. The Heart Protection Study investigators recommended treating persons at high risk for cardiovascular events with statins, regardless of the initial levels of serum lipids, age, or gender.⁸²

On the basis of these and other data,^{83,89–92} the American College of Cardiology (ACC)/American Heart Association (AHA) guidelines⁵⁴ and the updated National Cholesterol Education Program III guidelines⁹³ state that in very high-risk persons, a serum LDL cholesterol level of less than 70 mg/dL is a reasonable clinical strategy. When a high-risk person has hypertriglyceridemia or low HDL cholesterol, consideration can be given to combining a fibrate or nicotinic acid with an LDL cholesterol-lowering drug.^{54,93}

Diabetes mellitus

Diabetes mellitus is a risk factor for new coronary events in elderly men and women.^{52,73,94} In the Cardiovascular Health Study, an elevated fasting glucose level (>130 mg/dL) increased 5-year mortality 1.9 times.⁴⁹ At 40-month follow-up of 664 elderly men and at 48-month follow-up of 1488 elderly women, diabetes mellitus increased the relative risk of new coronary events 1.9 times in men and 1.8 times in women.⁵² Elderly diabetics without CAD have a higher incidence of new coronary events than elderly nondiabetics with CAD.⁹⁵

Persons with diabetes mellitus are more often obese and have higher serum LDL cholesterol and triglyceride levels and lower serum HDL cholesterol levels than do nondiabetics. Diabetics also have a higher prevalence of hypertension and LV hypertrophy than do nondiabetics. These risk factors contribute to the increased incidence of new CAD events in diabetics compared to nondiabetics. Increased age can further amplify these risk factor differences and contribute to greater CAD risk.

Diabetics with microalbuminuria have more severe angiographic CAD than diabetics without microalbuminuria.⁹⁶ Diabetics also have a significant increasing trend of HbA_{1c} levels over the increasing number of vessels with CAD.⁹⁷

Elderly persons with diabetes mellitus should be treated with dietary therapy, weight reduction if necessary, and appropriate drugs if necessary to control hyperglycemia. The HbA_{1c} level should be maintained at less than 7%.^{54,98} Other risk factors such as smoking, hypertension, dyslipidemia, obesity, and physical inactivity should be controlled. The serum LDL cholesterol level should be reduced to less than 70 mg/dL.^{54,93} The blood pressure should be reduced to less than 130/80 mm Hg.⁵⁵ Sulfonylureas should be avoided in person with CAD.^{99,100}

Obesity

Obesity was an independent risk factor for new CAD events in elderly men and women in the Framingham Heart Study.¹⁰¹ Disproportionate distribution of fat to the abdomen assessed

by the waist-to-hip circumference ratio has also been shown to be a risk factor for cardiovascular disease, mortality from CAD, and total mortality in elderly men and women.^{102,103}

Obese men and women with CAD must undergo weight reduction. Weight reduction is also a first approach to controlling mild hypertension, hyperglycemia, and dyslipidemia. Regular aerobic exercise should be used in addition to diet to treat obesity. The body mass index should be reduced to 18.5 to 24.9 kg/m².⁵⁴

Physical inactivity

Physical inactivity is associated with obesity, hypertension, hyperglycemia, and dyslipidemia. At 12-year follow-up in the Honolulu Heart Program, physically active men 65 years of age or older had a relative risk of 0.43 for CAD compared with inactive men.¹⁰⁴ Lack of moderate or vigorous exercise increased 5-year mortality in elderly men and women in the Cardiovascular Heart Study.⁴⁹

Moderate exercise programs suitable for elderly persons include walking, climbing stairs, swimming, or bicycling. However, care must be taken in prescribing any exercise program because of the high risk of injury in this age group. Group or supervised sessions, including aerobic classes, offered by senior health care plans are especially appealing. Exercise training programs are not only beneficial in preventing CHD¹⁰⁵ but have also been found to improve endurance and functional capacity in elderly persons after MI.^{105,106}

THERAPY OF STABLE ANGINA

Nitroglycerin is used for relief of the acute anginal attack. It is given either as a sublingual tablet or as a sublingual spray.¹⁰⁷ Long-acting nitrates prevent recurrent anginal attacks, improve exercise time until the onset of angina, and reduce exercise-induced ischemic ST-segment depression.^{108,109} To prevent nitrate tolerance, it is recommended that a 12- to 14-hour nitrate-free interval be established when using long-acting nitrate preparations. During the nitrate-free interval, the use of another antianginal drug will be necessary.

β -blockers prevent recurrent anginal attacks and are the drug of choice to prevent new coronary events.¹¹⁰ β -blockers also improve exercise time until the onset of angina and reduce exercise-induced ischemic ST-segment depression.¹¹⁰ β -blockers should be administered along with long-acting nitrates to all patients with angina unless there are contraindications to the use of these drugs. Antiplatelet drugs such as aspirin or clopidogrel should also be administered to all patients with angina to reduce new coronary events.^{111–113}

There are no class I indications for the use of calcium channel blockers in the treatment of patients with CAD.⁵⁴ However, if angina pectoris persists despite the use of β -blockers and nitrates, long-acting calcium channel blockers such as diltiazem or verapamil should be used in elderly patients with CAD and normal LV systolic function and amlodipine or felodipine in patients with CAD and abnormal LV systolic function as antianginal agents.¹⁰⁷

Ranolazine reduces frequency of angina episodes and nitroglycerin consumption and improves exercise duration and time to anginal attacks without clinically significant effects on heart rate or blood pressure.^{114,115} Ranolazine was approved for use as combination therapy when angina is not adequately controlled with other antianginal drugs. The

recommended dose of sustained release ranolazine is 750 mg or 1000 mg twice daily.

If angina persists despite intensive medical management, coronary revascularization with either coronary angioplasty or coronary artery bypass surgery should be considered.^{116,117} The use of other approaches to manage stable angina pectoris, which persists despite antianginal drugs and coronary revascularization, is discussed elsewhere.¹⁰⁷

ACUTE CORONARY SYNDROMES

Unstable angina pectoris is a transitory syndrome that results from disruption of a coronary atherosclerotic plaque that critically decreases coronary blood flow causing new onset angina pectoris or exacerbation of angina pectoris.¹¹⁸ Transient episodes of coronary artery occlusion or near occlusion by thrombus at the site of plaque injury may occur and cause angina pectoris at rest. The thrombus may be labile and cause temporary obstruction to flow. Release of vasoconstriction substances by platelets and vasoconstriction due to endothelial vasodilator dysfunction contribute to a further reduction in coronary blood flow, and in some patients, myocardial necrosis with NSTEMI occurs. Elevation of serum cardiospecific troponin I or T or creatine kinase-MB levels occur in patients with NSTEMI but not in patients with unstable angina.

Older patients with unstable angina pectoris should be hospitalized, and depending on their risk stratification, may need monitoring in an intensive care unit.¹¹⁸ In a prospective study of 177 consecutive unselected patients hospitalized for an acute coronary syndrome (91 women and 86 men) aged 70 to 94 years, unstable angina was diagnosed in 54%, NSTEMI in 34%, and STEMI in 12%.^{119–121} Obstructive CAD was diagnosed by coronary angiography in 94% of elderly men and in 80% of elderly women.¹¹⁹

Therapy

Treatment of patients with unstable angina pectoris/NSTEMI should be initiated in the emergency department. Reversible factors precipitating unstable angina pectoris should be identified and corrected. Oxygen should be administered to patients who have cyanosis, respiratory distress, congestive heart failure, or high-risk features. Oxygen therapy should be guided by arterial oxygen saturation and should not be given if the arterial oxygen saturation is more than 94%. Morphine sulfate should be administered intravenously when anginal chest pain is not immediately relieved with nitroglycerin or when acute pulmonary congestion and/or severe agitation is present.

Aspirin should be administered to all patients with unstable angina pectoris/NSTEMI unless contraindicated and continued indefinitely.¹²² The first dose of aspirin should be chewed rather than swallowed to ensure rapid absorption.

The American College of Cardiology (ACC)/American Heart Association (AHA) 2002 guidelines update states that clopidogrel should be administered for up to 9 months in addition to indefinite use of aspirin in hospitalized patients with unstable angina pectoris/NSTEMI in whom an early noninterventional approach is planned or in whom a percutaneous coronary intervention (PCI) is planned. Clopidogrel should be withheld for 5 to 7 days in patients in whom elective coronary artery surgery is planned.¹²² On the

basis of data from the Clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) trial^{123,124} and from the Clopidogrel for the Reduction of Events During Observation (CREDO) trial,¹²⁵ 81 mg of aspirin daily plus 75 mg of clopidogrel daily should be administered to patients with unstable angina/NSTEMI for at least 1 year.

Nitrates should be administered immediately in the emergency department to patients with unstable angina/NSTEMI.¹²⁶ Patients whose symptoms are not fully relieved with three 0.4 mg sublingual nitroglycerin tablets or a spray taken 5 minutes apart and the initiation of an intravenous β -blocker should be treated with continuous intravenous nitroglycerin.¹²⁶ Topical or oral nitrates are alternatives for patients without ongoing refractory symptoms.¹²⁶

β -blockers should be administered intravenously in the emergency department, unless there are contraindications to their use, followed by oral administration and continued indefinitely.¹²⁶ Metoprolol may be given intravenously in 5 mg increments over 1 to 2 minutes and repeated every 5 minutes until 15 mg has been given followed by oral metoprolol 100 mg twice daily. The target resting heart rate is 50 to 60 beats per minute.

An oral ACE inhibitor should also be given unless there are contraindications to its use and continued indefinitely.¹²⁶ In patients with continuing or frequently recurring myocardial ischemia despite nitrates and β -blockers, verapamil or diltiazem should be added to their therapeutic regimen in the absence of LV systolic dysfunction (class IIa indication).¹²⁶ The benefit of calcium channel blockers in the treatment of unstable angina pectoris is limited to symptom control.¹²⁶ Intra-aortic balloon pump counterpulsation should be used for severe myocardial ischemia that is continuing or occurs frequently despite intensive medical therapy or for hemodynamic instability in patients before or after coronary angiography.¹²⁶

A platelet glycoprotein IIb/IIIa inhibitor should also be administered in addition to aspirin and clopidogrel and heparin in patients in whom coronary angioplasty is planned.¹²² Abciximab can be used for 12 to 24 hours in patients with unstable angina/NSTEMI in whom coronary angioplasty is planned within the next 24 hours.¹²² Eptifibatid or tirofiban should be administered in addition to aspirin and low-molecular-weight heparin or unfractionated heparin to patients with continuing myocardial ischemia, an elevated cardiac-specific troponin I or T, or with other high-risk features in whom an invasive management is not planned.¹²²

Intravenous thrombolytic therapy is not recommended for the treatment of unstable angina/NSTEMI.¹²² Prompt coronary angiography should be performed without noninvasive risk stratification in patients who fail to stabilize with intensive medical treatment.¹²⁶ Coronary revascularization should be performed in patients with high-risk features to reduce coronary events and mortality.^{122,126–128}

On the basis of the available data, the ACC/AHA 2002 guidelines recommend the use of statins in patients with acute coronary syndromes and a serum LDL cholesterol of 100 mg/dL or higher 24 to 96 hours after hospitalization.¹²² Statins should be continued indefinitely after hospital discharge.^{89,93,122} The ACC/AHA 2002 guidelines also recommend use of a fibrate or nicotinic acid if the serum HDL cholesterol is less than 40 mg/dL, occurring as an isolated finding or in combination with other lipid abnormalities.¹²²

Patients should be discharged on aspirin plus clopidogrel, β -blockers, and on ACE inhibitors in the absence of contraindications. Nitrates should be given for ischemic symptoms. A long-acting nondihydropyridine calcium channel blocker may be given for ischemic symptoms that occur despite treatment with nitrates plus β -blockers. Hormonal therapy should not be administered to postmenopausal women.^{129,130}

THERAPY OF STEMI

Chest pain due to acute MI should be treated with morphine, nitroglycerin, and β -blockers.¹³¹ If arterial saturation is lower than 94%, oxygen should be administered. Aspirin should be given on day one of an acute MI and continued indefinitely to reduce coronary events and mortality.^{70,111,112,132,133} The first dose of aspirin should be chewed rather than swallowed. The addition of clopidogrel to aspirin is also beneficial in reducing coronary events and mortality.^{134,135} Early intravenous β -blockade should be used during acute MI and oral β -blockers continued indefinitely to reduce coronary events and mortality.^{70,136–143} ACE inhibitors should be given within 24 hours of acute MI and continued indefinitely to reduce coronary events and mortality.^{70,143–149} Statins should be given to patients with acute MI and a serum LDL cholesterol of 100 mg/dL or higher 24 to 96 hours after hospitalization.⁷⁰ Statins should be continued indefinitely after hospital discharge to reduce coronary events and mortality.^{78,86,87,93}

The ACC/AHA guidelines state there are no class I indications for the use of calcium channel blockers during or after acute MI.⁷⁰ However, if older persons have persistent angina after MI despite treatment with β -blockers and nitrates and are not suitable candidates for coronary revascularization, or if they have hypertension inadequately controlled by other drugs, a nondihydropyridine calcium channel blocker such as verapamil or diltiazem should be added to the therapeutic regimen if the LV ejection fraction is normal. If the LV ejection fraction is abnormal, amlodipine or felodipine should be added to the therapeutic regimen.

The ACC/AHA guidelines recommend using intravenous heparin in persons with acute MI undergoing primary coronary angioplasty or surgical coronary revascularization and in persons with acute MI at high risk for systemic embolization, such as persons with a large or anterior MI, atrial fibrillation, history of pulmonary or systemic embolus, or LV thrombus.⁷⁰ In persons with acute MI not receiving intravenous heparin, the ACC/AHA guidelines recommend using subcutaneous heparin 7500 U twice daily for 24 to 48 hours to decrease the incidence of deep venous thrombosis.⁷⁰

Thrombolytic therapy is beneficial in the treatment of STEMI in patients younger than 75 years of age.^{70,132,150–153} From the available data, one cannot conclude whether thrombolytic therapy is beneficial or harmful in patients older than 75 years with acute MI.¹⁵³ However, the data favor the use of primary coronary angioplasty in eligible patients both younger and older than 75 years with acute MI to reduce coronary events and mortality.^{153–158}

THERAPY AFTER MI

Elderly persons after MI should have their modifiable coronary risk factors intensively treated as discussed previously in this chapter. Aspirin or clopidogrel should be given

indefinitely to reduce new coronary events and mortality.^{70,111–113,159,160} The ACC/AHA guidelines recommend as class I indications for long-term oral anticoagulant therapy after MI: (1) secondary prevention of MI in post-MI patients unable to tolerate daily aspirin or clopidogrel; (2) post-MI patients with persistent atrial fibrillation; and (3) post-MI patients with LV thrombus.⁷⁰ Long-term warfarin should be given in a dose to achieve an INR between 2.0 and 3.0.¹⁶⁰

β -blockers (Table 41-2)^{70,136–143} and ACE inhibitors (Table 41-3)^{70,143–149,161–163} should be given indefinitely unless contraindications exist to the use of these drugs to reduce new coronary events and mortality. Long-acting nitrates are effective antianginal and antiischemic drugs.^{107–109}

There are no class I indications for the use of calcium channel blockers after MI.⁷⁰

Teo et al¹⁶⁴ analyzed randomized controlled trials comprising 20,342 persons that investigated the use of calcium channel blockers after MI. Mortality was 4% insignificantly higher in persons treated with calcium channel blockers.¹⁶⁴ In this study, β -blockers significantly reduced mortality by 19% in 53,268 persons.¹⁶⁴ In another study, elderly persons who were treated with β -blockers after MI had a 43% decrease in 2-year mortality and a 22% decrease in 2-year cardiac hospital readmissions than in elderly persons who were not treated with β -blockers.¹⁶⁵ Use of a calcium channel blocker instead of a β -blocker after MI doubled the risk of mortality.¹⁶⁵

Aldosterone antagonists

At 16-month follow-up of 6632 patients after MI with a LV ejection fraction of 40% or less and either heart failure or diabetes mellitus treated with ACE inhibitors or angiotensin receptor blockers and 75% with β -blockers, compared with the placebo, patients randomized to 50 mg of eplerenone daily had a significant 15% reduction in mortality and a 13% significant reduction in death from cardiovascular causes or hospitalization for cardiovascular events.¹⁶⁶ The ACC/AHA guidelines recommend an aldosterone antagonist in patients after MI treated with ACE inhibitors plus β -blockers if they have a LV ejection fraction of 40% or less with either heart failure or diabetes mellitus if they do not have significant renal dysfunction or hyperkalemia.⁵⁴

Antiarrhythmic therapy after MI

A meta-analysis of 59 randomized controlled trials comprising 23,229 persons that investigated the use of class I antiarrhythmic drugs after MI showed that mortality was 14% significantly higher in persons receiving class I antiarrhythmic drugs than in persons receiving no antiarrhythmic drugs.¹⁶⁴ None of the 59 studies showed a reduction in mortality by class I antiarrhythmic drugs.¹⁶⁴

In the Cardiac Arrhythmia Suppression Trials I and II, older age also increased the likelihood of adverse effects including death in persons after MI receiving encainide,

Table 41-2. Effect of β -Blockers on Mortality in Elderly Patients after Myocardial Infarction

Study	Follow-Up	Results
Goteborg Trial ¹³⁶	90 day	Compared with placebo, metoprolol caused a 45% significant decrease in mortality in patients aged 65–74 years.
Norwegian Multicenter Study ¹³⁷	17 mo (up to 33 mo)	Compared with placebo, timolol caused a 43% significant reduction in mortality in patients aged 65–74 years.
Norwegian Multicenter Study ¹³⁸	61 mo (up to 72 mo)	Compared with placebo, timolol caused a 19% significant decrease in mortality in patients aged 65–74 years.
Beta Blocker Heart Attack Trial ¹³⁹	25 mo (up to 36 mo)	Compared with placebo, propranolol caused a 33% significant decrease in mortality in patients aged 60–69 years.
Carvedilol Post-Infarct Survival Control in Left Ventricular Dysfunction Trial ¹⁴⁰	1.3 yr	Compared with placebo, carvedilol caused a 23% significant reduction in mortality, a 24% significant reduction in cardiovascular mortality, a 40% significant reduction in nonfatal myocardial infarction, and a 30% significant decrease in all-cause mortality or nonfatal myocardial infarction in patients, mean age 63 years.

Table 41-3. Effect of Angiotensin-Converting Enzyme Inhibitors on Mortality in Elderly Patients after Myocardial Infarction

Study	Follow-Up	Results
Survival and Ventricular Enlargement Trial ¹⁴⁷	42 mo (up to 60 mo)	In patients with MI and LVEF \leq 40%, compared with placebo, captopril reduced mortality 25% in patients aged \geq 65 years.
Acute Infarction Ramipril Efficacy Study ¹⁴⁸	15 mo	In patients with MI and clinical evidence of heart failure, compared with placebo, ramipril decreased mortality 36% in patients aged \geq 65 years.
Survival of Myocardial Infarction Long-Term Evaluation Trial ¹⁴⁹	1 yr	In patients with anterior MI, compared with placebo, zofenopril reduced mortality or severe heart failure 39% in patients aged \geq 65 years.
Trandolapril Cardiac Evaluation Study ¹⁶¹	24 to 50 mo	In patients, mean age 68 years, with LVEF \leq 35%, compared with placebo, trandolapril reduced mortality 33% in patients with anterior MI and 14% in patients without anterior MI.
Heart Outcomes Prevention Evaluation Study ¹⁶²	4.5 yr (up to 6 yr)	In patients aged \geq 55 years with MI (53%), cardiovascular disease (88%), or diabetes (38%) but no heart failure or abnormal LVEF, ramipril reduced MI, stroke, and cardiovascular death 22%.
European trial on reduction of cardiac events with perindopril in patients with stable coronary artery disease ¹⁶³	4.2 yr	In patients, mean age 60 years, with coronary artery disease and no heart failure, compared with placebo, perindopril reduced cardiovascular death, MI, or cardiac arrest 20%.

MI, myocardial infarction; LVEF, left ventricular ejection fraction.

flecainide, or moricizine.¹⁶⁷ Compared with no antiarrhythmic drug, quinidine or procainamide did not reduce mortality in elderly persons with CAD, normal or abnormal LV ejection fraction, and presence versus absence of ventricular tachycardia.¹⁶⁸

Compared with placebo, D,L-sotalol did not reduce mortality in post-MI persons followed for 1 year.¹⁶⁹ Mortality was also significantly higher at 148-day follow-up in persons treated with D-sotalol (5.0%) than in persons treated with a placebo.¹⁷⁰ On the basis of the available data, persons after MI should not receive class I antiarrhythmic drugs or sotalol.

In the European Myocardial Infarction Amiodarone Trial, 1486 survivors of MI with an LV ejection fraction of 40% or less were randomized to amiodarone (743 patients) or to a placebo (743 patients).¹⁷¹ At 2-year follow-up, 103 patients treated with amiodarone and 102 patients treated with a placebo had died.¹⁷¹ In the Canadian Amiodarone Myocardial Infarction Arrhythmia Trial, 1202 survivors of MI with nonsustained ventricular tachycardia or complex ventricular arrhythmias were randomized to amiodarone or to a placebo.¹⁷² Amiodarone was very effective in suppressing ventricular tachycardia and complex ventricular arrhythmias. However, the mortality rate at 1.8-year follow-up was not significantly different in the persons treated with amiodarone or a placebo.¹⁷² In addition, early permanent discontinuation of drug for reasons other than outcome events occurred in 36% of persons taking amiodarone.

In the Cardiac Arrest in Seattle: Conventional Versus Amiodarone Drug Evaluation Study, the incidence of pulmonary toxicity was 10% at 2 years in persons receiving amiodarone in a mean dose of 158 mg daily.¹⁷³ The incidence of adverse effects for amiodarone also approached 90% after 5 years of treatment.¹⁷⁴ On the basis of the available data, amiodarone should not be used in the treatment of persons after MI.

However, β -blockers have been shown to reduce mortality in persons with nonsustained ventricular tachycardia or complex ventricular arrhythmias after MI in patients with normal or abnormal LV ejection fraction.^{175–178} On the basis of the available data, β -blockers should be used in the treatment of elderly persons after MI, especially if nonsustained ventricular tachycardia or complex ventricular arrhythmias are present, unless there are specific contraindications to their use.

In the Antiarrhythmics Versus Implantable Defibrillators (AVID) trial, 1016 persons, mean age 65 years, with a history of ventricular fibrillation or serious sustained ventricular tachycardia were randomized to an automatic implantable cardioverter-defibrillator (AICD) or to drug therapy with amiodarone or D,L-sotalol.¹⁷⁹ Persons treated with an AICD had a 39% reduction in mortality at 1 year, a 27% reduction in mortality at 2 years, and a 31% reduction in mortality at 3 years.¹⁷⁹ If persons after MI have life-threatening ventricular tachycardia or ventricular fibrillation, an AICD should be inserted.

The Multicenter Automatic Defibrillator Implantation Trial (MADIT)

It randomized 1232 persons, mean age 64 years, with a prior MI and a LVEF of 30% or less to an AICD or to conventional medical therapy.¹⁸⁰ At 20-month follow-up, compared with conventional medical therapy, the AICD significantly decreased all-cause mortality 31% from 19.8% to 14.2%.¹⁸⁰

The effect of AICD therapy in improving survival was similar in persons stratified according to age, sex, LV ejection fraction, New York Heart Association class, and QRS interval.¹⁸⁰

In MADIT II, the reduction in sudden cardiac death in patients treated with an AICD was significantly reduced by 68% in 574 patients aged less than 65 years, by 65% in 455 patients aged 65 to 74 years, and by 68% in 204 patients aged 75 years.¹⁸¹ The median survival in 348 octogenarians treated with AICD therapy was greater than 4 years.¹⁸² These data favor considering the prophylactic implantation of an AICD in elderly postinfarction patients with a LVEF of 30% or lower.

HORMONE REPLACEMENT THERAPY

The Heart Estrogen/Progestin Replacement Study (HERS) investigated the effect of hormonal therapy versus a double-blind placebo on coronary events in 2763 women with documented CAD.¹⁸³ At 4.1-year follow-up, there were no significant differences between hormonal therapy and the placebo in the primary outcome (nonfatal MI or CAD death) or in any of the secondary cardiovascular outcomes. However, there was a 52% significantly higher incidence of nonfatal MI or death from CAD in the first year in persons treated with hormonal therapy than in persons treated with the placebo.¹⁸³ Women on hormonal therapy had a 289% significantly higher incidence of venous thromboembolic events and a 38% significantly higher incidence of gallbladder disease requiring surgery than women on the placebo.

At 6.8-year follow-up in the HERS trial, hormonal therapy did not reduce the risk of cardiovascular events in women with CAD.¹⁸⁴ The investigators concluded that hormonal therapy should not be used to decrease the risk of coronary events in women with IHD.¹⁸⁴ At 6.8-year follow-up in the HERS trial, all-cause mortality was insignificantly increased 10% by hormonal therapy.¹⁸⁴ The overall incidence of

Table 41-4. Medical Approach to Elderly Patients after Myocardial Infarction

1. Stop cigarette smoking.
2. Treat hypertension with β -blockers and angiotensin-converting enzyme (ACE) inhibitors; the blood pressure should be reduced to <140/85 mm Hg and to <130/80 mm Hg in persons with diabetes mellitus or renal insufficiency.
3. The serum low-density lipoprotein cholesterol should be reduced to <70 mg/dL with statins if necessary and at least 30% to 40%.
4. Diabetes mellitus, obesity, and physical inactivity should be treated.
5. Aspirin or clopidogrel, β -blockers, and ACE inhibitors should be given indefinitely unless contraindications exist to the use of these drugs.
6. Long-acting nitrates are effective antianginal and anti-ischemic drugs.
7. There are no class I indications for the use of calcium channel blockers after myocardial infarction (MI).
8. Postinfarction patients should not receive class I antiarrhythmic drugs, sotalol, or amiodarone.
9. An automatic implantable cardioverter-defibrillator should be implanted in postinfarction patients at very high risk for sudden cardiac death.
10. Hormone replacement therapy should not be administered to postmenopausal women after MI.
11. The two indications for coronary revascularization in elderly persons after MI are prolongation of life and relief of unacceptable symptoms despite optimal medical management.

venous thromboembolism at 6.8-year follow-up was significantly increased 208% by hormonal therapy.¹⁸⁴ At 6.8-year follow-up, the overall incidence of biliary tract surgery was significantly increased (48%), the overall incidence for any cancer was insignificantly increased (19%), and the overall incidence for any fracture was insignificantly increased (4%).¹⁸⁴

CORONARY REVASCULARIZATION

Medical therapy alone is the preferred treatment in elderly persons after MI (Table 41-4). The two indications for revascularization in elderly persons after MI are prolongation of life and relief of unacceptable symptoms despite optimal medical management. In a prospective study of 305 patients aged 75 years and older with chest pain refractory to at least two antianginal drugs, 150 patients were randomized

to optimal medical therapy and 155 patients to invasive therapy.^{116,117} In the invasive group, 74% had coronary revascularization (54% coronary angioplasty and 20% coronary artery bypass surgery). During the 6-month follow-up, one third of the medically treated group needed coronary revascularization for uncontrollable symptoms. At 6-month follow-up, death, nonfatal MI, or hospital admission for an acute coronary syndrome was significantly higher in the medically treated group (49%) than in the invasive group (19%).¹¹⁶ Revascularization by coronary angioplasty¹⁸⁵ or by coronary artery bypass surgery¹⁸⁶ in elderly persons is extensively discussed elsewhere. If coronary revascularization is performed, aggressive medical therapy must be continued.

The Frail Elderly Patient with Heart Disease

George A. Heckman

Kenneth Rockwood

INTRODUCTION

Despite a decline during recent decades in overall cardiovascular mortality in developed countries, the burden of cardiovascular disease remains substantial.¹ The prevalence of coronary artery disease (CAD) and heart failure (HF) increases with age, largely as a result of better survival of patients with acute cardiac events in the context of population aging.² The lifetime risk for symptomatic CAD after the age of 40 years is 49% in men and 32% in women.² The average age of patients suffering a first myocardial infarction is 64.5 years in men and 70.4 years in women.² Similarly, the prevalence of HF also rises sharply with age, and patients reaching the age of 80 years face a 20% lifetime risk of developing HF.³

Although the burden of heart disease is greatest among older patients, therapeutic recommendations are usually extrapolated from clinical trials conducted on relatively younger and healthier patients. Historically, a significant majority of potential candidates for these trials has been excluded because of multiple medical and age-associated comorbidities.⁴ Furthermore, clinical trials have generally measured "hard outcomes," such as rates of death, mortality, or other cardiovascular events, outcomes that may not be as important to some older patients as quality of life, preserving cognition, or maintaining functional independence in the community. The recent publication of the Hypertension in the Very Elderly Trial (HYVET) illustrates some recent progress made in this regard and the significant gaps that remain.⁵ In this multicenter randomized controlled trial of 3845 patients aged 80 years and over, treatment of hypertension with indapamide with or without perindopril for 2 years was well tolerated and reduced the risk of stroke, death, and HF. In contrast to most prior cardiovascular trials, HYVET specifically targeted older patients, with the average age of trial participants being almost 84 years, thus filling an important gap in hypertension management literature. However, compared with the general population, HYVET participants had fewer comorbid conditions, were not demented, and outcomes such as functional decline, caregiver burden, or institutionalization have not been reported. What is more, the recent report on dementia prevention in HYVET illustrates some of the pragmatic difficulties to be faced.⁶ The early and significant benefits of treatment meant that the main trial was stopped early. In consequence, there was no significant difference in the proportion on active treatment versus placebo that developed dementia. Even so, when the data from HYVET-Cog were combined with that of other antihypertension trials, a statistically significant reduction in dementia was seen.⁶ As the accompanying editorial made clear, though this is not entirely satisfactory, it is hard to imagine that mounting a placebo controlled trial to definitively address that question would be ethically permissible.⁷ Thus much of the question about generalizing studies on fit elderly people to frail elderly people comes down to this: At

what price should the evidence come? When is extrapolation justified? How do we distinguish between therapeutic adventurism and therapeutic nihilism? Here we aim to provide a framework to assist clinicians in the process of determining the most appropriate courses of action for frail older cardiac patients.

MAKING TREATMENT DECISIONS: SHOULD AGE MATTER?

Older patients with CAD are less likely to receive ACE-inhibitors, β -blockers, lipid-lowering agents, or antiplatelet agents.^{8,9} Similarly, older age in HF patients continues to be associated with a lower likelihood of receiving the recommended standard of care.¹⁰ Underlying these findings appears to be the assumption that aging is a homogenous phenomenon and that all older cardiac patients require the same clinical approach. Clearly, this is unjustified; chronologic age alone is an inadequate criterion upon which treatment decisions are made.

Some of the heterogeneity seen in aging can be accounted for by the development of chronic illnesses. According to the Canadian National Population Health Survey, the proportion of persons with no chronic illness declines with increasing age, from 44% of those aged 40 to 59 years, to 12% of those 80 or above.¹¹ In contrast, the proportion of persons with three or more chronic conditions in the same age brackets rises from 12% to 41%, respectively. However, the difference between successful and unsuccessful aging reflects more than just the burden of chronic disease, and is a manifestation of underlying frailty. Though consensus on a definition of frailty has yet to be achieved, frailty can be understood as a state of increased vulnerability due to reduced physiologic reserve and that is most often, but not exclusively, found in older persons.¹² In the Cardiovascular Health Study, prior myocardial infarction, angina, or HF were all associated with a greater risk of frailty.¹³ In a cohort of 309 patients aged 77 ± 5 years and hospitalized with CAD, frailty, as assessed by decreased gait velocity, was associated with an almost fourfold increased risk of mortality at 6 months.¹⁴ However, frailty is not invariably associated with chronic disease: although some older persons with chronic illness are frail, many are not.¹⁵

Assessing frailty can be considered akin to estimating a person's biologic age. Several reports show that biologic age can be inferred from a frailty index.¹⁶⁻¹⁸ Given that the mean values of a frailty index typically correlate very highly ($r^2 > 0.9$) with chronologic age, biologic age can be inferred for an individual based on their observed frailty index, in relation to the age at which that value is seen on average. In each study, an individual's frailty index value (i.e., that person's biologic age) was a more important predictor of mortality than chronologic age. These data suggest that chronologic age *per se* may not be an adequate factor for making treatment

decisions for older persons, but rather that a comprehensive assessment of frailty may provide more valid information upon which to base therapeutic recommendations.

The following clinical vignettes are provided to illustrate how assessing frailty can be incorporated into clinical decision making when considering interventions for older patients with cardiovascular disease.

Case 1: Ludwig B. is a bright, relatively healthy retired engineer with a history of hypertension controlled with hydrochlorothiazide, 12.5 mg daily. He is fully independent in performing his basic and instrumental activities of daily living and passed a driving test the year before. He stopped playing golf last year to look after his 75-year-old wife who has moderately severe Alzheimer's disease. He experiences a 1 hour episode of retrosternal chest pressure radiating to his left shoulder, but does not seek medical attention as he has to look after his wife. When he finally sees his family physician a week later, an ECG demonstrates new inferior Q waves and an echocardiogram demonstrates an ejection fraction of 55% with hypokinesis of the inferior wall of the left ventricle, consistent with a recent myocardial infarction. His family physician prescribes enteric-coated acetylsalicylic acid, an angiotensin-converting-enzyme inhibitor, and a β -blocker, all of which are well tolerated. Ludwig declines further investigations as he now feels well and must look after his wife. A cholesterol profile demonstrates an LDL of 145 mg/dL and an HDL of 35 mg/dL. Should Ludwig be prescribed a statin for secondary prevention of cardiovascular events?

Clinical trials have demonstrated that in patients who have suffered a myocardial infarction, statins reduce the risk of subsequent coronary events and mortality. However, inclusion criteria for the most recent trials have only included patients up to the age of 82.^{19,20} The family physician must consider whether the results of these trials are applicable to Ludwig, who is 87 years old. Using the CSHA Clinical Frailty Scale (Table 42-1), the family physician determines that Ludwig falls in category 3 (well, with treated comorbid disease), which is associated with a relatively good prognosis.²¹ The arguments for and against treating Ludwig with a statin are presented in Table 42-2. In this situation, the balance of arguments weighs in favor of offering Ludwig a statin.

Table 42-1. The Canadian Study of Health and Aging Clinical Frailty Scale

Frailty Level	Description
1. Very fit	Robust, active, energetic, well motivated, and fit; these people commonly exercise regularly and are in the fittest group for their age
2. Well	Without active disease but less fit than people in category 1
3. Well, with treated comorbid disease	Disease symptoms are well controlled compared with those in category 4
4. Apparently vulnerable	Although not frankly dependent, these people commonly complain of being "slowed up" or having disease symptoms
5. Mildly frail	With limited dependence on others for instrumental activities of daily living
6. Moderately frail	Help is needed with both instrumental and noninstrumental activities of daily living
7. Severely frail	Completely dependent on others for activities of daily living, or terminally ill

From Rockwood K, Song X, MacKnight C, et al. A global measure of fitness and frailty in elderly people. *CMAJ* 2005;173:489-95.

Case 2: Ludwig's 75-year-old wife Thelma has moderately severe Alzheimer's disease. She requires assistance for all instrumental activities of daily living, and with washing, grooming and dressing. She has episodes of urinary incontinence because she cannot always find her way to the washroom. She has had falls, requires a walker, and cannot leave the house unattended. Otherwise, she has no cardiovascular risk factors or other comorbid conditions and has never sustained a cardiovascular event. Routine cholesterol profile reveals an LDL of 145 mg/dL and an HDL of 35 mg/dL. Should Thelma be prescribed a statin for the primary prevention of cardiovascular events?

Statin are often recommended in the primary prevention of cardiovascular events, though the benefits may be marginal in patients with no other concomitant cardiovascular risk factors.²³ The family physician determines that Thelma falls within category 6 (moderately frail) of the CSHA Clinical Frailty Scale, which is associated with a poor prognosis over the medium term.²¹ Furthermore, the family physician considers the results of the NHANES 1 study, which found that high cholesterol was associated with CAD only in active individuals aged 65 to 74 years.²⁴ The arguments for and against treating Thelma with a statin are presented in Table 42-3 below. In this situation, the balance of arguments weighs against offering Thelma a statin.

Table 42-2. Arguments For and Against Treating Ludwig with a Statin

Arguments Favoring Statin Therapy	Arguments Against Statin Therapy
Ludwig is not very frail. He may be chronologically old, but not as old biologically	Ludwig's age exceeds clinical trial inclusion criteria and he is thus too old
No compelling evidence that atherosclerosis is substantially different in an 87-year-old person than it is in a 77-year-old person	Potential risk for adverse events ²²
Ludwig is otherwise healthy, has no other competing comorbidities, and therefore has a remaining life expectancy of approximately 5 years	
In the PROSPER trial, benefits of statin therapy became apparent after 1 year	
Ludwig is at high risk for a recurrent event, which might leave him unable to care for his wife	

Table 42-3. Arguments For and Against Treating Thelma with a Statin

Arguments Favoring Statin Therapy	Arguments Against Statin Therapy
Possible but unconfirmed benefits of statins in Alzheimer disease ²⁵	Thelma is frail. Her biologic age is greater than her chronologic age
Even a remotely small reduction in the risk of a cardiovascular event might permit Ludwig to look after his wife at home as long as possible	Thelma is inactive according to the NHANES 1 definition and therefore her cholesterol level is unlikely to be a risk factor for a coronary event
	Marginal benefit of statins in persons at low cardiovascular risk ²³
	Increased polypharmacy
	Potential risk for adverse events ²²

In summary, using chronologic age to determine whether to offer a particular therapy to an older patient may be an inadequate strategy. In the absence of reliable evidence from clinical trials in truly representative populations of older persons, clinical decision making needs to be individualized, consider patient and caregiver preferences, and may be facilitated by assessing a patient's degree of frailty.

Does treatment of heart disease improve outcomes of importance of older persons?

The majority of clinical trials in cardiology have focused on outcomes such as rates of mortality, hospitalization, coronary interventions, and other objective assessments of cardiovascular events. Older persons often have other goals and priorities: for example, compared with physicians, older patients with atrial fibrillation place more importance on avoiding disability from a stroke than on the risks of bleeding associated with anticoagulation.²⁶ Though a few recent trials have examined whether control of vascular risk factors has beneficial effects on cognitive decline, outcomes of interest to older persons, such as preventing functional, caregiver stress, and institutionalization are considered infrequently if at all.

Nurse-led HF management programs may be more successful when patient goals are taken into account.²⁷ Evidence from smaller trials and observational data support the benefits of HF therapies for older patients, which may include the preservation of function and cognition.²⁸ In a randomized placebo-controlled trial of 60 NYHA class II-III patients with HF from LV systolic dysfunction aged 81 ± 6 years, perindopril over 10 weeks was associated with a 37-meter increase in 6-minute walking distance compared to baseline, versus no significant change in the control group ($p < 0.001$).²⁹ A supervised exercise program over 18 weeks in 20 NYHA class III HF patients aged 63 ± 13 years and LV EF 35% or less, resulted in improvements in psychomotor speed and general attention.³⁰ Numerous observational studies suggest that ACE inhibitors prescribed to older HF patients result in slower functional decline, improved cognition, and less depression.^{31–34} Although these data require confirmation by larger clinical trials, they do support the notion that standard HF therapies have the potential to address outcomes of importance to frail older persons.

Few trials have addressed outcomes of interest to frail older patients with CAD. There is evidence to suggest that cognitive decline may develop up to 5 years after coronary artery bypass surgery.^{35–38} Even so, data on the mechanism of the decline or the impact of revascularization on function in older patients are sparse. In the Trial of Invasive versus Medical therapy in Elderly patients with chronic symptomatic CAD (TIME), 305 patients aged 75 years and older, 78% of whom had chronic CCS class III or IV angina despite being given at least two antianginal drugs, were randomized either to optimal medical therapy (148 patients) or early invasive therapy (153 patients).^{39,40} In the early invasive therapy group, 72% of patients underwent revascularization, which was associated with a significant early mortality hazard. However, after 1 year there were no statistically significant mortality differences between the two groups. In the first 6 months of follow-up, patients in the early invasive group experienced greater improvements in quality of life and functional capacity. During the second 6 months

of follow-up, patients in the optimal medical therapy group experienced more adverse cardiovascular events than those in the early invasive group. After 1 year, differences in quality of life between both groups disappeared, likely due to the 46% of patients in the optimal medical therapy group who underwent revascularization due to intolerable symptoms in the latter half of the year. In short, older patients with intolerable angina who proceed with an early invasive approach to treatment appear to face an early mortality hazard, which, should they survive, is offset by earlier improvement in quality of life and functional capacity, fewer cardiovascular events, and lower mortality over the subsequent year. Patients able to tolerate their angina may choose to undergo revascularization at a later date, at the expense of a greater risk of cardiovascular events over the subsequent year (Case 3).

Case 3: Following his myocardial infarction, Ludwig does well for 6 months. However, he subsequently develops angina. Despite optimal medical therapy with an ACE inhibitor, acetylsalicylic acid, a statin, a β -blocker, nitrates, and a calcium channel blocker, his chest pain continues to be brought on by climbing six steps and occasionally when he helps his wife dress. Clinical evaluation and investigations reveal no new ECG changes or evidence of HF. Ludwig expresses the wish to continue looking after his wife Thelma, whose cognition has remained relatively stable, for as long as possible. Should he undergo revascularization?

Recent data suggests that while adverse events related to percutaneous coronary interventions are more common in octogenarians than in younger patients, overall complication rates remain relatively low and have been improving over time.⁴¹ Arguments for and against submitting Ludwig to a coronary intervention are summarized in Table 42-4 below.

Ludwig undergoes percutaneous revascularization with resolution of his angina. His procedure is complicated by a false aneurysm of the right femoral artery, treated conservatively. He also experiences a transient ischemic attack affecting his speech, but with no permanent sequelae. His acetylsalicylic acid is replaced by clopidogrel. He is able to continue caring for his wife, who eventually dies at home from pneumonia 6 months later.

In summary, most clinical trials in cardiology do not consider all outcomes of importance to frail older persons. However, limited evidence exists to highlight the importance of considering these outcomes when considering interventions and therapies for older adults with heart disease.

Table 42-4. Arguments For and Against Submitting Ludwig to a Coronary Intervention

Arguments Favoring Intervention	Arguments Against Intervention
Successful intervention would allow him to more fully resume caring for his wife	Risk of complications such as stroke or death that would preclude him from looking after his wife
Delaying the intervention increases the likelihood of adverse coronary events in the near future	He can always undergo the procedure at a later date
He may as well undergo the procedure now, as there is a high likelihood that he will require one in the near future	

Are the manifestations of cardiac disease different in older persons?

The manifestations of heart disease in frail older persons are often at variance with the classical syndromes of angina pectoris due to CAD, or exertional dyspnea, orthopnea, paroxysmal nocturnal dyspnea and edema as a result of HF.^{42,43} Though such manifestations are often referred to as *atypical disease presentations*, they are so common—especially among frail patients—that they might more properly be referred to as *nonclassical*.

Nonclassical illness presentation is more likely to occur in older patients with concomitant functional impairment and/or frailty.⁴² Patients who are sedentary from other comorbidities may not experience exertional symptoms. In bed-bound patients, edema may accumulate over the sacrum rather than in the legs, and may reflect venous insufficiency, treatment with calcium-channel blockers, reduced oncotic pressure, or pulmonary disease, rather than HF.⁴³ Nonspecific sleep disturbances may be atypical manifestations of orthopnea, paroxysmal nocturnal dyspnea, or nocturia due to the mobilization of peripheral edema in the recumbent position.^{44,45} Psychiatric symptoms, such as anxiety or depressed mood, may be associated with symptomatic or undertreated HF in frail older persons.³⁴

In a cross-sectional cohort of 1939 persons aged 67 ± 11 years and hospitalized with an acute coronary syndrome, presenting symptoms included weakness and fatigue in more than 50%, anxiety in 34%, and vertigo or presyncope in 26%.⁴⁶ In a cross-sectional analysis of 247 older patients aged 76 ± 6 years hospitalized after an acute MI, only 22% had classic chest pain.⁴⁷ Almost 30% had a symptom complex of fatigue, sleep disturbance, psychological distress, dyspnea, and moderate pain, whereas almost half had multiple mild respiratory and gastrointestinal symptoms, fatigue, sleep disturbances, and pain. Delirium is one of the most common complications of myocardial infarction in persons aged 90 years and over.^{48,49}

The consequences of delayed or missed diagnoses as a result of nonclassical presentations can be significant. Hospitalized patients having nonclassical symptoms are more likely to suffer adverse consequences such as being restrained or institutionalized.⁴² Unrecognized myocardial infarctions in older persons not having classical angina or clinical evidence of HF are very common^{50–52} and are associated with a similar prognosis to recognized myocardial infarctions.⁵³

HEART DISEASE, POLYPHARMACY, AND COGNITIVE IMPAIRMENT

The prescription of multiple therapies to older cardiac patients, many of whom often suffer from multiple comorbidities, often leads to inappropriate polypharmacy. As a result, these patients may be at greater risk for adverse drug events, drug interactions, and nonadherence to therapy, especially when their cardiovascular illness is seen with concomitant cognitive impairment.

Older patients with heart disease are often prescribed diuretics and medications affecting the renin-angiotensin-aldosterone system, and should be followed closely for changes in renal function and the development of fluid and electrolyte abnormalities.²⁸ Older persons are more

susceptible to dehydration, particularly in the setting of an acute illness. If dehydration is suspected, serum electrolytes, creatinine, and urea should be measured without delay, and spironolactone temporarily withheld because of the risk of hyperkalemia.⁵⁴ The importance of appropriate prescribing and monitoring is underscored by the occurrence in 2001 in Ontario, Canada, of an estimated 560 additional hospitalizations and 73 deaths from hyperkalemia following more widespread use of spironolactone for HF after publication of the Randomized Aldactone Evaluation Study.⁵⁵

A number of cardiac medications have measurable anticholinergic activity, including commonly prescribed drugs such as warfarin, isosorbide dinitrate, hydrochlorothiazide, chlorthalidone, hydralazine, furosemide, nifedipine, and digoxin.^{56,57} Advanced age is a risk factor for digoxin toxicity, which can occur at serum concentrations generally considered normal (1.4 to 2.0 ng/mL).⁵⁸ The cumulative anticholinergic burden associated with prescribed medications can adversely affect cognition in older patients, including a greater predisposition to delirium, more severe delirium, and may possibly accelerate cognitive decline in patients with Alzheimer's disease.^{59–61}

Polypharmacy has been associated with an increased risk for falls.⁶² Recommendations to aggressively lower blood pressure in older patients can lead in some older patients, particularly those who are frail, to orthostatic and/or postprandial hypotension, resulting in falls, fracture, angina or strokes.^{63,64} In a cohort study of 4071 patients aged 83 years on average, excessive blood pressure lowering was associated with an increased mortality risk.⁶⁵ The highest survival rate was for systolic pressure of 130 to 139 and diastolic pressure of 80 to 89, with lower values associated with higher mortality. Prescribing physicians should monitor patients for orthostatic and postprandial hypotension and exercise caution when escalating doses of antihypertensive drugs.

The management of polypharmacy in older cardiac patients may often be complicated by concomitant, and often unsuspected, cognitive impairment. The same risk factors for heart disease are also risk factors for cognitive impairment.⁶⁶ Patients with HF in particular are prone to cognitive impairment through additional mechanisms, including hypoperfusion, hypercoagulability and other rheologic abnormalities, and concurrent depression.^{68,71} In HF patients, cognitive impairment has been associated with nonadherence to prescribed therapy, rehospitalization, functional decline, and mortality.^{72–75}

A variety of cognitive domains can be impaired in patients with heart disease, including difficulties learning new tasks as well as executive dysfunction.⁶⁷ Cognitive impairment is particularly common and problematic for patients with HF, who may have impaired memory, attention, processing speed, learning, and executive function deficits.⁶⁸ These deficits have the potential to interfere with adherence to lifestyle and dietary prescriptions, medications, regular weighing, and the recognition of early symptoms of decompensated HF.^{69,70} Rehospitalization for HF has been associated with medication mismanagement, and failure to recognize HF symptoms and take corrective action or seek medical attention in a timely manner.^{76–79}

Assessment of mood and cognition should be considered by clinicians prescribing new medications to older cardiac patients, particularly those with recurrent hospitalizations,

multiple functional deficits, polypharmacy, limited social support systems, or poorly controlled cardiovascular risk factors.^{28,80,81} Preliminary evidence suggests that treating depression may improve cognition in HF patients.⁷¹ Care should be taken to simplify medication regimens, preferably with once daily medications. Adherence to prescribed therapy may be improved through the use of aids, such as weekly dosettes or blister packs; close supervision by a pharmacist or caregiver; and ensuring adequate social support through family members or visiting nurses.⁸² Although referral of frail cardiac patients to chronic disease management programs or specialized geriatric services should be considered, the continued involvement of their primary care physicians is essential.²⁸ Transitional care programs based on Advanced Practice Nurse (APN)-led interventions to enhance self-management skills of older cardiac patients have been shown to decrease rates of adverse outcomes for up to 1 year following the intervention and are cost-effective.^{83,84}

CONCLUSION

Assessing frailty, cognition, and patient goals are essential to the appropriate management of heart disease in older persons. Although the use of some standard cardiac therapies may be beneficial for outcomes and goals of importance to frail older cardiac patients, clinicians must weigh these potential benefits against their potential risks, which include not only the possibility of adverse drug events, but also of falls and other geriatric syndromes. Clinical trials of cardiovascular therapies in representative populations of older cardiac patients and which assess all relevant outcomes are urgently required.

Coronary heart disease and stroke remain the major causes of death in people aged over 65 years in westernized societies, with an elevated blood pressure (BP) level being the biggest treatable risk factor. With the ever-increasing number of elderly people in the population, hypertension is pre-eminent as a public health problem. It is perhaps surprising to realize that it was only in 1985 that the first large trial of blood pressure reduction in the elderly population was published, demonstrating the benefits of treatment in terms of reducing cardiovascular complications.¹ Prior to this, a general reluctance to treat hypertension in older people prevailed, based it would seem on a few case reports of the adverse effects of antihypertensive drugs. This chapter deals with some of the more important aspects of hypertension in elderly people, while highlighting areas where important questions remain unanswered.

EPIDEMIOLOGY

Blood pressure increases with age. This has been shown in both cross-sectional and longitudinal studies in nearly all industrialized cultures. The rise in systolic blood pressure (SBP) is almost linear up to age 80 years, values tending to plateau thereafter. Diastolic blood pressure (DBP) levels plateau earlier, at 50 to 60 years, and then fall.² These changes herald the important age-related changes that occur in pulse pressure (PP) and mean arterial pressure (MAP). PP tends to rise steeply after the age of 60 years irrespective of the SBP levels when young; whereas MAP shows a much greater increase with age in those with high values in their 30s and 40s and reaches a plateau after the age of 50 to 60 years.

There are many factors governing these changes, both environmental and genetic. For example, blacks tend to have a greater age-related rise than whites, especially in women. Important sex differences in the BP changes with age are also found when comparing the results from cross-sectional and longitudinal studies, with the former showing women to have higher SBP and DBP values than men after 50 years of age. Cohort studies show a different pattern, with SBP increasing to the same degree in both sexes with little difference in age-related values; whereas DBP levels for women are consistently lower than for men, of the order of 5 mm Hg. It is possible that some of these differences in cross-sectional studies are due to selective mortality differences (such as death rates being higher in those with higher BP levels) resulting in an underrepresentation of those with initially high BP levels in the older age groups. Lifestyle differences probably account for some of these age-related alterations, little change in BP being seen with advancing years in some nonwesternized cultures.

Prevalence and incidence

The prevalence of hypertension is dependent on the definition used. Classically the threshold is the BP levels at which treatment appears to offer benefit over nontreatment, but the actual BP levels taken for defining hypertension have changed considerably recently. Definite hypertension, as originally

defined in the Framingham Heart Study (SBP = 160 mm Hg and/or DBP = 95 mm Hg or on antihypertensive treatment), was present in 39% of men and 48% of women in those aged 65–94 years.² In the United Kingdom, higher overall prevalence rates for hypertension have been reported, using the more liberal criteria (160/90 mm Hg) 61% of men and 63% of women aged 65 and over had hypertension, which rose to 78% and 83%, respectively, using a 140/90 mm Hg cut-off point.³ There are, however, marked differences in prevalence rates between countries (e.g., North American rates being about 50% for those aged 65 to 74 years compared with 80% for Germany).⁴ In the majority of these studies, these rates are based on two or three recordings at a single visit and, given the increased BP variability in older people, the estimates are probably too high and the rates based on repeated measurements are about 30% less than those quoted. For example, in a U.K. study of people aged 65 years and over, 52.2% had hypertension at first screening compared with 10.3% at the third visit 6 to 12 weeks later.⁵

As the systolic BP tends to increase to a greater extent than the diastolic BP with advancing years, isolated systolic hypertension (ISH) is the commonest form of hypertension in older people. Prevalence rates for ISH in the BIRNH Study were 9.9% in men and 11.7% in women aged 65 to 74 years, compared with rates for diastolic hypertension (DBP = 95 mm Hg) of 15.8% and 10.6%.⁶ For those aged 75 to 89, ISH rates increased to 15.3% and 17.4% in men and women, whereas diastolic hypertension (DH) fell to 7.7% in men but increased slightly to 11.2% in women. Interestingly, 84% of all female hypertensives in the study were aware of their diagnosis, compared with less than 70% of men, highlighting the need for BP screening in this age group. Other studies using multiple BP recordings made on several visits have found prevalence rates for ISH of 4.2%, combined hypertension (CH) in 3.9%, and isolated DH of 1% in those aged 65 to 84 years.⁵

Favorable trends in terms of decreasing hypertension prevalence are being reported. In the United States, rates have declined progressively since 1971. For example, in the NHANES study, rates of hypertension in men aged 60 to 74 fell from 37.9% in 1971–1974 to 35.4% in 1988–1991, and for women from 64.7% in 1971–1974 to 51.1% in 1988–1991.³ Incidence rates have changed little, being of the order of 9% and 6% per 2 years for men and women, respectively, in those aged 70 to 79 years.⁷ However, reliable incidence data are relatively scarce, particularly in the very elderly population.

Blood pressure and risk

Framingham data have shown that elderly hypertensives have three times the risk of a cardiovascular (CV)-related death than age- and sex-matched normotensives.⁸ There has been much discussion as to whether this relationship between BP and CV mortality is linear, U-shaped, or J-shaped, giving rise to the opinion that there may be an optimum level to which elevated BP values should be reduced. Intervention studies have suggested that reducing

BP levels too much may paradoxically increase cardiovascular and noncardiovascular risk. However, a U- or J-shaped relationship between BP and CV mortality has been reported in the placebo arms of these studies, so this could not be an effect of treatment per se.

Many of the studies suggesting an increased risk with lower BP levels were of relatively short duration and did not control for potentially confounding variables. The largest meta-analysis of prospective observational studies to date, involving nearly 1 million adults with no previous history of CV disease, has clearly shown a log-linear relation between increasing BP levels and CV mortality at least up to the age of 89 years with no evidence of a J- or U-shaped effect down to SBP levels of 115 mm Hg and DBP values of 75 mm Hg. A reduction in SBP of 20 mmHg would reduce risk of stroke mortality by 74% in those aged 40–49 years but only by 33% in those aged 80–89 years; for CHD the figures were 0.49 and 0.67 respectively. However, as the absolute risk of stroke and CHD events is much greater in the elderly, a 20 mm Hg lower SBP or a 10 mm Hg lower DBP would result in an annual difference in absolute risk that is almost 10 times greater in those aged 80 to 89 years compared with the 50- to 59-year-old group.⁹ For the very elderly, blood prospective observational studies have suggested high BP is not a risk factor for mortality and low values are associated with excess mortality.¹⁰

SBP, DBP, and risk

Systolic blood pressure is a bigger risk factor than DBP for cardiovascular disease in older people. In the Copenhagen heart study,¹¹ the risk ratio (RR) for stroke due to ISH (SBP = 160 mm Hg, DBP <90 mm Hg) in men was 2.7, but for diastolic hypertension (DBP = 90 mm Hg irrespective of SBP) it was 1.7 compared with normotensives. For myocardial infarction no such difference was seen in the relative risk between ISH and diastolic hypertension. More important, borderline ISH (SBP 140 to 159, DBP <90 mm Hg) in the Physicians Health Study¹² was associated with a 32% increase in CV events compared with normotensives, and a 56% increase in CV deaths. If future studies show that treatment of borderline ISH reduces CV risk, this will have enormous implications because over 20% of those aged over 70 years fall into this BP category.

Pulse pressure and risk

Pulse pressure increases greatly after the age of 50 years as a result of arterial wall stiffening with the associated increase in SBP and fall in DBP. In older age groups in the Framingham study,¹³ coronary heart disease was found to be inversely related to DBP at any given level of SBP = 120 mm Hg, suggesting that higher pulse pressure is as important, if not more so, than any other component of BP in predicting CHD risk (Figure 43-1). Pulse pressure was a better predictor than SBP, independent of DBP levels, for estimating the development of congestive heart failure (CHF); for each 10 mm Hg increase in pulse pressure there was a 14% increased risk of CHF, compared with a 9% increase for the same change in SBP.

Although SBP and PP are the best predictors of coronary heart disease, the same is not necessarily true for stroke. Mean arterial pressure has been found, in some studies

Figure 43-1. Influence of systolic and diastolic blood pressure on CHD risk in 50- to 79-year-olds. CHD hazard ratios are determined from the level of DBP within SBP groups. Hazard ratios are set to a reference value of 1.0 for an SBP of 130 and a DBP of 80 mm Hg. All estimates are adjusted for age, sex, body mass index, smoking, glucose tolerance, and total/HDL cholesterol. (Data from the Framingham study, reprinted from Franklin et al. [1999].¹³)

at least, to be a better predictor of stroke than either SBP or PP. In the Systolic Hypertension in the Elderly Programme,¹⁴ a 10 mm Hg increase in PP was associated with a relative risk of stroke of 1.11 (1.01 to 1.22) compared with 1.20 (1.02 to 1.42) for a similar MAP rise.

The finding that PP is as good a predictor of coronary heart disease as SBP has potential implications for treating hypertension because there seems little point in lowering SBP and DBP to the same extent, (keeping PP unchanged) because this may contribute to maintaining some degree of CV risk. It would thus appear that, in elderly people, CHD events are more closely related to pulsatile load than steady-state components of blood pressure. This may explain why, overall, 30% to 60% of all CV events in the elderly population are attributable to mild or moderate hypertension.

PATHOGENESIS

Mean arterial pressure (MAP) is determined by cardiac output and peripheral vascular resistance (PVR) and is the steady-state component of blood pressure. The dynamic component, pulse pressure (PP), is the variation around the mean state and is influenced by large artery stiffness, early pulse-wave reflection, left ventricular ejection, and heart rate. A rise in PVR and large artery stiffness will increase the systolic BP component, whereas a decrease in PVR or an increase in large artery stiffness will result in a fall in diastolic BP, the latter being the dominant change in older hypertensives.

The main cardiovascular pathophysiologic changes associated with aging are arterial dilation and a decrease in large artery compliance, especially in the aorta, because of the loss of elastic fibers in the vessel wall and a concomitant increase in collagen. Arterial stiffening leads to enhanced pulse-wave velocity and early reflected waves augmenting the late systolic aortic pressure wave, resulting in a systolic increase and diastolic fall. The rise in mean aortic pressure is augmented by the rise in PVR, seen particularly in older women, enhanced by impaired endothelial release of nitric oxide, especially in older hypertensives. The increase in systolic load puts excess mechanical strain on the left ventricle, leading to concentric wall thickening. Because coronary artery perfusion is primarily dependent on the diastolic

pressure, any reduction in DBP can have adverse effects on coronary artery perfusion, especially as left ventricular myocardial demands are increased in hypertension. Intimal wall damage results in the development of atherosclerosis and an increased likelihood of thrombosis.

The other main features associated with hypertension in old age are a reduction in heart rate, cardiac output, intravascular volume, and glomerular filtration rate, and decreased cardiac baroreceptor sensitivity (BRS) although cerebral autoregulation is unimpaired with normal aging and hypertension.^{15,16} This decrease in cardiac BRS accounts for the increase in BP variability found in older hypertensives, and it perhaps plays a role in the increased susceptibility to postural hypotension. Both renal plasma flow and plasma renin activity (PRA) levels decrease with age, the fall in PRA being more marked in elderly hypertensives than in normotensives. Plasma norepinephrine (norepinephrine) levels increase with age and are associated with a decrease in β -adrenoreceptor sensitivity. The effect of age and hypertension on α -adrenoreceptor sensitivity is still unclear.

OTHER CARDIOVASCULAR RISK FACTORS

Hypertension should not be considered in isolation. Irrespective of the age of the patient, it is important that overall cardiovascular risk be assessed, taking into account other important risk elements such as cholesterol levels, smoking habits, and the presence or absence of diabetes.

Lipid abnormalities

Early data suggested that serum total cholesterol (TC) levels increase with age and remain a significant independent predictor for CHD in men. The effect in women is less clear because the number studied has been too small to draw firm conclusions. The SHEP study¹⁴ found that TC and LDL cholesterol remained significant indicators of risk in both sexes, such that a 1 mmol/L increase in TC was associated with a 30% to 35% higher CHD event rate. More recently the Prospective Studies Collaboration meta-analysis of prospective observational studies involving more than 900,000 adults has shown increasing TC levels to be a risk factor for CV mortality even in the very old, though the risk is attenuated with age such that a 1 mmol/L lower TC was linked to a significant reduction in the HR for CHD to 0.57 in those aged 50 to 59 years compared with 0.85 in the 80- to 89-year-old group.¹⁷ As in previous studies the effect was greater in men than women in the older age groups, but the effect was seen in both sexes up to 90 years. However, for stroke, the link with TC was not as strong as for CHD. For a similar TC reduction, there was a significant lowering of the HR for stroke by 9% in 50- to 59-year-olds compared with a nonsignificant 5% increase in the HR in those aged 80 to 89 years. For CHD, but not stroke, the ratio of TC to HDL-cholesterol was a better predictor than TC alone but the predictive power fell with age, a 1.33 lower ratio being related to a 31% decrease in CHD mortality in the age 70- to 89-year-group compared with a 44% reduction in 40- to 59-year-olds. For stroke in those aged 70 to 89 years and with a SBP greater than 145 mm Hg, TC was negatively correlated with hemorrhagic and total stroke mortality, a 1 mmol/L lower TC.

Diabetes mellitus

Up to 10% of elderly people with hypertension will have impaired glucose tolerance, and diabetes doubles the risk of developing coronary heart disease and stroke in those aged 65 to 94 years. Like total cholesterol, however, its impact on CV events falls with age: women remain slightly more at risk than men, though the absolute risk from diabetes is greater in the elderly than the young.

Body mass index

Increasing body mass index (BMI) is associated with an elevation in blood pressure, but the risk of obesity-related hypertension declines with age, there being a threefold increase in hypertension in obese 20- to 45-year-olds compared with a 1.5 increase in 65- to 94-year-olds. For each unit of BMI increase (kg/m^2), SBP can be expected to increase by 1.2 mm Hg and DBP by 0.7 mm Hg.

Interestingly, for elderly hypertensive men, CV relative risk increases from 1.8 to 2.9 between the lowest and highest tertiles of BMI, whereas the reverse is true for women. Even so, hypertension still more than doubles the risk of developing CV disease in both sexes. In the European Working Party on Hypertension in the Elderly (EWPHE) study,¹⁸ those with the lowest total mortality and CV terminating events were found in the moderately obese group with a BMI of 28 to 29 kg/m^2 , whereas those with a BMI of 26 to 27 had the lowest cardiovascular mortality. Truncal obesity (reflected in an increased waist to hip ratio) is more strongly related to hypertension and is a better predictor for coronary heart disease and stroke than BMI alone.

Smoking

Although the number of smokers decreases with age, smoking remains a significant risk factor for CV mortality in older persons (the relative risk is 2.0 for males and 1.6 for females). The relative risk of stroke among older hypertensive smokers is five times that of normotensives but 20 times that of normotensive nonsmokers. The benefits of stopping smoking in terms of reducing coronary heart disease and stroke mortality are still present even in the 70- and over age group, with the excess risk of mortality declining within 1 to 5 years of quitting. Older smokers should therefore be encouraged to stop. Hypertensive cigarette smokers have an increased relative risk of stroke nearly quadruple that of hypertensive nonsmokers (pipe/cigar use still increases the risk threefold). Encouragingly, hypertensive exsmokers of less than 20 cigarettes per day have, after only a few years of quitting, a similar risk to that of hypertensive nonsmokers.

Atrial fibrillation and left ventricular hypertrophy

In patients with atrial fibrillation, hypertension doubles the stroke risk compared with normotensives. Electrocardiographically diagnosed left ventricular hypertrophy (LVH) increases with age, reported prevalence rates being 6% in men and 5% in women aged 65 to 74 years, compared with 9.4% and 10.8%, respectively, in those aged over 85. LVH has a significant effect on CV risk. Its presence in those aged 65 to 94 years nearly triples the risk for men and quadruples that in women, but this effect is less than that seen in younger age groups with a similar blood pressure.

Alcohol and diet

ALCOHOL

The association between high alcohol consumption and blood pressure has been known for a very long time, although the relationship is not linear in most epidemiologic studies. It takes on a J- or U-shaped form, with the lowest incidence of hypertension being seen in those consuming around 5 to 10 units of alcohol per week. Large falls in BP (19/10 mm Hg) have been recorded with abstinence in those aged 70 to 74 years who had a long history of heavy alcohol intake. Excessive alcohol intake has been directly related to stroke risk. It is unknown whether this is due to its direct pressor effect or to some other mechanisms, such as alcohol-induced cerebral vasoconstriction or cardiac dysrhythmia, particularly atrial fibrillation. As there appears to be a mild protective effect of a small amount of alcohol in older people, two units per day would seem a reasonable upper limit to recommend.

DIET

The relationship between dietary sodium intake and hypertension strengthens with age. For a 100 mmol/day increase, mean BP rises by 5 mm Hg in those aged 20 years but this more than doubles in those aged 60 to 69 years. Conversely, increasing potassium intake by 60 mmol per day reduces BP in older people by as much as 10/6 mm Hg. Increasing potassium dietary intake may also reduce stroke risk independently of its hypotensive effect. The average daily potassium intake in elderly people in the United Kingdom is around 60 to 70 mmol. This could be raised to over 100 mmol simply by increasing consumption of vegetables and fruit.

Physical exercise

Even mild-to-moderate physical exercise such as walking for 30 minutes three to four times a week has a hypotensive effect. Vigorous exercise in young to middle-aged persons prevents stroke in later life. Whether these effects are mediated solely through BP-lowering or are a result of other mechanisms, such as exercise-induced decreases in fibrinogen levels or an increase in HDL cholesterol, is unknown.

Hormone replacement

There has been considerable controversy over the benefits or otherwise of hormone replacement therapy (HRT) in CV disease prevention. A recent overview has suggested treatment has no significant effect on all-cause mortality, nonfatal myocardial infarction rates, or CHD death but a significant 29% increase in stroke risk and therefore cannot be recommended to reduce CV disease.¹⁹ The effect of HRT in hypertensives is unknown and data are insufficient to see if the general increased risk of stroke is further increased in this group.

COMPLICATIONS OF HYPERTENSION

Stroke

Hypertension remains the major treatable risk factor for stroke, although the attributable risk for increasing BP levels decreases with age. For a 10 mm Hg increase in usual diastolic BP, the risk of stroke is almost doubled. A reduction of 9/5 mm Hg can be expected to produce about a 30% reduction in stroke incidence, whereas a fall of 18/10 mm Hg

halves the risk; these expectations are irrespective of baseline BP levels.

The relative risk of cerebral infarction varies depending on the hypertension type in older age groups.²⁰ Isolated systolic hypertension (ISH) is a bigger risk factor (ratio 2.3) than is combined systolic and diastolic hypertension (ratio 1.5). The population attributable risk for stroke in those aged 70 to 79 years with ISH is about 21% for women and 17% for men, whereas for those aged 50 to 59 years the figures are 5% for women and 4% for men. Although the relative risk of stroke from raised BP decreases with age, this is not because hypertension per se loses its effect as a risk factor, but that more strokes occur in those with "normal" blood pressure. Intracerebral hemorrhage is also closely related to hypertension, the relative risk varying from 2.0 to 9.0 between studies—being greater for combined hypertension than ISH, particularly in younger patients.

Raised BP levels are common in the first days to weeks after stroke, and BP levels tend to settle spontaneously. There is, however, increasing evidence that raised BP levels following acute stroke are associated with a poor outcome in terms of death and dependency.²¹ There is a small but convincing body of evidence to suggest an almost linear relationship between increased BP values in the poststroke period and stroke recurrence rate.

BP and asymptomatic cerebrovascular disease

Deep white matter lesions (leukoaraiosis) in asymptomatic hypertensive elderly patients are frequently found on magnetic resonance scanning. Whether these lesions account for the age-related cognitive impairment seen with hypertension that has been reported in many studies is unknown. It is also uncertain whether they increase the risk of subsequent cerebral infarction or hemorrhage. Isolated systolic hypertension, in particular, is associated with these subcortical lesions, and good BP control appears to have a protective effect. Large diurnal falls in BP are associated with silent subcortical white matter lesions and lacunar infarcts, but these are found also in those who have marked nocturnal rises in BP.

Cognitive impairment

The influence of blood pressure on cognitive decline and psychomotor function, over and above its association with vascular dementia, has been much debated. Some studies show no such relationship whereas others report a strong positive correlation with both vascular and Alzheimer-type dementia. A recent overview has suggested that increasing BP levels in midlife are a risk factor for cognitive impairment and dementia in old age, but that there is an inverse correlation between BP measured in old age and dementia in cross-sectional studies. The results of longitudinal studies of BP and cognition in later life are inconsistent, as are those for BP and dementia, though the majority suggest a low BP is common in those with severe cognitive impairment.²² Treating hypertension even with small falls in BP is associated with improvements in MMSE scores and immediate and delayed memory scores.²³ A recent meta-analysis showed treating hypertension in the very elderly significantly reduced the risk of dementia by 13%.²⁴ The pathogenesis of hypertension-related cognitive impairment is unclear. It could be

linked to a decrease in cerebral blood flow with increasing BP levels and alteration in the cerebral metabolism over and above the changes associated with leukoaraiosis.

Cardiac disease

The relationship between coronary heart disease and hypertension is discussed in Chapter 34. Hypertension accelerates the development of coronary artery atheroma through many mechanisms, particularly in association with metabolic abnormalities as in the insulin-resistance syndrome. Increased blood glucose and insulin levels, and changes in total cholesterol, HDL and LDL levels, and endothelial dysfunction result in impaired endothelial-dependent relaxation and increased leukocyte adherence, smooth muscle proliferation, intimal macrophagic accumulation, fibrosis, and arterial medial wall thickening. These changes, along with increased vascular oxidative stress and free radical production (see Chapter 32), result in inflammatory changes in the arterial wall, monocyte migration into the intima, and plaque formation.

DIAGNOSIS AND EVALUATION

General issues

Assessment of blood pressure levels in elderly people can pose particular problems, but it is essential that accurate measurements be made if patients are not to receive unnecessary or inadequate treatment. Minute-to-minute BP variations occur with respiratory and vasomotor changes. During the 24-hour period, BP fluctuations are related to mental and physical activity, sleep, and postprandial changes. Seasonal variations are also seen, with BP levels being higher during the winter months. Hypertensive patients have a greater absolute BP variability than normotensives, but when corrected for baseline values little difference exists. Clinically important differences are frequently found between individual readings at a single visit and between visits. Large falls in BP with repeated measurements in elderly hypertensives have been reported in nearly every placebo-controlled interventional trial, the effect increasing with age and amounting to as much as a 10/5 mm Hg decrease. The tendency for BP levels to decrease with time is related in part to regression to the mean and familiarity with the procedure of BP measurement. The British Hypertension Society (BHS) guidelines recommend that in uncomplicated cases an average of two readings be taken sitting on four occasions over a 2- to 3-month period during initial assessment.²⁵ It is particularly important to measure BP levels 1 and 3 minutes after standing to assess postural BP change in view of the frequency of orthostatic hypotension in this age group.

Measuring blood pressure

With the expected phasing out of mercury sphygmomanometers and their replacement by semiautomatic devices, it is important that manufacturers provide accurate equipment validated in the elderly. A list of BP measuring devices that have been validated for use in young and elderly persons is constantly updated on the British Hypertension Society Web site (www.bhsoc.org). Cuff size is important as undercuffing gives falsely high BP values. Cuff width should be equal to two thirds of the distance between axilla and antecubital fossa, and when the bladder is placed over the

brachial artery, it should cover at least 80% of the arm's circumference—which should be kept supported at heart level. Clinicians should obtain both standard and large cuffs and ensure they are used appropriately.

The measurement should be taken in both arms initially because more than 10% of elderly people have at least a 10 mm Hg difference between arms. The arm with the highest reading should be used for subsequent measurements. All elderly people should have their BP measured every 5 years up to age 80 years at least, and in those with high normal BP (135 to 139/85 to 89 mm Hg) it should be assessed annually.

Ambulatory blood pressure monitoring

The role of ambulatory monitoring (ABPM) in the assessment of elderly people with hypertension is still being defined. Twenty-four-hour monitoring reduces the variability and the alerting response to measurement, so that 75% of elderly hypertensives will have lower ABPM measurements than clinic values. Casual measurements tend to be in the order of 20/10 mm Hg higher than 24-hour values. Daytime BP values are the best predictor of target organ damage.

The value of other information that the 24-hour ABPM profile can provide, such as day-night differences, is unknown. The Syst-Eur study²⁶ has emphasized that ABPM is a significantly better predictor of CV risk than are casual measurements. ABPM could be recommended in the following cases:

- To diagnose white-coat hypertension (persistently elevated clinic BP levels while normotensive on ABPM)
- When BP appears resistant to therapy (using three or more agents)
- In those with symptoms of postural hypotension and postprandial hypotension

However, there is little justification as yet to use it routinely in all elderly hypertensive patients because it is expensive and time-consuming, though generally well tolerated.

Suggested normal values are: daytime $\leq 135/85$ mm Hg; nighttime $< 120/70$ mm Hg; and 24-hour $\leq 130/80$ mm Hg. Abnormal values are: daytime $> 140/90$ mm Hg; nighttime $> 125/75$ mm Hg; and 24-hour $> 135/85$ mm Hg.²⁷

Cuff measurements tend to underestimate intra-arterial levels of systolic BP by up to 5 to 10 mm Hg, and to overestimate diastolic BP by about 5 to 15 mm Hg. "Pseudohypertension" refers to falsely high noninvasive recordings caused by arterial rigidity, which prevents the vessel collapsing during cuff inflation. The prevalence of this condition in an unselected elderly population is probably very low, of the order of 1% to 2%. Unfortunately there is no accurate way of predicting the condition. Osler's maneuver (said to be positive when the radial artery is still palpable following the occlusion of the brachial artery) is unreliable.

Clinical assessment and investigations

One common feature of hypertension in young and elderly people alike is that it is very often asymptomatic. Complaints often attributed to increased BP levels, such as headache, are in fact unrelated in most cases. History and examination should include assessment for the presence of important CV risk factors (such as diabetes), for symptoms and signs of secondary causes of hypertension, and for evidence of target organ damage. Other important factors to be considered are the presence of confusion, urinary incontinence, decreased

mobility, other medication use (for possible drug interactions which will affect the need for and type of antihypertensive agent)—all of which will influence treatment decisions. Examination should focus on evidence of target organ damage, including peripheral pulses and bruits (renal or carotid), and cardiac murmurs. Ophthalmoscopy is used for possible malignant-phase and diabetic changes, and a neurologic examination for signs of cerebrovascular disease and vascular dementia.

Initial investigations should include height, weight, blood samples for urea and electrolytes, creatinine and glucose estimations, and a 12-lead ECG (to exclude ischemic change, dysrhythmias, and left ventricular hypertrophy). In those aged ≤ 70 years for primary prevention, and in those ≤ 75 years for secondary prevention, total cholesterol and HDL cholesterol levels along with urine analysis for protein and blood should be included. Chest x-ray is of doubtful benefit, except in those who may have heart failure or chest disease. Plasma calcium and uric acid levels may also be useful to look for primary hyperparathyroidism (which is more frequent in elderly people with hypertension) and to check for gout. Echocardiography is rarely needed.

Renal artery stenosis is the only major secondary cause of hypertension in this age group. It should be considered:

- When there is a sudden onset or rapid progression of hypertension
- If BP control suddenly becomes difficult, particularly in those at greater risk of atherosclerotic renal artery stenosis, diabetics, smokers, and those with peripheral vascular disease
- In those developing malignant phase hypertension
- Where there is rapid deterioration of renal function, particularly after starting angiotensin-converting enzyme inhibitors

Renal ultrasound is not reliable for making the diagnosis of renal artery stenosis, although a significant difference in renal size may be suggestive. Captopril renography is not always helpful, and imaging techniques—either duplex ultrasonography or MR angiography—are the mainstays of diagnosis.²⁸

MANAGEMENT OF HYPERTENSION

This section summarizes briefly the results of the important trials of drug therapy on outcome in elderly people. Space does not allow a full description of each trial.

Several recent large intervention studies have assessed the effects of antihypertensive drug treatment on outcome in elderly people, all of which have shown a positive benefit for active treatment. This is perhaps surprising given the heterogeneity of the patients included in the trials (those with combined hypertension, combined and ISH, or ISH alone, the presence or absence of target organ damage, and varying CV risk factors), the differences in antihypertensive drugs used, and the varying length of follow-up.

Published trials

TRIALS IN COMBINED HYPERTENSION

The first large trial solely in elderly patients, which awoke widespread interest, was the European Working Party Hypertension in the Elderly (EWPHE) trial published in 1985.¹ The results suggested that, for every 1000 elderly patients treated for 1 year initially with a diuretic, 11 fatal cardiac events, 6 fatal and 11 nonfatal strokes, and 8 cases of congestive cardiac failure would be prevented. Other randomized controlled trials that have enrolled hypertensive patients over 70 years include: that reported by Kuramoto et al²⁹ using thiazide diuretics as first-line therapy; the Hypertension in Elderly People trial,³⁰ using β -blockers; the MRC elderly study,³¹ using thiazides or β -blockers; and the STOP-Hypertension trial,³² again using thiazides or β -blockers as first-line agents. These have all shown the benefits of treatment in reducing cardiovascular disease (Table 43-1).

MORTALITY. Of the five studies noted above, only the STOP-Hypertension trial reported a significant reduction in all-cause mortality following treatment (relative risk 0.57; 95% CI = 0.37 to 0.87). A meta-analysis of these five trials demonstrates an insignificant overall reduction in total mortality (odds ratio [OR] 0.90; 0.79 to 1.02), but overall

Table 43-1. Compelling and Possible Indications, Contraindications, and Cautions for Use of the Major Classes of Antihypertensive Drugs in Elderly People

Class of Drug	Compelling Indications	Possible Indications	Compelling Contraindications	Possible Contraindications
A. ACE inhibitors	Heart failure	Chronic renal disease Left ventricular dysfunction Type 1 diabetic neuropathy	Renovascular Type 2 diabetic neuropathy	Renal impairment disease PVD
B. Beta-blockers	Myocardial infarction Angina	Heart failure	Asthma/COPD Heart block	Heart failure Dyslipidemia PVD
C. Calcium antagonists (dihydropyridine)	Elderly ISH	Elderly angina	—	—
D. Thiazide diuretics Others	Elderly		Gout	Dyslipidemia
Alpha-blockers All antagonists	Prostatism ACE-inhibitor-induced cough	Dyslipidemia Heart failure Intolerance of other antihypertensive drugs	Urinary incontinence Renovascular disease	Postural hypotension PVD
Calcium antagonists with (rate-limiting)	Angina	Myocardial infarction	Heart block Heart failure	Combination with blockade

See text for explanation of ABCD classification.

Abbreviations: ACE, angiotensin-converting enzyme; ISH, isolated systolic hypertension; COPD, chronic obstructive pulmonary disease; PVD, peripheral vascular disease. Adapted from Ramsey LE, Williams B, Johnston GD, et al. Guidelines for the management of hypertension: Report of the third working party of the British Hypertension Society. *J Hum Hypertens* 1999;9:569–92.

cardiovascular deaths were significantly reduced (OR 0.78; 0.66 to 0.92), as were CHD deaths (OR 0.73; 0.59 to 0.91) and stroke deaths (OR 0.68; 0.50 to 0.94).

NONFATAL EVENTS. An overall picture of treatment effects on nonfatal events is difficult to formulate because different trials used different criteria for defining nonfatal events; for example, "cerebrovascular events" may have included or excluded transient ischemic attacks or minor strokes. With these provisos in mind, nonfatal stroke events were significantly reduced (OR 0.69; 0.54 to 0.87), as were CV events (OR 0.72; 0.60 to 0.88), but with considerable variation between trials. For example, nonfatal stroke events in the STOP-Hypertension trial were reduced by 38% and in the HEP trial by 27%, and nonfatal coronary events by 20% in HEP and by 9% in EWPHE.³³ The benefits of treatment in terms of proportional risk reduction were similar between studies (a 35% to 40% decrease in all stroke events), but the absolute benefit seen was related to the underlying patient risk. In the MRC study,³¹ strokes prevented per 1000 patient years of treatment were approximately 2.5, compared with approximately 14 in the STOP-Hypertension trial.³² Drug therapy reduced the risk of hemorrhagic stroke within just 1 year of starting treatment, and within 2 years for ischemic stroke.

TRIALS IN ISOLATED SYSTOLIC HYPERTENSION

Trials involving ISH patients only (SHEP,³⁴ Syst-Eur,³⁵ and Syst-China³⁶) have shown similar reductions in stroke and, to a lesser extent, coronary heart disease. Syst-Eur and Syst-China were unique in their time because they were the first to use calcium channel blockers (CCBs) as first-line antihypertensive treatment. Concerns had been raised about decreasing diastolic pressure further in patients with ISH because low DBP levels in cross-sectional longitudinal studies have been shown to be associated with an adverse prognosis in this age group. However, these worries do not seem justified because in the SHEP study treatment reduced DBP from 77.5 mm Hg to 68 mm Hg and yet significant reductions were seen in fatal and nonfatal stroke and myocardial infarct rates. Overall for the ISH studies there were significant reductions in total mortality by 17%, in CV mortality by 25%, and in fatal and nonfatal stroke by 37%. These benefits are similar to those seen in non-ISH trials.

COMBINED RESULTS

The combined results of the CH and ISH trials are shown in Figure 43-2. They suggest that only 45 elderly people with hypertension would need to be treated for 5 years to prevent one CHD event, compared with 180 younger hypertensives. For stroke the benefits are even greater, with only 22 elderly patients needing treatment to prevent a cerebrovascular event compared with 113 under 65 years. These benefits were achieved with relatively modest reductions in BP of about 20/10 mm Hg. Drug compliance among elderly hypertensives is generally as good as that for younger patients despite numerous factors that can affect this, including poor eyesight and hearing, confusion, etc. Simple once-daily drug regimens, and perhaps increased use of combined preparations, will improve compliance and therefore blood pressure control.

There is now convincing evidence that antihypertensive treatment should be introduced in nearly all patients up to

Figure 43-2. Effects of treatment on fatal and nonfatal events. Data from randomized outcome trials involving hypertensive patients aged 70 years and over.^{1,29–36}

the age of 80 years if they have a systolic BP equal to 160 mm Hg and/or a diastolic BP equal to 100 mm Hg despite nonpharmacologic measures (see later discussion). Treatment should also be introduced in those patients with an SBP of 140 to 159 mm Hg and/or DBP equal to 90 to 99 mm Hg if target organ damage or other CV risk factors such as diabetes are present and their 10-year CHD risk is 15% (equivalent to a 20% CV risk). This risk can now be easily calculated using the Joint British Societies Coronary Risk Prediction Chart²⁴ or a similar computer program. This chart cannot be used to predict risk in those aged over 75 years or those on treatment, but it can be used for assessing the need for statin therapy based on the TC:HDL-cholesterol ratio and for the introduction of aspirin (see later discussion).

Target BP levels for treatment

Target blood pressure levels in trials have varied considerably and have also fallen considerably with time; for instance, target levels in the HEP study were 170/105 mm Hg, compared with less than 140 mm Hg for systolic BP in SHEP. The fact that the degree of CV risk reduction was so similar between studies is even more remarkable. However, with the concern still present about a potential U- or J-shaped relationship between BP levels on treatment and outcome, it was unclear how far BP should be reduced because no trial had specifically looked at this aspect in elderly patients, or in those with ISH. Results from the EWPHE trial¹ suggested that all-cause mortality was lower in those with an SBP on treatment of 150 mm Hg compared with those who achieved an SBP of 130 mm Hg.

The HOT study has gone some way to answering questions.³⁷ This recruited 18,790 patients aged 50 to 80 years (mean 61.5 years) with a diastolic BP of 100 to 115 mm Hg who were randomized to three target DBP groups: ≤ 80 mm Hg; ≤ 85 mm Hg; or ≤ 90 mm Hg. All patients received initial therapy with the dihydropyridine calcium-channel blocker felodipine. In addition, patients were randomized to low-dose aspirin (75 mg daily) or no aspirin. Unfortunately it proved difficult to reach target BPs, particularly in the two lowest groups of DBP, despite triple therapy in the majority of patients. No differences were seen in outcome measures

between the three target BP groups, apart from a borderline-significant reduction in myocardial infarctions in the less than 80 mm Hg group compared with the less than 90 mm Hg group. However, combining all patient groups showed that the lowest risk point for major cardiovascular events was a mean achieved SBP of 138.5 mm Hg and a DBP of 82.6 mm Hg, and CV mortality was lowest with a BP of 138.8/86.5 mm Hg. For stroke, the lowest estimated incidence was with an SBP of 142 mm Hg with no definite minimum DBP level. In a diabetic subgroup, however, major CV events were highly significantly reduced, the risk being halved for those in the ≤ 80 mm Hg group compared with the ≤ 90 mm Hg group. There seems to be little to be gained in reducing the diastolic BP below 80 mm Hg except in diabetic patients.

Based on these results, the British Hypertension Society guidelines recommend that clinic BP levels for optimal control should be SBP less than 140 mm Hg and DBP less than 85 mm Hg, and in diabetics less than 130/80 mm Hg, with minimum recommended levels for BP control of less than 150/90 mm Hg and 140/85 mm Hg, respectively.²⁵

It is important to bear in mind that introducing antihypertensive treatment is only part of the risk-reduction process. It is the level of blood pressure while on treatment that is a much better predictor of subsequent events than baseline values—hence the need to achieve these target levels. This will mean three or more different antihypertensive agents in 20% to 30% of elderly hypertensives. It is also important that other CV risk factors be dealt with simultaneously, such as raised lipid levels and smoking.

Prophylaxis

ASPIRIN USE

Although aspirin reduces deaths following myocardial infarction and stroke, its routine use in patients with uncomplicated hypertension has been unclear. In the HOT study,³⁷ those randomized to 75 mg of aspirin had a 15% (1% to 27%) reduction in major CV events, and MIs were reduced by 36% (15% to 51%); but stroke, total, and CV mortality rates were unaffected by treatment. Similar results were seen in a thrombosis prevention trial of men aged 45 to 69 years at high risk of CHD.³⁸ Both studies emphasized that if any benefit from aspirin were to be achieved, BP levels must be controlled (i.e., $<150/90$ mm Hg before aspirin is started in patients with uncomplicated hypertension).

For elderly patients matters are less clear because the benefits of prophylactic aspirin use appear to decrease with age. There was a 52% risk reduction with aspirin for CHD in those aged 45 to 49, compared with 29% increase in those aged 60 to 69 years. Those least likely to benefit were patients with a systolic BP greater than 145 mm Hg compared with those with SBP less than 130 mm Hg.

Elderly hypertensive patients should receive low-dose aspirin (75 mg daily) only if BP levels are well controlled and their 10-year CV risk is equal to 15%, unless there are other specific indications (i.e., after stroke or MI, with diabetes, or other evidence of target organ damage). Even then, good BP control should be the aim.

Statin use

No studies of statin use have specifically targeted people with hypertension, young or old. Conclusions drawn are therefore based on subgroup analysis of the large trials.

Insufficient data exist to support lipid-lowering therapy for primary prevention in patients aged over 75 years, and so routine lipid screening over this age is unnecessary. With regard to those at high CV risk and in secondary prevention, there have been just three large studies of statin use in patients up to the age of 82 years.^{39,40} The results suggest that a much more proactive stance should be taken. Evidence indicates that 65- to 82-year-olds with risk factors for, or established, CV disease and a TC level equal to 3.5 to 4.0 mmol/L will benefit from statin therapy in terms of reducing subsequent major CV events by about 20% to 25%, although the results for stroke were inconsistent ranging from no benefit to a 25% reduction over 5 years. Stroke patients in the nonacute phase with a mean TC of 5.5 mmol/L also benefit from cholesterol reduction with a statin, subsequent stroke events being reduced by 16% and CV events by 20%.⁴¹

There are no long-term studies of the effects of diet on lipid levels and CV events. Such measures are likely to reduce TC only by 10%. Effective reductions will therefore require potentially expensive statin treatment. Evidence suggests statin therapy could be justified in those with a 10-year CHD risk of 6%, which would mean that nearly two thirds of the elderly population should be on treatment! This is unlikely to be possible, so guidelines recommend that patients up to the age of 75 years with CHD or overt atherosclerotic diseases should be considered for secondary prevention with a view to reducing TC to ≤ 5 mmol/L or by 25%, whichever is greater (or LDL cholesterol to ≤ 3 mmol/L or by 30%). For primary prevention, those up to the age of 70 years with TC equal to 5 mmol/L and a 10-year CHD risk greater than 30% should be considered for treatment.

Nonpharmacologic methods

There is a general lack of enthusiasm for nondrug measures to reduce BP in elderly patients, despite the evidence of their efficacy (see later discussion). Various guidelines have emphasized their importance as first-line treatment in trying to achieve normotension and in reducing other CV risk factors.

WEIGHT LOSS

A 2-kg weight loss over a 6-month period will reduce blood pressure by about 4/5 mm Hg in elderly hypertensive subjects.⁴² However, constant encouragement is needed to maintain this weight loss if the long-term benefit is to be seen. A body weight within 10% of ideal (or a BMI <26 kg/m²) should be encouraged, not just for its hypotensive effects but also to improve glycemic control and lipid profiles, and to improve mobility and respiratory and cardiac function.

SALT RESTRICTION

The hypotensive effect of reducing sodium intake increases with age. In elderly people with hypertension, an 80 mmol/day decrease in sodium intake will result in an 8 mm Hg fall in SBP.⁴³ This level of sodium reduction can be achieved simply by avoiding salty foods and not adding salt while cooking or at the table. Reducing salt added to processed food would make even greater reductions possible.

INCREASING POTASSIUM INTAKE

Increasing potassium intake by 40 mmol/day will have a significant hypotensive action, reducing clinic BP by 10/6 mm Hg and 24-hour BP levels by 6/2 mm Hg.⁴⁴ In addition,

increasing dietary potassium intake may reduce stroke rates over and above any hypotensive action. The average intake of potassium in the United Kingdom is about 60 to 70 mmol/day, and an intake of 100 to 110 mmol/day can be achieved by encouraging greater consumption of fresh fruit and vegetables. Potassium supplements are not routinely recommended for their hypotensive action, and care must obviously be taken in those with renal impairment.

REDUCING ALCOHOL INTAKE

The alcohol-hypertension link has been firmly established, but the relationship is nonlinear. Most epidemiologic studies have shown a J-shaped curve, with the lowest incidence of hypertension in those drinking about 1 unit (10 g) of alcohol per day.⁴⁵ Low levels of alcohol intake also appear to have a protective effect with regard to the development of coronary heart disease, even in older individuals, by raising HDL levels and having an antithrombotic effect.

OTHER MEASURES

Changing magnesium and calcium intake have not been found to have a significant effect on BP in the elderly population, although increasing vitamin C intake does have a mild hypotensive action and a positive effect on the lipid profile in older hypertensives.⁴⁶ Caffeine may have an acute pressor effect in caffeine-naïve persons, but regular caffeine intake does not have a pressor effect (although some studies have shown increasing consumption is associated with an increased CHD risk). Mild aerobic exercise (walking 30 minutes a day three to four times a week) results in important reductions in BP (approximately 20/10 mm Hg) in older hypertensives. It also decreases stroke risk independently of its hypotensive action, and improves glucose profiles, reduces weight, and improves general well-being.⁴⁷

COMBINED EFFECTS

The combined effect of dietary interventions has been investigated in two important studies. The Dietary Approaches to Stop Hypertension (DASH) trial⁴⁸ studied the effects of a special diet rich in vegetables and fruit and low in dairy products. It compared this to a standard diet, while varying levels of sodium intake in persons with and without hypertension. The DASH diet with a low sodium intake resulted in a BP fall of 7 mm Hg in normotensives and 11.5 mm Hg in hypertensives—similar effects to those that might be seen with a thiazide diuretic (see later). However, the duration of the trial was only 30 days.

The Trial of Non-pharmacologic intervention in the Elderly (TONE) study⁴² randomized elderly hypertensives who were normotensive on monotherapy to drug treatment withdrawal and either sodium reduction (and, if obese, sodium reduction or weight loss or the combination) or usual care with a 30-month follow-up. End points of restarting hypotensive drug treatment or developing a CV event were significantly reduced by all the interventions, with a 53% risk reduction in the obese on the combined sodium-restriction and weight-loss diet. The study was underpowered to find a significant decrease in CV events alone, but the nutritional interventions were well tolerated.

Approximately 25% of elderly people with mild hypertension could remain off drug treatment for 12 months or more using nonpharmacologic measures. Predictors of those

who will remain normotensive include the absence of ECG evidence of LVH, obesity, and patients with well-controlled SBP levels prior to withdrawal of treatment. In general, nonpharmacologic methods should be tried initially in all patients and given time to work, although constant encouragement will be needed. In the majority of patients drug therapy will also be needed. Important synergistic effects between nonpharmacologic and drug treatments are found, such as in sodium restriction with those patients treated with ACE inhibitors.

Drug treatments

THIAZIDES

Low-dose thiazide diuretics remain the first-choice antihypertensive agents in elderly patients for combined or isolated systolic hypertension.²⁴ Their mode of action has not been fully resolved, but is in part due to a reduction in peripheral vascular resistance. Although there are concerns that thiazides may induce postural hypotension, this is not a significant side effect. Mild hypokalemia, hyponatremia, and hyperuricemia can occur but are not normally clinically significant if low doses are used. Impotence can still be a problem with these agents in all age groups. Serum electrolytes should be checked before and a few weeks after starting treatment to assess the need for additional potassium supplementation.

B-ADRENORECEPTOR BLOCKERS

β -blockers, such as thiazide diuretics, have been used as first-line therapy in several large intervention trials in the elderly. There are, however, theoretical reasons why they may not be the most obvious choice in elderly patients with hypertension because they reduce cardiac output and renin levels that are already reduced, and increase peripheral resistance. Although they can effectively reduce BP in this age group, they do not have a good side effect profile. For instance, in the MRC study in the elderly,³¹ 30% of the β -blocker group were withdrawn because of major side effects, compared with 15% in the diuretic limb and 4% of those on a placebo. There were also significant differences between treatment limbs in outcome measures in the trial. The β -blocker group showed no significant reduction in coronary events, unlike the diuretic group.

A recent meta-analysis of all trials in elderly patients with hypertension using diuretics and/or β -blockers as first-line agents showed that, although β -blockers prevented all stroke events, they did not reduce stroke mortality; nor did they reduce CHD events, CV, or all-cause mortality, whereas diuretics showed a positive and significant advantage in all these outcome measures.⁴⁹

In view of these findings, patient compliance and economic factors, thiazides are the drug of first choice for initial therapy. However, as over half of such patients will require two or more agents, β -blockers should still be considered as additional therapy but probably more as fourth-line agents except in certain elderly patient groups where β -blockers may still be considered as first-line agents (e.g., those who have had a previous myocardial infarction or have angina).

CALCIUM-CHANNEL BLOCKERS

Recent intervention studies involving elderly people with hypertension—the Syst-Eur,³⁴ Syst-China,³⁵ and HOT³⁷ studies—have used members of the dihydropyridine CCB

group as first-line therapy. There has been considerable debate about the safety of the dihydropyridines, and various meta-analyses have arrived at diametrically opposite conclusions. It is clear that the placebo-controlled intervention studies in the elderly using dihydropyridine CCBs as first-line treatment have shown significant benefits, particularly in terms of stroke and CV risk reduction. We still need the security of long-term safety data, but trial evidence indicates that these agents are generally well tolerated and effective, so are recommended as first-line agents in patients with isolated systolic hypertension in whom thiazide diuretics cannot be tolerated.²³ Short-acting calcium-channel blockers have no role in the treatment of hypertension.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS AND ANGIOTENSIN RECEPTOR BLOCKERS

ACE inhibitors (ACEIs) are effective antihypertensive agents in young and old alike. First-dose hypotension may occur, especially in patients who are on large-dose diuretics, so it is usually recommended that these agents be stopped for a few days before initiating ACEI therapy. Hyperkalemia can be a problem, so potassium-sparing diuretics should be stopped with the introduction of these drugs. Problems with renal impairment have been reported in older patients taking NSAIDs and those with preexisting renal impairment. Renal failure may be precipitated in those with occult renal artery stenosis, so it is recommended that urea and electrolytes be checked before and 1 to 2 weeks after starting treatment. Cough can be a problem in about 10% of patients, so an All antagonist may be a suitable alternative. There are theoretical reasons to suggest that the combination of ACE and All inhibitors could be potentially synergistic in their hypotensive actions, although it is too early to recommend this combination.

There are now several outcome studies using ACEIs as first-line therapy in the elderly. STOP-2 trial⁵⁰ compared the newer antihypertensive agents—a dihydropyridine CCB and an ACEI—against standard therapy with β -blockers and diuretics. Overall there was little difference in terms of outcome measures between the new and old agents. A comparison of the ACEI and CCB groups showed a greater reduction in myocardial infarction and congestive heart failure in the ACEI group (by 23% and 22%, respectively) but a greater decrease in stroke mortality with CCBs. Overall CV mortality, total mortality, and all major CV events were similar in the ACEI and CCB groups, with CV mortality being 20.5 per 1000 patient years in the ACEI group and 19.2 per 1000 patient years in the CCB group. There have been no large outcome studies using ACEIs as first-line therapy in elderly people with hypertension. Angiotensin receptor blockers (ARBs) have also been shown to be highly effective agents in the elderly hypertensive patient and do not have the troublesome side effect of cough seen with ACEIs.

OTHER AGENTS

α -Blockers still have a minor role in treating elderly people with hypertension and are usually used as additional, rather than first-line, therapy. The withdrawal of doxazosin as initial therapy in the ALLHAT study⁵¹ because of increased risks of heart failure and stroke compared with chlorthalidone supports this policy. α -Blockers may have a role in men with prostatic symptoms, and they can be used in renal

failure, although postural hypotension and urinary incontinence remain a drawback in a significant number of patients.

Methyldopa, hydralazine, and centrally acting agents are rarely used because of their adverse side effect profiles. The former two agents need to be taken more than once a day, which does not aid compliance. There seems little reason to use agents that do not have a 24-hour hypotensive action when taken once daily.

COMBINATION THERAPY

More than 50% of these patients will need two or more agents if adequate blood pressure control is to be achieved.³⁷ Not all agents have a synergistic effect. For example, the addition of a calcium-channel blocker to a thiazide diuretic in most studies has a minimal additional hypotensive effect. Adoption of the British Hypertension Society's "ACD strategy" will help form logical combinations, such that antihypertensive combinations are likely to have an additional hypotensive effect if their mechanisms of action are complementary.

The first-line agents in the elderly should be a thiazide diuretic (D) or, if that is not tolerated, a calcium-channel blocker (C). If control is not achieved, a first-line agent of the other group (i.e., ACEIs (A) or ARB) could be tried. If good control is still not obtained, an additional agent from the other group is added along the following lines in the elderly: (C or D) add (A) add (D or C) add to combination (A+C+D) fourth-line agent (e.g. α -blocker, or β -blocker or spironolactone or amiloride) (see Table 43-1). It has been suggested the protective effect of blood pressure lowering is not substantially affected by the type of drug class given but is more dependent on the level of BP lowering achieved.⁵²

SPECIAL CASES

The 80 and over age group

Several trials have included patients over the age of 80, but it has been unclear whether they benefit from treatment. Longitudinal studies have shown that raised blood pressure in the very old (aged 75 to 80+ years) is not as big a risk factor as in younger people. However, the SHEP study³⁴ showed that only the 80 and over age group had a significant reduction in CV risk with active treatment compared with placebo, although there were similar trends in the 60 and over and 70 and over age groups. A meta-analysis of these trials⁵³ that included all the patients aged 80 and over showed that treatment prevented 34% (18% to 52%) of strokes, with a reduction in major CV events (23%) and heart failure (42%). However, total mortality was increased by 15% in the actively treated group, leaving physicians with a considerable dilemma as what is best for very old hypertensive patients.

The Hypertension in the Very Elderly Trial (HYVET)⁵⁴ was specifically designed to assess if lowering BP (with a diuretic \pm ACEI regime) reduced CV events in the 80 and over age group. After a relatively short follow-up period of 1.8 years, active treatment significantly lowered BP by 15/6 mm Hg and reduced the risk of fatal and nonfatal stroke by 30%, heart failure by 64%, and total mortality by 21%, and there were less side effects than in the placebo group. Given these important findings, patients aged 80 and over with newly diagnosed hypertension and who are generally fit with a reasonable life expectancy should be considered

for treatment whether they have evidence of target organ damage or not. Those who reach 80 years of age already on treatment this should be continued.

Type II diabetes

Hypertension is common in elderly type II diabetics. Nearly two thirds will have raised BP levels that require treatment. Elderly diabetics as much as their younger counterparts should be treated aggressively in terms of BP reduction. The UK Prospective Diabetes Study⁵⁵ showed that strict BP control reduces stroke by 44% (11% to 65%) and death related to diabetes by 32% (6% to 51%). A subgroup of elderly diabetics in the SHEP study³⁴ did similarly well, with a 5-year reduction of major CV events of 34% (6% to 54%) compared with placebo, and a reduction of nonfatal and fatal CHD events by 54% (12% to 76%). The HOT study³⁷ also included a group of diabetics and only this group showed a significantly better outcome in those in whom diastolic BP was reduced to less than 80 mm Hg compared with less than 90 mm Hg on treatment, with a 50% reduction in CV end points in the lowest BP group. Diabetics in the STOP-2 study showed no difference in outcome between those on conventional therapy (low-dose thiazide diuretic or β -blocker) and those on the newer agents (ACE inhibitors and CCBs). This again highlights how it is the degree of BP reduction and not the agent used that predicts CV risk, and diabetics require lower target BP levels as evidenced by the HOT study. Hence, in diabetics, BP levels for the introduction of therapy should be equal to 140/90 mm Hg (lower starting BP levels than for nondiabetics) with optimum control levels set at less than 140/80 mm Hg. No one group of antihypertensive agents appears more efficacious than another.

Cognitive function, dementia, and quality of life

Although increased blood pressure has been associated with impaired cognitive function, this does not mean that antihypertensive treatment will reduce this decline. Indeed, it has been suggested that antihypertensive treatment may actually hasten it. Reassuringly, the MRC study in the elderly found no difference in the changes in cognitive function between β -blocker- or diuretic-treated patients compared with the placebo over a 54-month follow-up.⁵⁶

Since hypertension is associated with both vascular dementia and Alzheimer's disease, it might be hoped that treatment could slow down or prevent cognitive decline. The Syst-Eur study,³⁵ encouragingly for a relatively short follow-up period of 2 years, found that active treatment reduced the incidence of dementia by 50% (though the numbers actually involved were very small) and improved the Mini Mental State score slightly, whereas in the placebo group scores deteriorated significantly. However, the SHEP study³⁴ failed to find a decrease in the incidence of dementia with active treatment. The cognitive arm of the HYVET study²⁴ did not find BP lowering in the very elderly reduced dementia but the follow-up period was probably too short to see any benefit. Combining all trials assessing the effects of BP lowering in elderly hypertensives on dementia found a 13% reduction with active treatment.²⁴

Although there are relatively limited numbers of studies assessing the long-term effects of antihypertensives on quality-of-life measures, most have shown a long-term

benefit. Quality of life should be an essential part of the overall patient assessment, but it does not necessarily require a lengthy or complex questionnaire. Simple clinical assessment of possible changes in physical function (e.g., mobility and balance, and ability for self-care), sexual function, energy levels and mood, cognitive function, life satisfaction, and social interaction is sufficient. Of particular importance are the effects of treatment on cognitive function, mood, and mobility. Thiazide diuretics appear to be the "cleanest" in terms of effects on quality-of-life factors, but there are at present too few data on the newer agents to assess whether some of the positive qualities of these agents (e.g., improved mood with ACEI use) are borne out in large clinical trials.

Stroke

Antihypertensive treatment helps to prevent primary stroke, but in the acute stroke and poststroke situation, the evidence for reducing an elevated BP is less clear. Acutely postictus, BP is frequently raised but the few antihypertensive intervention studies have been disappointing. β -blockers and calcium-channel blockers given orally or intravenously have been shown either to have no effect on prognosis or to be associated with an adverse outcome. The numbers of patients studied have been small and the study design often questionable, so there is a desperate need for a suitable trial to assess whether lowering of BP in the acute situation is of benefit. Until such evidence is available, in the majority of cases raised blood pressure is probably best left untreated, at least for the first 2 weeks.

Trials of BP reduction in the weeks and months following stroke have also been disappointing. There have been only two randomized intervention trials that have specifically recruited patients with raised BP levels following stroke, and only three others that have included both normotensive and hypertensive individuals. Overall these studies have shown that treatment does not reduce stroke recurrence or total

KEY POINTS

Hypertension

- Hypertension is the main treatable risk factor for cerebrovascular and coronary artery disease in elderly people, although significant numbers of elderly hypertensives remain inadequately treated.
- Those aged up to at least 90 years with sustained systolic BP ≥ 160 mm Hg and/or diastolic BP ≥ 100 mm Hg should be treated. Those with an SBP of 140–159 mm Hg and/or a DBP of 90–99 mm Hg, evidence of target organ damage (TOD), or a CVD risk of $\geq 20\%$ over 10 years (nearly all those aged 70 years plus), should also receive antihypertensive treatment.
- Hypertension should not be treated in isolation; other cardiovascular risk factors (e.g., cholesterol levels, smoking, and diabetes) should also be treated and aspirin added if the 10-year CV risk is $>20\%$.
- Lifestyle changes (e.g., salt restriction, increasing exercise) should be considered before, and in conjunction with, antihypertensive drug therapy.
- Thiazide diuretics remain the preferred first-line therapy, although dihydropyridine calcium-channel blockers may be useful alternative agents in those with isolated systolic hypertension. Target clinic BP levels on treatment should be $<140/85$ mm Hg in nondiabetics and $<140/80$ mm Hg in diabetics. The majority of patients will require two or more antihypertensive drugs to achieve these levels.

mortality, but it does reduce the number of nonfatal strokes by 19% (5% to 32%) and all major CV events by 18% (5% to 28%). The PROGRESS Trial taking patients with controlled BP levels several weeks to months after stroke has shown the benefits of the combination of perindopril and indapamide in reducing stroke recurrence by 43% and major vascular events by 40%.⁵⁷

SUMMARY

Hypertension is the biggest single treatable risk factor for stroke and cardiovascular disease in the elderly, but it is becoming increasingly appreciated that other elements that dictate cardiovascular risk in older people—such as diabetes and abnormal lipid profiles—also require active management. Nonpharmacologic methods of BP reduction should initially be tried in all patients. Thiazide diuretics are the first-choice antihypertensive in the vast majority of patients, there being no evidence to date that any of the newer antihypertensive agents are more efficacious. It is the level of BP reduction rather than any specific treatment that is important

in reducing event rates, and the majority of patients will need two or more antihypertensive agents to obtain adequate BP control. Effective treatment leads to a substantial reduction in cerebrovascular and coronary heart disease events within a short time of starting treatment, without producing adverse side effects or compromising quality of life. Statin therapy and prophylactic aspirin use (when BP levels are controlled) are warranted in patients at the appropriate level of cardiovascular risk.

Although we have come a long way in a short time in terms of evidence-based management of the older hypertensive patient, there is still no room for complacency. Too many elderly patients remain undiagnosed or inadequately treated, in terms of BP reduction and management of other cardiovascular risk factors, for the full benefits of treatment to be realized.

AORTIC STENOSIS

Etiology and prevalence

Valvular aortic stenosis (AS) in older persons is usually due to stiffening, scarring, and calcification of the aortic valve leaflets. The commissures are not fused as in rheumatic AS. Calcific deposits in the aortic valve are common in older persons and may lead to valvular AS.¹⁻⁷ Aortic cuspal calcium was present in 295 of 752 men (36%), mean age 80 years, and in 672 of 1663 women (40%), mean age 82 years.⁶ Of 2358 persons, mean age 81 years, 378 (16%) had valvular AS, 981 (42%) had valvular aortic sclerosis (thickening of or calcific deposits on the aortic valve cusps with a peak flow velocity across the aortic valve ≤ 1.5 m/sec), and 999 (42%) had no valvular AS or aortic sclerosis.⁷ Calcific deposits in the aortic valve were present in 22 of 40 necropsy patients (55%) aged 90 to 103 years.² Calcium of the aortic valve and mitral annulus may coexist.^{1-3,8,9}

In the Helsinki Aging Study, calcification of the aortic valve was diagnosed by Doppler echocardiography in 28% of 76 persons aged 55 to 71 years, in 48% of 197 persons aged 75 to 76 years, in 55% of 155 persons aged 80 to 81 years, and in 75% of 124 persons aged 85 to 86 years.⁵ Aortic valve calcification, aortic sclerosis, and mitral annular calcium (MAC) are degenerative processes,^{1,2,10-12} accounting for their high prevalence in an elderly population.

Otto et al¹¹ showed that the early lesion of degenerative AS is an active inflammatory process with some similarities to atherosclerosis, including lipid deposition, macrophage and T-cell infiltration, and basement membrane disruption. In a study of 571 persons, mean age 82 years, 292 persons (51%) had calcified or thickened aortic cusps or root.¹³ A serum total cholesterol ≥ 200 mg/dL, a history of hypertension, diabetes mellitus, and a serum high-density lipoprotein cholesterol less than 35 mg/dL were more prevalent in older persons with calcified or thickened aortic cusps or root than in older persons with normal aortic cusps and root.¹³

In the Helsinki Aging Study, age, hypertension, and a low body mass index were independent predictors of aortic valve calcification.¹⁴ In 5201 persons older than 65 years of age in the Cardiovascular Health Study, independent clinical factors associated with degenerative aortic valve disease included age, male gender, smoking, history of hypertension, height, and high lipoprotein(a) and low-density lipoprotein (LDL) cholesterol levels.¹² In 1275 older persons, mean age 81 years, AS was present in 52 of 202 persons (26%) with 40% to 100% extracranial carotid arterial disease (ECAD) and in 162 of 1073 persons (15%) with 0% to 39% ECAD.¹⁵ In 2987 persons, mean age 81 years, symptomatic peripheral arterial disease occurred in 193 of 462 persons (42%) with AS and in 639 of 2525 persons (25%) without AS.¹⁶

In 290 persons, mean age 79 years, with valvular AS who had follow-up Doppler echocardiograms, older persons with MAC had a greater reduction in aortic valve area/year than older persons without MAC.¹⁷ Significant independent risk factors for progression of valvular AS in 102 persons, mean age 76 years, who had follow-up Doppler echocardiograms

were cigarette smoking and hypercholesterolemia.¹⁸ Palta et al¹⁹ also showed that cigarette smoking and hypercholesterolemia accelerate the progression of AS. These and other data suggest that aortic valve calcium, MAC, and coronary atherosclerosis in older persons have similar predisposing factors.¹¹⁻²¹

A retrospective analysis of 180 elderly patients with mild AS who had follow-up Doppler echocardiograms at 2 or more years showed that significant independent predictors of the progression of AS were male gender, cigarette smoking, hypertension, diabetes mellitus, a serum low-density lipoprotein cholesterol equal to 125 mg/dL at follow-up, a serum high-density lipoprotein cholesterol less than 35 mg/dL at follow-up, and use of statins (inverse association).²² A retrospective analysis of 174 patients, mean age 68 years, with mild to moderate AS showed that statin therapy reduced the progression of AS.²³ In a retrospective study of 156 patients, mean age 77 years, with AS, at 3.7-year follow-up, statin therapy decreased the progression of AS by 54%.²⁴

In a prospective open-label study of 121 patients with an aortic valve area between 1.0 and 1.5 cm², 61 patients with a serum LDL cholesterol greater than 130 mg/dL were treated with rosuvastatin and 60 patients with a serum LDL cholesterol less than 130 mg/dL did not receive statins.²⁵ At 73-week follow-up, patients treated with rosuvastatin had significantly less progression of AS. These data differ from the results reported in 155 patients in the Scottish Aortic Stenosis and Lipid Lowering Trial, Impact on Regression Study, which included patients with extensive aortic valve calcification.²⁶ Two trials are in progress investigating the effect of statins on AS.

The frequency of AS increases with age. Valvular AS diagnosed by Doppler echocardiography was present in 141 of 924 men (15%), mean age 80 years, and in 322 of 1881 women (17%), mean age 81 years.²⁷ Severe valvular AS (peak gradient across aortic valve of ≥ 50 mm Hg or aortic valve area <0.75 cm²) was diagnosed in 62 of 2805 older persons (2%).²⁷ Moderate valvular AS (peak gradient across aortic valve of 26 to 49 mm Hg or aortic valve area of 0.75 to 1.49 cm²) was present in 149 of 2805 older persons (5%).²⁷ Mild valvular AS (peak gradient across aortic valve of 10 to 25 mm Hg or aortic valve area ≥ 1.50 cm²) occurred in 250 of 2805 older persons (9%).²⁷ In 501 unselected persons aged 75 to 86 years in the Helsinki Aging Study, critical AS was present in 3% and moderate-to-severe AS in 5% of the 501 older persons.⁵

Pathophysiology

In valvular AS, there is resistance to ejection of blood from the left ventricle (LV) into the aorta, with a pressure gradient across the aortic valve during systole and an increase in LV systolic pressure. The pressure overload on the LV leads to concentric LV hypertrophy, with an increase in LV wall thickness and mass, normalizing systolic wall stress, and maintenance of normal LV ejection fraction and cardiac output.^{28,29} A compensated hyperdynamic response is common

in older women.³⁰ Older persons with a comparable degree of AS have more impairment of LV diastolic function than do younger persons.³¹ Coronary vasodilator reserve is more severely impaired in the subendocardium in patients with LV hypertrophy caused by severe AS.³²

The compensatory concentric LV hypertrophy leads to abnormal LV compliance, LV diastolic dysfunction with decreased LV diastolic filling, and increased LV end-diastolic pressure, further increased by left atrial systole. Left atrial enlargement develops. Atrial systole plays an important role in diastolic filling of the LV in persons with AS.³³ Loss of effective atrial contraction may cause immediate clinical deterioration in persons with severe AS.

Sustained LV hypertrophy eventually leads to LV chamber dilatation with reduced LV ejection fraction and ultimately congestive heart failure (CHF). The stroke volume and cardiac output decrease, the mean left atrial and pulmonary capillary pressures increase, and pulmonary hypertension occurs. Older persons with both obstructive and nonobstructive coronary artery disease have an increased incidence of LV enlargement and LV systolic dysfunction.³⁴ In a percentage of older persons with AS, the LV ejection fraction will remain normal and LV diastolic dysfunction will be the main problem.

In 48 older persons with CHF associated with unoperated severe valvular AS, the LV ejection fraction was normal in 30 persons (63%).³⁵ The prognosis of persons with AS and LV diastolic dysfunction is usually better than that of persons with AS and LV systolic dysfunction, but is worse than that of persons without LV diastolic dysfunction.^{35,36}

Symptoms

Angina pectoris, syncope or near syncope, and CHF are the three classic manifestations of severe AS. Angina pectoris is the most common symptom associated with AS in older persons. Coexistent coronary artery disease (CAD) is frequently present in these persons. However, angina pectoris may occur in the absence of CAD as a result of an increase in myocardial oxygen demand with a decrease in myocardial oxygen supply at the subendocardial level. Myocardial ischemia in persons with severe AS and normal coronary arteries is due to inadequate LV hypertrophy with increased LV systolic and diastolic wall stresses causing reduced coronary flow reserve.³⁷

Syncope in persons with AS may be caused by decreased cerebral perfusion following exertion when arterial pressure falls because of systemic vasodilatation in the presence of a fixed cardiac output. LV failure with a reduction in cardiac output may also cause syncope. In addition, syncope at rest may be caused by a marked decrease in cardiac output secondary to transient ventricular fibrillation or transient atrial fibrillation or transient atrioventricular block related to extension of the valve calcification into the conduction system. Coexistent cerebrovascular disease with transient cerebral ischemia may contribute to syncope in older persons with AS.

Exertional dyspnea, paroxysmal nocturnal dyspnea, orthopnea, and pulmonary edema may be caused by pulmonary venous hypertension associated with AS. Coexistent CAD and hypertension may contribute to CHF in older persons with AS. Atrial fibrillation may also precipitate CHF in these persons.

CHF, syncope, or angina pectoris was present in 36 of 40 older persons (90%) with severe AS, in 66 of 96 older

persons (69%) with moderate valvular AS, and in 45 of 165 older persons (27%) with mild valvular AS.³⁸

Sudden death occurs mainly in symptomatic AS persons.^{35,38–41} It may also occur in 3% to 5% of asymptomatic persons with AS.^{39,42} Marked fatigue and peripheral cyanosis in persons with AS may be caused by a low cardiac output. Cerebral emboli causing stroke or transient cerebral ischemic attack, bacterial endocarditis, and gastrointestinal bleeding may also occur in older persons with AS.

Signs

A systolic ejection murmur heard in the second right intercostal space, down the left sternal border toward the apex, or at the apex is classified as an aortic systolic ejection murmur (ASEM).^{3,4,42,43} An ASEM is commonly heard in older persons^{1,3,42} occurring in 265 of 565 unselected older persons (47%).³ Of 220 older persons with an ASEM and technically adequate M-mode and two-dimensional echocardiograms of the aortic valve, 207 (94%) had aortic cuspal or root calcification or thickening.³ Of 75 older persons with an ASEM, valvular AS was diagnosed by continuous-wave Doppler echocardiography in 42 persons (56%).⁴³

Table 44-1 shows that an ASEM was heard in 100% of 19 older persons with severe AS, in 100% of 49 older persons with moderate AS, and in 95% of 74 older persons with mild AS.⁴ However, the ASEM may become softer or absent in persons with CHF associated with severe AS because of a low cardiac output. The intensity and maximal location of the ASEM and transmission of the ASEM to the right carotid artery do not differentiate among mild, moderate, and severe AS.^{3,4,43} The ASEM may be heard only at the apex in some older persons with AS. The apical systolic ejection murmur may also be louder and more musical than the basal systolic ejection murmur in some older persons with AS. The intensity of the ASEM in valvular AS increases with squatting and by inhalation of amyl nitrite and decreases during the Valsalva maneuver.

Prolonged duration of the ASEM and late peaking of the ASEM best differentiate severe AS from mild AS.^{3,4,43} However, the physical signs do not distinguish between severe and moderate AS (see Table 44-1).^{4,43}

Table 44-1. Correlation of Physical Signs of Aortic Stenosis With Severity of Aortic Stenosis in Older Persons

	SEVERITY OF AORTIC STENOSIS		
	Mild (n = 74) (%)	Moderate (n = 49) (%)	Severe (n = 19) (%)
Aortic systolic ejection murmur	95	100	100
Prolonged duration aortic systolic ejection murmur	3	63	84
Late-peaking aortic systolic ejection murmur	3	63	84
Prolonged carotid upstroke time	3	33	53
A ₂ absent	0	10	16
A ₂ reduced or absent	5	49	74

A₂, aortic component of second heart sound
Adapted from Aronow WS et al.⁴

A prolonged carotid upstroke time does not differentiate between severe and moderate AS in older persons.^{4,43} A prolonged carotid upstroke time was palpable in 3% of older persons with mild AS, in 33% of older persons with moderate AS, and in 53% of older persons with severe AS (see Table 44-1).⁴ Stiff noncompliant arteries may mask a prolonged carotid upstroke time in older persons with severe AS. The pulse pressure may also be normal or wide rather than narrow in older persons with severe AS because of loss of vascular elasticity. An aortic ejection click is rare in older persons with severe AS because of loss of vascular elasticity. An aortic ejection click is rare in older persons with AS because the valve cusps are immobile.^{4,43}

An absent or reduced A_2 occurs more frequently in older persons with severe or moderate AS than in persons with mild AS (see Table 44-1). However, an absent or decreased A_2 does not differentiate between severe and moderate AS.^{4,43} The presence of atrial fibrillation, reversed splitting of S_2 , or an audible fourth heart sound at the apex also does not differentiate between severe and moderate AS in older persons.⁴³ The presence of a third heart sound in older persons with AS usually indicates the presence of LV systolic dysfunction and elevated LV filling pressure.⁴⁴

Electrocardiography and chest roentgenography

Echocardiography is more sensitive than electrocardiography in diagnosing LV hypertrophy in an older person with AS.⁴ In 19 older persons with severe valvular AS, LV hypertrophy was diagnosed by electrocardiography in 58% of persons and by echocardiography in 100% of persons.⁴ In 49 older persons with moderate AS, LV hypertrophy was diagnosed by electrocardiography in 31% of persons and by echocardiography in 96% of persons. In 74 older persons with mild valvular AS, LV hypertrophy was diagnosed by electrocardiography in 11% of persons and by echocardiography in 74% of persons.⁴ Rounding of the LV border and apex may occur as a result of concentric LV hypertrophy. Poststenotic dilatation of the ascending aorta is commonly seen. Calcification of the aortic valve is best seen by echocardiography or fluoroscopy.

Involvement of the conduction system by calcific deposits may occur in older persons with AS. In a study of 51 older persons with AS who underwent aortic valve replacement, conduction defects occurred in 58% of 31 persons with MAC and in 25% of 20 persons without MAC.⁹ In another study of 77 older persons with AS, first-degree atrioventricular block occurred in 18% of persons, left bundle branch block in 10% of persons, intraventricular conduction defect in 6% of persons, right bundle branch block in 4% of persons, and left axis deviation in 17% of persons.⁴⁵

Complex ventricular arrhythmias may be detected by 24-hour ambulatory electrocardiograms in persons with AS. Older persons with complex ventricular arrhythmias associated with AS have a higher incidence of new coronary events than older persons with AS and no complex ventricular arrhythmias.⁴⁶

Echocardiography and Doppler echocardiography

M-mode and two-dimensional echocardiography and Doppler echocardiography are very useful in the diagnosis of AS. Of 83 persons with CHF or angina pectoris and a systolic

precordial murmur in whom severe AS was diagnosed by Doppler echocardiography, AS was not clinically diagnosed in 28 persons (34%).⁴⁷ Echocardiography can detect thickening, calcification, and reduced excursion of aortic valve leaflets.³ LV hypertrophy is best diagnosed by echocardiography.⁴ Chamber dimensions and measurements of LV end-systolic and end-diastolic volumes, LV ejection fraction, and assessment of global and regional LV wall motion give important information on LV systolic function.

Doppler echocardiography is used to measure peak and mean transvalvular gradients across the aortic valve and to identify associated valve lesions. Aortic valve area can be calculated by the continuity equation using pulsed Doppler echocardiography to measure LV outflow tract velocity, continuous-wave Doppler echocardiography to measure transvalvular flow velocity, and two-dimensional long-axis view to measure LV outflow tract area.^{48,49} Aortic valve area can be detected reliably by the continuity equation in older persons with AS.⁴⁹

Shah and Graham⁵⁰ reported that the agreement in quantitation of the severity of AS between Doppler echocardiography and cardiac catheterization was greater than 95%. Persons with a peak jet velocity greater than 4.5 m/sec had critical AS, and those with a peak jet velocity less than 3.0 m/sec had noncritical AS. Slater et al⁵¹ demonstrated a concordance between Doppler echocardiography and cardiac catheterization in the decision to operate or not to operate in 61 of 73 persons (84%) with valvular AS. In 75 persons, mean age 76 years, with valvular AS, the Bland-Altman plot showed that 4 of the 75 persons (5%) had disagreement between cardiac catheterization and Doppler echocardiography that was outside the 95% confidence limits.⁵²

Cardiac catheterization was performed in 105 persons in which Doppler echocardiography demonstrated an aortic valve area ≤ 0.75 cm² or a peak jet velocity ≥ 4.5 m/sec, consistent with critical AS.⁵³ Doppler echocardiography was 97% accurate in this subgroup. Cardiac catheterization was performed in this study in 133 persons with noncritical AS. Doppler echocardiography was 95% accurate in this subgroup. Although most older persons do not require cardiac catheterization before aortic valve surgery, they require selective coronary arteriography before aortic valve surgery. Persons in whom Doppler echocardiography shows a peak jet velocity between 3.6 and 4.4 m/sec and an aortic valve area greater than 0.8 cm² should undergo cardiac catheterization if they have cardiac symptoms attributable to AS.⁴⁹ Persons with a peak jet velocity between 3.0 and 3.5 m/sec and a LV ejection fraction less than 50% may have severe AS, requiring aortic valve replacement, and should undergo cardiac catheterization.⁵⁰ Persons with a peak jet velocity between 3.0 and 3.5 m/sec and a LV ejection fraction greater than 50% probably do not need aortic valve replacement but should undergo cardiac catheterization if they have symptoms of severe AS.⁵⁰

Natural history

Ross and Braunwald³⁹ demonstrated that the average survival rate was 3 years after the onset of angina pectoris in persons with severe AS. Ross and Braunwald³⁹ reported that the average survival rate after the onset of syncope in persons with severe AS was 3 years and showed that the average survival rate after the onset of CHF in persons with severe AS was 1.5 to 2 years.

Persons with symptomatic severe valvular AS have a poor prognosis.^{38–41,54} At the National Institutes of Health, 52% of persons with symptomatic severe valvular AS not operated on were dead at 5 years.^{40,41} At 10-year follow-up, 90% of these persons were dead.

At 4-year follow-up of patients aged 75 to 86 years in the Helsinki Aging Study, the incidence of cardiovascular mortality was 62% in persons with severe AS and 35% in persons with moderate AS.⁵⁵ At 4-year follow-up, the incidence of total mortality was 76% in persons with severe AS and 50% in persons with moderate AS.⁵⁵

In a prospective study, at 19-month follow-up (range 2 to 36 months), 90% of 30 persons with CHF associated with unoperated severe AS and a normal LV ejection fraction were dead.³⁵ At 13-month follow-up (range 2 to 24 months), 100% of 18 persons with CHF associated with unoperated severe AS and an abnormal LV ejection fraction were dead.³⁵

Table 44-2 shows the incidence of new coronary events in older persons with no, mild, moderate, and severe AS. Independent risk factors for new coronary events in this study were prior myocardial infarction, AS, male gender, and increasing age.³⁸ In this prospective study, at 20-month follow-up of 40 older persons with severe AS, CHF, syncope, or angina pectoris was present in 36 of 37 persons (97%) who developed new coronary events and in none of 3 persons (0%) without new coronary events.³⁸ At 32-month follow-up of 96 older persons with moderate valvular AS, CHF, syncope, or angina pectoris was present in 65 of 77 persons (84%) who developed new coronary events and in 1 of 19 persons (5%) without new coronary events.³⁸ At 52-month follow-up of 165 older persons with mild AS, CHF, syncope, or angina pectoris was present in 40 of 103 persons (39%) who developed new coronary events and in 5 of 62 persons (8%) without new coronary events.³⁸

In a prospective study of 981 persons, mean age 82 years, with aortic sclerosis and of 999 persons, mean age 80 years, without valvular aortic sclerosis, older persons with aortic sclerosis had at 46-month follow-up at 1.8 times higher chance of developing a new coronary event than those without valvular aortic sclerosis.⁷ Otto et al⁵⁶ also reported in 5621 men and women ≥ 65 years of age that AS and aortic sclerosis increased cardiovascular morbidity and mortality.

Kennedy et al⁵⁷ followed 66 persons with moderate AS diagnosed by cardiac catheterization (aortic valve area 0.7 to 1.2 cm²). In 38 persons with symptomatic moderate AS and 28 persons with minimally symptomatic moderate AS, the probabilities of avoiding death from AS were 0.86 for persons and 1.0 for persons with minimally symptomatic moderate AS at 1-year follow-up, 0.77 for persons with symptomatic AS and 1.0 for persons with minimally symptomatic AS at 2 years, 0.77 for persons with symptomatic AS and 0.96 for persons with minimally symptomatic AS at

3 years, and 0.70 for persons with symptomatic AS and 0.90 for persons with minimally symptomatic AS at 4 years.⁵⁷ During 35-month mean follow-up in this study, 21 persons underwent aortic valve replacement.

Hammermeister et al⁵⁸ followed 106 persons with unoperated AS in the Veterans Administration Cooperative Study on Valvular Heart Disease for 5 years. During follow-up, 60 of 106 persons (57%) died. Multivariate analysis demonstrated that measures of the severity of the AS, the presence of CAD, and the presence of CHF were the important predictors of survival in unoperated persons.

Studies have shown that patients with asymptomatic severe AS are at low risk for death and can be followed until symptoms develop.^{59–62} Turina et al⁵⁹ followed 17 persons with asymptomatic or mildly symptomatic AS. During the first 2 years, none died or had aortic valve surgery. At 5-year follow-up, 94% were alive and 75% were free of cardiac events. Kelly et al⁶⁰ followed 51 asymptomatic persons with severe AS. During 17-month follow-up, 21 (41%) of the persons became symptomatic. Only 2 of the 51 persons (4%) died of cardiac causes. In both persons, death was preceded by the development of angina pectoris or CHF. Pellikka et al⁶¹ showed that 113 of 143 persons (79%), mean age 72 years, with asymptomatic severe AS were not initially referred for aortic valve replacement or percutaneous aortic balloon valvuloplasty. During 20-month follow-up, 37 of 113 persons (33%) became symptomatic. The actuarial probability of remaining free of cardiac events associated with AS, including cardiac death and aortic valve surgery, was 95% at 6 months, 93% at 1 year, and 74% at 2 years. No asymptomatic person with severe AS developed sudden death while asymptomatic.

Rosenheck et al⁶² followed 126 persons with asymptomatic severe AS for 22 months. Eight persons died and 59 persons developed symptoms necessitating aortic valve replacement. Event-free survival was 67% at 1 year, 56% at 2 years, and 33% at 4 years. Five of the 6 deaths from cardiac disease were preceded by symptoms. Of the persons with moderately or severely calcified aortic valves whose aortic jet velocity increased by 0.3 m/sec or more within 1 year, 79% underwent aortic valve replacement or died within 2 years of the observed increase.

However, recent data have demonstrated that asymptomatic severe AS should be considered for aortic valve replacement (AVR).^{63,64} Of 338 patients with severe asymptomatic AS, mean age 71 years, 99 (29%) had AVR during a mean follow-up of 3.5 years.⁶³ Survival at 1, 2, and 5 years in the nonoperated patients was 67%, 56%, and 38%, respectively, compared with 94%, 93%, and 90%, respectively, in those who underwent AVR ($p < 0.0001$).⁶³ In this study, unoperated patients had a 48% significant reduction in mortality if they were treated with statins and a significant 48% reduction in mortality if they were treated with β -blockers.⁶³

Table 44-2. Incidence of New Coronary Events in Older Persons With No, Mild, Moderate, and Severe Aortic Stenosis (AS)

	No AS (n = 1496)	Mild AS (n = 165)	Moderate AS (n = 96)	Severe AS (n = 40)
Age (yr)	81	84	85	85
Follow-up (mo)	49	52	32	20
New coronary events (%)	41	62	80	93

Adapted from Aronow WS, et al.³⁸

Data were analyzed for 622 patients, mean age 72 years, with asymptomatic severe AS at the Mayo Clinic.⁶⁴ After the initial diagnosis, 166 patients (27%) developed chest pain, shortness of breath, or syncope and had AVR. Another 97 patients (16%) had AVR in the absence of symptoms. The operative mortality was 2% for the symptomatic patients and 1% for the asymptomatic patients. The survival of the 263 patients who had AVR was not significantly different from an age- and sex-matched population. The 10-year survival was 64% for symptomatic patients and 64% for asymptomatic patients who had AVR.⁶⁴ At 3 years after the diagnosis of severe AS, 52% of the 622 patients had had symptoms develop, undergone AVR, or died.⁶⁴ Absence of AVR was an independent risk factor for mortality with a hazard ratio of 3.53.

Medical management

Prophylactic antibiotics should not be used to prevent bacterial endocarditis in persons with AS regardless of severity, according to current American Heart Association (AHA) guidelines.⁶⁵ Persons with CHF, exertional syncope, or angina pectoris associated with moderate or severe AS should undergo AVR promptly. Valvular surgery is the only definitive therapy in these older persons.⁶⁶ Medical therapy does not relieve the mechanical obstruction to left ventricular outflow and does not relieve symptoms or progression of the disorder. Persons with asymptomatic AS should report the development of symptoms possibly related to AS immediately to the physician. If significant AS is present in asymptomatic older persons, clinical examination and an electrocardiogram and Doppler echocardiogram should be performed at 6-month intervals if AVR is not being considered. Nitrates should be used with caution in persons with angina pectoris and AS to prevent the occurrence of orthostatic hypotension and syncope. Diuretics should be used with caution in persons with CHF to prevent a decrease in cardiac output and hypotension. Vasodilators should be avoided. Digitalis should not be used in persons with CHF and a normal LV ejection fraction unless needed to control a rapid ventricular rate associated with atrial fibrillation.

Aortic valve replacement

Table 44-3 lists four class I indications and one class IIa indication for performing AVR in elderly patients with AS.⁶⁷ AVR is the procedure of choice for symptomatic elderly patients with severe AS. Other class I indications for AVR in elderly patients with severe AS include patients undergoing

Table 44-3. American College of Cardiology/American Heart Association Indications for Aortic Valve Replacement in Persons With Severe Aortic Stenosis (AS)

1. Patients with symptomatic severe AS (class I indication)
2. Patients with severe AS undergoing coronary artery bypass surgery (class I indication)
3. Patients with severe AS undergoing surgery on the aorta or other heart valves (class I indication)
4. Patients with severe AS and a left ventricular ejection fraction <50% (class I indication)
5. Patients with moderate AS undergoing coronary artery bypass surgery or surgery on the aorta or other heart valves (class IIa indication)

Adapted from Bonow RO, et al.⁶⁷

coronary artery bypass surgery (CABS), undergoing surgery on the aorta or other heart valves, and patients with a LV ejection fraction less than 50%.⁶⁷ Patients with moderate AS undergoing CABS or surgery on the aorta or other heart valves have a class IIa indication for AVR.⁶⁷

Although the American College of Cardiology (ACC)/AHA guidelines do not recommend AVR in patients with asymptomatic severe AS and normal LV ejection fraction, there are recent data suggesting otherwise.^{63,64} The data from these two recent studies favor AVR in patients with a diagnosis of asymptomatic severe AS when there is a low institutional perioperative mortality.

Echocardiography is recommended in asymptomatic patients with AS every 1 year for severe AS, every 1 to 2 years for moderate AS, and every 3 to 5 years for mild AS.⁶⁴ AVR is the procedure of choice for symptomatic older persons with severe AS. The bioprosthesis has less structural failure in older persons than in younger persons and may be preferable to the mechanical prosthetic valve for AS replacement in the elderly due to the anticoagulation issue.^{68,69} Persons with mechanical prostheses need anticoagulant therapy indefinitely. Patients with porcine bioprostheses may be treated with aspirin in a dose of 75 to 100 mg daily unless the patient has atrial fibrillation, abnormal LV ejection fraction, previous thromboembolism, or a hypercoagulable condition.^{67,70} Table 44-4 lists four class I indications and two class IIa indications for antithrombotic therapy in patients with AVR.⁶⁷

Arom et al⁷¹ performed aortic valve replacement in 273 persons aged 70 to 89 years (mean age 75 years), 162 with AVR alone, and 111 with AVR plus CABS. Operative mortality was 5%. Late mortality at 33-month follow-up was 18%. Actuarial analysis showed at 5-year follow-up that overall survival was 66% for persons with AVR alone, 76% for persons with AVR plus CABS, and 74% for a similar age group in the general population.

Culliford et al⁷⁰ performed AVR in 71 persons aged \geq 80 years, 35 with AVR alone, and 36 with AVR plus CABS. Hospital mortality was 6% in persons with AVR alone and 19% in persons with both AVR plus CABS. At 1-year

Table 44-4. Indications for Antithrombotic Therapy in Patients With Aortic Valve Replacement (AVR)

1. After AVR with bileaflet mechanical or Medtronic Hall prostheses, if no risk factors, administer warfarin to maintain INR between 2.0–3.0; if risk factors are present, the INR should be maintained between 2.5–3.5 (class I indication).
2. After AVR with Starr-Edwards valves or mechanical disc valves (other than Medtronic Hall prostheses), in patients with no risk factors, warfarin should be administered to maintain INR between 2.5–3.5 (class I indication).
3. After AVR with a bioprosthesis and no risk factors, administer aspirin in a dose of 75–100 mg daily (class I indication).
4. After AVR with a bioprosthesis and risk factors, administer warfarin to maintain an INR between 2.0–3.0 (class I indication).
5. During the first 3 months after AVR with a mechanical prosthesis, it is reasonable to give warfarin to maintain an INR between 2.5–3.5 (class II_a indication).
6. During the first 3 months after AVR with a bioprosthesis in patients with no risk factors, it is reasonable to give warfarin to maintain an INR between 2.0–3.0 (class IIa indication).

Risk factors include atrial fibrillation, prior thromboembolism, left ventricular systolic dysfunction, and hypercoagulable condition.

Modified from Bonow RO, et al.⁶⁷

follow-up, survival from late cardiac death was 100% for persons who had AVR alone and 96% for persons who had AVR plus CABS. At 3-year follow-up, survival from late cardiac death was 100% for persons who had AVR alone and 91% for persons who had AVR plus CABS. Freedom from all valve-related complications (thromboembolism, anticoagulant-related complications, endocarditis, and reoperation or prosthetic failure) was 93% at 1-year follow-up and 80% at 3-year follow-up. At follow-up, 65% of survivors were in New York Heart Association (NYHA) functional class I or II, 31% in NYHA functional class III, and 4% in NYHA functional class IV.

Levinson et al⁷² performed AVR in 71 octogenarians, mean age 82 years. The operative mortality was 9% in these older persons. At 28-month follow-up, 100% of the survivors were in NYHA functional class I or II. Actuarial 1-, 5-, and 10-year survival rates were 83%, 67%, and 49%, respectively. A United Kingdom heart valve registry showed in 1100 persons aged ≥ 80 years (56% women) who underwent AVR that the 30-day mortality was 6.6%.⁷³ The actuarial survival was 89% at 1 year, 79% at 3 years, 69% at 5 years, and 46% at 8 years.

AVR is associated with a reduction in LV mass and in improvement of LV diastolic filling.^{74,75} Hoffman and Burckhardt⁷⁶ performed a prospective study in 100 persons who had AVR. At 41-month follow-up, the yearly cardiac mortality rate was 8% in persons with electrocardiographic LV hypertrophy and repetitive ventricular premature complexes ≥ 2 couplets per 24 hours during 24-hour ambulatory monitoring and 0.6% in persons without either of these findings.

If LV systolic dysfunction in persons with severe AS is associated with critical narrowing of the aortic valve rather than myocardial fibrosis, it often improves after successful AVR.⁷⁷ In 154 persons, mean age 73 years, with AS and a LV ejection fraction $\leq 35\%$ who underwent AVR, the 30-day mortality was 9%. The 5-year survival was 69% in persons without significant CAD and 39% in persons with significant CAD. NYHA functional class III or IV was present in 58% of persons before surgery versus 7% of persons after surgery. Postoperative LV ejection fraction was measured in 76% of survivors at a mean of 14 months after surgery. Improvement in LV ejection fraction was found in 76% of persons.⁷⁷

Balloon aortic valvuloplasty

AVR is the procedure of choice for symptomatic older persons with severe AS. In a Mayo Clinic study, the actuarial survival of 50 older persons, mean age 77 years, with symptomatic severe AS in whom AVR was refused (45 persons) or deferred (5 persons) was 57% at 1 year, 37% at 2 years, and 25% at 3 years.⁷⁸ Because of the poor survival in this group of persons, balloon aortic valvuloplasty should be considered when operative intervention is refused or deferred.

Balloon aortic valvuloplasty is effective palliative therapy for some older persons with symptomatic AS, although restenosis with recurrence of symptoms is common.^{79–88} Rodriguez et al⁸⁵ found that in 42 older persons, mean age 78 years, undergoing aortic valvuloplasty that the 2-year survival was 36% in persons with LV ejection fractions less than 40% and 80% in persons with LV ejection fractions greater than 40%. The 2-year event-free survival (freedom from aortic valve surgery or severe CHF) was 0% in persons with LV ejection

fractions less than 40% and 34% in persons with LV ejection fractions greater than 40%.⁸⁵ Block and Palacios⁸⁰ showed recurrence of symptoms, death, or hemodynamic evidence of restenosis in 56% of 90 older persons, mean age 79 years, an average of 5.5 months after aortic valvuloplasty. Kuntz et al⁸⁶ found immediate clinical improvement after successful aortic valvuloplasty in the majority of 205 older persons, mean age 78 years, but restenosis in more than 50% of the persons within 1 to 2 years. On the basis of the available data, balloon aortic valvuloplasty should be considered for older persons with symptomatic severe AS who are not candidates for aortic valve surgery and possibly for persons with severe LV dysfunction as a bridge to subsequent valve surgery.^{86–88}

Percutaneous transcatheter implantation of aortic valve prostheses

Percutaneous heart valve implantation may be performed in nonsurgical patients with end-stage calcific AS.^{89,90} Ongoing trials will define the clinical role for this therapy.

Eighteen high-risk patients, mean age 76 years, with severe AS and moderate CAD amenable to percutaneous coronary intervention (PCI) had combined PCI followed by minimally invasive AVR.⁹¹ One of 18 patients (6%) died postoperatively with no late mortality after a mean follow-up of 19 months.⁹¹ This hybrid strategy may be a new therapeutic approach for elderly high-risk patients with combined CAD and severe AS.

AORTIC REGURGITATION

Etiology and prevalence

Acute aortic regurgitation (AR) in older persons may be due to infective endocarditis, rheumatic fever, aortic dissection, trauma following prosthetic valve surgery, or rupture of the sinus of Valsalva, and causes sudden severe LV failure. Chronic AR in older persons may be caused by valve leaflet disease (secondary to any cause of AS, infective endocarditis, rheumatic fever, congenital heart disease, rheumatoid arthritis, ankylosing spondylitis, following prosthetic valve surgery, or myxomatous degeneration of the valve), or by aortic root disease. Examples of aortic root disease causing chronic AR in older persons include association with systemic hypertension, syphilitic aortitis, cystic medial necrosis of the aorta, ankylosing spondylitis, rheumatoid arthritis, Reiter's disease, systemic lupus erythematosus, Ehler-Danlos syndrome, and pseudoxanthoma elasticum. Mild or moderate AR was also diagnosed by Doppler echocardiography in 9 of 29 persons (31%) with hypertrophic cardiomyopathy,⁹² Margonato et al⁹³ linked the increased prevalence of AR with age to aortic valve thickening.

The prevalence of AR increases with age.^{93–95} In a prospective study of 450 unselected persons, mean age 82 years, AR was diagnosed by pulsed Doppler echocardiography in 39 of 114 men (34%) and in 92 of 336 women (27%).⁹⁵ Severe or moderate AR was diagnosed in 74 of 450 older persons (16%). Mild AR was diagnosed in 57 of 450 older persons (13%). In a prospective study of 924 men, mean age 80 years, and 1881 women, mean age 82 years, valvular AR was diagnosed by pulsed Doppler recordings of the aortic valve in 282 of 924 men (31%) and in 542 of 1881 women (29%).²⁷

Pathophysiology

The primary determinants of AR volume are the regurgitant orifice area, the transvalvular pressure gradient, and the duration of diastole.⁹⁶ Chronic AR increases LV ventricular end-diastolic volume. The largest LV end-diastolic volumes are seen in persons with chronic severe AR. LV stroke volume increases to maintain the forward stroke volume. The increased preload causes an increase in LV diastolic stress and the addition of sarcomeres in series. This results in an increase in the ratio of the LV chamber size to wall thickness. This pattern of LV hypertrophy is called eccentric LV hypertrophy.

Primary myocardial abnormalities or ischemia due to coexistent CAD decrease the contractile state. LV diastolic compliance decreases, LV end-systolic volume increases, LV end-diastolic pressure rises, left atrial pressure increases, and pulmonary venous hypertension results. When the LV end-diastolic radius-to-wall thickness ratio rises, LV systolic wall stress increases abnormally because of the preload and afterload mismatch.^{29,97} Additional stress then decreases the LV ejection fraction response to exercise.⁹⁸ Eventually, the LV ejection fraction, forward stroke volume, and effective cardiac output are decreased at rest. We demonstrated that an abnormal resting LV ejection fraction occurred in 8 of 25 older persons (32%) with CHF associated with chronic severe AR.⁹⁹

In persons with acute severe AR, the LV cannot adapt to the increased volume overload. Forward stroke volume falls, LV end-diastolic pressure increases rapidly to high levels,¹⁰⁰ and pulmonary hypertension and pulmonary edema result. The rapid rise of the LV end-diastolic pressure to exceed the left atrial pressure in early diastole causes premature closure of the mitral valve.¹⁰¹ This prevents backward transmission of the elevated LV end-diastolic pressure to the pulmonary venous bed.

Symptoms

Persons with acute AR develop symptoms due to the sudden onset of CHF, with marked dyspnea and weakness. Persons with chronic AR may remain asymptomatic for many years. Mild dyspnea on exertion and palpitations, especially on lying down, may occur. Exertional dyspnea, orthopnea, paroxysmal nocturnal dyspnea, fatigue, and edema are common clinical symptoms when LV failure occurs. Syncope is rare. Angina pectoris occurs less often in persons with AR than in persons with AS and may be due to coexistent CAD. However, nocturnal angina pectoris, often accompanied by flushing, diaphoresis, and palpitations, may develop when the heart rate slows and the arterial diastolic pressure falls to very low levels. Most persons with severe AR who do not have surgery die within 2 years after CHD develops.¹⁰²

Signs

The AR murmur is typically a high-pitched blowing diastolic murmur that begins immediately after A₂. The diastolic murmur is best heard along the left sternal border in the third and fourth intercostal spaces when AR is due to valvular disease. The murmur is best heard along the right sternal border when AR is due to dilatation of the ascending aorta. The diastolic murmur is best heard with the diaphragm of the stethoscope with the person sitting up, leaning forward,

and holding the breath in deep expiration. The severity of AR correlates with the duration of the diastolic murmur, not with the intensity of the murmur.

Grayburn et al¹⁰³ heard an AR murmur in 73% of 82 persons with AR and in 8% of 24 persons without AR. Saal et al¹⁰⁴ heard an AR murmur in 80% of 35 persons with AR and in 10% of 10 persons without AR. Meyers et al¹⁰⁵ heard an AR murmur in 73% of 66 persons with AR and in 22% of 9 persons without AR. An AR murmur was heard in 95% of 74 older persons with severe or moderate AR diagnosed by pulsed Doppler echocardiography, in 61% of 57 older persons with mild AR, and in 3% of 319 older persons with no AR.⁹⁵

In persons with chronic severe AR, the LV apical impulse is diffuse, hyperdynamic, and displaced laterally and inferiorly. A rumbling diastolic murmur (Austin Flint) may be heard at the apex, with its intensity reduced by inhalation of amyl nitrite. A short basal systolic ejection murmur is heard. A palpable LV rapid filling wave and an audible S₃ at the apex are usually found. Physical findings due to a large LV stroke volume and a rapid diastolic runoff in persons with severe AR include a wide pulse pressure with an increased systolic arterial pressure and an abnormally low diastolic arterial pressure, an arterial pulse that abruptly rises and collapses, a bisferiens pulse, bobbing of the head with each heart beat, booming systolic and diastolic sounds heard over the femoral artery, capillary pulsations, and systolic and diastolic murmurs heard over the femoral artery when compressing it proximally and distally.

Electrocardiography and chest roentgenography

The electrocardiogram may initially be normal in persons with acute severe AR. Roberts and Day¹⁰⁶ demonstrated in 30 necropsy persons with chronic severe AR that the electrocardiogram did not accurately predict the severity of AR or cardiac weight. Using various electrocardiographic criteria, the prevalence of LV hypertrophy varied from 30% (RV₆>RV₅) to 90% (total 12-lead QRS voltage >175 mm). The P-R interval was prolonged in 28% of persons, and the QRS duration was ≥ 0.12 second in 20% of persons.¹⁰⁶

The chest x-ray in persons with acute severe AR may show a normal heart size and pulmonary edema. The chest x-ray in persons with chronic severe AR usually shows a dilated LV, with elongation of the apex inferiorly and posteriorly and a dilated aorta. Aneurysmal dilatation of the aorta suggests that aortic root disease is causing the AR. Linear calcifications in the wall of the ascending aorta are seen in syphilitic AR and in degenerative disease.

Echocardiography and Doppler echocardiography

M-mode and two-dimensional echocardiography and Doppler echocardiography are very useful in the diagnosis of AR. Two-dimensional echocardiography can provide information showing the cause of the AR and measurements of LV function. Eccentric LV hypertrophy is diagnosed by echocardiography if the LV mass index is increased with a relative wall thickness less than 0.45.¹⁰⁷⁻¹⁰⁹ Echocardiographic measurements reported to predict an unfavorable response to aortic valve replacement in persons with chronic AR include a LV

end-systolic dimension greater than 55 mm,¹¹⁰ a LV shortening fraction less than 25%,¹¹⁰ a LV diastolic radius-to-wall thickness ratio greater than 3.8,¹¹¹ a LV end-diastolic dimension index greater than 38 mm/m²,¹¹¹ and a LV ventricular end-systolic dimension index greater than 26 mm/m.¹¹¹

Grayburn et al¹⁰³ found that pulsed Doppler echocardiography correctly identified the presence of AR in 57 of 57 persons (100%) with $\geq 2+$ AR and in 22 of 25 persons (88%) with 1+ AR. Saal et al¹⁰⁴ showed that pulsed Doppler echocardiography identified the presence of AR in 34 of 35 persons (97%) with documented AR. Continuous-wave Doppler echocardiography has also been demonstrated to be very useful in diagnosing and quantitating AR.^{112,113} AR is best assessed by color flow Doppler imaging.¹¹⁴

Natural history

The natural history of chronic AR is significantly different than the natural history of acute AR. Persons with acute AR should have immediate aortic valve replacement because death may occur within hours to days. In one study of persons with hemodynamically significant chronic AR treated medically, 75% were alive at 5 years after diagnosis.^{54,115} Of persons with moderate-to-severe chronic AR, 50% were alive at 10 years after diagnosis.^{54,115} The 10-year survival rate for persons with mild-to-moderate chronic AR was 85% to 95%.^{54,116}

In another study of 14 persons with chronic severe AR who did not have surgery, 13 (93%) died within 2 years of developing CHF.¹⁰² The mean survival time after the onset of angina pectoris is 5 years.¹¹⁵

During 8-year follow-up of 104 asymptomatic persons with chronic severe AR and normal LV ejection fraction, 2 persons (2%) died suddenly, and 23 persons (22%) had aortic valve replacement.¹¹⁷ Of the 104 persons, 19 (18%) had aortic valve replacement because of cardiac symptoms and 4 persons (4%) had aortic valve replacement because of the development of LV systolic dysfunction in the absence of cardiac symptoms. Multivariate analysis showed that age, initial end-systolic dimension, and rate of change in end-systolic dimension and resting LV ejection fraction during serial studies predicted the outcome.

In a prospective study, at 24-month follow-up (range 7 to 55 months) of 17 persons, mean age 83 years, with CHF associated with unoperated severe chronic AR and a normal LV ejection fraction, 15 persons (88%) were dead.⁹⁹ At 15-month follow-up (range 8 to 21 months) of eight persons, mean age 85 years, with CHF associated with unoperated severe chronic AR and an abnormal LV ejection fraction, eight persons (100%) were dead.⁹⁹

Medical and surgical management

Asymptomatic persons with mild or moderate AR do not require therapy. Prophylactic antibiotics should not be used to prevent bacterial endocarditis in persons with AR, according to current AHA guidelines.⁶⁵ Echocardiographic evaluation of LV end-systolic dimension should be performed yearly if the measurement is less than 50 mm but every 3 to 6 months if the LV end-systolic dimension is 50 to 54 mm. Aortic valve replacement should also be considered when the LV ejection fraction approaches 50% before the decompensated state.¹¹¹

Persons with asymptomatic, chronic severe AR should be treated with hydralazine,¹¹⁸ nifedipine,¹¹⁹ or preferably angiotensin-converting enzyme therapy¹²⁰ to decrease the LV

volume overload. Infections should be treated promptly. Systemic hypertension increases the regurgitant flow and should be treated. Drugs that reduce LV function should not be used. Arrhythmias should be treated. Persons with AR due to syphilitic aortitis should receive a course of penicillin therapy. Prophylactic resection should be considered in persons with Marfan's syndrome when the aortic root diameter exceeds 55 mm.¹²¹

Bacterial endocarditis should be treated with intravenous antibiotics. Indications for AVR in persons with AR due to bacterial endocarditis are CHF, uncontrolled infection, myocardial or valvular ring abscess, prosthetic valve dysfunction or dehiscence, and multiple embolic episodes.¹²²⁻¹²⁴

CHF should be treated with sodium restriction, diuretics, digoxin if the LV ejection fraction is abnormal, vasodilator therapy, and aortic valve replacement. Angina pectoris should be treated with nitrates.

Persons with acute severe AR should undergo AVR immediately. Persons with chronic severe AR should have aortic valve repair if they develop symptoms of CHF, angina pectoris, or syncope.^{67,117} AVR should also be performed in asymptomatic persons with chronic severe AR if they develop LV systolic dysfunction.^{67,117} ACC/AHA indications for performing AVR in elderly patients with severe chronic AR are listed in Table 44-5.

Older persons undergoing aortic valve replacement for severe AR have an excellent postoperative survival if the preoperative LV ejection fraction is normal.¹¹²⁻¹¹⁴ If LV systolic dysfunction was present for less than 1 year, persons also did well postoperatively. However, if the person with severe AR has an abnormal LV ejection fraction and impaired exercise tolerance and/or the presence of LV systolic dysfunction for longer than 1 year, the postoperative survival is poor.¹²⁵⁻¹²⁷ After AVR, women exhibit an excess late mortality, suggesting that surgical correction of severe chronic AR should be considered at an earlier stage in women.¹²⁸

The operative mortality for AVR in older persons with severe AR is similar to that in older persons with AVR for valvular AS. The mortality rate is slightly increased in persons with infective endocarditis and in those persons needing replacement of the ascending aorta plus AVR. The bioprosthesis is preferable to the mechanical prosthetic valve for AVR in older persons as in older persons with valvular AS.^{68,69} Persons with porcine bioprostheses may be treated with antiplatelet therapy alone unless they have atrial fibrillation, abnormal LV ejection fraction, previous thromboembolism, or a hypercoagulable state.⁶⁷

Table 44-5. American College of Cardiology/American Heart Association Indications for Aortic Valve Replacement in Persons With Chronic Severe Aortic Regurgitation (AR)

1. Symptomatic patients with severe AR and normal or abnormal left ventricular (LV) ejection fraction (class I indication)
2. Asymptomatic patients with severe AR and LV ejection fraction $\leq 50\%$ at rest (class I indication)
3. Patients with severe AR undergoing coronary artery bypass surgery or surgery on the aorta or other heart valves (class I indication)
4. Asymptomatic patients with severe AR with LV ejection fraction $>50\%$ but a LV end-diastolic dimension >75 mm or a LV end-systolic dimension >55 mm (class IIa indication)

Adapted from Bonow RO, et al.⁶⁷

Of 450 patients with severe AR, 273 (61%) had a LV ejection fraction equal to 50%, 134 (30%) had a LV ejection fraction of 35% to 50%, and 43 patients (10%) had a LV ejection fraction less than 35%.¹²⁹ The operative mortality was 3.7% for patients with a normal LV ejection fraction, 6.7% for patients with a LV ejection fraction of 35% to 50%, and 14% for patients with a LV ejection fraction less than 35%.¹²⁹ At 10-year follow-up, survival rates were 70% for patients with a normal LV ejection fraction, 56% for patients with a LV ejection fraction of 35% to 50%, and 41% for patients with a LV ejection fraction less than 35%.

In a prospective study, AVR in 38 persons with severe AR normalized LV chamber size and mass in two thirds of persons undergoing surgery.¹³⁰ At 9-month follow-up after AVR, 58% of persons had a normal LV end-diastolic dimension and 50% of persons had a normal LV mass. During further follow-up (18 to 56 months postoperatively) 66% of persons had a normal LV end-diastolic dimension and 68% of persons had a normal LV mass. The LV end-diastolic dimension normalized in 86% of persons with a preoperative LV end-systolic dimension ≤ 55 mm. A preoperative LV end-systolic dimension greater than 55 mm was present in 81% of persons with postoperative persistent LV dilatation.

MITRAL ANNULAR CALCIUM

MAC is a chronic degenerative process that is common in older persons, especially women. The amount of calcium may vary from a few spicules to a large mass behind the posterior cusp, often extending to form a ridge or ring encircling the mitral leaflets, occasionally lifting the leaflets toward the left atrium. Sphincter function loss of the mitral annulus and mechanical stretching of the mitral leaflets can cause improper coaptation of the leaflets during systole, resulting in mitral regurgitation (MR).⁸

Although the calcific mass may immobilize the mitral valve, actual calcification of the leaflets is rare. In persons with severe MAC, the calcification may extend inward to involve the underside of the leaflets. Mitral stenosis (MS) may result from severe calcific deposits within the mitral annulus protruding into the orifice.^{131,132} Calcific deposits may extend from the mitral annulus into the membranous portions of the ventricular septum, involving the conduction system and causing rhythm and conduction disturbances.^{9,133,134} Although the annular calcium is covered with a layer of endothelium, ulceration of this lining can expose the underlying calcific deposits, which may serve as a nidus for platelet-fibrin aggregation and subsequent thromboembolic (TE) episodes.^{135–137} In persons with endocarditis associated with MAC, the avascular nature of the mitral annulus predisposes to periannular and myocardial abscesses.^{138–141}

Prevalence

MAC is a degenerative process that increases with age and occurs more frequently in women than in men.* MAC was present in 298 of 924 men (36%), mean age 80 years, and in 985 of 1881 women (52%), mean age 81 years.²⁷

Predisposing factors

Because calcific deposits in the mitral annulus, in the aortic valve cusps, and in the epicardial coronary arteries are commonly associated in older persons and have similar predisposing factors, Roberts²⁰ suggested that MAC and aortic cuspal calcium are a form of atherosclerosis. MAC and aortic cuspal calcium may coexist.* The prevalence of CAD is higher in men and women with aortic valve calcium⁶ and with MAC^{6,150–152} than in men and women without aortic valve calcium and MAC.

Breakdown of lipid deposits on the ventricular surface of the posterior mitral leaflet at or below the mitral annulus and on the aortic surfaces of the aortic valve cusps is probably responsible for the calcification.⁸ Increased LV systolic pressure due to AS increases stress on the mitral apparatus and may accelerate development of MAC.^{2,3,8,135,149} Tricuspid annular calcium and MAC may also coexist and have similar predisposing factors.¹⁵³

Systemic hypertension increases with age and predisposes to MAC.† Persons with diabetes mellitus also have a higher prevalence of MAC than nondiabetic persons.^{2,8,21,148} MAC occurs in the teens in persons with serum total cholesterol levels greater than 500 mg/dL.¹⁵⁵ Waller and Roberts² suggested that hypercholesterolemia predisposes to MAC. The prevalence of hypercholesterolemia with a serum total cholesterol ≥ 200 mg/dL was higher in older persons with MAC than in older persons without MAC.²¹

Roberts and Waller¹⁵⁶ found that chronic hypercalcemia predisposes to MAC. Older persons with chronic renal insufficiency have a higher prevalence of MAC and aortic valve calcium than older persons with normal renal function.^{157,158} Persons undergoing dialysis for chronic renal insufficiency have an increased prevalence of MAC.^{156–164} MAC has also been found to be a marker of LV dilatation and reduced LV systolic function in persons with end-stage renal disease on peritoneal dialysis.¹⁶⁴ Cardiac calcium in persons with chronic renal failure has been attributed to secondary hyperparathyroidism.^{161,164} Nair et al¹⁴⁸ found a similar mean serum calcium, a higher mean serum phosphorus, and a higher mean product of serum calcium and phosphorus in persons younger than 60 years with MAC than in a control group. However, Aronow et al²¹ demonstrated no significant difference in mean serum calcium, serum phosphorus, or product of serum calcium and phosphorus between elderly persons with and without MAC.

By accelerating LV systolic pressure, hypertrophic cardiomyopathy predisposes to MAC.⁸ Kronzon and Glassman¹⁶⁵ diagnosed MAC in 12 of 18 persons (67%) older than 55 years with hypertrophic cardiomyopathy and in 4 of 28 persons (14%) younger than 55 years with hypertrophic cardiomyopathy. Nair et al¹⁶⁶ observed MAC in 12 of 42 persons (27%) with hypertrophic cardiomyopathy. Their persons with both MAC and hypertrophic cardiomyopathy were older than their persons with hypertrophic cardiomyopathy and no MAC. Motamed and Roberts¹⁶⁷ demonstrated MAC in 30 of 100 autopsy persons (30%) with hypertrophic cardiomyopathy older than 40 years and in none of 100 autopsy persons (0%) younger than 40 years with hypertrophic cardiomyopathy. Aronow and Kronzon¹⁶⁸ diagnosed MAC in

*References 2, 3, 10, 20, 27, 121, 135, 142–147.

*References 2, 8, 20, 21, 135, 144, 148, 149.

†References 2, 8, 21, 135, 144, 154.

13 of 17 older persons (76%) with hypertrophic cardiomyopathy and in 176 of 362 older persons (49%) without hypertrophic cardiomyopathy.

Diagnosis

Calcific deposits in the mitral annulus are J, C, U, or O shaped and are seen in the posterior third of the heart shadow.^{135,143,159,169–175} MAC may be diagnosed by chest x-ray films or by fluoroscopy.¹⁷⁵ However, the procedures of choice for diagnosing MAC are M-mode and two-dimensional echocardiography.

Posterior MAC is diagnosed by M-mode echocardiography when a band of dense echoes is recorded anterior to the LV posterior wall and moving parallel with it.¹⁷⁶ These echoes end at the atrioventricular junction and merge with the LV posterior wall on echocardiographic sweep from the aortic root to the LV apex. Anterior MAC is diagnosed by M-mode echocardiography when a continuous band of dense echoes is observed at the level of the anterior mitral leaflet in both systole and diastole.¹⁷⁶ These echoes are contiguous with the posterior wall of the aortic root. Calcification may extend from the mitral annulus throughout the base of the heart and into the mitral and aortic valves.

Using multiple echocardiographic views, MAC may be classified as mild, moderate, or severe.^{151,177} The echo densities in mild MAC involve less than one third of the annular circumference (<3 mm in width) and are usually restricted to the angle between the posterior leaflet of the mitral valve and the LV posterior wall. The echo densities in moderate MAC involve less than two thirds of the annular circumference (3 to 5 mm in width). The echo densities in severe MAC involve more than two thirds of the annular circumference (>5 mm in width), usually extending beneath the entire posterior mitral leaflet with or without making a complete circle.

MAC was diagnosed in the original chest x-ray report in three of eight persons (38%) with MAC diagnosed at autopsy.¹⁴³ Schott et al¹⁵⁹ diagnosed MAC by chest x-ray films in 2 of 41 persons (5%) with MAC diagnosed by echocardiography. Dashkoff et al¹⁷⁸ detected MAC by chest x-ray films in five of eight persons (63%) with MAC diagnosed by echocardiography.

In a blinded prospective study, MAC was diagnosed by M-mode and two-dimensional echocardiography in 55% of 604 older persons.¹⁷⁵ The diagnosis of MAC by chest x-ray films using a lateral chest x-ray in addition to the posterior-anterior or anterior-posterior chest x-ray had a sensitivity of 12%, a specificity of 99%, a positive predictive value of 95%, and a negative predictive value of 47%. Persons with radiographic MAC were more likely than persons without radiographic MAC to have a more severe form of the disease, with significant MR, functional MS, or conduction defects. However, persons with echocardiographically severe MAC and significant MR, functional MS, or conduction defects may have no evidence of MAC on chest x-ray films.

Chamber size

Persons with MAC have a higher prevalence of left atrial enlargement* and LV enlargement^{143,144,148,177,179} than persons without MAC. In a prospective study of 976 older

Table 44-6. Prevalence of Apical Systolic Murmurs of Mitral Regurgitation (MR) and of Mitral Stenosis (MS) in Persons With Mitral Annular Calcium

PREVALENCE OF MR MURMUR		PREVALENCE OF MS MURMUR

17/104	16,176	7/104	7,176
129/293	44,146	28/293	10,146
43/100	43,182	6/100	6,182

persons (526 with MAC and 450 without MAC), left atrial enlargement was 2.4 times more prevalent in persons with MAC than in the group without MAC.¹⁸⁰

Atrial fibrillation

Persons with MAC also have a higher prevalence of atrial fibrillation than persons without MAC.* The prevalence of atrial fibrillation was increased 12 times,¹⁴⁴ 5 times,¹⁷⁷ and 2.8 times¹⁸¹ more in persons with MAC than in persons without MAC.

Conduction defects

Because of the close proximity of the mitral annulus to the atrioventricular node and the bundle of His, persons with MAC have a higher prevalence of conduction defects, such as sinoatrial disease, atrioventricular block, bundle branch block, left anterior fascicular block, and intraventricular conduction defect, than persons without MAC.^{9,133–135,149,177} The calcific deposits may also extend into the membranous portions of the interventricular septum involving the conduction system, or may even extend to the left atrium, interrupting interatrial and intra-atrial conduction. In addition, MAC may be associated with a sclerodegenerative process in the conduction system. Nair et al¹⁷⁷ showed in their study that persons with MAC had a higher incidence of permanent pacemaker implantation because of both atrioventricular block and sinoatrial disease than persons without MAC.

Mitral regurgitation

MAC is thought to generate systolic murmurs by the sphincter action loss of the annulus and the mechanical stretching of the mitral leaflets causing MR and from vibration of the calcified ring or vortex formation around the annulus. Table 44-6 shows that the prevalence of apical systolic murmurs of MR in persons with MAC ranged from 12% to 100% in different studies.[†] Table 44-7 states the prevalence of MR diagnosed by Doppler echocardiography in persons with MAC.^{179,182,183} The prevalence of mitral regurgitation associated with MAC ranged from 54% to 97% in the Doppler echocardiographic studies.^{179,182,183}

The greater the severity of MAC, the greater the severity of MR associated with MAC. Moderate to severe MR was diagnosed by Doppler echocardiography in 33% of 51 persons

*References 135, 143–145, 147, 177, 180, 181.

†References 135, 143–145, 147, 177, 180, 181.

Table 44-7. Prevalence of Mitral Regurgitation (MR) and of Mitral Stenosis (MS) Diagnosed by Doppler Echocardiography in Persons With Mitral Annular Calcium

PREVALENCE OF MR		PREVALENCE OF MS	
No.	%	No.	%
28/51	55,183	4/51	8,183
54/100	54,182	6/100	6,182
28/29	97,179	83/1028	8,181

with MAC by Labovitz et al¹⁸³ and in 22% of 1028 older persons with MAC by Aronow et al.¹⁸¹ Kaul et al¹⁷⁹ diagnosed severe MR in 7% of their 29 persons with MAC. Kaul et al¹⁷⁹ also concluded from their study that MR in persons with MAC is caused by a decreased sphincteric action of the mitral annulus, with MAC preventing the posterior annulus from contracting and assuming a flatter shape during systole.

Mitral stenosis

An apical diastolic murmur may be heard in persons with MAC as a result of turbulent flow across the calcified and narrowed annulus (annular stenosis). Table 44-6 shows that the prevalence of apical diastolic murmurs of MS in persons with MAC ranged from 0% to 25% in different studies.* Table 44-7 indicates that MS associated with MAC was diagnosed by Doppler echocardiography in 8% of 51 persons by Labovitz et al,¹⁸³ in 6% of 100 persons by Aronow and Kronzon,¹⁸² and in 8% of 1028 persons by Aronow et al.¹⁸¹

The decrease of mitral valve orifice in persons with MAC is due to the annular calcium and to decreased mitral excursion and mobility secondary to calcium at the base of the leaflets.¹⁸² The commissures are fused in rheumatic MS but are not fused in MS associated with MAC. The mitral leaflet margins in MAC may be thin and mobile, and the posterior mitral leaflet may move normally during diastole. However, Doppler echocardiographic recordings show increased transvalvular flow velocity and prolonged pressure halftime and, therefore, smaller mitral valve orifice in persons with MS, regardless of the cause.

Bacterial endocarditis

Bacterial endocarditis, with a high incidence of *Staphylococcus aureus* endocarditis, may complicate MAC.^{135,138–141,147} Persons with MAC associated with chronic renal failure are especially at increased risk for developing bacterial endocarditis.¹⁵⁶ The calcific mass erodes the endothelium under the mitral valve, which is exposed to transient bacteremia. The avascular nature of the mitral annulus interferes with antibiotics reaching a nidus of bacteria, predisposing to periannular and myocardial abscesses and, consequently, to a poor prognosis.^{138–141} Therefore Burnside and DeSanctis¹³⁸ recommended prophylactic antibiotics to prevent bacterial endocarditis in persons with MAC.

Nair et al¹⁷⁷ observed at 4.4-year follow-up no significant difference in incidence of bacterial endocarditis in

Table 44-8. Incidence of New Cardiac Events in Persons With and Without Mitral Annular Calcium (MAC)

	CARDIAC EVENTS		
	MAC (%)	No MAC (%)	Relative Risk
<i>Nair et al</i> ¹⁷⁷ (99 with MAC, 101 without MAC)			
Total cardiac death	31	2	15.5

All persons (526 with MAC, 450 without MAC)	42	28	1.5

*Myocardial infarction, primary ventricular fibrillation, or sudden cardiac death.

99 persons younger than 61 years with MAC compared with a control group of 101 persons. However, Aronow et al¹⁴⁷ demonstrated at 39-month follow-up a 3% incidence of bacterial endocarditis in 526 older persons with MAC and a 1% incidence of bacterial endocarditis in 450 elderly persons without MAC. On the basis of these data, we recommend using prophylactic antibiotics to prevent bacterial endocarditis in persons with MAC.

Cardiac events

In a prospective study of 107 persons (8 lost to follow-up) younger than 61 years of age with MAC and 107 (6 lost to follow-up) age- and sex-matched control subjects, Nair et al¹⁷⁷ observed at 4.4-year follow-up that persons with MAC had a higher incidence of new cardiac events than control subjects (Table 44-8). In a prospective study of 526 older persons with MAC and 450 older persons without MAC, Aronow et al¹⁴⁷ found at 39-month follow-up that the incidence of new cardiac events (myocardial infarction, primary ventricular fibrillation, or sudden cardiac death) was also higher in older persons with MAC than in older persons without MAC.

Mitral valve replacement

Nair et al¹⁸⁴ reported that mitral valve replacement can be accomplished in persons with MAC with morbidity and mortality similar to those in persons without MAC. Following mitral valve replacement, subsequent morbidity and mortality during 4.4-year follow-up were also similar in persons with and without MAC.

Cerebrovascular events

Although the increased prevalence of atrial fibrillation, MS, MR, left atrial enlargement, and CHF predisposes persons with MAC to TE stroke, some investigators consider MAC a marker of other vascular disease causing stroke rather than

*References 131, 132, 143, 144, 146, 171, 176, 182.

the primary embolic source.¹⁸⁵ However, the prevalence of prior stroke was higher in 280 African-American, Hispanic, and white men with MAC (40%) than in 484 African-American, Hispanic, and white men without MAC (27%) and in 876 African-American, Hispanic, and white women with MAC (36%) than in 799 African-American, Hispanic, and white women without MAC (22%).¹⁸⁶ In addition, six prospective studies have demonstrated an increased incidence of new cerebrovascular events in persons with MAC than in persons without MAC.^{151,177,181,187–189}

Nair et al¹⁷⁷ showed at 4.4-year follow-up in 107 persons (8 lost to follow-up) younger than 61 years with MAC and 107 (6 lost to follow-up) age- and sex-matched control subjects that persons with MAC had a five times higher incidence of new TE cerebrovascular events than persons without MAC. The Framingham Heart Study observed at 8 years follow-up in 160 persons with MAC and 999 persons without MAC that the incidence of stroke was increased 2.7 times more in persons with MAC than in persons without MAC.¹⁸⁷ At 39-month follow-up of 526 older persons with MAC and 450 older persons without MAC, Aronow et al¹⁴⁷ observed a 1.5 times higher incidence of new TE stroke in persons with MAC than in persons without MAC if atrial fibrillation was present, a 1.6 times higher incidence of new TE stroke in persons with MAC than in persons without MAC if sinus rhythm was present, and a 1.7 times higher incidence of new TE stroke in all persons with MAC than in all persons without MAC. The Boston Area Anticoagulation Trial for Atrial Fibrillation study demonstrated at 2.2 years follow-up in 129 persons with atrial fibrillation and MAC, and 291 persons with atrial fibrillation without MAC, a four times higher incidence of ischemic stroke in persons with MAC than in persons without MAC.¹⁸⁸ At 45-month follow-up, Aronow et al¹⁸⁹ showed that the incidence of TE stroke was 1.5 times higher in 101 persons with 40% to 100% ECAD and MAC than in 49 persons with 40% to 100% ECAD and no MAC, and 2.2 times higher in 365 persons with MAC and 0% to 39% ECAD than in 413 persons with no MAC and 0% to 39% ECAD.

Table 44-9 shows the incidence of new TE stroke at 44-month follow-up in 310 older persons with chronic atrial fibrillation and in 1838 older persons with sinus rhythm, mean age 81 years.¹⁸¹ MS and the severity of MR were

Table 44-9. Incidence of New Thromboembolic (TE) Stroke at 44 Months

	TE Stroke (%)
Atrial fibrillation, no MAC (n = 85)	35
Atrial fibrillation with MS due to MAC (n = 42)	74
Atrial fibrillation with MAC and 2–4+ MR (n = 90)	59
Atrial fibrillation with MAC and 0–1+ MR (n = 93)	48
Sinus rhythm, no MAC (n = 1035)	9
Sinus rhythm with MS due to MAC (n = 41)	32

Sinus rhythm with MAC and 0–1+ MR (n = 625)	24

MAC, mitral annular calcium; MS, mitral stenosis; MR, mitral regurgitation. Adapted from Aronow WS et al.¹⁸¹

diagnosed by Doppler echocardiography in this study. In older persons with chronic atrial fibrillation, MAC increased the incidence of new TE 2.1 times if MS was associated with MAC, 1.7 times if 2 to 4+ MR was associated with MAC, and 1.4 times if 0 to 1+ MR was present.¹⁸¹ In older persons with sinus rhythm, MAC increased the incidence of new TE stroke 3.6 times if MS was associated with MAC, 3.1 times if 2 to 4+ MR was associated with MAC, and 2.7 times if 0 to 1 MR was present.¹⁸¹

There was a higher prevalence of MAC in older persons with 40% to 100% ECAD (67% of 150 persons) than in older persons with 0% to 39% ECAD (47% of 778 persons).¹⁸⁹ The increased prevalence of significant ECAD contributes to a higher incidence of TE stroke in older persons with MAC. Thrombi of the mitral annulus also contribute to TE stroke in older persons with MAC.^{190–192} In addition, MAC is associated with complex intra-aortic debris, which could contribute to TE stroke.¹⁹³

Since persons with MAC and atrial fibrillation or sinus rhythm have a higher incidence of TE stroke than persons without MAC, antithrombotic therapy should be considered in persons with MAC and no contraindications to antithrombotic therapy. In the Boston Area Anticoagulation Trial for Atrial Fibrillation study, warfarin significantly reduced the incidence of TE stroke in persons with MAC by about 90%.^{194,195}

Until data from prospective, randomized studies evaluating the efficacy and risk of antithrombotic therapy in persons with MAC are available, we recommend treating persons with MAC associated with either atrial fibrillation, MS, or moderate to severe MR with warfarin treatment if they have no contraindications to anticoagulant therapy. The INR should be maintained between 2.0 and 3.0. The efficacy of antiplatelet treatment in persons with MAC is unknown.

MITRAL STENOSIS

Prevalence and etiology

MS due to rheumatic heart disease was diagnosed by Doppler echocardiography in 3 of 924 men (0.3%), mean age 80 years, and in 34 of 1881 women (2%), mean age 81 years.²⁷ The most common cause of MS in older persons is MAC. The differentiation of MS due to rheumatic heart disease from MS caused by MAC by echocardiography has been discussed in the section on MAC. In a study of 1699 persons, mean age 81 years, the prevalence of rheumatic MS was 6% in persons with atrial fibrillation versus 0.4% in persons with sinus rhythm.¹⁸¹

Pathophysiology

MS leads to an increase in left atrial pressure, pulmonary capillary pressure, and right ventricular and pulmonary artery systolic pressure, causing pulmonary hypertension. Atrial fibrillation predisposes persons with MS to develop stroke, peripheral arterial embolism, and CHF.

Symptoms and signs

If MS is moderate or severe (especially if atrial fibrillation is present), exertional dyspnea, orthopnea, paroxysmal nocturnal dyspnea, and pulmonary edema may develop. Pulmonary hypertension leads to right-sided CHF. Hemoptysis may result from ruptured bronchial veins.

The loud first heart sound and opening snap heard in persons with MS may become softer or disappear if valvular calcification is present. An apical low frequency diastolic murmur heard as a rumble with presystolic accentuation is heard at the point of maximum apical impulse. The low frequency diastolic murmur begins after the opening snap, is prolonged with increasing severity of the MS, and increases in intensity after inhalation of amyl nitrite. The closer the opening snap is heard to A₂, the more severe the MS. If atrial fibrillation develops, the presystolic accentuation usually disappears.

Diagnostic tests

The electrocardiogram and chest x-ray will often show left atrial enlargement in persons with MS. Electrocardiographic right ventricular hypertrophy (RVH) is usually present with severe MS. Documentation of MS and of the severity is made by Doppler echocardiography. Echocardiography will also rule out left atrial myxoma, which can mimic mitral stenosis.

Management of mitral stenosis

A rapid ventricular rate associated with atrial fibrillation is controlled by digoxin and/or β -blockers, verapamil, or diltiazem. Diuretics should be used to control congestive symptoms. Unloading therapy with vasodilators is not beneficial and may cause a significant reduction in cardiac output. Long-term anticoagulation with oral warfarin is indicated in persons with MS and atrial fibrillation (especially) or sinus rhythm to prevent systemic embolization. The INR should be maintained between 2.0 and 3.0. Prophylactic antibiotics should not be used to prevent bacterial endocarditis in persons with MS, according to recent AHA guidelines.⁶⁵

Interventional therapy is indicated for symptomatic persons with severe MS. A mitral valve area of 1.0 cm² or less is considered severe MS. Mitral valve replacement is usually performed because the calcified mitral valve is usually not amenable to open mitral commissurotomy. For the few older persons who have an uncalcified mitral valve or mild calcific deposits, flexible mitral valve leaflets, and no or mild MR, percutaneous balloon valvuloplasty is the procedure of choice.¹⁹⁶

ACUTE MITRAL REGURGITATION

Acute severe MR in older persons may be caused by ruptured chordae tendineae or development of a flail mitral valve secondary to acute myocardial infarction, infective endocarditis, papillary muscle rupture, or mucoid degeneration of the mitral valve cusps. Acute severe MR usually results in severe CHF with pulmonary edema and right-sided CHF.

Signs

The MR murmur associated with acute severe MR is characteristically a harsh systolic murmur (with an associated palpable thrill) heard at the apex, which begins with the first heart sound but ends early when the noncompliant left atrium can no longer accept the large regurgitant volume. The first heart sound is soft, and the pulmonic component of the second heart sound is increased. A left ventricular third heart sound gallop and an atrial fourth heart sound gallop are heard at the apex.

Diagnosis and management

Doppler echocardiography confirms the diagnosis of severe MR. Transesophageal echocardiography provides a highly accurate anatomic assessment of the cause of the acute MR and assists in determining whether the mitral valve can be repaired or must be replaced.¹⁹⁷ CHF needs to be managed medically. Infective endocarditis should be treated with appropriate antibiotics. Mitral valve surgery should be performed urgently.

CHRONIC MITRAL REGURGITATION

Prevalence and etiology

Chronic MR was present in 298 of 924 men (32%), mean age 80 years, and in 630 of 1881 women (33%), mean age 81 years.²⁷ MR 2 to 4+ was present in 10% of 2148 persons, mean age 81 years.¹⁶⁴ The commonest cause of MR in older persons is MAC.¹⁴⁶ Other causes of chronic MR in older persons include papillary muscle dysfunction after myocardial infarction, rheumatic heart disease, myxomatous degeneration of the mitral valve leaflets and chordae tendineae with mitral valve prolapse (MVP), ruptured chordae tendineae, and following endocarditis. MR may also result from alteration in the geometry of the mitral annulus occurring with dilatation of the LV and CHF.

Pathophysiology

The regurgitant volume gradually increases in chronic MR, increasing the left atrial volume during systole and the LV volume during diastole. Eccentric LV hypertrophy occurs. Atrial fibrillation develops, and the LV cannot maintain an effective forward stroke volume because of depressed LV contractility. Left-sided CHF develops, resulting in increased pulmonary artery and right ventricular systolic pressure, and eventually right-sided CHF. Decreased LV systolic and diastolic function in persons with chronic MR contribute to the clinical manifestations of CHF.¹⁹⁸ Unrecognized MR may contribute to acute pulmonary edema in persons with normal or abnormal LV systolic function.¹⁹⁹

Symptoms and signs

Older persons with chronic MR may be asymptomatic or have a reduction in exercise tolerance with easy fatigability. Dyspnea on exertion will develop with significant MR and progress to orthopnea, paroxysmal nocturnal dyspnea, and dyspnea at rest caused by left-sided CHF. Right-sided CHF will cause ankle swelling, anorexia, and right upper abdominal tenderness from hepatic congestion. Symptoms may also result from the development of atrial fibrillation. Atypical chest pain, palpitations, or syncope due to arrhythmias may be associated with MVP. In some persons, acute pulmonary edema may be the initial manifestation of severe MR from MVP.²⁰⁰

The heart murmur associated with chronic MR is heard as an apical holosystolic, late systolic, or early systolic murmur beginning with the first heart sound but ending in midsystole. The holosystolic murmur may radiate to the left axilla, to the back, and over the entire precordium. A nonejection systolic click may precede the mid-to-late systolic apical murmur associated with MVP. With severe MR, the first heart sound becomes decreased, and a LV third heart sound is heard at the apex.

Diagnosis

Doppler echocardiography can quantitate the severity of MR and assess LV size and function. Doppler echocardiography and especially transesophageal echocardiography can also determine the cause of the MR. Vegetations are seen with infective endocarditis. MVP and thickening of the mitral valve leaflets suggest myxomatous degeneration. MAC can be diagnosed. Thickened retracted leaflets and chordal fusion suggest rheumatic heart disease as the cause of MR. A flail mitral valve and ruptured chordae tendineae can be diagnosed. The sensitivity of transesophageal echocardiography in diagnosing specific causes of MR was 82% for vegetations, 99% for MVP, 100% for a flail mitral valve, and 84% for ruptured chordae tendineae.¹⁹⁷ In persons with severe chronic MR, the electrocardiogram may show atrial fibrillation or left atrial enlargement, LV hypertrophy in about 50% of persons, and RVH in approximately 15% of persons.

Management

Older persons with chronic MR should have Doppler echocardiograms every 6 to 12 months. There are no long-term studies supporting the use of vasodilator therapy in asymptomatic persons with chronic MR. Angiotensin-converting enzyme inhibitors should be used in treating persons with symptomatic chronic MR.²⁰¹ Persons with atrial fibrillation should be treated with long-term oral warfarin therapy to maintain the INR between 2.0 and 3.0. CHF should be treated with standard medical therapy. Prophylactic antibiotics should not be used to prevent bacterial endocarditis in persons with MR, according to current AHA guidelines.⁶⁵

Timing of surgery

Of 478 persons with nonischemic chronic severe MR undergoing surgery, the cause of MR was MVP in 79%, rheumatic in 8%, endocarditis in 8%, and miscellaneous in 4%.²⁰² Surgical repair of the mitral valve was performed in 68% of persons and mitral valve replacement in 32% of persons. CABS was performed in 27% of persons in association with mitral valve surgery.²⁰²

The operative mortality was 0% for persons younger than 75 years of age. In persons 75 years of age and older, the operative mortality was 3.6% in persons with NYHA class I or II symptoms and 12.7% in persons with severe symptoms.²⁰² In persons with a LV ejection fraction \geq 60%, the 10-year survival was 79% in persons with class I or II symptoms versus 49% in persons with class III or IV symptoms.²⁰² In persons with a LV ejection fraction less than 60%, the 10-year survival was 75% in persons with class I or II symptoms versus 41% in persons with class III or IV symptoms.²⁰²

Table 44-10 lists the ACC/AHA class indications for performing mitral valve surgery in persons with nonischemic severe MR.⁶⁷ Older persons with chronic nonischemic MR who have NYHA class I symptoms and normal LV function should be followed at 3- to 6-month intervals.⁶⁷ If LV dysfunction, atrial fibrillation, or pulmonary hypertension develops, the person should be considered for cardiac catheterization and possible mitral valve surgery, especially if it is thought that the mitral valve can be repaired.⁶⁷

The prognosis for the person with ischemic MR is worse than that for MR from other causes. CABS may improve LV

Table 44-10. Indications for Mitral Valve Surgery in Persons With Nonischemic Severe Mitral Regurgitation

1. Acute symptomatic MR (class I indication)
2. Persons with NYHA class II, III, or IV symptoms in the absence of severe LV dysfunction defined as a LV ejection fraction $<$ 30% and/or LV end-systolic dimension $>$ 55 mm (class I indication)
3. Asymptomatic persons with mild to moderate LV dysfunction defined as a LV ejection fraction of 30% to 60% and/or a LV end-systolic dimension of 40 to 55 mm (class I indication)
4. Mitral valve repair is recommended over mitral valve replacement in the majority of patients with severe chronic MR who require surgery (class I indication)
5. Mitral valve repair is reasonable for asymptomatic patients if the likelihood of successful repair without residual MR is $>$ 90% (class IIa indication)
6. Mitral valve surgery is reasonable for asymptomatic patients, normal LV function, and new onset of atrial fibrillation (class IIa indication)
7. Mitral valve surgery is reasonable for asymptomatic patients, normal LV function, and a pulmonary artery pressure $>$ 50 mm Hg at rest or $>$ 60 mm Hg with exercise (class IIa indication)
8. Mitral valve surgery is reasonable in patients with a primary abnormality of the mitral apparatus, NYHA class III or IV symptoms, and severe LV dysfunction in whom mitral valve repair is highly likely (class IIa indication)

MR, mitral regurgitation; NYHA, New York Heart Association; LV, left ventricular. Adapted from Bonow RO et al.⁶⁷

function and decrease ischemic MR.⁶⁷ The best operation for ischemic MR is controversial.⁶⁷

TRICUSPID REGURGITATION

In older persons, tricuspid regurgitation (TR) is usually caused by dilatation of the right ventricle and tricuspid annulus associated with right-sided heart failure resulting from left-sided heart failure or pulmonary hypertension associated with pulmonary vascular disease. The murmur of TR is usually high-pitched and holosystolic heard in the third or fourth intercostal space at the left sternal border and occasionally in the subxiphoid area, and increases with inspiration in 50% of persons. When TR is mild, the systolic murmur may be a short ejection murmur or absent. P₂ is increased with pulmonary hypertension. If TR is severe, a prominent large V wave is seen in the jugular venous pulse. Systolic pulsation of an enlarged tender liver is commonly present. Ascites and peripheral edema are frequent. Diagnosis of TR is confirmed by Doppler echocardiography. Medical treatment of CHF is indicated. Surgery is rarely necessary

TRICUSPID STENOSIS

Tricuspid stenosis (TS) in older persons is rare and due to multivalvular rheumatic heart disease or the carcinoid syndrome. Symptoms of right-sided heart failure occur. A low-frequency diastolic rumble is heard in the third or fourth intercostal space at the left sternal border, which increases with intensity with inspiration. A prominent A wave with poor or absent Y descent is seen in the jugular venous pulse. The electrocardiogram shows tall right atrial P waves and no RVH. The chest x-ray shows a dilated right atrium without an enlarged pulmonary artery segment. Diagnosis of TS is confirmed by Doppler echocardiography.

Medical therapy is indicated for mild TS. Balloon valvotomy is recommended for persons with TS with signs of right-sided heart failure or with a marked reduction in exercise tolerance due to an inability to increase cardiac output. If the tricuspid valve is calcified (rarely), tricuspid valve replacement is indicated. A porcine bioprosthetic heart valve is recommended in the tricuspid position.

PULMONIC REGURGITATION

In older persons, pulmonic regurgitation (PR) is almost always due to pulmonary hypertension resulting from left-sided heart failure or pulmonary vascular disease. A high-pitched,

blowing decrescendo murmur beginning immediately after P_2 is heard in the second and third intercostal space to the left of the sternum. Diagnosis of PR is confirmed by Doppler echocardiography. Management of PR is directed at treating the underlying disorder and trying to reduce pulmonary artery pressure.

VENTRICULAR ARRHYTHMIAS

The presence of three or more consecutive ventricular premature complexes (VPCs) on an electrocardiogram (ECG) is diagnosed as ventricular tachycardia (VT).^{1,2} VT is considered sustained if it lasts (30 seconds and nonsustained if it lasts <30 seconds).² Complex ventricular arrhythmias (VA) include VT or paired, multiform, or frequent VPCs. I consider frequent VPCs an average of 30/hr on a 24-hour ambulatory ECG or 6/min on a 1-minute rhythm strip of an ECG.^{2,3} Simple VA include infrequent VPCs and no complex forms.

The prevalence of nonsustained VT diagnosed by 24-hour ambulatory ECGs in older persons without cardiovascular disease was 4%,^{1,4,5} 2%,⁶ and 4% in 729 elderly women and 13% in 643 elderly men in the Cardiovascular Health Study.⁷ The prevalence of nonsustained VT detected by 24-hour ambulatory ECGs was 9% in elderly persons with hypertension, valvular heart disease, or cardiomyopathies and 16% in elderly persons with coronary artery disease (CAD).⁵

The prevalence of complex VA in elderly persons without cardiovascular disease detected by 24-hour ambulatory ECGs was 50%,¹ 31%,⁴ 30%,⁵ 20%,⁶ 16% in women, and 28% in men,⁷ and 33%.³ The prevalence of complex VA detected by 24-hour ambulatory ECGs was 55% in elderly persons with hypertension, valvular heart disease, or cardiomyopathies,⁵ 68% in elderly persons with CAD,⁵ and 55% in 843 elderly persons with heart disease.³ Complex VA were present on a 1-minute strip of an ECG in 2% of 104 elderly persons without cardiovascular disease and 4% of 843 elderly persons with cardiovascular disease.³ In elderly persons with cardiovascular disease, there is a higher prevalence of VT and of complex VA in persons who have an abnormal left ventricular (LV) ejection fraction,⁸ echocardiographic LV hypertrophy,⁹ or silent myocardial ischemia.¹⁰

Prognosis of ventricular arrhythmias

NO HEART DISEASE

Nonsustained VT or complex VA diagnosed by 24-hour ambulatory ECGs,^{5,11,12} or by 12-lead ECGs with 1-minute rhythm strips³ in elderly persons with no clinical evidence of heart disease were not associated with an increased incidence of new coronary events. Exercise-induced nonsustained VT¹³ or complex VA,¹⁴ in elderly persons with no clinical evidence of heart disease also were not associated with an increased incidence of new coronary events. Therefore asymptomatic nonsustained VA or complex VA in elderly persons without heart disease should not be treated with antiarrhythmic drugs.

HEART DISEASE

In elderly persons with heart disease, nonsustained VT^{5,10,12} or complex VA^{3,5,10,12} increased the incidence of new coronary events. At 2-year follow-up of 391 elderly persons with heart disease, the incidence of new coronary events was increased 6.8 times in elderly persons with VT plus an abnormal LV ejection fraction and 7.6 times in elderly persons with complex VA plus an abnormal LV ejection fraction.⁵

At 27-month follow-up of 468 elderly persons with heart disease, the incidence of primary ventricular fibrillation or sudden cardiac death was increased 7.1 times in elderly persons with VT plus echocardiographic LV hypertrophy and 7.3 times in persons with complex VA plus echocardiographic LV hypertrophy.¹² At 37-month follow-up of 404 elderly persons with heart disease, the incidence of new coronary events was increased 2.5 times in elderly persons with VT plus silent ischemia and 4.0 times in elderly persons with complex VA plus silent ischemia.¹⁰

General therapy

Underlying causes of complex VA should be treated when possible. Treatment of congestive heart failure (CHF), LV dysfunction, digitalis toxicity, hypokalemia, hypomagnesemia, myocardial ischemia by antiischemic drugs such as β -blockers or by coronary revascularization, hypertension, LV hypertrophy, hypoxia, and other conditions may abolish or reduce complex VA. The person should not smoke or drink alcohol and should avoid drugs that may cause or increase complex VA.

All elderly persons with CAD should be treated with aspirin,^{15–17} with β -blockers,^{16–22} with angiotensin-converting enzyme (ACE) inhibitors,^{16,17,23–28} and with statins^{16,17,29–34} unless there are contraindications to these drugs.

Age-related physiologic changes may affect absorption, distribution, metabolism, and excretion of cardiovascular drugs.³⁵ Numerous physiologic changes occur with aging that affect pharmacodynamics, resulting in changes in end-organ responsiveness to cardiovascular drugs.³⁵ Drug interactions between antiarrhythmic drugs and other cardiovascular drugs are common, especially in elderly persons.³⁵ Important drug-disease interactions also occur in elderly persons.³⁵ Class I antiarrhythmic drugs are more proarrhythmic than class III antiarrhythmic drugs. Except for β -blockers, all antiarrhythmic drugs can cause torsades des pointes VT (polymorphous appearance associated with a prolonged QT interval).

Class I antiarrhythmic drugs

Class I antiarrhythmic drugs are sodium channel blockers. Class Ia antiarrhythmic drugs have intermediate channel kinetics and prolong repolarization. These drugs include disopyramide, procainamide, and quinidine. Class Ib antiarrhythmic drugs have rapid channel kinetics and shorten repolarization slightly. These drugs include lidocaine, mexiletine, phenytoin, and tocainide. Class Ic antiarrhythmic drugs have slow channel kinetics and have little effect on repolarization. These drugs include encainide, flecainide, lorcaïnide, moricizine, and propafenone. None of the class I antiarrhythmic drugs have been demonstrated in controlled, clinical trials to decrease sudden cardiac death, total cardiac death, or total mortality.

Table 45-1 shows the effect of class I antiarrhythmic drugs on mortality in persons with heart disease and complex VA.^{36–42} A meta-analysis of six double-blind studies of persons with chronic atrial fibrillation (AF) who underwent direct-current cardioversion to sinus rhythm showed that the mortality at

Table 45-1. Effect of Class I Antiarrhythmic Drugs on Mortality in Persons With Heart Disease and Complex Ventricular Arrhythmias

Study	Results
International Mexiletine and Placebo Antiarrhythmic Coronary Trial ³⁶	At 1-year follow-up, mortality was 7.6% for mexiletine and 4.8% for the placebo
Cardiac Arrhythmia Suppression Trial I ^{37,38}	At 10-month follow-up, mortality for arrhythmia or cardiac arrest was 4.5% for encainide or flecainide versus 1.2% for the placebo; mortality was 7.7% for encainide or flecainide versus 3.0% for the placebo; adverse events including death were more frequent in elderly persons taking encainide or flecainide
Cardiac Arrhythmia Suppression Trial II ^{38,39}	At 18-month follow-up, mortality for arrhythmia or cardiac arrest was 8.4% for moricizine versus 7.3% for the placebo; 2-year survival rate was 81.7% for moricizine versus 85.6% for the placebo; adverse events including death were more frequent in elderly persons taking moricizine
Aronow et al ⁴⁰	At 2-year follow-up, mortality was 65% for quinidine or procainamide versus 63% for no antiarrhythmic drug; quinidine or procainamide did not reduce sudden death, total cardiac death, or total mortality in elderly persons with ischemic or nonischemic heart disease, abnormal or normal LV ejection fraction, and presence or absence of VT
Moosvi et al ⁴¹	2-year sudden death survival was 69% for quinidine, 69% for procainamide, and 89% for no antiarrhythmic drug; 2-year total survival was 61% for quinidine, 57% for procainamide, and 71% for no antiarrhythmic drug
Hallstrom et al ⁴²	At 108-month follow-up, the adjusted relative risk of death or recurrent cardiac arrest on quinidine or procainamide versus no antiarrhythmic drug was 1.17

LV, left ventricular; VT, ventricular tachycardia.

Table 45-2. Effect of β -blockers on Mortality in Persons With Heart Disease and Complex Ventricular Arrhythmias

Study	Results
Hallstrom et al ⁴²	At 108-month follow-up, the adjusted relative risk of death or recurrent cardiac arrest for β -blockers versus no antiarrhythmic drug was 0.62
Beta Blocker Heart Attack Trial ⁴⁶⁻⁴⁸	At 25-month follow-up, propranolol reduced sudden cardiac death by 28% in persons with complex VA and by 16% in persons without VA; propranolol decreased total mortality by 34% in persons aged 60–69 years
Norwegian Propranolol Study ⁴⁹	High-risk survivors of acute MI treated with propranolol for 1 year had a 52% decrease in sudden cardiac death
Aronow et al ⁵⁰	At 29-month follow-up, compared with no antiarrhythmic drug, propranolol caused a 47% reduction in sudden cardiac death, a 37% decrease in total cardiac death, and a 20% borderline significant decrease in total death
Cardiac Arrhythmia Suppression Trial ⁵¹	Persons on β -blockers had a reduction in all-cause mortality of 43% at 30 days, of 46% at 1 year, and of 33% at 2 years and a decrease in arrhythmic death or cardiac arrest of 66% at 30 days, of 53% at 1 year, and of 36% at 2 years; β -blockers were an independent factor for reduced arrhythmic death or cardiac arrest by 40% and for decreased all-cause mortality by 33%

VA, ventricular arrhythmias; MI, myocardial infarction.

1 year was higher in persons treated with quinidine (2.9%) than in persons treated with a placebo (0.8%).⁴³

Of 1330 patients in the Stroke Prevention in Atrial Fibrillation Study, 127 were treated with quinidine, 57 with procainamide, 34 with flecainide, 20 with encainide, and 7 with amiodarone.⁴⁴ The adjusted relative risk of cardiac mortality was increased 1.8 times and the adjusted relative risk of arrhythmic death was increased 2.1 times in persons receiving antiarrhythmic drugs versus no antiarrhythmic drugs.⁴⁴ In persons with a history of CHF, the adjusted relative risk of cardiac death was increased 3.3 times and the adjusted relative risk of arrhythmic death was increased 5.8 times in persons taking antiarrhythmic drugs versus no antiarrhythmic drugs.⁴⁴

An analysis was made of 59 randomized, controlled clinical trials including 23,229 patients that investigated the use of class I antiarrhythmic drugs after myocardial infarction (MI).⁴⁵ The class I antiarrhythmic drugs investigated included aprindine, disopyramide, encainide, flecainide, imipramine, lidocaine, mexiletine, moricizine, phenytoin, procainamide, quinidine, and tocainide. Mortality was increased in persons receiving class I antiarrhythmic drugs versus persons receiving no antiarrhythmic drugs (odds ratio = 1.14).⁴⁵ None of the 59 studies showed that the use of a class I antiarrhythmic drug decreased mortality in persons after MI.⁴⁵

On the basis of the available data, none of the class I antiarrhythmic drugs should be used to treat VT or complex VA in elderly or younger persons with heart disease.

Calcium channel blockers

Calcium channel blockers are not useful in the therapy of complex VA. Although verapamil can terminate a left septal VT, hemodynamic collapse can occur if intravenous verapamil is given to persons with the more common forms of VT. An analysis was made of randomized, controlled clinical trials including 20,342 patients that investigated the use of calcium channel blockers after MI.⁴⁵ Mortality was insignificantly increased in persons receiving calcium channel blockers than in persons receiving no antiarrhythmic drugs (odds ratio = 1.04).⁴⁵

On the basis of the available data, none of the calcium channel blockers should be used to treat VT or complex VA in elderly or younger persons with heart disease.

β -blockers

An analysis of 55 randomized, controlled clinical trials including 53,268 persons that investigated the use of β -blockers after MI showed that mortality was decreased in persons receiving β -blockers versus a placebo (odds ratio = 0.81).⁴⁵ β -blockers caused a greater decrease in mortality in older persons than in younger persons.^{18-21,46} Table 45-2 indicates the effect of β -blockers on mortality in persons with heart disease and complex VA.^{42,46-51}

The decrease in mortality by β -blockers in elderly persons with heart disease and complex VA is due more to an antiischemic effect than to an antiarrhythmic effect.⁵²

β -blockers also abolish the circadian distribution of sudden cardiac death or fatal MI,⁵³ markedly decrease the circadian variation of complex VA,⁵⁴ and abolish the circadian variation of myocardial ischemia.⁵⁵

On the basis of the available data, β -blockers should be used to treat older and younger persons with heart disease and complex VA if there are no contraindications to the use of β -blockers.

Angiotensin-converting enzyme inhibitors

ACE inhibitors have been demonstrated to reduce sudden cardiac death in some studies of persons with CHF.^{24,56} ACE inhibitors should be used to reduce total mortality in older and younger persons with CHF,^{24,26,56,57} an anterior MI,²⁵ and a LV ejection fraction (40% after MI).^{23,26,58} ACE inhibitors should be administered to treat elderly and younger persons with CHF with abnormal LV ejection fraction^{24,26,56,57} or with normal LV ejection fraction.^{59,60}

On the basis of the available data, ACE inhibitors should be used to treat older and younger persons with VT or complex VA associated with CHF, an anterior MI, or a LV ejection fraction (40% after MI) if there are no contraindications to the use of ACE inhibitors. β -blockers should be administered in addition to ACE inhibitors in treating these persons.⁵⁸

Class III antiarrhythmic drugs

Class III antiarrhythmic drugs are potassium channel blockers, which prolong repolarization manifested by an increase in QT interval on the ECG. These drugs are effective in suppressing complex VA, including nonsustained VT by increasing the refractory period. However, antiarrhythmic aggravation can occur, especially torsades des pointes.

Table 45-3 shows the effect of class III antiarrhythmic drugs on mortality in persons with heart disease.^{61–66} None of the class III antiarrhythmic drugs has been found in a double-blind, randomized, placebo-controlled clinical trial

Table 45-3. Effect of Class III Antiarrhythmic Drugs on Mortality in Persons With Heart Disease

Study	Results
Julien et al ⁶¹	At 1-year follow-up, mortality was not different in persons after MI on d,l-sotalol versus a placebo
Waldo et al ⁶²	At 148-day follow-up, mortality in persons after MI was increased by d-sotalol (5.0%) versus a placebo (3.1%)
Singh et al ⁶³	At 2-year follow-up of persons with CHF and complex VA, survival was not different for amiodarone versus a placebo
Canadian Amiodarone MI Arrhythmia Trial ⁶⁴	At 1.8-year follow-up of persons after MI with complex VA, mortality was not different for amiodarone versus a placebo
European MI Amiodarone Trial ⁶⁵	At 21-month follow-up of persons after MI, mortality was not different for amiodarone (13.9%) versus a placebo (13.7%)
Sudden Cardiac Death in Heart Failure Trial ⁶⁶	At 45.5-month follow-up, compared with a placebo, amiodarone caused an insignificant (6%) increase in mortality, and implantable cardioverter-defibrillator therapy significantly reduced mortality by 23%

MI, myocardial infarction; CHF, congestive heart failure; VA, ventricular arrhythmias.

to decrease mortality in persons with heart disease and complex VA.

In 481 persons with VT, d,l-sotalol caused torsades des pointes (12 persons) or an increase in VT episodes (11 persons) in 23 persons (5%).⁶⁷ On the basis of the available data, β -blockers are preferred to the use of d,l-sotalol in treating elderly and younger persons with heart disease and VT or complex VA.

Amiodarone is very effective in suppressing VT and complex VA associated with heart disease.^{63,64,66,68} However, the incidence of adverse effects from amiodarone approaches 90% after 5 years of therapy.⁶⁹ In the Cardiac Arrest in Seattle: Conventional Versus Amiodarone Drug Evaluation study, the incidence of pulmonary toxicity was 10% at 2 years in persons receiving 158 mg of amiodarone daily.⁶⁸ Amiodarone can also cause hyperthyroidism, hypothyroidism, and cardiac, dermatologic, gastrointestinal, hepatic, neurologic, and ophthalmologic adverse effects.

Because amiodarone has not been demonstrated to reduce mortality in elderly or younger persons with VT or complex VA associated with prior MI or CHF and has a very high incidence of toxicity, β -blockers are preferred to the use of amiodarone in treating these persons. There are some data suggesting that persons receiving amiodarone plus β -blockers had a better survival time than persons receiving amiodarone.⁷⁰

Invasive intervention

If persons have life-threatening VT or ventricular fibrillation resistant to antiarrhythmic drugs, invasive intervention should be conducted. Persons with critical CAD and severe myocardial ischemia should undergo coronary artery bypass graft surgery to reduce mortality.⁷¹

Surgical ablation of the arrhythmogenic focus in persons with life-threatening ventricular tachyarrhythmias can be curative. This treatment includes aneurysmectomy or infarctectomy and endocardial resection with or without adjunctive cryoablation based on activation mapping in the operating room.^{72–74} However, the perioperative mortality rate is high. Endoaneurysmorrhaphy with a pericardial patch combined with mapping-guided subendocardial resection frequently cures recurrent VT with a low operative mortality and improvement of LV systolic function.⁷⁵ Radiofrequency catheter ablation of VT has also been beneficial in the management of selected persons with arrhythmogenic foci of monomorphic VT.^{76–78}

Automatic implantable cardioverter-defibrillator

The automatic implantable cardioverter-defibrillator (AICD) is the most effective treatment for persons with life-threatening VT or ventricular fibrillation. Table 45-4 indicates the effect of the AICD on mortality in persons with ventricular tachyarrhythmias.^{79–85} Tresch et al^{73,74} showed in retrospective studies that the AICD was very effective in treating life-threatening VT in elderly and younger persons. The Canadian Implantable Defibrillator Study found that persons most likely to benefit from an AICD were those with two of the following factors: age (70 years), LV ejection fraction (35%), and New York Heart Association function class III or IV.⁸⁶

In MADIT-II, the reduction in sudden cardiac death in patients treated with an AICD was significantly reduced: by

Table 45-4. Effect of the Automatic Implantable Cardioverter-Defibrillator on Mortality in Persons With Ventricular Tachyarrhythmias

Study	Results
Multicenter Automatic Defibrillator Implantation Trial ⁷⁹	At 27-month follow-up, the AICD caused a 54% reduction in mortality
Antiarrhythmics Versus Implantable Defibrillators Trial ⁸⁰	Compared with drug therapy, the AICD caused a 39% decrease in mortality at 1 year, a 27% reduction in mortality at 2 years, and a 31% decrease in mortality at 3 years
Canadian Implantable Defibrillator Study ⁸¹	Compared with amiodarone, at 3 years, total mortality rate was insignificantly decreased by 20% and the arrhythmic mortality was insignificantly reduced by 33%
Cardiac Arrest Study Hamburg ⁸²	Propafenone was stopped at 11 months because mortality from sudden death and cardiac arrest recurrence was 23% for propafenone versus 0% for an AICD
Cardiac Arrest Study Hamburg ⁸³	Compared with amiodarone or metoprolol, the 2-year mortality was decreased 37% by an AICD
Multicenter Unsustained Tachycardia Trial ⁸⁴	Compared with electrophysiologic guided antiarrhythmic drug therapy, the 5-year total mortality was borderline significantly decreased 20% by an AICD and the 5-year risk of cardiac arrest or death from arrhythmia was decreased 76% by an AICD
Multicenter Automatic Defibrillator Implantation Trial II ⁸⁵	At 20-month follow-up, compared with medical therapy, the AICD caused a 31% significant reduction in mortality

68% in 574 patients aged less than 65 years, by 65% in 455 patients aged 65 to 74 years, and by 68% in 204 patients aged 75 years.⁸⁷ The median survival in 348 octogenarians treated with AICD therapy was greater than 4 years.⁸⁸

At 26-month follow-up, survival was 91% for persons treated with metoprolol plus an AICD versus 83% for persons treated with d,l-sotalol plus an AICD.⁸⁹ An observational study in 78 persons with CAD and life-threatening VA treated with an AICD showed at 490-days follow-up that the use of lipid-lowering drugs reduced recurrences of life-threatening VA.⁹⁰ During 33-month follow-up of 1038 patients, mean age 70 years, who had AICDs, use of β -blockers significantly reduced the frequency of appropriate AICD shocks.⁹¹ At 32-month follow-up of 965 of these patients, all-cause mortality was significantly reduced 46% by use of β -blockers, 42% by use of statins, and 29% by use of ACE inhibitors or angiotensin receptor blockers.⁹² These data favor using β -blockers, statins, and ACE inhibitors or angiotensin receptor blockers in the treatment of persons with AICDs.

The ACC/AHA guidelines recommend that class I indications for treatment with an AICD are (1) cardiac arrest due to VT or ventricular fibrillation not caused by a transient or reversible cause; (2) spontaneous sustained VT; (3) syncope of undetermined origin with clinically relevant, hemodynamically significant sustained VT or ventricular fibrillation induced at electrophysiologic study when drug therapy is ineffective, not tolerated, or not preferred; and (4) nonsustained VT with CAD, prior MI, LV systolic dysfunction, and inducible ventricular fibrillation or sustained VT at electrophysiologic study that is not suppressed by a class I antiarrhythmic drug.⁹³

The updated ACC/AHA guidelines for treatment of CHF with a class I indication recommend use of an AICD in (1) patients with current or prior symptoms of CHF and reduced LV ejection fraction with a history of cardiac arrest, VF, or hemodynamically destabilizing VT; (2) in patients with CAD at least 40 days after MI, a LV ejection fraction equal to 30%, NYHA class II or III symptoms on optimal medical therapy, and an expected survival greater than 1 year; (3) in patients with nonischemic cardiomyopathy, a LV ejection fraction equal to 30%, NYHA class II or III symptoms on optimal medical therapy, and an expected survival greater

than 1 year; and (4) with a class IIa indication in patients with a LV ejection fraction of 30% to 35% of any origin with NYHA class II or III symptoms on optimal medical therapy, and an expected survival greater than 1 year.⁹⁴ An AICD should also be used in patients with CHF requiring cardiac resynchronization therapy.⁹⁵

ATRIAL FIBRILLATION

Atrial fibrillation (AF) is the most common sustained cardiac arrhythmia. The prevalence of AF increases with age.^{96–99} The prevalence of AF in 2101 persons, mean age 81 years, was 5% in persons aged 60 to 70 years, 13% in persons aged 71 to 90 years, and 22% in persons aged 91 to 103 years.⁹⁷ Chronic AF was present in 16% of elderly men and in 13% of elderly women.⁹⁷ The prevalence of chronic AF in a study of 1563 persons, mean age 80 years, living in the community and seen in an academic geriatrics practice was 9%.⁹⁹

AF may be paroxysmal or chronic. Episodes of paroxysmal AF may last from a few seconds to several weeks. Spontaneous conversion of paroxysmal AF to sinus rhythm occurs in 68% of persons having AF of less than 72 hours duration.¹⁰⁰

Predisposing factors

Factors predisposing to AF include alcohol, atrial myxoma, atrial septal defect, cardiomyopathies, chronic lung disease, conduction system disease, CHF, CAD, diabetes mellitus, drugs, emotional stress, excessive coffee, hypertension, hyperthyroidism, hypoglycemia, hypokalemia, hypovolemia, hypoxia, myocarditis, neoplastic disease, pericarditis, pneumonia, postoperative state, pulmonary embolism, systemic infection, and valvular heart disease. Table 45-5 lists the increased prevalence of echocardiographic findings in 254 older persons with chronic AF compared with 1445 older persons with sinus rhythm, mean age 81 years.¹⁰¹ In the Framingham Heart Study, low serum thyrotropin levels were independently associated with a 3.1 times increase in the development of new AF in elderly persons.¹⁰²

Associated risks

The Framingham study showed that the incidence of death from cardiovascular causes was 2.0 times higher in men and 2.7 times higher in women with chronic AF than in men and

Table 45-5. Echocardiographic Findings in 254 Persons With Chronic Atrial Fibrillation and 1,445 Persons With Sinus Rhythm, Mean Age 81 Years

LV, left ventricular.

women with sinus rhythm.¹⁰³ The Framingham study also demonstrated that after adjustment for preexisting cardiovascular conditions, the odds ratio for mortality in persons with AF was 1.5 in men and 1.9 in women.¹⁰⁴ At 42-month follow-up of 1359 persons, mean age 81 years, with heart disease, persons with AF had a 2.2 times higher probability of developing new coronary events than those with sinus rhythm after controlling for other prognostic variables.¹⁰⁵ In 106,780 Medicare beneficiaries (65 years of age from the Cooperative Cardiovascular Project treated for acute MI, AF was present in 22%.¹⁰⁶ Compared with sinus rhythm, elderly persons with AF had a higher in-hospital mortality (25% versus 16%), 30-day mortality (29% versus 19%), and 1-year mortality (48% versus 33%).¹⁰⁶ AF was an independent predictor of in-hospital mortality (odds ratio = 1.2), 30-day mortality (odds ratio = 1.2), and 1-year mortality (odds ratio = 1.3).¹⁰⁶ Elderly persons developing AF during hospitalization had a worse prognosis than elderly persons who had AF.¹⁰⁶

AF is an independent risk factor for thromboembolic (TE) stroke, especially in older persons.^{96,97} In the Framingham study, the relative risk of stroke in persons with nonrheumatic AF compared with persons in sinus rhythm was 2.6 times higher in persons aged 60 to 69 years, 3.3 times higher in persons aged 70 to 79 years, and 4.5 times higher in persons aged 80 to 89 years.⁹⁶ AF was an independent risk factor for TE stroke in 2101 persons, mean age 81 years, with a relative risk of 3.3.⁹⁷ The 3-year incidence of TE stroke was 38% in persons with AF and 11% in persons with sinus rhythm.⁹⁷ The 5-year incidence of TE stroke was 72% in persons with AF and 24% in persons with sinus rhythm.⁹⁷

AF was present in 313 of 2384 persons (13%), mean age 81 years.¹⁰⁷ AF was present in 201 of 1024 persons (17%) with LV hypertrophy and in 112 of 1360 persons (8%) without LV hypertrophy.¹⁰⁷ At 44-month follow-up, both AF (risk ratio = 3.2) and LV hypertrophy (risk ratio = 2.8) were independent risk factors for new TE stroke. The higher prevalence of LV hypertrophy in elderly persons with chronic AF contributes to the higher incidence of TE stroke in elderly persons with AF.

At 45-month follow-up of 1846 persons, mean age 81 years, both AF (risk ratio = 3.3) and 40% to 100% extracranial carotid arterial disease (ECAD) (risk ratio = 2.5) were independent risk factors for new TE stroke.¹⁰⁸ Elderly persons with both chronic AF and 40% to 100% ECAD had a 6.9 times higher probability of developing new TE stroke than those with sinus rhythm and no significant ECAD.¹⁰⁸

Symptomatic cerebral infarctions were present in 22% of 54 autopsied patients aged 70 years or older with paroxysmal AF.¹⁰⁹ Symptomatic cerebral infarction was 2.4 times more common in older persons with paroxysmal AF than in older persons with sinus rhythm.¹⁰⁹ AF also causes silent cerebral infarction.¹¹⁰

AF is a predisposing factor for CHF in older persons. As much as 30% to 40% of LV end-diastolic volume may be attributable to left atrial contraction in older persons. Absence of a coordinated left atrial contraction decreases late diastolic filling of the LV because of loss of the atrial kick. A fast ventricular rate associated with AF also shortens the diastolic filling period, which further decreases LV filling.

A retrospective analysis of the Studies of Left Ventricular Dysfunction Prevention and Treatment Trials found that AF was an independent risk factor for all-cause mortality (relative risk = 1.3), progressive pump failure death (relative risk = 1.4), and death or hospitalization for CHF (relative risk = 1.3).¹¹¹

AF was present in 132 of 355 persons (37%), mean age 80 years, with prior MI, CHF, and an abnormal LV ejection fraction.¹¹² AF was present in 98 of 296 persons (33%), mean age 82 years, with prior MI, CHF, and a normal LV ejection fraction.¹¹² In this study, AF was an independent risk factor for mortality with a risk ratio of 1.5.¹¹²

A fast ventricular rate associated with chronic or paroxysmal AF may cause a tachycardia-related cardiomyopathy, which may be an unrecognized curable cause of CHF.^{113,114} Control of a fast ventricular rate by radiofrequency ablation of the atrioventricular (AV) node with permanent pacing caused an improvement in LV ejection fraction in persons with medically refractory AF.¹¹⁵

Clinical symptoms

Elderly persons with AF may be symptomatic or asymptomatic with their arrhythmia detected by physical examination or by an ECG. Examination of a person after a stroke may lead to the diagnosis of AF. Symptoms may include palpitations, skips in heartbeat, fatigue on exertion, exercise intolerance, cough, dizziness, chest pain, and syncope. A fast ventricular rate associated with loss of atrial contraction reduces cardiac output and may cause hypotension, angina pectoris, CHF, acute pulmonary edema, and syncope, especially in elderly persons with mitral stenosis, aortic stenosis, or hypertrophic cardiomyopathy.

Diagnostic tests

When AF is suspected, a 12-lead ECG with a 1-minute rhythm strip should be obtained to confirm the diagnosis. If paroxysmal AF is suspected, a 24-hour AECG should be obtained. All persons with AF should have an M-mode, 2-dimensional, and Doppler echocardiogram to determine the presence and severity of cardiac abnormalities causing AF and to identify risk factors for stroke. Appropriate tests for noncardiac causes of AF should be performed when clinically indicated. Thyroid function tests should be performed as AF or CHF may be the only clinical manifestations of apathetic hyperthyroidism in elderly persons.

General treatment measures

Along with drug therapy, treatment of AF should include therapy of the underlying disorder (such as hyperthyroidism, pneumonia, or pulmonary embolism) when possible.

Surgical candidates for mitral valve replacement should undergo surgery if it is clinically indicated. If mitral valve replacement is not performed in persons with significant mitral valve disease, elective cardioversion should not be performed in persons with AF. Precipitating factors such as CHF, hypoxia, hypokalemia, hypoglycemia, hypovolemia, and infection should be treated immediately. Alcohol, coffee, and drugs (especially sympathomimetics) that precipitate AF should be avoided. Paroxysmal AF associated with the tachycardia-bradycardia (sick sinus) syndrome should be treated with permanent pacing in combination with the use of drugs to slow a fast ventricular rate associated with AF.¹¹⁶

Control of very fast rapid ventricular rate

Immediate direct-current cardioversion should be performed in persons who have paroxysmal AF with a very fast ventricular rate associated with an acute MI, chest pain caused by myocardial ischemia, hypotension, severe CHF, or syncope. Intravenous verapamil,¹¹⁷ diltiazem,¹¹⁸ or β -blockers^{119–122} may be used to immediately slow a very fast ventricular rate associated with AF.

Control of fast ventricular rate

Digitalis glycosides are ineffective in converting AF to sinus rhythm.¹²³ Digoxin is also ineffective in slowing a fast ventricular rate associated with AF if there is associated hyperthyroidism, fever, hypoxia, acute blood loss, or any condition involving increased sympathetic tone.¹²⁴ However, digoxin should be used for slowing a fast ventricular rate in AF unassociated with increased sympathetic tone, the Wolff-Parkinson-White syndrome, or hypertrophic obstructive cardiomyopathy, especially if there is LV systolic dysfunction. The usual maintenance oral dose of digoxin administered to persons with AF is 0.25 mg to 0.5 mg daily, with the dose decreased to 0.125 mg to 0.25 mg daily for elderly persons who are more susceptible to digitalis toxicity.¹²⁵

Oral verapamil,¹²⁶ diltiazem,¹²⁷ or a β -blocker¹²⁸ should be added to the therapeutic regimen if a fast ventricular rate associated with AF occurs at rest or during exercise despite digoxin. These drugs act synergistically with digoxin to depress conduction through the AV junction. In a study of digoxin 0.25 mg daily, diltiazem-CD 240 mg daily, atenolol 50 mg daily, digoxin 0.25 mg plus diltiazem-CD 240 mg daily, and digoxin 0.25 mg plus atenolol 50 mg daily, digoxin and diltiazem as single drugs were least effective and digoxin plus atenolol was most effective in controlling ventricular rate in AF during daily activity.¹²⁹

Amiodarone is the most effective drug for slowing a fast ventricular rate associated with AF.^{130,131} However, its adverse effect profile limits its use in the treatment of AF. Oral doses of 200 mg to 400 mg of amiodarone daily may be administered to selected persons with symptomatic life-threatening AF refractory to other drug therapy.

Therapeutic concentrations of digoxin do not decrease the frequency of episodes of paroxysmal AF or the duration of episodes of paroxysmal AF detected by 24-hour AECGs.^{132,133} In fact, digoxin has been demonstrated to increase the duration of episodes of paroxysmal AF, a result consistent with its action in reducing the atrial refractory period.¹³² Therapeutic concentrations of digoxin also do not prevent a rapid ventricular rate from developing in persons with paroxysmal AF.^{132–134} Therefore digoxin should

be avoided in persons with sinus rhythm with a history of paroxysmal AF.

Nondrug therapies

Radiofrequency catheter modification of AV conduction should be performed in persons with symptomatic AF in whom a fast ventricular rate cannot be slowed by drug therapy.^{135,136} If this procedure does not control the fast ventricular rate associated with AF, complete AV block produced by radiofrequency catheter ablation followed by permanent pacemaker implantation should be performed.^{137,138} In 44 patients, mean age 78 years, radiofrequency catheter ablation followed by pacemaker implantation was successful in ablating the AV junction in 43 of 44 patients (98%) with AF and a rapid ventricular rate not controlled by drug therapy.¹³⁸

In persons with CHF and chronic AF, AV junction ablation with implantation of a VVIR pacemaker was superior to drug therapy in controlling symptoms in a randomized, controlled study of 66 persons.¹³⁹ Surgical techniques have also been developed for use in persons with AF in whom a rapid ventricular rate cannot be slowed by drug treatment.^{140–142} Appropriate indications for using an implantable Atrioverter in the treatment of AF need further investigation.¹⁴³

Tachycardia-bradycardia syndrome

Paroxysmal AF associated with the tachycardia-bradycardia (sick sinus) syndrome should be treated with a permanent pacemaker in combination with drugs to decrease a rapid ventricular rate associated with AF.¹¹⁶ Ventricular pacing is an independent risk factor for the development of chronic AF in persons with paroxysmal AF associated with the tachycardia-bradycardia syndrome.¹⁴⁴ Persons with paroxysmal AF associated with the tachycardia-bradycardia syndrome and no signs of AV conduction abnormalities should be treated with atrial pacing or dual-chamber pacing rather than with ventricular pacing because atrial pacing is associated with less AF, less TE complications, and a lower risk of AV block than is ventricular pacing.¹⁴⁵

Wolff-Parkinson-White syndrome

Direct-current cardioversion should be performed if a fast ventricular rate in paroxysmal AF associated with the Wolff-Parkinson-White syndrome is life-threatening or fails to respond to drug treatment. Drug treatment for paroxysmal AF associated with the Wolff-Parkinson-White syndrome includes propranolol plus procainamide, disopyramide, or quinidine.¹⁴⁶ Digoxin, verapamil, and diltiazem are contraindicated in persons with AF associated with the Wolff-Parkinson-White syndrome because these drugs shorten the refractory period of the accessory AV pathway, causing faster conduction down the accessory pathway. This results in a marked increase in ventricular rate. Radiofrequency catheter ablation or surgical ablation of the accessory conduction pathway should be considered in persons with AF and fast AV conduction over the accessory pathway.¹⁴⁷

Slow ventricular rate

Many elderly persons are able to tolerate AF without the need for treatment because the ventricular rate is slow as a result of concomitant AV nodal disease. These persons should not be treated with a drug that depresses AV conduction.

A permanent pacemaker should be implanted in persons with AF who develop cerebral symptoms such as dizziness or syncope associated with ventricular pauses greater than 3 seconds that are not drug-induced, as documented by a 24-hour AECG. If persons with AF have drug-induced symptomatic bradycardia and the causative drug cannot be discontinued, a permanent pacemaker must be implanted.

Elective cardioversion

Elective direct-current cardioversion has a higher success rate of converting AF to sinus rhythm than does medical cardioversion.¹⁴⁸ Unfavorable conditions for elective cardioversion of chronic AF to sinus rhythm include duration of AF greater than 1 year, moderate to severe cardiomegaly, echocardiographic left atrial dimension greater than 45 mm, digitalis toxicity (contraindication), slow ventricular rate (contraindication), sick sinus syndrome (contraindication), mitral valve disease, CHF, chronic obstructive lung disease, recurrent AF despite antiarrhythmic drugs, and inability to tolerate antiarrhythmic drugs. Elective cardioversion of AF either by direct current or by antiarrhythmic drugs should not be performed in asymptomatic elderly persons with chronic AF.

Antiarrhythmic drugs that have been used to convert AF to sinus rhythm include amiodarone, disopyramide, dofetilide, encainide, flecainide, ibutilide, procainamide, propafenone, quinidine, and sotalol. None of these drugs are as successful as direct-current cardioversion (which is 80% to 90% successful) in converting AF to sinus rhythm. All of these drugs are proarrhythmic and may aggravate or cause cardiac arrhythmias.

Encainide and flecainide caused atrial proarrhythmic effects in 6 of 60 persons (10%).¹⁴⁹ The proarrhythmic effects included conversion of AF to atrial flutter with a 1-to-1 AV conduction response and a very fast ventricular rate.¹⁴⁹ Flecainide has induced VT and ventricular fibrillation in persons with chronic AF.¹⁵⁰ Antiarrhythmic drugs including amiodarone, disopyramide, flecainide, procainamide, propafenone, quinidine, and sotalol caused cardiac adverse effects in 73 of 417 patients (18%) hospitalized for AF.¹⁵¹ Class IC drugs such as encainide, flecainide, and propafenone should be avoided in persons with prior MI or LV systolic dysfunction because these drugs may cause life-threatening ventricular tachyarrhythmias in these persons.³⁸

Ibutilide and dofetilide are class III antiarrhythmic drugs that have recently been used to try to convert AF to sinus rhythm. Twenty-three of 79 persons (29%) with AF treated with intravenous ibutilide converted to sinus rhythm.¹⁵² Polymorphic ventricular tachycardia developed in 4% of persons taking ibutilide in this study.¹⁵² All of these persons had abnormal LV systolic function. Eleven of 75 persons (15%) with AF treated with intravenous dofetilide converted to sinus rhythm.¹⁵³ Torsade de pointes occurred in 3% of persons treated with intravenous dofetilide.¹⁵⁴ After 1 month, 22 of 190 patients (12%) with CHF and AF had sinus rhythm restored with dofetilide compared with 3 of 201 patients (1%) treated with a placebo.¹⁵⁴ Torsade de pointes developed in 25 patients (3%) treated with dofetilide and in none of the patients (0%) treated with a placebo.¹⁵⁴ Direct-current cardioversion of AF has a higher success rate in converting AF to sinus rhythm and a lower incidence of cardiac adverse effects than any antiarrhythmic drug. However,

pretreatment with ibutilide has been shown to facilitate transthoracic cardioversion of AF.¹⁵⁵

Unless transesophageal echocardiography has shown no thrombus in the left atrial appendage before cardioversion,¹⁵⁶ oral warfarin therapy should be administered for 3 weeks before elective direct-current cardioversion or drug cardioversion of persons with AF to sinus rhythm.¹⁵⁷ Anticoagulant therapy should be administered at the time of cardioversion and continued until sinus rhythm has been maintained for 4 weeks.¹⁵⁷ After direct-current or drug cardioversion of AF to sinus rhythm, the left atrium becomes stunned and contracts poorly for 3 to 4 weeks, predisposing to TE stroke unless the patient is receiving oral warfarin.^{158,159} The maintenance dose of oral warfarin should be titrated by serial prothrombin times so that the INR is 2.0 to 3.0.¹⁵⁷ A controlled, randomized, prospective clinical trial is needed to compare conventional anticoagulant treatment before cardioversion of AF with a transesophageal echocardiography-guided strategy.¹⁶⁰

Use of antiarrhythmic drugs to maintain sinus rhythm

The efficacy and safety of antiarrhythmic drugs after cardioversion of AF to maintain sinus rhythm has been questioned. It has not been demonstrated that persons cardioverted from AF to sinus rhythm will have a decreased incidence of subsequent TE stroke. A meta-analysis of six double-blind, placebo-controlled studies of quinidine involving 808 persons who had direct-current cardioversion of chronic AF to sinus rhythm found that 50% of persons receiving quinidine and 25% of persons receiving a placebo were in sinus rhythm at 1 year.⁴³ However, the mortality was higher in persons treated with quinidine (2.9%) than in persons treated with a placebo (0.8%).⁴³ In a study of 406 persons, mean age 82 years, with heart disease and complex VA, the incidence of adverse effects causing drug cessation was 48% for quinidine and 55% for procainamide.⁴⁰ The incidence of total mortality at 2-year follow-up was insignificantly higher in persons receiving quinidine or procainamide than in persons not receiving an antiarrhythmic drug.⁴⁰

In another study, 98 persons were randomized to sotalol and 85 persons to quinidine after direct-current cardioversion of AF to sinus rhythm.¹⁶¹ At 6-month follow-up, 52% of sotalol-treated persons and 48% of quinidine-treated persons were in sinus rhythm.¹⁶¹ At 1-year follow-up of 100 persons with AF cardioverted to sinus rhythm, 30% of 50 persons randomized to propafenone and 37% of 50 persons randomized to sotalol remained in sinus rhythm.¹⁶²

Of 1330 persons in the Stroke Prevention in Atrial Fibrillation (SPAF) Study, 127 persons were receiving quinidine, 57 procainamide, 34 flecainide, 20 encainide, 15 disopyramide, and 7 amiodarone.⁴⁴ Patients taking an antiarrhythmic drug had a 2.7 times increased adjusted relative risk of cardiac mortality and a 2.3 times increased adjusted relative risk of arrhythmic death compared with persons not taking an antiarrhythmic drug.⁴⁴ Persons with a history of CHF taking an antiarrhythmic drug had a 4.7 times increased relative risk of cardiac death and a 3.7 times higher relative risk of arrhythmic death than persons with a history of CHF not taking an antiarrhythmic drug.⁴⁴

A meta-analysis of 59 randomized, controlled studies comprising 23,229 persons, including elderly persons, that

investigated the use of aprindine, disopyramide, encainide, flecainide, imipramine, lidocaine, mexiletine, moricizine, phenytoin, procainamide, quinidine, and tocainide after MI showed that the mortality was higher in persons receiving class I antiarrhythmic drugs (odds ratio = 1.14) than in persons not receiving an antiarrhythmic drug.⁴⁵ None of the 59 studies demonstrated a decrease in mortality by class I antiarrhythmic drugs.⁴⁵

Ventricular rate control

Because maintenance of sinus rhythm with antiarrhythmic drugs may need serial cardioversions, exposes persons to the risks of proarrhythmia, sudden cardiac death, and other adverse effects, and needs the use of anticoagulant treatment in persons in sinus rhythm who have a high risk of recurrence of AF, many cardiologists, including myself, prefer the treatment strategy, especially in elderly persons, of ventricular rate control plus anticoagulant treatment in persons with AF. β -blockers such as propranolol (10 mg to 30 mg, three to four times daily) can be administered to control ventricular arrhythmias⁵⁰ and following conversion of AF to sinus rhythm. Should AF recur, β -blockers have the additional advantage of slowing the ventricular rate. β -blockers are also the most effective drugs in preventing and treating AF after coronary artery bypass graft surgery.¹⁶³ In a double-blind, randomized placebo-controlled study of 394 persons receiving metoprolol CR/XL or a placebo after cardioversion of persistent AF, metoprolol was more effective than a placebo in preventing recurrence of AF and in decreasing the ventricular heart rate if AF recurred.¹⁶⁴

The Atrial Fibrillation Follow-Up Investigation of Rhythm Management (AFFIRM) Study randomized 4060 patients, mean age 70 years (39% women), with paroxysmal or chronic AF of less than 6 months duration and with high risk for stroke to either maintenance of AF with ventricular rate control or to an attempt to maintain sinus rhythm with antiarrhythmic drugs after cardioversion.¹⁶⁵ Patients in both arms of this study were treated with warfarin. All-cause mortality at 5 years was insignificantly increased (15%) in the maintenance of sinus rhythm group compared with the ventricular rate control group (24% vs. 21%).¹⁶⁵ TE stroke was insignificantly reduced in the ventricular rate control group (5.5% vs. 7.1%), and all-cause hospitalization was significantly reduced in the ventricular rate control group (73% vs. 80%).¹⁶⁵ In both groups, the majority of strokes occurred after warfarin was stopped or when the INR was subtherapeutic. There was no significant difference in quality of life or functional status between the two treatment groups.¹⁶⁵

The Rate Control Versus Electrical Cardioversion for Persistent Atrial Fibrillation Study Group randomized 522 patients with persistent AF after a previous electrical cardioversion to receive treatment aimed at ventricular rate control or rhythm control.¹⁶⁶ Both groups were treated with oral anticoagulants. At 2.3-year follow-up, the composite end point of death from cardiovascular causes, heart failure, TE complications, bleeding, implantation of a pacemaker, and severe adverse effects of drugs was 17.2% in the ventricular rate control group versus 22.6% in the rhythm control group.¹⁶⁶ In this study, women randomized to rhythm control had a 3.1 times significant increase in cardiovascular morbidity or mortality versus women randomized to ventricular rate control.¹⁶⁷

Table 45-6. Risk Factors for New Thromboembolic Stroke in 312 Elderly Persons With Chronic Atrial Fibrillation

Variable	Risk Ratio
Age	1.03/yr increase
Prior stroke	1.6
Abnormal LV ejection fraction	1.8
Mitral stenosis	2.0
LV hypertrophy	2.8
Abnormal LV ejection fraction	1.8
Serum total cholesterol	1.01 per 1 mg/dL increase
Serum high-density lipoprotein cholesterol	1.04 per 1 mg/dL decrease

LV, left ventricular.

The 2-year mortality was similar in 1009 patients with AF and CHF treated with rate control or rhythm control.¹⁶⁸ During 19-month follow-up of 110 patients with a history of AF treated with antiarrhythmic drug therapy, recurrent AF was diagnosed by ECG recordings in 46% of the patients and by an implantable monitoring device in 88% of the patients.¹⁶⁹ AF lasting longer than 48 hours was detected by the monitoring device in 50 of the 110 patients (46%). Nineteen of these 50 patients (38%) were completely asymptomatic.¹⁶⁹

RISK FACTORS FOR THROMBOEMBOLIC STROKE

Risk factors for TE stroke in persons with AF include age,^{96,170–173} diabetes mellitus,¹⁷¹ echocardiographic left atrial enlargement,^{174,175} echocardiographic LV systolic dysfunction,^{173,175,176} echocardiographic LV hypertrophy,^{173,174} ECAD,¹⁰⁸ history of CHF,^{171,176,177} prior MI,^{170,171,174,178} hypertension,^{171,174,176,177} mitral annular calcium,^{170,179} prior arterial thromboembolism,* rheumatic mitral stenosis,^{173,174} and women older than 75 years.¹⁷⁶ Table 45-6 lists independent risk factors for new TE stroke in 312 persons with chronic AF, mean age 84 years.

In the SPAF Study involving persons, mean age 67 years, with nonrheumatic AF, recent CHF (within 3 months), a history of hypertension, prior arterial thromboembolism, echocardiographic LV systolic dysfunction, and echocardiographic left atrial enlargement were independently associated with new TE events.^{175,177} The incidence of new TE events was 18.6% per year if three or more risk factors were present, 6.0% per year if 1 or 2 risk factors were present, and 1.0% per year if none of these risk factors was present.¹⁷⁵ In the SPAF III Study, persons, mean age 72 years, were considered to be at high risk for developing TE stroke if they had either a previous thromboembolism, CHF, or abnormal LV systolic function, a systolic blood pressure higher than 160 mm Hg, or the person was a woman older than 75 years of age.¹⁷⁶

Antithrombotic therapy

Prospective, randomized studies have shown that warfarin was effective in reducing the incidence of TE stroke in persons with nonvalvular AF.^{171,176,180–186} Analysis of pooled

*References 97, 103, 171–173, 176, 177, 180.

data from five randomized controlled trials demonstrated that warfarin decreased the incidence of new TE stroke by 68% and was more effective than aspirin in decreasing TE stroke.¹⁷¹ Nonrandomized observational data from an elderly population mean age 83 years, found that 141 persons with chronic AF treated with oral warfarin to achieve an INR between 2.0 and 3.0 (mean INR was 2.4) had a 67% decrease in new TE stroke compared with 209 persons with chronic AF treated with oral aspirin.¹⁸⁷ Compared with aspirin, warfarin caused a 40% decrease in new TE stroke in persons with prior stroke, a 31% reduction in new TE stroke in persons with no prior stroke, a 45% decrease in new TE stroke in persons with an abnormal LV ejection fraction, and a 36% reduction in new TE stroke in persons with a normal LV ejection fraction.¹⁸⁷

At 1.1-year follow-up in the SPAF III Study, persons with nonvalvular AF considered to be at high risk for developing TE stroke randomized to therapy with oral warfarin to achieve an INR between 2.0 and 3.0 had a 72% decrease in ischemic stroke or systemic embolism compared with persons randomized to therapy with oral aspirin 325 mg daily plus oral warfarin to achieve an INR between 1.2 to 1.5.¹⁷⁶ Adjusted-dose warfarin caused an absolute decrease in ischemic stroke or systemic embolism of 6.0% per year.¹⁷⁶ In the Second Copenhagen Atrial Fibrillation, Aspirin, Anticoagulation (AFASK) Study, low-dose warfarin plus aspirin was also less effective in decreasing stroke or a systemic TE event in persons with AF (7.2% after 1 year) than was adjusted-dose warfarin to achieve an INR between 2.0 to 3.0 (2.8% after 1 year).¹⁸⁸

Analysis of pooled data from five randomized controlled trials showed that the annual rate of major hemorrhage was 1.0% for the control group, 1.0% for the aspirin group, and 1.3% for the warfarin group.¹⁷¹ The incidence of major hemorrhage in persons taking adjusted-dose warfarin to achieve an INR of 2.0 to 3.0 in the SPAF III Study (mean age 72 years) was 2.1%.¹⁷⁶ In the Second Copenhagen AFASK Study, the incidence of major hemorrhage in persons, mean age 73 years, was 0.8% per year for persons taking adjusted-dose warfarin to achieve an INR between 2.0 and 3.0 and 1.0% per year for persons treated with aspirin, 300 mg daily.¹⁸⁸ The incidence of major hemorrhage in elderly persons, mean age 83 years, was 4.3% (1.4% per year) for persons with chronic AF taking warfarin to maintain an INR between 2.0 and 3.0 and 2.9% (1.0% per year) for persons with chronic AF treated with aspirin, 325 mg daily.¹⁸⁷

In the SPAF III Study, 892 persons, mean age 67 years, at low risk for developing new TE stroke were treated with oral aspirin, 325 mg daily.¹⁸⁹ Mean follow-up was 2 years. The incidence of new ischemic stroke or systemic embolism (primary events) was 2.2% per year.¹⁸⁹ The incidence of new ischemic stroke or systemic embolism was 3.6% in persons with a history of hypertension and 1.1% in persons without a history of hypertension.¹⁸⁹

In the Anticoagulation and Risk Factor in Atrial Fibrillation Study, women off warfarin had significantly higher annual rates of thromboembolism (3.5%) than men (1.8%).¹⁹⁰ Warfarin was associated with significantly lower adjusted TE rates for both women (60% reduction) and men (40% reduction) with similar annual rates of major bleeding (1.0% and 1.1%, respectively).¹⁹⁰

The Atrial Fibrillation Clopidogrel Trial with Irbesartan for the Prevention of Vascular Events (ACTIVE W) demonstrated in patients with AF that the annual risk of first occurrence of stroke, noncentral nervous system systemic embolus, MI, or vascular death was 3.93% in 3371 patients randomized to warfarin to maintain an INR between 2.0 and 3.0, and 5.60% in 3335 patients randomized to clopidogrel 75 mg daily plus aspirin 75 to 100 mg daily, with a 44% significant decrease in the primary outcome attributed to warfarin.¹⁹¹ The incidence of major bleeding was insignificantly (10%) higher in patients treated with clopidogrel plus aspirin than in persons treated with warfarin.¹⁹¹

On the basis of the available data, elderly persons with chronic or paroxysmal AF who are at high risk for developing TE stroke or who have a history of hypertension and who have no contraindications to anticoagulation therapy should receive long-term oral warfarin to achieve an INR of 2.0 to 3.0.^{157,192} Hypertension must be controlled. Whenever the person has a prothrombin time taken, the blood pressure should also be checked. The physician prescribing the dose of oral warfarin should be aware of the numerous drugs that potentiate the effect of warfarin causing an increased prothrombin time and risk of bleeding.³⁵ Elderly persons with AF who are at low risk for developing TE stroke or who have contraindications to therapy with long-term oral warfarin should be treated with aspirin 325 mg orally daily.

ATRIAL FLUTTER

Atrial flutter is usually paroxysmal and only rarely chronic. Untreated persons with atrial flutter and no disease of the AV junction usually have a 2:1 AV conduction response with an atrial rate of about 300 beats/min and a ventricular rate of 150 beats/min. Over time, atrial flutter usually degenerates into AF.

Management of atrial flutter is similar to management of AF. Direct-current cardioversion is the treatment of choice for converting atrial flutter to sinus rhythm.¹⁹³ Atrial flutter treated with intravenous ibutilide in 38% of 78 persons converted to sinus rhythm.¹⁵⁰ Atrial flutter treated with intravenous dofetilide in 54% of 16 persons converted to sinus rhythm.¹⁵¹ Atrial pacing may also be used to try to convert atrial flutter to sinus rhythm.¹⁹⁴

Intravenous verapamil,¹¹⁷ diltiazem,¹¹⁸ or β -blockers^{119–122} may be used to immediately slow a very rapid ventricular rate associated with atrial flutter. Oral verapamil,¹²⁶ diltiazem,¹²⁷ or a β -blocker¹²⁸ should be added to the therapeutic regimen if a rapid ventricular rate associated with atrial flutter occurs at rest or during exercise despite digoxin. Amiodarone is the most effective drug for slowing a rapid ventricular rate associated with atrial flutter.¹³¹ Digoxin, verapamil, and diltiazem are contraindicated in persons with atrial flutter associated with the Wolff-Parkinson-White syndrome because these drugs shorten the refractory period of the accessory AV pathway, causing more rapid conduction down the accessory pathway. Drugs such as quinidine should never be used to treat persons with atrial flutter who are not being treated with digoxin, a β -blocker, verapamil, or diltiazem as a 1:1 AV conduction response may develop.

Persons with atrial flutter are at increased risk for developing new TE stroke.^{195,196} Anticoagulant therapy should be administered before direct-current cardioversion or drug

cardioversion of persons with atrial flutter to sinus rhythm using the same guidelines as for converting AF.^{157-160,192} Persons with chronic atrial flutter should be treated with oral warfarin with the INR maintained between 2.0 and 3.0.^{157,192}

Radiofrequency catheter ablation of atrial flutter is a highly successful procedure, especially when the right atrial isthmus is incorporated in the atrial flutter circuit.^{197,198} Demonstration of bi-directional isthmus block after catheter ablation predicts a high long-term success rate.¹⁹⁸ A second radiofrequency catheter ablation may be needed in up to one third of patients, especially in those with right atrial enlargement.¹⁹⁷ Radiofrequency catheter ablation was successful in converting 63 of 70 patients (90%), mean age 78 years, with atrial flutter to sinus rhythm.¹³⁸

ATRIAL PREMATURE COMPLEXES

The prevalence of frequent atrial premature complexes (APCs) diagnosed by 24-hour AECGs in older persons was 18% in 729 older women and 28% in 643 older men in the Cardiovascular Health Study⁷ and 28% in 407 persons, mean age 82 years.⁸ Although frequent APCs may trigger a paroxysm of AF, atrial flutter, or supraventricular tachycardia (SVT), they are of no clinical significance when found incidentally and should not be treated. If a supraventricular tachyarrhythmia is triggered by frequent APCs, a β -blocker should be administered.

SUPRAVENTRICULAR TACHYCARDIA

The ventricular rate in paroxysmal SVT usually ranges between 140 and 220 beats per minute and is extremely regular. The prevalence of short bursts of paroxysmal SVT diagnosed by 24-hour AECGs in 1476 persons, mean age 81 years, with heart disease was 33%.¹⁷² At 42-month follow-up of 1359 persons, mean age 81 years, with heart disease, paroxysmal SVT was not associated with an increased incidence of new coronary events.¹⁰⁵ At 43-month follow-up of 1476 persons, mean age 81 years, paroxysmal SVT was not associated with an increased incidence of new TE stroke.¹⁷²

Sustained episodes of SVT should first be treated by increasing vagal tone by carotid sinus massage or the Valsalva maneuver. If vagal maneuvers are unsuccessful, intravenous adenosine is the drug of choice.¹⁹⁹ Intravenous verapamil, diltiazem, or β -blockers may also be used. If these measures do not convert SVT to sinus rhythm, direct-current cardioversion should be used.

Most persons with paroxysmal SVT do not require long-term therapy. If long-term therapy is required because of symptoms due to frequent episodes of SVT, digoxin, propranolol, or verapamil may be administered.²⁰⁰ These drugs are the initial drug of choice for AV nodal reentrant and AV reentrant SVT, the commonest forms of SVT. For SVT associated with the Wolff-Parkinson-White syndrome, flecainide or propafenone may be used if there is no associated heart disease.²⁰¹ If heart disease is present, quinidine, procainamide, or disopyramide plus a β -blocker or verapamil should be used.²⁰¹ Radiofrequency catheter ablation should be used to treat older persons with symptomatic, drug-resistant SVT and should be considered an early treatment option.^{138,202}

Radiofrequency catheter ablation was successful in converting 60 of 66 patients, mean age 78 years, with SVT to sinus rhythm.¹³⁸

ACCELERATED ATRIOVENTRICULAR RHYTHM

Accelerated AV junctional rhythm also called nonparoxysmal AV junctional tachycardia (NPJT) is a form of SVT and is caused by enhanced impulse formation within the AV junction rather than by reentry.²⁰³ This arrhythmia is usually due to recent aortic or mitral valve surgery, acute MI, or digitalis toxicity. The ventricular rate usually ranges between 70 and 130 beats/min. Treatment of NPJT is directed toward correction of the underlying disorder. Hypokalemia, if present, should be treated with potassium. Digitalis should be stopped if digitalis toxicity is present. β -blockers may be given cautiously if this is warranted by clinical circumstances.

PAROXYSMAL ATRIAL TACHYCARDIA WITH ATRIOVENTRICULAR BLOCK

Digitalis toxicity causes 70% of cases of paroxysmal atrial tachycardia (PAT) with AV block. Digoxin and diuretics causing hypokalemia should be stopped in these persons. If the serum potassium is low or low-normal, potassium chloride is the treatment of choice. Intravenous propranolol will cause conversion to sinus rhythm in about 85% of persons with digitalis-induced PAT with AV block and in about 35% of persons with PAT with AV block not induced by digitalis.²⁰⁴ By increasing AV block, propranolol may also be beneficial in slowing a rapid ventricular rate in PAT with AV block.

MULTIFOCAL ATRIAL TACHYCARDIA

Multifocal atrial tachycardia (MAT) is usually associated with acute illness, especially in older persons with pulmonary disease. MAT is best managed by treatment of the underlying disorder. Intravenous verapamil has been reported to be effective in controlling the ventricular rate in MAT, with occasional conversion to sinus rhythm.²⁰⁵ However, the author found intravenous verapamil not very effective in treating MAT.²⁰⁶ The tendency of intravenous verapamil to aggravate preexisting arterial hypoxemia also limits its use in the group of persons most likely to develop MAT.²⁰⁵

BRADYARRHYTHMIAS

With aging, there is a loss of specialized muscle cells (called P cells) within the sinus node, which are responsible for initiating impulse formation. By age 75 years, the sinus node may consist of less than 10% P cells.²⁰⁷ A progressive increase in the amount of collagen within the sinus node also occurs with aging.²⁰⁸ There is an age-related reduction in conducting cells in the His bundle and both bundle branches, which are the distal parts of the cardiac conduction system. Diseases associated with aging such as CAD, hypertension, and valvular heart disease also adversely affect the cardiac conduction system.

Numerous drugs can cause bradyarrhythmias and conduction disturbances. Hypothyroidism, hyperkalemia, hypokalemia, and hypoxia can also depress cardiac impulse

formation and conduction. Drugs and endocrine and metabolic disorders causing reversible cardiac impulse formation and conduction abnormalities must be considered before deciding to implant a permanent pacemaker.

A 12-lead ECG with a 1-minute strip may detect bradyarrhythmias caused by a sick sinus syndrome, AV block, right and left bundle branch block, bifascicular block, and trifascicular block. ECG manifestations of sick sinus syndrome include severe sinus bradycardia, sinus pause or arrest, sinus exit block, sinus node reentrant rhythm, AF or atrial flutter with a slow ventricular rate not drug-induced, failure of restoration of sinus rhythm after cardioversion for tachyarrhythmias, a longer than 3-second pause after carotid sinus massage, and a tachycardia-bradycardia syndrome. The tachycardia-bradycardia syndrome is characterized by paroxysmal AF, atrial flutter, or SVT followed by periods of sinus bradycardia, sinus arrest, or sinoatrial block.

Dyspnea, weakness, fatigue, falls, angina pectoris, CHF, episodic pulmonary edema, dizziness, faintness, slurred speech, personality changes, paresis, and convulsions in older persons may be caused by bradyarrhythmias. Death may result from prolonged ventricular asystole. Older persons with symptoms that may be due to bradyarrhythmias should have a 12-lead ECG with a 1-minute rhythm strip. Since ECG abnormalities may be intermittent, a 24-hour AECG may need to be performed.

In a prospective study of 148 persons, mean age 82 years, with unexplained syncope, 24-hour AECGs diagnosed bradyarrhythmias with pauses greater than 3 seconds requiring permanent pacemaker implantation in 21 persons (14%).² Of these 21 persons, 8 had sinus arrest, 7 had advanced second-degree AV block, and 6 had AF with a slow ventricular rate not drug-induced. At 38-month follow-up after pacemaker implantation, recurrent syncope developed in only 3 of the 21 older persons (14%).²

In some older persons without clinical evidence of heart disease and recurrent episodes of unexplained syncope, a patient-activated memory loop event recorder may be used to capture the ECG tracings preceding and during syncope.²⁰⁹ Older persons with unexplained syncope and heart disease should undergo an electrophysiologic study.²⁰⁹ Table 45-7 shows class I indications for permanent pacemaker implantation.⁹³ Modes of pacing, pacemaker codes, and pacemaker follow-up are discussed in detail elsewhere.²¹⁰

DEFINITION

Syncope (derived from the Greek words, “syn” meaning “with” and the verb “koptein” meaning “to cut” or more appropriately in this case “to interrupt”) is a symptom, defined as a transient, self-limited loss of consciousness, usually leading to falling. The onset of syncope is relatively rapid, and the subsequent recovery is spontaneous, complete, and usually prompt.

EPIDEMIOLOGY

Syncope is a common symptom, experienced by up to 30% of healthy adults at least once in their life time.^{1,2} Syncope accounts for 3% of emergency department visits and 1% of medical admissions to a general hospital.³ Syncope is the seventh most common reason for emergency admission of patients over 65 years of age.⁴ The cumulative incidence of syncope in a chronic care facility is close to 23% over a 10-year period with an annual incidence of 6% and recurrence rate of 30% over 2 years. The age of first faint, a commonly used term for syncope, is less than 25 years in 60% of persons but 10% to 15% of individuals have their first faint after age 65 years.^{5,6}

Syncope due to a cardiac cause is associated with higher mortality rates irrespective of age. In patients with a non-cardiac or unknown cause of syncope, older age, a history of congestive cardiac failure, and male sex are important prognostic factors of mortality.⁷ It remains undetermined whether syncope is directly associated with mortality or is merely a marker of more severe underlying disease.² [Figure 46-1](#) details the age-related difference in prevalence of benign vasovagal syncope compared with other causes of syncope.

PATHOPHYSIOLOGY

The temporary cessation of cerebral function that causes syncope results from transient and sudden reduction of blood flow to parts of the brain (brain stem reticular activating system) responsible for consciousness. The predisposition to vasovagal syncope starts early and lasts for decades. Other causes of syncope are uncommon in young adults, but much more common as persons age.^{8,9}

Regardless of the cause, the underlying mechanism responsible for syncope is a drop in cerebral oxygen delivery below the threshold for consciousness. Cerebral oxygen delivery, in turn, depends on both cerebral blood flow and oxygen content. Any combination of chronic or acute processes that lowers cerebral oxygen delivery below the “consciousness” threshold may cause syncope. Age-related physiologic impairments in heart rate, blood pressure, cerebral blood flow, and blood volume control, in combination with comorbid conditions and concurrent medications account for the increased incidence of syncope in the older person. Blunted baroreflex sensitivity with aging is manifested as a

reduction in the heart rate response to hypotensive stimuli. Older adults are prone to reduced blood volume because of excessive salt wasting by the kidneys as a result of a decline in plasma renin and aldosterone, a rise in atrial natriuretic peptide, and concurrent diuretic therapy.⁸ Low blood volume together with age-related diastolic dysfunction can lead to a low cardiac output, which increases susceptibility to orthostatic hypotension and vasovagal syncope.¹⁰ Cerebral autoregulation, which maintains a constant cerebral circulation over a wide range of blood pressure changes, is altered in the presence of hypertension and possibly by aging; the latter is still controversial.¹¹ In general it is agreed that sudden mild to moderate declines in blood pressure can affect cerebral blood flow greatly and render an older person particularly vulnerable to presyncope and syncope. Syncope may thus result either from a single process that markedly and abruptly decreases cerebral oxygen delivery or from the accumulated effect of multiple processes, each of which contributes to the reduced oxygen delivery.¹²

Multifactorial causes

Previously up to 40% of patients with recurrent syncope remained undiagnosed despite extensive investigations, particularly older patients who have marginal cognitive impairment and for whom a witnessed account of events is often unavailable. More recently, diagnostic yield for all ages has improved with application of guidelines.¹³ Although diagnostic investigations are available, the high frequency of unidentified causes in clinical studies may occur because patients failed to recall important diagnostic details^{14,15} because of the stringent diagnostic criteria used in clinical studies or, probably most often, because the syncopal episode resulted from a combination of chronic and acute factors rather than from a single obvious disease process.¹⁶ Indeed, a multifactorial cause likely explains the majority of cases of syncope in older persons who are predisposed because of multiple chronic diseases and medication effects superimposed on the age-related physiologic changes described above.¹⁷ Common factors that in combination may predispose to, or precipitate, syncope include anemia, chronic lung disease, congestive heart failure, and dehydration. Medications that may contribute to, or cause, syncope are listed in [Table 46-1](#).

Individual causes of syncope

Common causes of syncope are listed in [Table 46-2](#). The most frequent individual causes of syncope in older patients are neurally mediated syndromes, including carotid sinus syndrome, orthostatic hypotension, and postprandial hypotension and arrhythmias, including both tachyarrhythmias and bradyarrhythmias. These disease processes are described in the next section. Disorders that may be confused with syncope and which may, or may not, be associated with loss of consciousness are listed in [Table 46-3](#). In older patients, 75% of syncope is due to noncardiac causes and 15% is due to cardiac causes.¹⁸

Figure 46-1. Comparison of ages of first syncope in 443 patients with vasovagal syncope and 88 patients with syncope of other known cause.

Table 46-1. Drugs That Can Cause or Contribute to Syncope

Drug	Mechanism	
Diuretics	Volume depletion	
Vasodilators		
Angiotensin-converting enzyme inhibitors	Reduction in systemic vascular resistance and venodilation	
Calcium channel blockers		
Hydralazine	Centrally acting antihypertensives	
Nitrates		
Alpha adrenergic blockers		
Prazosin		
Other antihypertensive drugs		
Alpha methyl dopa		
Clonidine		
Guanethidine		
Hexamethonium		
Labetalol

Encainide		
Flecainide		
Quinidine		
Procainamide		
Sotalol		
Digoxin	Cardiac arrhythmias	
Psychoactive drugs		
Tricyclic antidepressants		
Phenothiazines		
Monamine oxidase inhibitors		
Barbiturates		
Alcohol		
		Central nervous system effects causing hypotension; cardiac arrhythmias

Table 46-2. Causes of Syncope

Reflex Syncopal Syndromes

- Vasovagal faint (common faint)
- Carotid sinus syncope
- Situational faint
 - Acute hemorrhage
 - Cough, sneeze
 - Gastrointestinal stimulation (swallow, defecation, visceral pain)
 - Micturition (postmicturition)
 - Postexercise
 - Pain, anxiety
- Glossopharyngeal and trigeminal neuralgia

Orthostatic

- Aging
- Antihypertensives
- Autonomic failure
 - Primary autonomic failure syndromes (e.g., pure autonomic failure, multiple system atrophy, Parkinson's disease with autonomic failure)
 - Secondary autonomic failure syndromes (e.g., diabetic neuropathy, amyloid neuropathy)
- Medications (see Table 46-1)
- Volume depletion
 - Hemorrhage, diarrhea, Addison's disease, diuretics, febrile illness, hot weather

Cardiac Arrhythmias

- Sinus node dysfunction (including bradycardia/tachycardia syndrome)
- Atrioventricular conduction system disease
- Paroxysmal supraventricular and ventricular tachycardias
- Implanted device (pacemaker, ICD) malfunction, drug-induced proarrhythmias

Structural Cardiac or Cardiopulmonary Disease

- Cardiac valvular disease
- Acute myocardial infarction/ischemia
- Obstructive cardiomyopathy
- Atrial myxoma
- Acute aortic dissection
- Pericardial disease/tamponade
- Pulmonary embolus/pulmonary hypertension

Cerebrovascular

- Vascular steal syndromes

Multifactorial

Table 46-3. Disorders Commonly Misdiagnosed as Syncope

- Transient ischemic attacks (TIA) of carotid or vertebro-basilar origin
- Hypoglycemia and other metabolic disorders
- Some forms of epilepsy
- Alcohol and other intoxications
- Hyperventilation with hypocapnia

PRESENTATION

The underlying mechanism of syncope is transient cerebral hypoperfusion. In some forms of syncope, there may be a premonitory period in which various symptoms (e.g., light-headedness, nausea, sweating, weakness, and visual disturbances) offer warning of an impending syncopal event.¹⁸ Often, however, loss of consciousness occurs without warning.^{14,15} Recovery from syncope is usually accompanied by almost immediate restoration of appropriate behavior and orientation. Amnesia for loss of consciousness occurs in many older individuals and in those with cognitive impairment. The postrecovery period may be associated with fatigue of varying duration. In young patients, nausea, blurred vision, and sweating predict noncardiac syncope; only dyspnea predicts cardiac syncope in older patients.¹⁸

Syncope and falls are often considered two separate entities with different causes. Recent evidence suggests, however, that these conditions may not always distinctly be separate.¹⁹ In older adults, determining whether patients who have fallen have had a syncopal event can be difficult. Half of syncopal episodes are unwitnessed and older patients may have amnesia for loss of consciousness.¹⁵ Amnesia for loss of consciousness has been observed in half of patients with carotid sinus syndrome who experience falls and a quarter of all patients with carotid sinus syndrome irrespective of presentation.²⁰ Emerging evidence suggests a high incidence of falls in addition to traditional syncopal symptoms in older patients with sick sinus syndrome and atrioventricular conduction disorders. Thus syncope and falls may be indistinguishable and may, in some cases, be manifestations of similar pathophysiologic processes. The presentation of specific causes of syncope is presented in the following sections.

EVALUATION

The initial step in the evaluation of syncope is to consider whether there is a specific cardiac or neurologic cause or whether the cause is likely multifactorial.^{21–23} The starting point for the evaluation of syncope is a careful history and physical examination. A witness account of events is important to ascertain when possible.^{24,25} Three key questions should be addressed during the initial evaluation: (1) Is loss of consciousness attributable to syncope? (2) Is heart disease present or absent? and (3) Are there important clinical features in the history and physical examination that suggest the cause?

Differentiating true syncope from other “nonsyncopal” conditions associated with real or apparent loss of consciousness is generally the first diagnostic challenge and influences the subsequent diagnostic strategy. A strategy for differentiating true syncope and nonsyncope is outlined in

Figure 46-2 and Figure 46-3. The presence of heart disease is an independent predictor of a cardiac cause of syncope, with a sensitivity of 95% and a specificity of 45%.²⁶

Patients frequently complain of dizziness alone or as a prodrome to syncope and unexplained falls. Four categories of dizzy symptoms—vertigo, dysequilibrium, light-headedness and others—have been recognized. The categories have neither the sensitivity nor specificity in older patients, as in younger ones. Dizziness, however, may more likely be attributable to a cardiovascular diagnosis if associated with pallor, syncope, prolonged standing, palpitations, or the need to lie down or sit down when symptoms occur.

Initial evaluation may lead to a diagnosis based on symptoms, signs, or electrocardiograph (ECG) findings. Under such circumstances, no further evaluation is needed and treatment, if any, can be planned. More commonly, the initial evaluation leads to a suspected diagnosis (see Figure 46-3), which needs to be confirmed by directed testing.^{1,27} If a diagnosis is confirmed by specific testing, treatment may be initiated. On the other hand, if the diagnosis is not confirmed, then patients are considered to have unexplained syncope and should be evaluated following a strategy such as that outlined in Figure 46-3. It is important to attribute a diagnosis, if possible, rather than assume that an abnormality known to produce syncope or hypotensive symptoms is the cause. To attribute a diagnosis, patients should have symptom reproduction during investigation and preferably alleviation of symptoms with specific intervention. It is not uncommon for more than one predisposing disorder to coexist in older patients, rendering a precise diagnosis difficult. In older persons treatment of possible causes without clear verification of attributable diagnosis may often be the only option.

An important issue in patients with unexplained syncope is the presence of structural heart disease or an abnormal ECG. These findings are associated with a higher risk of arrhythmias and a higher mortality at 1 year.²⁸ In these patients, cardiac evaluation consisting of echocardiography, stress testing, and tests for arrhythmia detection, such as prolonged electrocardiographic and loop monitoring or electrophysiologic study are recommended. The most alarming ECG sign in a patient with syncope is probably alternating complete left and right bundle branch block, or alternating right bundle branch block with left anterior or posterior fascicular block, suggesting trifascicular conduction system disease and intermittent or impending high-degree AV block. Patients with bifascicular block (right bundle branch block plus left anterior or left posterior fascicular block, or left bundle branch block) are at high risk of developing high-degree AV block. A significant problem in the evaluation of syncope and bifascicular block is the transient nature of high degree AV block and therefore the long periods required to document it by ECG.

In patients without structural heart disease and a normal ECG, evaluation for neurally mediated syncope should be considered. The tests for neurally mediated syncope consist of tilt testing and carotid sinus massage.

The majority of older patients with syncope are likely have a multifactorial cause and thus both predisposing and precipitating causes should be sought in the history, examination, and laboratory evaluation, particularly if the initial evaluation does not suggest an obvious single cause.

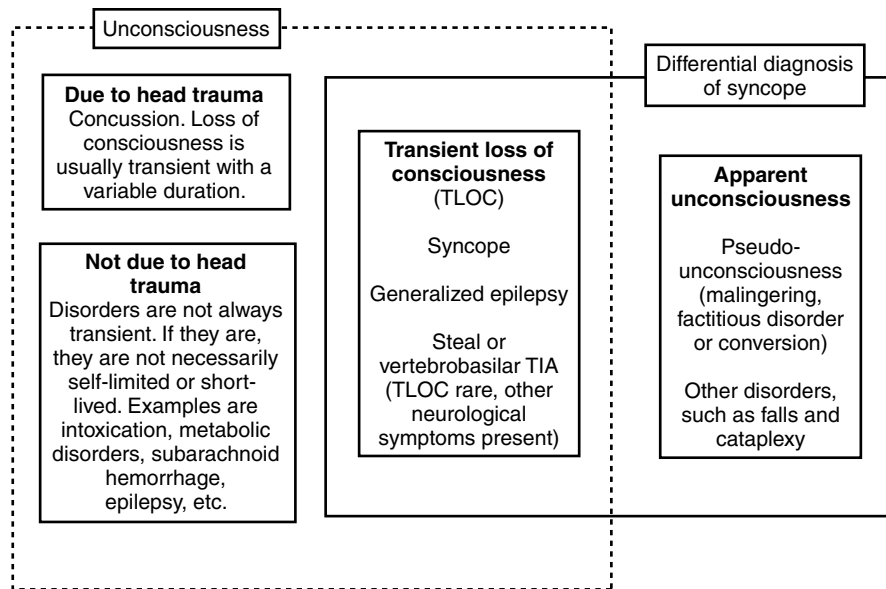

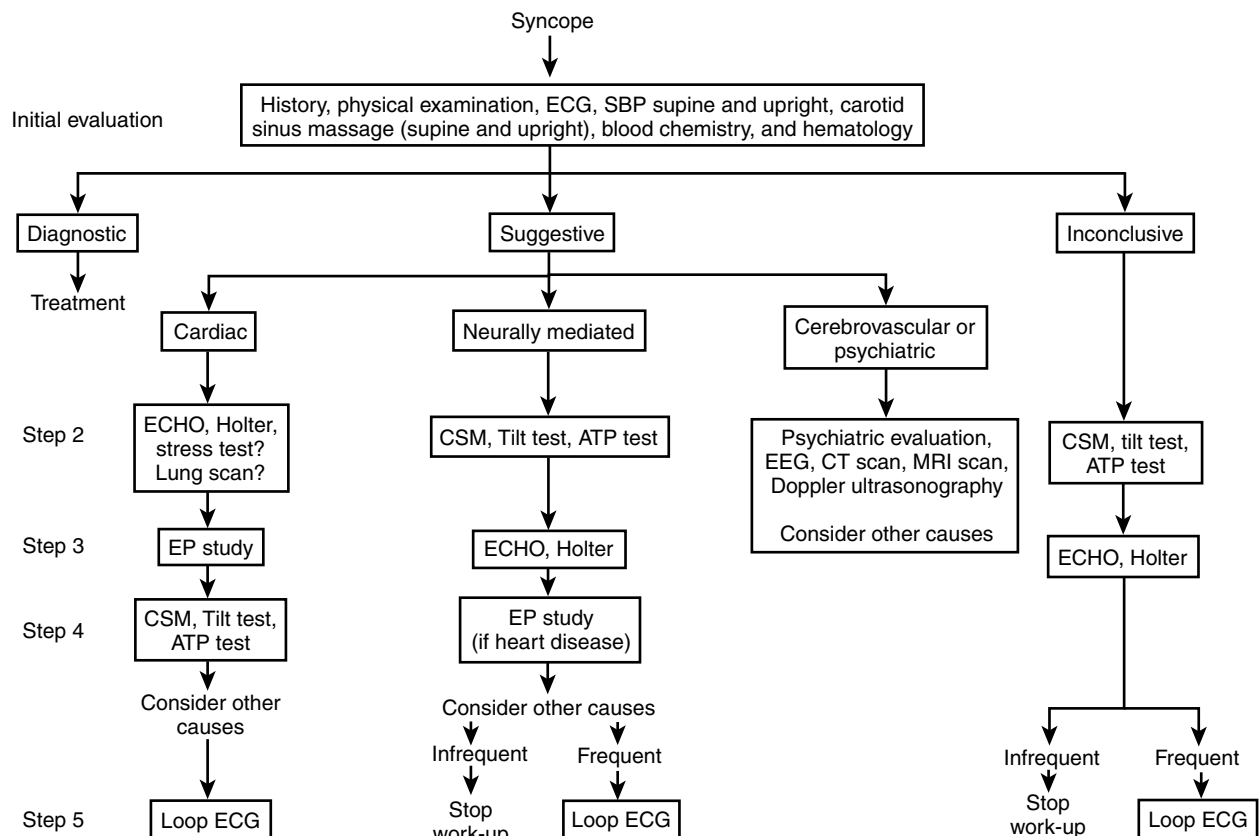

Figure 46-2. Syncope in relation to real and apparent loss of consciousness.

Figure 46-3. An approach to the evaluation of syncope for all age groups. *ATP test*, adenosine provocation test; *CSM*, carotid sinus massage; *ECHO*, echocardiogram; *EEG*, electroencephalogram; *EP study*, electrophysiologic study; *ECG*, electrocardiogram.

The presentation, evaluation, and management of other common causes of syncope are presented in the following sections. These causes may occur as the sole cause of a syncopal episode or as one of multiple contributing causes.

ORTHOSTATIC HYPOTENSION

Pathophysiology

Orthostatic or postural hypotension is arbitrarily defined as either a 20 mm Hg fall in systolic blood pressure or a 10 mm Hg fall in diastolic blood pressure on assuming an

upright posture from a supine position. Orthostatic hypotension implies abnormal blood pressure homeostasis and is a frequent observation with advancing age. Prevalence of postural hypotension varies between 4% and 33% among community living older persons depending on the methodology used. Higher prevalence and larger falls in systolic blood pressure have been reported with increasing age and often signify general physical frailty. Orthostatic hypotension is an important cause of syncope, accounting for 14% of all diagnosed cases in a large series. In a tertiary referral clinic dealing with unexplained syncope, dizziness, and falls, 32% of patients over age 65 years had orthostatic hypotension as a possible attributable cause of symptoms.

Aging

The heart rate and blood pressure responses to orthostasis occur in three phases: (1) an initial heart rate and blood pressure response, (2) an early phase of stabilization, and (3) a phase of prolonged standing. All three phases are influenced by aging. The maximum rise in heart rate and the ratio between the maximum and the minimum heart rate in the initial phase decline with age, implying a relatively fixed heart rate irrespective of posture. Despite a blunted heart rate response, blood pressure and cardiac output are adequately maintained on standing in active, healthy, well-hydrated, and normotensive older persons because of decreased vasodilation and reduced venous pooling during the initial phases and increased peripheral vascular resistance after prolonged standing. However, in older persons with hypertension and cardiovascular disease receiving vasoactive drugs, these circulatory adjustments to orthostatic stress are disturbed, rendering them vulnerable to postural hypotension.²⁹

Hypertension

Hypertension further increases the risk of hypotension by impairing baroreflex sensitivity and reducing ventricular compliance. A strong relationship between supine hypertension and orthostatic hypotension has been reported among unmedicated institutionalized older persons. Hypertension increases the risk of cerebral ischemia from sudden declines in blood pressure. Older persons with hypertension are more vulnerable to cerebral ischemic symptoms even with modest and short-term postural hypotension because the threshold for cerebral autoregulation is altered by prolonged elevation of blood pressure. In addition, antihypertensive agents impair cardiovascular reflexes and further increase the risk of orthostatic hypotension.

Medications

Drugs (Table 46-1) are important causes of orthostatic hypotension. Ideally establishing a causal relationship between a drug and orthostatic hypotension requires identification of the culprit medicine, abolition of symptoms by withdrawal of the drug, and rechallenge with the drug to reproduce symptoms. Rechallenge is often omitted in clinical practice in view of the potential serious consequences. In the presence of polypharmacy, which is common in the older person, it becomes difficult to identify a single culprit drug because of the synergistic effect of different drugs and drug interactions. Thus all drugs should be considered as possible contributors to orthostasis.

Other conditions

A number of nonneurogenic conditions are also associated with postural hypotension. These conditions include myocarditis, atrial myxoma, aortic stenosis,³⁰ constrictive pericarditis, hemorrhage, diarrhea, vomiting, ileostomy, burns, hemodialysis, salt losing nephropathy, diabetes insipidus, adrenal insufficiency, fever, and extensive varicose veins. Volume depletion for any reason is a common sole, or contributing, cause of postural hypotension, and, in turn, syncope.

Primary autonomic failure syndromes

Three distinct clinical entities, namely pure autonomic failure (PAF), multiple system atrophy (MSA), or Shy-Drager syndrome (SDS), and autonomic failure associated with idiopathic Parkinson's disease (IPD) are associated with orthostatic hypotension. PAF, the least common condition and a relatively benign entity, was previously known as idiopathic orthostatic hypotension. Symptoms of this condition include orthostatic dizziness, defective sweating, impotence, and bowel disturbances. No other neurologic deficits are found and resting plasma noradrenaline levels are low. MSA is the most common and has the poorest prognosis. Clinical manifestations include features of dysautonomia and motor disturbances due to striatonigral degeneration, cerebellar atrophy, or pyramidal lesions. Additional neurologic deficits include muscle atrophy, distal sensory-motor neuropathy, pupillary abnormalities, restriction of ocular movements, disturbances in rhythm and control of breathing, life-threatening laryngeal stridor, and bladder disturbances. Psychiatric manifestations and cognitive defects are usually absent. Resting plasma noradrenaline levels are usually within the normal range but fail to rise on standing or tilting.

The prevalence of orthostatic hypotension in Parkinson's disease rises with advancing years and with the number of medications prescribed. Cognitive impairment, in particular abnormal attention and executive function, is more common in Parkinson's disease with orthostatic hypotension, suggesting a possible causal association with hypotension including watershed lesions. Orthostatic hypotension in Parkinson's disease can also be due to autonomic failure and or to side effects of anti-Parkinsonian medications.

Secondary autonomic dysfunction

Autonomic nervous system involvement is seen in several systemic diseases. A large number of neurologic disorders are also complicated by autonomic dysfunction, which may involve several organs leading to a variety of symptoms in addition to orthostatic dizziness, including anhidrosis, constipation, diarrhea, impotence, retention of urine, urinary incontinence, stridor, apneic episodes, and Horner's syndrome. Among the most serious and prevalent conditions associated with a orthostasis due to autonomic dysfunction are diabetes, multiple sclerosis, brain stem lesions, compressive and noncompressive spinal cord lesions, demyelinating polyneuropathies (Guillain-Barré's syndrome), chronic renal failure, chronic liver disease, and connective tissue disorders.

Presentation

The clinical manifestations of orthostatic hypotension are due to hypoperfusion of the brain and other organs. Depending on the degree of fall in blood pressure,

symptoms can vary from dizziness to syncope associated with a variety of visual defects, from blurred vision to blackout. Other reported ischemic symptoms are nonspecific lethargy and weakness, suboccipital and paravertebral muscle pain, low back ache, calf claudication, and angina. Several precipitating factors for orthostatic hypotension have been identified including speed of positional change, prolonged recumbency, warm environment, raised intrathoracic pressure (coughing, defecation, micturition), physical exertion, and vasoactive drugs.³¹

Evaluation

The diagnosis of orthostatic hypotension involves a demonstration of a postural fall in blood pressure after active standing. Reproducibility of orthostatic hypotension depends on the time of measurement and on autonomic function. The diagnosis may be missed on casual measurement during the afternoon. The procedure should be repeated during the morning after maintaining supine posture for at least 10 minutes. Sphygmomanometer measurement will detect hypotension which is sustained. Phasic blood pressure measurements are more sensitive for detection of transient falls in blood pressure. Active standing is more appropriate than head-up tilt because the former more readily represents the physiologic alpha adrenergic vasodilation due to calf muscle activation. Once a diagnosis of postural hypotension is made, the evaluation involves identifying the cause or causes of orthostasis mentioned above.

Management (Table 46-4)

The goal of therapy for symptomatic orthostatic hypotension is to improve cerebral perfusion. There are several nonpharmacologic interventions that should be tried in

Table 46-4. Management of Orthostatic Hypotension in Older Persons

Identify and Treat Correctable Causes
Reduce or eliminate drugs causing orthostatic hypotension (see Table 46-2)
Avoid situations that may exacerbate orthostatic hypotension:
Standing motionless
Prolonged recumbency
Large meals
Hot weather
Hot showers
Straining at stool or with voiding
Isometric exercise
Ingesting alcohol
Hyperventilation
Dehydration
Raise the head of the bed to a 5- to 20-degree angle
Wear waist-high custom-fitted elastic stockings and an abdominal binder
Participate in physical conditioning exercises, i.e.,
Controlled postural exercises using the tilt table
Avoid diuretics and eat salt-containing fluids (unless congestive heart failure is present)
Caffeine
Drug therapy
Fludrocortisone
Midodrine
Desmopressin
Erythropoietin

the first instance. These interventions include avoidance of precipitating factors for low blood pressure, elevation of the head of the bed at night by at least 20 degrees, and application of graduated pressure from an abdominal support garment or from stockings. Medications known to contribute to postural hypotension should be eliminated or reduced. There are reports to suggest benefit from implantation of cardiac pacemakers, in a small number of patients, by increasing heart rate during postural change. However, the benefits of tachypacing on cardiac output in patients with maximal vasodilation are short lived, probably because venous pooling and vasodilation dominate. A large number of drugs have been used to raise blood pressure in orthostatic hypotension, including fludrocortisone, midodrine, ephedrine, desmopressin (DDAVP), octreotide, erythropoietin, and nonsteroidal antiinflammatory agents. Fludrocortisone (9-alpha fluohydrocortisone) in a dose of 0.1 to 0.2 mg, causes volume expansion, reduces natriuresis, and sensitizes alpha adrenoceptors to noradrenaline. In older people, the drug can be poorly tolerated in high doses and for long periods. Adverse effects include hypertension, cardiac failure, depression, edema, and hypokalemia. Midodrine is a directly acting sympathomimetic vasoconstrictor of resistance vessels. Treatment is started at a dose of 2.5 mg three times daily and requires gradual titration to a maximum dose of 45 mg/day. Adverse effects include hypertension, pilomotor erection, gastrointestinal symptoms, and central nervous system toxicity. Side effects are usually controlled by dose reduction. Midodrine can be used in combination with low dose fludrocortisone with good effect. DDAVP has potent antidiuretic and mild pressor effects. Intranasal doses of 5 to 40 microgram at bed time are useful. The main side effect is water retention. This agent can also be combined with fludrocortisone with synergistic effect. The drug treatment for orthostatic hypotension in older persons requires frequent monitoring for supine hypertension, electrolyte imbalance, and congestive heart failure. One option for treating supine hypertension, which is most prominent at night, is to apply a GTN patch after going to bed, remove it in the morning, and take midodrine +/- fludrocortisone 20 minutes before rising. This is effective provided that the older person remains in bed throughout the night. Nocturia is therefore an important consideration. To capture these coexistent diurnal BP variations of supine hypertension and morning orthostasis, 24-hour ambulatory BP monitoring is the preferred investigation for the management of postural hypotension. Postprandial hypotension, due to splanchnic vascular pooling, often co-exists with orthostatic hypotension in older patients.

CAROTID SINUS SYNDROME AND CAROTID SINUS HYPERSENSITIVITY

Pathophysiology

Carotid sinus syndrome is an important but frequently overlooked cause of syncope and presyncope in older persons.⁹ Episodic bradycardia and/or hypotension resulting from exaggerated baroreceptor mediated reflexes or carotid sinus hypersensitivity characterize the syndrome. The syndrome is diagnosed in persons with otherwise unexplained recurrent syncope who have carotid sinus hypersensitivity. The latter is considered present if carotid sinus massage produces

asystole exceeding 3 seconds (cardioinhibitory), or a fall in systolic blood pressure exceeding 50 mm Hg in the absence of cardioinhibition (vasodepressor) or a combination of the two (mixed).^{13,32}

Epidemiology

Up to 30% of the healthy aged population have carotid sinus hypersensitivity. The prevalence is higher in the presence of coronary artery disease or hypertension. Abnormal responses to carotid sinus massage are more likely to be observed in individuals with coronary artery disease and in those on vasoactive drugs known to influence carotid sinus reflex sensitivity such as digoxin, beta blockers, and alpha methyl dopa. Other hypotensive disorders such as vasovagal syncope and orthostatic hypotension coexist in one third of patients with carotid sinus hypersensitivity. In centers which routinely perform carotid sinus massage in all older patients with syncope, carotid sinus syndrome is the attributable cause of syncope in 30%.³³ This frequency needs to be interpreted within the context that these centers evaluate a pre-selected group of patients who have a higher likelihood of carotid sinus syndrome than the general population of older persons with syncope. The prevalence in all older persons with syncope is unknown.

Carotid sinus syndrome is virtually unknown before the age of 50 years; its incidence increases with age thereafter. Males are more commonly affected than females and the majority have either coronary artery disease or hypertension. Carotid sinus syndrome is associated with appreciable morbidity. Approximately half of patients sustain an injury, including a fracture, during symptomatic episodes. In a prospective study of falls in nursing home residents, a threefold increase in the fracture rate in those with carotid sinus hypersensitivity was observed. Indeed, carotid sinus hypersensitivity can be considered as a modifiable risk factor for fractures of the femoral neck. Carotid sinus syndrome is not associated with an increased risk of death. The mortality rate in patients with the syndrome is similar to that of patients with unexplained syncope and the general population matched for age and sex. Mortality rates are similar for the three subtypes of the syndrome.

The natural history of carotid sinus hypersensitivity has not been well investigated. In one study, the majority (90%) of persons with abnormal hemodynamic responses but without syncopal symptoms, remained symptom free during an average follow-up of 20 months while half of those who had syncope had symptom recurrence. More recent neuropathologic research suggests that carotid sinus hypersensitivity is associated with neurodegenerative pathology at the cardiovascular center in the brain stem. Why some persons with carotid sinus hypersensitivity develop syncope as a consequence and others remain asymptomatic is not clear.

Presentation

The syncopal symptoms are usually precipitated by mechanical stimulation of the carotid sinus, such as head turning, tight neckwear, neck pathology, and by vagal stimuli such as prolonged standing. Other recognized triggers for symptoms are the postprandial state, straining, looking or stretching upwards, exertion, defecation, and micturition. In a significant number of patients, no triggering event can be identified. Abnormal response to carotid sinus massage (see

later discussion) may not always be reproducible, necessitating repetition of the procedure if the diagnosis is strongly suspected.

Evaluation

CAROTID SINUS MASSAGE

Carotid sinus reflex sensitivity is assessed by measuring heart rate and blood pressure responses to carotid sinus massage (Figure 46-4). Cardioinhibition and vasodepression are more common on the right side. In patients with cardioinhibitory carotid sinus syndrome, more than 70% have a positive response to right-sided carotid sinus massage either alone or in combination with left-sided carotid sinus massage. There is no fixed relationship between the degree of heart rate slowing and the degree of fall in blood pressure.

Carotid sinus massage is a crude and unquantifiable technique and is prone to intraobserver and interobserver variation. More scientific diagnostic methods using neck chamber suction or drug-induced changes in blood pressure can be used for carotid baroreceptor activation, but are not validated for routine clinical use. The recommended duration of carotid sinus massage is from 5 to 10 seconds. The maximum fall in heart rate usually occurs within 5 seconds of the onset of massage (Figure 46-2).

Complications resulting from carotid sinus massage include cardiac arrhythmias and neurologic sequelae. Fatal arrhythmias are extremely uncommon and have generally only occurred in patients with underlying heart disease undergoing therapeutic rather than diagnostic massage. Digoxin toxicity has been implicated in most cases of ventricular fibrillation. Neurologic complications result from either occlusion of, or embolization from, the carotid artery. Several authors have reported cases of hemiplegia following

Figure 46-4. Procedure for carotid sinus massage while upright.

carotid sinus stimulation, often in the absence of hemodynamic changes. Complications from carotid sinus massage, however, are uncommon. In a prospective series of 1000 consecutive cases, no patient had cardiac complications and 1% had transient neurologic symptoms, which resolved. Persistent neurologic complications were uncommon, occurring in 0.04% of cases.³⁴ Carotid sinus massage should not be performed in patients who have had a recent cerebrovascular event or myocardial infarction.

Symptom reproduction during carotid sinus massage is preferable for a diagnosis of carotid sinus syndrome. Symptoms reproduction may not be possible for older patients with amnesia for loss of consciousness. Spontaneous symptoms usually occur in the upright position. It may thus be worth repeating the procedure, with the patient upright on a tilt table, even after demonstrating a positive response when supine. This reproduction of symptoms aids in attributing the episodes to carotid sinus hypersensitivity, especially in patients with unexplained falls who deny loss of consciousness. In one third of patients, a diagnostic response is only achieved during upright carotid sinus massage.

Management

No treatment is necessary in persons with asymptomatic carotid sinus hypersensitivity.³⁵ There is no consensus, however, on the timing of therapeutic intervention in the presence of symptoms. Considering the high rate of injury in symptomatic episodes in older persons and the low recurrence rate of symptoms, it is prudent to treat all patients with a history of two or more symptomatic episodes. The need for intervention in those individuals with a solitary event should be assessed on an individual basis, taking into consideration the severity of the event and the patient's comorbidity.

Treatment strategies in the past included carotid sinus denervation achieved either surgically or by radioablation. Both procedures have largely been abandoned. Dual chamber cardiac pacing is the treatment of choice in patients with symptomatic cardioinhibitory carotid sinus syndrome. Atrial pacing is contraindicated in view of the high prevalence of both sinoatrial and atrioventricular block in patients with carotid sinus hypersensitivity. Ventricular pacing abolishes cardioinhibition but fails to alleviate symptoms in a significant number of patients because of aggravation of a coexisting vasodepressor response or the development of pacemaker-induced hypotension, referred to as pacemaker syndrome. The latter occurs when ventriculo-atrial conduction is intact as is the case for up to 80% of patients with the syndrome. Atrioventricular sequential pacing (dual chamber) is thus the treatment of choice and because this maintains atrioventricular synchrony, there is no risk of pacemaker syndrome. With appropriate pacing, syncope is abolished in 85% to 90% of patients with cardioinhibition.

In a recent report of cardiac pacing in older fallers, (mean age of 74 years) who had cardioinhibitory carotid sinus hypersensitivity, falls during 1 year of follow up were reduced by two thirds in patients who received dual chamber systems.³³ Syncopal episodes were reduced by half. Over half of the patients in the aforementioned series had gait abnormalities and three quarters had balance abnormalities, which would render individuals more susceptible to falls under hemodynamic circumstances, thus further suggesting the multifactorial nature of many falls and syncopal episodes.²²

Treatment of vasodepressor carotid sinus syndrome is less successful because of a poor understanding of its pathophysiology. Ephedrine has been reported to be useful, but long-term use is limited by side effects. Dihydroergotamine is effective but poorly tolerated. Fludrocortisone, a mineralocorticoid widely used in the treatment of orthostatic hypotension, is used in the treatment of vasodepressor carotid sinus syndrome with good results but its use is limited in the longer term by adverse effects. A recent small randomized controlled trial suggests good benefit with midodrine (an alpha agonist). Surgical denervation of the carotid artery may be a valid treatment option.^{36,37}

VASOVAGAL SYNCOPE

Pathophysiology

The normal physiologic responses to orthostasis, as described earlier, are an increase in heart rate, rise in peripheral vascular resistance (increase in diastolic blood pressure), and minimal decline in systolic blood pressure to maintain an adequate cardiac output. In patients with vasovagal syncope, these responses to prolonged orthostasis are paradoxical. The precise sequence of events leading to vasovagal syncope is not fully understood. The possible mechanism involves a sudden fall in venous return to the heart, rapid fall in ventricular volume, and virtual collapse of the ventricle due to vigorous ventricular contraction. The net result of these events is stimulation of ventricular mechano-receptors and activation of Bezold-Jarisch reflex leading to peripheral vasodilatation (hypotension) and bradycardia. Several neurotransmitters, including serotonin, endorphins, and arginine vasopressin, play an important role in the pathogenesis of vasovagal syncope possibly by central sympathetic inhibition, although their exact role is not yet well understood.³⁸

Healthy older persons are not as prone to vasovagal syncope as younger adults. Due to an age-related decline in baroreceptor sensitivity, the paradoxical responses to orthostasis (as in vasovagal syncope) are possibly less marked in older persons. However hypertension, atherosclerotic cerebrovascular disease, cardiovascular medications, and impaired baroreflex sensitivity can cause dysautonomic responses during prolonged orthostasis (in which blood pressure and the heart decline steadily over time) and render older persons susceptible to vasovagal syncope. Diuretic or age-related contraction of blood volume further increases the risk of vasovagal syncope.³⁹

Presentation

The hallmark of vasovagal syncope is hypotension and/or bradycardia sufficiently profound to produce cerebral ischemia and loss of neural function. Vasovagal syncope has been classified into cardioinhibitory (bradycardia), vasodepressor (hypotension), and mixed (both) subtypes depending on the blood pressure and heart rate response. In most patients, the manifestations occur in three distinct phases: a prodrome or aura, loss of consciousness, and postsyncopal phase. A precipitating factor or situation is identifiable in most patients. Common precipitating factors include extreme emotional stress, anxiety, mental anguish, trauma, physical pain, or anticipation of physical pain (e.g., anticipation of venesection), warm environment, air travel and prolonged standing. The commonest triggers in older individuals are

prolonged standing and vasodilator medication. Some patients experience symptoms in specific situations, such as micturition, defecation, and coughing. Prodromal symptoms include extreme fatigue, weakness, diaphoresis, nausea, visual defects, visual and auditory hallucinations, dizziness, vertigo, headache, abdominal discomfort, dysarthria, and paresthesia. The duration of prodrome varies greatly from seconds to several minutes, during which some patients take actions such as lying down to avoid an episode. Older patients may have poor recall for prodromal symptoms. The syncopal period is usually brief during which some patients develop involuntary movements, usually myoclonic jerks but tonic clonic movements also occur. Thus vasovagal syncope may masquerade as a seizure. Recovery is usually rapid but older patients can experience protracted symptoms, such as confusion, disorientation, nausea, headache, dizziness, and a general sense of ill health.

Evaluation

Several methods have evolved to determine an individual's susceptibility to vasovagal syncope, such as Valsalva maneuvers, hyperventilation, ocular compression, and immersion of the face in cold water. However, these methods are poorly reproducible and lack correlation with clinical events. Using the strong orthostatic stimulus of head-upright tilting and maximal venous pooling, vasovagal syncope can be reproduced in a susceptible individual.⁴⁰ Head-up tilting as a diagnostic tool was first reported in 1986⁴¹ and since then validity of this technique in identifying susceptibility to neurocardiogenic syncope has been established. Subjects are tilted head up for 40 minutes at 70 degrees. Heart rate and blood pressure are measured continuously throughout the test. A test is diagnostic or positive if symptoms are reproduced with a decline in blood pressure of greater than 50 mm Hg or to less than 90 mm Hg. This may be in addition to significant heart rate slowing. As with carotid sinus syndrome, the hemodynamic responses are classified as vasodepressor, cardioinhibitory, or mixed. The cardioinhibitory response is defined as asystole in excess of 3 seconds or heart rate slowing to less than 40 beats/min for a minimum of 10 seconds. Orthostatic hypotension, vasovagal syncope, and carotid sinus hypersensitivity may overlap particularly in older patients.⁴²

The sensitivity of head-up tilting can be further improved by provocative agents, which accentuate the physiologic events leading to vasovagal syncope. One agent is intravenous isoprenaline, which enhances myocardial contractility by stimulating β -adreno-receptors. Isoprenaline is infused, before head-up tilting, at a dose of 1 mcg per minute and gradually increased to a maximum dose of 3 mcg per minute to achieve a heart rate increase of 25%. Though the sensitivity of head-up tilt testing improves by about 15%, the specificity is reduced. In addition as a result of the decline in β -receptor sensitivity with age, isoprenaline is less well tolerated, less diagnostic, and has a much higher incidence of side effects. The other agent that can be used as a provocative agent and is better tolerated in older persons is sublingual nitroglycerin, which, by reducing venous return due to vasodilation can enhance the vasovagal reaction in susceptible individuals. Nitroglycerin provocation during head-up tilt testing is thus preferable to other provocative tests in older patients.^{40,43} The duration of testing is less, cannulation is

not required, and the sensitivity and specificity are better than for isoprenaline.

Because syncopal episodes are intermittent, external loop recording will not capture events unless they occur approximately every 2 to 3 weeks. Implantable loop recorders (Reveal; Medtronic) can aid diagnosis by tracking bradyarrhythmias or tachyarrhythmias, causing less frequent syncope. To date no implantable BP monitors are available with the exception of intracardiac monitors, which are not recommended for diagnosis of a benign condition such as vasovagal syncope.^{44,45}

Management

Avoidance of precipitating factors and evasive actions, such as lying down during prodromal symptoms, have great value in preventing episodes of vasovagal syncope. Withdrawal or modification of culprit medications is often the only necessary intervention in older persons. Doses and frequency of antihypertensive medications can be tailored by information from 24-hour ambulatory monitoring. Older patients with hypertension who develop syncope—either orthostatic or vasovagal—while taking antihypertensive drugs, present a difficult therapeutic dilemma and should be treated on an individual basis.

Many patients experience symptoms without warning, necessitating drug therapy. A number of drugs are reported to be useful in alleviating symptoms. Fludrocortisone (100 to 200 mcg/day) works by its volume expanding effect. Recent reports suggest that serotonin antagonists, such as fluoxetine (20 mg/day) and sertraline hydrochloride (25 mg/day), are also effective although further trials are necessary to validate this finding. Midodrine acts by reducing peripheral venous pooling and thereby improving cardiac output and can be used either alone or in combination with fludrocortisone but with caution. Elastic support hose, relaxation techniques (biofeedback), and conditioning using repeated head-up tilt as therapy have been adjuvant therapies. Permanent cardiac pacing is beneficial in some patients who have recurrent syncope due to cardioinhibitory responses.⁴⁶

POSTPRANDIAL HYPOTENSION

The effect of meals on the cardiovascular system was appreciated from postprandial exaggeration of angina, which was demonstrated objectively by deterioration of exercise tolerance following food. Postprandial reductions in blood pressure manifesting as syncope and dizziness were subsequently reported, leading to extensive investigation of this phenomenon. In healthy older subjects, systolic blood pressure falls by 11 to 16 mm Hg, and the heart rate rises by 5 to 7 beats/min 60 minutes after meals of varying compositions and energy content. However the change in diastolic blood pressure is not as consistent. In older persons with hypertension, orthostatic hypotension and autonomic failure, the postprandial blood pressure fall is much greater and without the corresponding rise in heart rate.⁴⁷ These responses are marked if the energy and simple carbohydrate content of the meal is high. In the majority of fit and frail older persons, most postprandial hypotensive episodes go unnoticed.⁴⁸ When systematically evaluated, postprandial hypotension was found in over one third of nursing home residents.

Postprandial physiologic changes include increased splanchnic and superior mesenteric artery blood flow at the expense of peripheral circulation and a rise in plasma insulin levels without corresponding rises in sympathetic nervous system activity. Vasodilator effects of insulin and other gut peptides, including neurotensin and VIP contribute to hypotension. The clinical significance of a fall in blood pressure after meals is difficult to quantify. However, postprandial hypotension is causally related to recurrent syncope and falls in older persons. A reduction in simple carbohydrate content of food, its replacement with complex carbohydrates or high protein, high fat, and frequent small meals are effective interventions for postprandial hypotension. Drugs useful in the treatment of postprandial hypotension include fludrocortisone and indomethacin, octreotide, and caffeine. Given orally along with food, caffeine prevents hypotensive symptoms in fit and frail older persons but should preferably be given in the mornings as tolerance develops if it is taken throughout the day.^{49,50}

SUMMARY

Syncope is a common symptom in older adults due to age-related neurohumoral and physiologic changes plus chronic diseases and medications, which reduce cerebral oxygen

delivery through multiple mechanisms. Common individual causes of syncope encountered by the geriatrician are orthostatic hypotension, carotid sinus syndrome, vasovagal syncope, postprandial syncope, sinus node disease, atrioventricular block, and ventricular tachycardia. Algorithms for the assessment of syncope are similar to those for young adults, but the prevalence of ischemic and hypertensive disorders and cardiac conduction disease is higher in older adults and the cause is more often multifactorial. A systematic approach to syncope is needed with the goal being to identify either a single likely cause or multiple treatable contributing factors. Management is then based on removing or reducing the predisposing or precipitating factors through various combinations of medication adjustments, behavioral strategies, and more invasive interventions in select cases, such as cardiac pacing, cardiac stenting, and intracardiac defibrillators. It is often not possible to clearly attribute a cause of syncope in older persons who frequently have more than one possible cause and pragmatic management of each diagnosis is recommended.

For a complete list of references, please visit online only at www.expertconsult.com

The prevalence of atherosclerosis increases with advancing age, so it is hardly surprising that the majority of a vascular surgeon's patients are elderly and have a full range of concomitant diseases typical of such patients. Equally, specialists in geriatric medicine frequently find vascular disease in the patients they treat. Decisions regarding treatment need to be balanced against quality of life and cardiac and respiratory risk factors. In many patients neither invasive investigation by arteriography nor vascular surgery will be indicated. However, vascular surgery is now being performed with increasing safety in patients who have longer life expectancies. The principle of balancing benefit against risk of treatment is emphasized repeatedly throughout this chapter.

Elderly people suffer a range of vascular conditions, but this chapter covers the three most common problems presenting to vascular surgeons: (1) vascular disease of the limb, either acute or chronic; (2) carotid disease; and (3) abdominal aortic aneurysm. New techniques are rapidly changing our approach to the management of vascular conditions; for example, the use of percutaneous transluminal angioplasty as the sole treatment for lower-limb critical ischemia,¹ and the introduction of endovascular stent-grafts for the treatment of abdominal aortic aneurysms.²

ARTERIAL DISEASE OF THE LIMB

Most patients with peripheral vascular disease have symptoms of chronic ischemia. This ranges from intermittent claudication with a benign prognosis, to critical ischemia having rest pain, gangrene, ischemic ulceration, and the threat of amputation.

Acute ischemia of a limb may be due to emboli, but it is now more usually secondary to thrombosis in diseased arteries. The majority of emboli lodge at the bifurcation of a main vessel, giving rise to distal dysfunction. Acute ischemia may have some or all of the classic symptoms such as pain, pallor, paresthesia, paralysis, and lack of pulse.

Chronic peripheral vascular disease PREVALENCE

Atherosclerosis is the most common disease affecting peripheral arteries in the elderly population and may severely limit mobility and quality of life.³ Amputation for peripheral vascular disease or gangrene is the second most common operation in patients aged over 90 years.⁴ At least one third of patients with arterial stenosis or arterial occlusion, particularly involving the superficial femoral artery at the adductor canal, are asymptomatic.⁵ However, approximately 50% of patients having intermittent claudication have a superficial femoral artery occlusion.⁶ The prevalence of claudication is only 1.0% to 1.5% in men aged under 50 years, but it rises substantially thereafter—up to 20% to 25% in those over 85.^{7,8}

PROGNOSIS

Only 10% of individuals with intermittent claudication consult a doctor and only a minority of these will ever come to surgery.⁹ The outlook for the legs in patients with claudication

is good, but peripheral vascular disease is a strong predictor of subsequent mortality, which more than doubles that of nonclaudicants.^{10–12} The majority of claudicants die from associated cardiovascular events, in particular stroke and myocardial infarction, and this high mortality risk is only partly explained by the expected association of peripheral vascular disease with coronary artery disease owing to the generalized nature of atherosclerosis.^{13–15} In the Speedwell prospective heart disease study,¹⁵ men with intermittent claudication had a 30%, 5-year mortality compared with 6% in men without intermittent claudication. The increased risk of cardiovascular death may stem from repeated ischemia/reperfusion injury in the leg muscle, leading to leukocyte and platelet activation and increased thrombogenicity.¹⁶

INVESTIGATIONS

Investigation of patients with intermittent claudication should concentrate on identifying risk factors for cardiac and cerebrovascular events. Smoking is strongly associated with intermittent claudication, as are diabetes, hypertension, and abnormal lipid levels.^{10,15,17} In diabetic patients, there is increased involvement of small vessels with distal artery occlusion, which carries a poor prognosis.¹¹

The ankle brachial pressure index (ABPI) may be helpful in quantifying the severity of peripheral vascular disease, but only a minority of patients with abnormal APBIs are symptomatic.¹⁸ As a general rule, patients with a mean ABPI of less than 0.6 who have symptoms or leg ulcers need vascular surgical assessment.¹⁹

Rest pain, ischemic ulceration, or gangrene is an absolute indication for investigation with a view to treatment. Duplex imaging or angiography may be used to identify the sites of stenotic or occlusive disease, but they are indicated only if surgery or angioplasty is being considered. Duplex imaging has become increasingly important in the diagnosis and follow-up of arterial lesions because it is noninvasive and can be repeated on many occasions to monitor disease progress, graft patency, and the need for intervention. It identifies arterial occlusions and hemodynamically significant stenoses with a sensitivity and specificity of 92% and 97%, respectively, and has the potential to replace angiography. The presence of multiple stenoses is the main limitation on diagnostic accuracy.^{20–22} Duplex imaging alone can be used to predict the indication for percutaneous transluminal angioplasty.²³

TREATMENT

Treatment is directed at control of risk factors for cardiovascular and cerebrovascular mortality, such as hypertension, hyperlipidemia, and diabetes. Surgery or angioplasty for peripheral vascular disease is rarely indicated for intermittent claudication, but it may be offered to those whose symptoms are intolerable for their lifestyle despite a period of conservative care. The best advice for patients with claudication is to stop smoking, lose weight if appropriate, and keep walking. Exercise training can improve claudication distances significantly.²⁴

The treatment for rest pain, ischemic ulceration, or gangrene depends on the state of the peripheral circulation. New treatment modalities have revolutionized the revascularization of lower-limb ischemia. Percutaneous transluminal angioplasty is becoming the most frequent option in the treatment of both claudication and revascularization for critical ischemia. If there is a lesion amenable to angioplasty, then this should be treated. Alternatively, whether reconstructive surgery is indicated depends on the level and length of arterial occlusions and the severity of disease distally in the limb.

Acute limb ischemia

The clinical distinction between arterial thrombosis or embolism can be difficult, but errors in diagnosis lead to a higher surgical failure rate and higher hospital mortality.^{25,26} Acute ischemia of the lower limb may occur due to embolization into a previously patent arterial tree, but it is now more likely to be due to thrombosis in diseased arteries. The most frequent site of origin for an arterial embolus is the heart, resulting from poor atrial emptying in atrial fibrillation or from a mural thrombus following myocardial infarction. Alternatively, an embolus may originate from a previously undiscovered ventricular or aortic aneurysm.

Arterial emboli to the arm are infrequent and usually seen only in elderly patients. Approximately two thirds of emboli are of cardiac origin, although peripheral aneurysm may account for up to 20% of cases.^{27,28} Conservative management is appropriate for many of these patients if the hand is viable and the pressure index (relative to the opposite normal arm) is greater than 0.6.^{29,30} Surgical embolectomy can be performed under local anesthetic and achieves excellent results. However, there is an associated mortality of greater than 10%, related predominantly to the underlying cardiac condition.²⁷

Management of femoral embolism

Early femoral embolectomy is the standard for acute leg ischemia in patients with a strong clinical suspicion of an embolus, such as those with a short history of ischemia (less than 72 hours), an embolic source such as atrial fibrillation, and no past history of intermittent claudication.³¹ Embolectomy using a Fogarty catheter will usually restore limb perfusion, but it has been associated with a 16% to 26% mortality due predominantly to coexisting cardiac disease.^{31–33} Following embolectomy, the patient should be given long-term anticoagulant therapy, initially by heparin infusion and then with oral anticoagulants. Investigation by full blood count, echocardiography, and duplex imaging of the arterial supply to the leg is essential.

Management of acute thrombosis

In contrast, the management of acute critical ischemia due to arterial thrombosis is one of the more demanding surgical emergencies and should be dealt with only by an experienced vascular team. There is usually a little more time to make the diagnosis and arrange treatment as a collateral circulation offers some protection. Heparin should be given as soon as possible to reduce extension of the thrombus. If the limb is not completely anesthetic or paralyzed there should be sufficient time for adequate preoperative investigations by urgent duplex imaging and angiography if indicated to assess the distal arterial tree.

Intra-arterial thrombolysis achieves lysis of such thrombi (or emboli) in approximately two thirds of cases.³⁴ Accelerated techniques of lysis, such as clot suction and the pulse-spray method, may be undertaken in as little as 30 minutes, but higher doses of thrombolytic agents tend to increase the risk of hemorrhagic complications.³⁵ Following lysis, the underlying arterial disease should be treated either by transluminal angioplasty or by arterial reconstruction. In patients requiring urgent surgery, "on table" operative angiography may be performed (Figure 47-1) to assess the extent of the occlusion and the quality of the distal arteries. This should be repeated on completion of surgery to check the reconstruction and give an indication of prognosis.

Outcome of limb salvage for severe ischemia

An aggressive policy of revascularization achieves limb and patient survival rates of approximately 75% at 1 year, even in the elderly population.³⁶ Almost all patients with severe leg ischemia should be offered a limb salvage procedure because this is associated with a better quality of life (Figure 47-2).³⁷ The availability of specialist vascular surgeons reduces the frequency of major lower limb amputations, with a concomitant increase in the number of distal reconstructions.³⁸ Arterial reconstruction to save the leg and alleviate pain is preferable to an amputation, particularly as few elderly patients regain mobility and independence after lower-limb amputation and most require institutional care or at least homes adapted for wheelchair use.³² Although the initial operative costs of reconstructive surgery are higher than those of amputation, this cost is more than offset by the duration of inpatient stay and the high community costs of rehabilitating amputees.³³

CAROTID DISEASE

Diagnosis and investigations

DIAGNOSIS

Carotid disease may be asymptomatic or may occur with stroke, transient ischemic attacks (TIAs), or possibly with vague symptoms such as dizziness. Carotid artery stenosis may cause stroke by hypoperfusion or by emboli; indeed many strokes are preceded by TIAs that are ignored by the patient and the doctor.

Carotid bruits can occur in the absence of significant internal carotid artery disease, and severe carotid disease may not produce a bruit. Thus a bruit is not a reliable indicator of underlying carotid disease.^{39,40} In a study examining the predisposing factors for acute cerebral infarction, only 14% had cervical bruits.⁴¹ All patients presenting with either TIAs, or who recover from an appropriate stroke and are fit for surgery, should undergo carotid imaging; significant carotid artery disease is found in just over 30% of those with anterior circulation infarcts as classified by the Oxford Community Stroke Project Classification.^{42,43}

INVESTIGATIONS

Noninvasive techniques to assess carotid disease include color duplex Doppler imaging, which incorporates continuous-wave Doppler to estimate blood velocity, and B-mode ultrasound to image the whole vessel. High-resolution B-mode scanning has also been shown to give prognostic information:

Figure 47-1. A sequence of arteriograms from a patient with acute right lower limb ischemia. In **A**, there is no visualization of “run-off” below a recent occlusion in the proximal popliteal artery. Subsequent on-table angiogram using the distal popliteal artery revealed a patent anterior tibial artery. In **B**, the completed bypass (with reversed saphenous vein) is shown.

Figure 47-2. Prolonged rest ischemia, often requiring opiates, leads to distress, malaise, and general disability. Physiotherapy should be started immediately to release the flexion contracture of the knee.

echo-lucent (soft) plaque may have a greater propensity for embolization than echo-dense (hard) plaque.⁴⁴

Portable continuous-wave Doppler (**Figure 47-3**) can be used to assess the blood flow at the bifurcation and in both the internal and external carotid arteries as far as the mandible. An experienced vascular technologist can readily distinguish the waveforms from each of these three vessels. Those from the internal carotid artery have a high diastolic component caused by low peripheral resistance from the cerebral circulation. In comparison, the external signal is more pulsatile with a sharp initial peak and usually a characteristic small second peak resembling the flow signals from the peripheral arteries. Increased blood velocity through a stenotic area is detected by increased frequency in the Doppler shift so that the grade of stenoses more than 50% may be easily detected. As stenoses less than 50% have little or no hemodynamic significance, diagnostic accuracy and the value of the investigation improves as the degree of stenosis increases.

Although this method is simple, quick, and accurate for detecting stenoses of greater than 50%, mistakes can be made in heavily calcified vessels that may appear occluded if calcification prevents ultrasound penetration. In these circumstances, and where there are clinical symptoms relevant to carotid artery disease, duplex Doppler (**Figure 47-4**) should be used to guide therapy. Occasionally, even duplex imaging may be difficult to interpret; in particular, total occlusion may be falsely diagnosed as trickles of blood flow through a very tight stenosis. In these cases digital subtraction angiography is indicated.

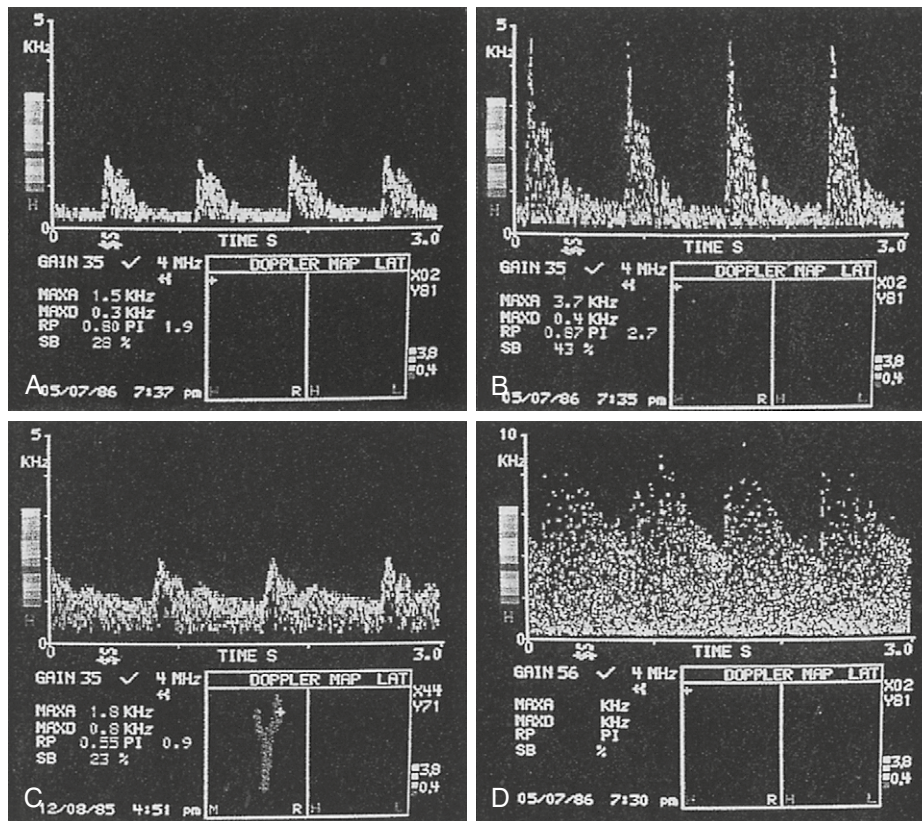

Figure 47-3. Doppler spectral analysis flow signals in normal (A) common carotid artery; (B) external carotid artery; and (C) internal carotid artery. (D) A stenosed internal carotid artery demonstrating increased Doppler frequencies.

Figure 47-4. B-mode image of the carotid bifurcation demonstrating the jugular vein, common carotid (CCA), and internal carotid (ICA) arteries. An ulcerated, calcified plaque is seen at the origin of the internal carotid.

The most important risk of angiography is transient or permanent neurologic deficits, with estimates in the ranges 0.5% to 4% and 0.09% to 1.3%, respectively. Local complications include hematoma, dissection of the femoral artery, and embolism. Systemic complications such as allergic reactions and renal failure also occur. The overall complication rate is in the range 0.9% to 10%.^{45,46}

In contrast, color duplex ultrasound is noninvasive and risk-free and has a positive predictive value of more than 95% for significant stenosis.⁴⁷ The controversial issue of whether ultrasound alone is adequate as the definitive investigation before surgery is now resolving. Both magnetic resonance and digital subtraction angiography may well underestimate or overestimate the degree of carotid stenosis if a large plaque is situated asymmetrically within the vessel lumen.^{48,49} It is also argued that angiography is necessary to exclude additional stenotic lesions elsewhere in the cerebral circulation, typically in the carotid siphon, or coincidental cerebral aneurysms, but the relevance of these so-called "tandem lesions" is uncertain.⁵⁰ Computed tomography (CT) angiography provides another noninvasive alternative in carotid assessment, but has yet to gain widespread acceptance.⁵¹ In patients with a recent acute stroke, a cerebral CT scan (Figure 47-5) should be performed to exclude intracerebral hemorrhage.

The risks and cost of angiography do not justify its routine use before carotid surgery. Exceptions to this policy are if the duplex imaging is inconclusive, or if the artery appears to be occluded on ultrasound when it is important to exclude the possibility of "trickle flow" through a very tight stenosis.

Carotid surgery

BENEFITS

The role of carotid surgery in the prevention of stroke in symptomatic patients with severe stenosis (70% to 99%) of the internal carotid artery is now well established. In the North American Carotid Surgery Trial,⁵² covering 50
