*Note that a low serum phosphate level is always accompanied by a high fibroblast growth factor (FGF)-23 level, irrespective of the disease type.¹⁰ XLH: X-linked hypophosphatemia; ADHR: autosomal dominant hypophosphatemic rickets; OOM: oncogenic osteomalacia; ARHR: autosomal recessive hypophosphatemic rickets.

[†]Normal value ranges may vary among different laboratories.

In general, hypophosphatemia can produce a wide range of complications including rickets and osteomalacia, cardiac contractility defects, skeletal muscle weakness, anorexia, irritability, confusion, and seizures (Table 85-3), whereas hyperphosphatemia can cause nephrocalcinosis, nephrolithiasis, and band keratopathy. The main causes of hyperphosphatemia are listed in Table 85-4. Moreover, dysregulation of calcium, phosphate and vitamin D metabolism in chronic kidney diseases play an important role in the development of secondary hyperparathyroidism. Such imbalance is associated with renal osteodystrophy and high cardiovascular mortality caused by coronary artery calcification and myocardial fibrosis of the uremic hearts.¹⁷ Animal studies have shown that increased vitamin D activity and hyperphosphatemia are associated with development of features of premature aging,^{18–20} although the human application of such observations requires additional examination. It is, however, clear that the elderly population is particularly at risk of developing clinical complications related to low vitamin D levels, as their ability to generate the precursor of vitamin D in the skin is reduced with the advancement of age, changes in lifestyle that reduce outdoor physical activities, and immobility.^{21, 22} Moreover, the public health messages and widely spread information of the adverse effect of chronic unprotected sunlight exposure, at times, may lead to overprotection. Older individuals may either avoid sunlight

or use protective agents to reduce sun exposure, which would further contribute to inadequate vitamin D levels, leading to osteoporosis and a higher incidence of fracture.²³

CONCLUSION

Older adults tend to have a reduced reserve of water because of their impaired ability to restore water balance. The hormonal mediators of water, electrolyte, and mineral balance are less responsive with age, making older adults more susceptible to age-related diseases. Moreover, the thirst sensation diminishes with age, along with the urine-concentrating abilities; this

all leads to a significantly reduced ability to maintain water, electrolyte, and mineral ion balance, which confers increased risks of disease in elderly individuals.²⁴ Dehydration is often linked to infection, and is associated with mortality in elderly individuals. As such, health care professionals should monitor the risk factors and signs of dehydration in elderly patients to reduce the disease burden related to water, electrolyte, and mineral imbalance.

The prostate gland lies between the bladder base and pelvic floor and is intimately associated with each structure. Secretions of the seminal vesicle and vas deferens are conducted through its substance to the ejaculatory duct, which terminates in the urethra at the verumontanum. Exocrine secretion products, largely under androgenic control, are discharged into prostatic acini and include zinc, citric acid, and numerous enzymes—acid phosphatase, coagulases, fibrinolysins, and proteolytic enzymes—that form a significant part of the seminal plasma acting to support the physiological changes required for transport of spermatozoa.

DEVELOPMENT

The embryonic prostate differentiates in response to androgen secretion by the fetal testis commencing about the eighth week of intrauterine life.¹ Androgenic activity at the time of puberty results in rapid growth to a weight of approximately 20 g by the age of 20 years. Thereafter, weight remains reasonably constant until 40 to 50 years of age when growth of benign adenomatous (prostatic) hyperplasia (BPH) becomes increasingly common with advancing years. Autopsy studies reveal BPH in more than 40% of men in their 50s and almost 90% of men in their 80s;² figures are confirmed by community-based studies involving transrectal ultrasound estimation of prostatic volume.³

Castration before puberty prevents prostatic development as well as the later emergence of both BPH and prostate cancer. Removal of testes in the adult leads to involution of the gland,⁴ but replacement reactivates growth though only to and not beyond the normal adult size.

The action of androgen on the prostate cell is highly complex and only partially understood. Within the prostate, testosterone is converted to its active metabolite, 5 α -dihydrotestosterone (DHT), by the 5 α -reductase enzyme located on the nuclear membrane. Most evidence suggests that prostatic epithelial cells per se are unresponsive to DHT, which acts via signaling between stromal and epithelial components of the tissue; epidermal growth factor (Figure 86-1) and transforming growth factor- α (TGF α) provide the most potent mitogenic stimulus.⁵ The importance of DHT to prostatic growth has been illustrated by the studies of Imperato-McGinley and colleagues into males from the Dominican Republic with an autosomal recessive form of male pseudohermaphroditism caused by deficiency of the 5 α -reductase enzyme. These children develop phenotypically into men at puberty with normal serum testosterone, but with prostates that remain impalpable.⁶ These observations form the basis of the development of the 5 α -reductase inhibitors presently widely prescribed for men with early symptomatic BPH.

Morphology

Early work by Lowsley⁷ concerning the anatomy of the prostate has been superseded in recent years by the extensive studies of McNeal and associates.^{8,9} They described peripheral and central zones of the gland (Figure 86-2) as distinct

from earlier lobe terminology; the central zone, approximately one third of the gland mass, completely surrounds the ejaculatory ducts, whereas the peripheral zone extends to the apex and wraps around the central zone like an eggcup. The benign prostatic hypertrophy mass arises from the periurethral zone (within the transitional zone) and this extends from the bladder neck to the region of the verumontanum, but never caudal to that structure. By contrast, prostate cancer usually arises from the peripheral zone, explaining the difficulties in identifying early disease endoscopically via the urethra (discussed later).

Much confusion has been created by this conflicting prostatic terminology over the years. Surgeons refer to "lateral" and "middle" lobes at operation, but clearly these are all contained within the periurethral transitional zones. The true exocrine prostate is not removed in operations for BPH, although patients frequently assume—not unnaturally—that "prostatectomy" means removal of the entire gland. The operation of radical prostatectomy for cancer does, however, involve extirpation of all prostatic tissue—each zone and contained BPH tissue en bloc.

The substance of the prostate consists of glandular tissue, stroma, and smooth muscle. The preprostatic sphincter lies at the bladder neck (Figure 86-3) and is responsible for preventing retrograde ejaculation during intercourse. This α -adrenergic muscle is inevitably removed during the operation of transurethral resection (TUR) for BPH, but lack of leakage following the procedure shows, however, that this sphincter is not normally responsible for urinary continence. α -Adrenergic fibers are present throughout the gland and

Figure 86-1. Prostate epithelial cells (CAPE-1) in culture. 5- α -DHT stimulation is no greater than control, whereas EGF stimulation leads to significantly enhanced stimulation.

may be implicated in the etiology of chronic inflammatory conditions of the gland (discussed later); pharmacologic manipulation by α -adrenergic blocking agents provides a useful therapeutic approach to patients with mild prostatic obstruction.

The continence mechanism lies intimately related to the apex of the prostate at the level of the pelvic floor. Studies by Gosling¹⁰ and coworkers clearly show that the true external urethral sphincter lies within a sleeve of connective tissue, which separates it from the periurethral striated (levator ani) pelvic floor muscle (see Figure 86-3). This latter muscle is innervated via the pudendal nerve and is responsible for emergency continence requiring extra voluntary effort such as occurs during laughing, coughing, or sneezing. The nerve supply to the (slow twitch) specialized external urethral sphincter remains debatable; horseradish peroxidase techniques have suggested it travels via the pelvic nerve to terminate in the ventral horn of S2-S3 on Onuf's Nucleus X.¹¹ Damage to this sphincter, which by anatomic definition must be distal the verumontanum, during TUR by inexperienced surgeons will inevitably lead to postoperative genuine stress incontinence.

ASSESSMENT OF THE PROSTATE

The prostate is relatively accessible to a number of techniques that may confirm normal or abnormal morphologic features. In a broader sense, prostatic investigations may also encompass assessment of vesicourethral dysfunction, the gland being intimately involved in the storage and voiding disorders of the lower urinary tract.

Rectal examination

Digital rectal examination can by definition only assess the posterior aspect of the peripheral zone of the prostate. The periphery of the gland and the midline sulcus, as well as the texture of the gland may be recorded, but inevitably the experience of the examiner is crucial for accuracy of diagnosis. Rectal examination gives a poor indication of prostatic size; glands may protrude variably into the rectal lumen and other factors, such as a full bladder in acute or chronic retention of urine, may displace the bladder base and prostate downward leading to an erroneous assessment of volume. Additionally, prostatic size is not related to the presence or absence of outflow tract obstruction,¹² but nevertheless the examination remains an essential technique of assessment, particularly with regard to the detection of neoplastic change.

Plain X-ray of abdomen

A single film showing kidneys, ureter, and bladder (KUB) may frequently be performed before prostatic surgery, chiefly to exclude bladder stone. Although the size of the gland cannot be assessed on these films, abnormalities such as calcification may be seen within the gland substance, perhaps indicating past inflammatory disease within the prostatic ducts.

Intravenous urogram

For many years, urography was routinely performed before prostatectomy,¹³ and although it is now accepted that this is unnecessary in the majority of cases,¹⁴ radiologists continue to report on the size of the prostate as judged by shadows on bladder films (Figure 86-4). Clinical experience suggests that such assessment can be very misleading, not only because of other causes of intravesical impressions

Figure 86-6. MRI scans. A, Transverse (axial) section through prostate. Posterio-laterally on the left a distortion of the capsule is clearly seen but penetration has probably not occurred. B, Sagittal section through the prostate. The relationship of bladder, prostate and other pelvic structures is clearly seen. C, Transverse section showing invasion of right seminal vesicle (T3b). Left SV normal.

Magnetic resonance (MR) scans are commonly employed to detect sites of anatomic treatment failure (PSA elevation) after radical retropubic prostatectomy before salvage therapy; recent studies utilize similar imaging following treatment failure of new therapeutic modalities such as high-intensity frequency ultrasound (HIFU).²¹

Overall it is accepted that the acquisition and interpretation of MR scans requires highly trained personnel. Most urologists agree that under such circumstances there is a marginal advantage to MRI as compared to transrectal ultrasound even when performed by an experienced operator in terms of practical staging diagnostics in patients with localized prostate cancer.²²

SERUM MARKERS OF PROSTATIC DISEASE

Acid phosphatase

Since the report of Gutman and Gutman²³ noting high acid phosphatase levels in men with metastatic prostate disease, acid phosphatase estimations were widely used in the

staging of prostate cancer. Unfortunately, lack of sensitivity with regard to localized disease precluded its use for cancer detection, and the test has now effectively been replaced by PSA, although some authorities still employ it to monitor results of therapy in patients with proven bony metastatic disease.

Prostate-specific antigen

This serum protease was isolated from prostatic tissue in 1979 by Wang and associates²⁴ and has rapidly emerged as the most important marker of prostatic epithelial activity. Contrary to widespread public opinion, this marker is not cancer specific (Figure 86-7) but may be elevated in other pathologies such as inflammation or benign hyperplasia. Prostate-specific antigen (PSA) varies with the proportion of ductal epithelial cells, so it is not surprising that higher values are found in patients with larger glands and that age-adjusted ranges have been proposed.²⁵ Damage to epithelial cells either by inflammation or other means such as elective prostate biopsy may elevate levels markedly, often for some weeks, making interpretation difficult in an already

Figure 86-7. Prostate-specific antigen levels in patients with benign prostatic hyperplasia, localized prostate cancer (bone scan negative), and metastatic prostate cancer. Open circles represent seven patients with raised acid phosphatase suggesting metastatic disease despite apparently negative scans. The degree of overlap between the values can be clearly seen, illustrating that PSA is a marker of prostate epithelium and not a specific indicator of prostate cancer. Dotted line: discriminant analysis identifies 58 ng/mL as optimum cutoff distinguishing between skeletal and nonskeletal disease. See text for details. (Data with permission from Pantelides ML, Bowman SP, George NJR. Levels of PSA that predicts skeletal spread in prostate cancer. *Br J Urol* 1992;17:299–303.)

cancer-anxious patient. To avoid unnecessary interventions, *no diagnostic pathway should be entered without at least two confirmatory PSA records.*

In general, cancer may be found on biopsy in 25% to 30% of men with PSA between 4 and 10 ng/mL and an ever-increasing proportion in those with greater values. Most patients with PSA above 50 ng/mL will have skeletal metastases (see [Figure 86-7](#)). Despite age-adjusted ranges cutoff values remain problematic,²⁶ and even below 4 mg approximately 15% of men may have positive biopsies.²⁷

The level of PSA at presentation guides therapeutic choices available to those later found to have cancer confirmed on biopsy. For patients with PSAs >20 ng/mL, high surgical margin positivity following radical prostatectomy determines that this modality is rarely (discussed later) offered under these circumstances; this option is usually offered to patients with a PSA under 10 ng/mL. Naturally, surgery is usually reserved for patients with cancer discovered at an early age (<70 years), but extended life expectancy has led many surgeons, particularly in the United States, to offer this modality to otherwise fit men between 70 and 80 years of age.

Although such radical treatment options may not be appropriate to the majority of elderly men, increased life span and regular medical checkups determine that active management of elevated PSA levels in this group is of increasing clinical importance. *No patient, whatever his age, should be allowed to develop by default the morbidity associated with skeletal metastases.* Annual

PSA checks are a minimum standard for care of the elderly with subsequent management (discussed later) based on PSA risk stratification.

PSA CHARACTERISTICS AND PSA ISOFORMS

Various aspects of PSA characteristics have been studied to improve its performance in relation to clinical risk including PSA velocity (doubling time) and aged-specific reference ranges,²⁵ which, though very helpful in younger men, are of limited value in the older age group where larger volumes of benign tissue serve to confuse the picture.

Studies have extended the utility of PSA by showing that it may exist in the serum in two modes: free and bound or complexed forms.²⁸ Determination of these fractions has added new impetus to the search for a test that can distinguish between BPH and cancer; tumor cells may stimulate production of α -chymotrypsin (ACT), with which binding may occur, leading to higher levels of complexed PSA-ACT than is detected in patients with simple BPH.²⁹ The determination of the free or complex forms in practical terms is usually limited to the most difficult diagnostic group of patients—those with a presenting PSA between 4 to 10 ng/mL. Free levels below 15% have been associated with the increased chance of a positive biopsy (30% to 50%), but a prospective multicenter study showed only a moderate increase in specificity when compared to total PSA values.³⁰ Other isoforms such as proPSA and benign PSA have failed significantly to improve on the free PSA performance.³¹ PCA3, a marker over expressed in 95% of patients with prostate cancer, is measured in urine after rectal examination.³² It shows diagnostic promise particularly in the problematic 4 to 10 ng group but is not yet widely accepted in clinical practice.³³

CLINICAL ASPECTS OF PROSTATIC DISEASE

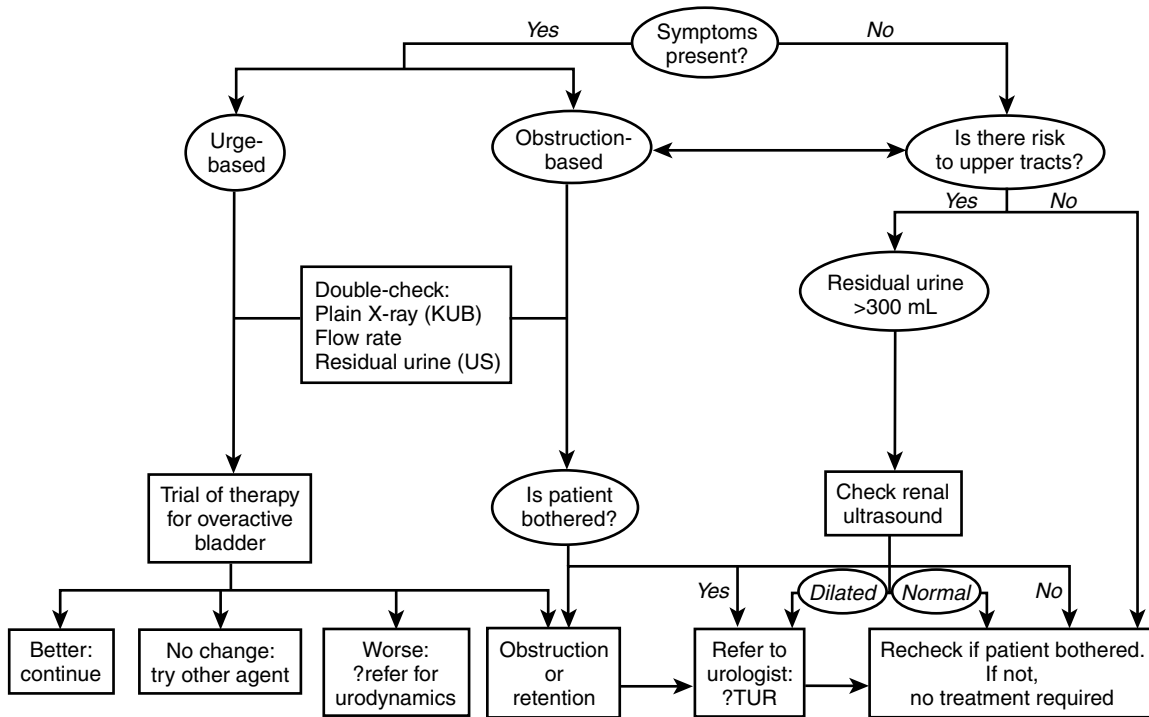

Prostatitis

Inflammation of the prostatic ducts and acini may occur at any age, although it is more common in its typical form in the third, fourth, and fifth decades. The infection, commonly by coliform organisms, may lead to severe systemic illness with high fever, rigors, and acute perineal discomfort. More chronic forms of the disorder may be difficult to eradicate, and it is suggested that spasm of α -adrenergic smooth muscle as well as general pelvic floor tension may contribute to poor duct drainage and, hence, persisting symptoms. Combination therapy using both antibiotics and smooth/ striated muscle relaxants has been advocated in such cases.³⁴

In older men, prostatic infection is usually related to the presence of residual urine and outflow tract obstruction. Infection commonly spreads distally down the vas deferens leading to epididymo-orchitis; in earlier times, bilateral vasectomy was commonly performed at the time of (open) prostatic surgery to prevent this almost inevitable consequence of the infected residual. In general, the presence of lower urinary tract infection associated with poor bladder emptying will demand surgical intervention after a period of suitable antibiotic treatment so as to reduce the residual volume. In patients for whom surgery is inappropriate or contraindicated, direct installation of antibiotics into the bladder by a self-catheterization has been described³⁵ and tried in the elderly with some success.

Benign prostatic hyperplasia

WORK-UP FOR A PATIENT WITH BENIGN PROSTATIC HYPERTROPHY (A NORMAL AGE-ADJUSTED PSA)

SYMPTOM COMPLEXES AND TERMINOLOGY

It has already been noted that BPH arises chiefly in the periurethral zone and affects a high proportion of men as part of the aging process. It is essential to appreciate, however, that the presence of hyperplasia per se does not imply either significant obstruction to the lower urinary tract or association with particular clinical symptom complexes that may be related to vesicourethral dysfunction rather than the enlarged prostate gland.

These three components—hyperplasia, symptoms, and obstruction—have been brought together in a classic diagram by Hald³⁶ (Figure 86-8) demonstrating that although all three may be found in a minority of cases, each may exist alone or with one other in a random association.

Urologists have argued for many years against the usage of the common phrase *prostatism* employed to describe a wide range of symptoms relating to the male lower urinary tract. Not only does this imply, often wrongly, that the symptoms may be due to the hyperplasia, but it also suggests that therapeutic attention to the gland will cure the patient. *Obstruction* should be reserved for those patients proven to be obstructed by urodynamic tests—lower urinary tract symptoms (LUTS) more exactly describe the symptom complex that may or may not be associated with the gland.³⁷

Associated detrusor dysfunction

The reaction of the bladder to the presence of emergent BPH is responsible for the symptom complexes that are associated with the condition. These changes are best understood if the filling and voiding segments of the micturition cycle are considered independently.

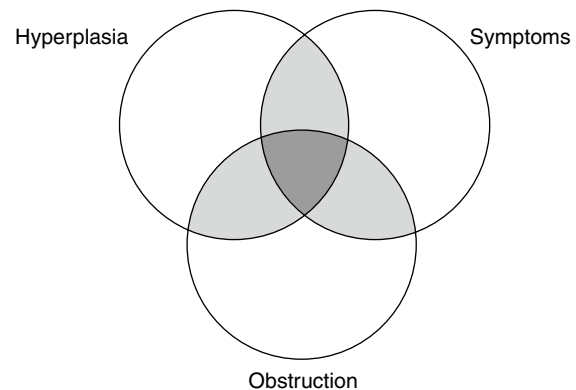

Figure 86-8. Interlocking diagram demonstrating the interdependence of lower urinary tract symptoms, outflow tract obstruction, and hyperplastic tissue when considering symptoms of patients with “prostatism.” Significant volumes of hyperplasia may not necessarily be associated either with obstruction or symptoms, whereas all three may be present in some cases. (Adapted with permission from Hald T. *Urodynamics in benign prostatic hypertrophy: A survey. The Prostate 1989; (suppl 2):69–77.*)

FILLING PHASE

The bladder, receiving urine at 1 mL/min from the kidneys under normal circumstances in temperate climates, normally responds by accommodating the physiologic volume (400/500 mL) at low (less than 5 cm H₂O) intrinsic detrusor pressure. This normal reaction to filling may be observed even in the presence of significant outflow obstruction.

More commonly, however, the growth of the emerging gland may give rise to *bladder overactivity*—abnormal intrinsic detrusor pressure waves during filling that lead the patient to experience

frequency, nocturia, urgency, and possibly urge incontinence. Unfortunately, not all bladder overactivity is related to prostatic obstruction, there being a significant association with old age and neurologic disorder (when overactivity is correctly called detrusor hyperreflexia). Careful studies have shown that approximately two thirds of older men being investigated for "prostatic" symptoms have bladder overactivity, and of these only two thirds will lose their overactivity following prostatectomy.³⁸ Unfortunately, there is no test at present that can detect preoperatively which patients will not lose their bladder overactivity postoperatively. Persistence of the disorder following surgery leaves a very unhappy patient with significantly worse urge symptoms that may take many months to settle (Figure 86-9).

VOIDING PHASE

As with the filling phase, significant prostatic hyperplasia may not necessarily affect vesicourethral function. This observation presumably explains in part the large number of

elderly men who have apparently enlarged glands on rectal examination but who deny any impairment to micturition performance. More typically, however, two types of bladder dysfunction are found in association with BPH—typical high-pressure obstructed voiding or relatively low-pressure underactive detrusor function.

High-pressure/low-flow voiding is the classic reaction to mechanical blockage of the urethra by BPH leading to typical symptoms of hesitancy, poor stream, and gradually increasing frequency by day and night. Additionally (discussed earlier) symptoms of bladder overactivity may superimpose problems related to urgency and urge incontinence.

Low-pressure/low-flow underactive bladders have been recognized only relatively recently but may account for 20% to 25% of patients with outflow tract symptomatology. The reason for the abnormal detrusor function remains unknown, although the condition has been likened to a nonobstructive myopathy.³⁹ Men with low-flow voiding also complain

Figure 86-9. Urodynamic (cystometry) traces from patients with (A) bladder overactivity probably associated with obstruction, and (B) bladder overactivity probably not associated with obstruction. In both cases the patient presented with urgency, frequency, and a poor flow. It remains extremely difficult to determine which patient might benefit from outflow tract surgery without urodynamic investigation. In the cases illustrated, patient A would probably benefit significantly from surgery, whereas patient B would probably become significantly worse. P_{det} , intrinsic detrusor pressure; P_{ves} , pressure within bladder; P_{abd} , pressure within abdomen (rectal line). U: patient experienced urgency sufficient to mention to the investigator. Vertical dotted line: commencement of move from supine to erect investigation position.

of frequency and poor stream (often prolonged and interrupted), which is impossible to separate from high-pressure/low-flow voiding except by invasive urodynamic tests (Figure 86-10). It has been recognized increasingly that inclusion of such low-pressure/low-flow patients in prostatectomy series leads to reportedly “poor outcomes” from the procedure.^{40,41} In this group, an otherwise satisfactory outcome from TURP will not include a “fire hose” postoperative flow rate, but patients may be well satisfied with such outcomes if counseled appropriately in the preoperative period.

Bladder dysfunction and retention

Sudden increase in prostate size, such as may occur during hemorrhage or infarction, may cause acute (painful) retention of urine, but these conditions are unusual. It is a common observation that patients on urologic waiting lists for outflow tract obstruction rarely present in acute retention; by contrast men admitted with this condition have usually not seen their general practitioner previously, and the precipitating factor seems often to relate to acute fluid loading and subsequent overstretching of the unrelieved bladder—as happens, for example, during a long coach trip.

Chronic (painless) retention of urine is broadly divided into two forms: the relatively common low-pressure “floppy” bladder, which may become complicated by infection but which has normal upper tracts; and the unusual high-pressure “tense” bladder, which frequently is seen in patients with few if any lower tract symptoms but which usually is associated with bilateral upper tract dilatation and obstructive uropathy.⁴²

High-pressure chronic retention (HPCR) is specifically associated with sterile urine, late onset enuresis (discussed later), and renal impairment in its later stages. However, elevated creatinine levels may occur for many reasons in the elderly, and this has led to a misdiagnosis of HPCR in many patients with other forms of retention, the true incidence of the condition only being approximately 1 in 20 men with significant retention of urine.⁴²

Investigation in benign adenomatous hyperplasia

Audit studies have led to rationalization of investigations required to assess the patient with BPH. Frequency/volume charts filled in by the patient at home are helpful in revealing nonprostatic causes of urinary tract disorders such as fluid excretion patterns related to cardiovascular disease or excessive tea drinking. Following urine microscopy and culture, rectal examination, and palpation of the abdomen for chronic retention of urine, plain X-ray of the abdomen (KUB) will detect potential operative problems such as bladder calculus. An independent flow rate test, correctly performed (greater than 150 mL voided, no Valsalva pushes permitted) is mandatory (see Figure 86-10). Intravenous urography is no longer advised unless the patient complains of, or is found on urine testing to suffer from, significant hematuria.⁴³ As noted previously, only 5% of men with significant residual urine have upper tract changes; for this reason, if a residual urine of greater than 300 mL is detected by suprapubic ultrasound, upper tract ultrasound is advised to assess renal anatomy. In summary, audit studies suggest that patients without blood in their urine or residual urine < 300 mL do not require any form of upper tract studies before consideration for surgery.

Figure 86-10. Independent flow rate traces. 1: Normal flow rate, younger male. 2,3: Normal flow rates, older male (>70 years). 4,5: Poor flow rate. It is not possible to determine whether the reduced rate is related to outflow tract obstruction or underactive detrusor function—see text for details. Stippled line: lower limit of normality.

Management of patients with benign adenomatous hyperplasia

Many patients come to their doctor because a friend has recently been admitted in acute painful retention or they have seen a television program about prostate cancer. A negative workup followed by reassurance permits these patients to return to their normal lifestyle without the need for any intervention.

PATIENTS WITH INCONTINENCE

Stress incontinence is rare in neurologically normal males and when observed is usually the result of prostatic surgery where the sphincter mechanism has been damaged during the procedure. By contrast, urge incontinence is common, particularly in the older age group, and is chiefly related, in the presence of sterile urine, to bladder overactivity. The therapeutic approach to overactivity is mentioned later and is discussed more fully in Chapter 109. “Late onset” enuresis, mentioned earlier, refers to the loss of a small amount of urine (damp nightwear or underclothes) when the patient is asleep at night or dozing by day. Direct enquiry is usually required for this highly specific symptom of HPCR to be elicited.

PATIENTS WITH HIGH PRESSURE/LOW-FLOW VOIDING

Advice for patients with uncomplicated obstructive symptoms—hesitancy, poor stream, and moderate frequency/nocturia (no urge or urge incontinence)—will depend to a large extent on the patient’s own circumstances and preferences. Frequency may not trouble a retired man as much as a clerical officer at his desk. Reassurance, particularly concerning prostate cancer, may be all that is required, and it is tempting to propose that the reduction in α -adrenergic periprostatic tone might be responsible for the noted improvement.

More usually, however, active intervention will be required, and typically the choice will be between medical therapy and operation (transurethral resection of the prostate, TUR). Only in particularly critical cases will (irreversible) surgery be considered before a trial of (reversible) medical treatment, which typically will involve the use of α_1 blocking agents, α reductase inhibitors (ARI), or a combination of both (Table 86-1).

Table 86-1. α -Blockers

Finasteride
Dual 5α Reductase Inhibitor
Dutasteride

α -Blockers are reasonably fast acting, producing symptomatic relief greater than the observed increment in flow rate might suggest.⁴⁴ Modified release preparations permitting a long-acting single daily dose may be of benefit to elderly patients. α -Blockers are the accepted first-line therapy for most men with obstructive BPH symptoms and are always indicated for those patients undergoing trial removal of urethral catheter such as maybe required, for example, after routine orthopedic surgery.

The slow ARI onset of action has long been recorded.⁴⁵ Finasteride, a type 2 ARI, was initially considered no better than placebo when treating symptomatic BPH in the veterans' group study,⁴⁶ but despite its very slow onset of action, the Medical Therapy of Prostate Symptoms (MTOPS) Study later suggested a benefit for Finasteride in symptom scores and risks of subsequent painful retention in patients with relatively small glands (a mean of 36.3 mL).⁴⁷ The socioeconomic cost-effectiveness of the reduced acute retention rate had been questioned in a widely quoted editorial comment⁴⁸ on an earlier study, which observed that treatment with Finasteride for 4 years reduced the probability of surgery and acute painful retention.⁴⁹ Nevertheless, a recent analysis of MTOPS follow-up data demonstrated that Finasteride led to a significant reduction in prostate volume (25%) over a 4½-year period;⁵⁰ whether such dual therapy remains economically viable continues as a matter of debate.

Further combination studies have examined men with larger (a mean of 55 mL) prostates, perhaps more appropriate for an elderly population, and found symptomatic improvement using an alpha blocker and the dual 5ARI dutasteride, which was greater than either drug taken alone.⁵¹ Importantly, it is advisable that any Finasteride cancer-related anxieties aroused by the Prostate Cancer Prevention Trial (PCPT) should be discussed carefully with the patient before ARI treatment.⁵² Finally, it is noteworthy that, despite the relatively slow onset of action, Finasteride has been found to be effective in reducing bleeding from the prostate surface, which can be persistent and troublesome in some elderly patients.⁵³

For patients with severe "simple" obstruction, TUR offers the unquestioned gold standard in terms of measured outcomes. Despite the significant comorbidity of the elderly treatment population, a rapid resolution of symptoms ensures that the great majority of patients submitted with the correct indications are delighted with the results of treatment.

PATIENTS WITH UNDERACTIVE DETRUSOR FUNCTION

It has already been emphasized that it is not possible to separate patients with underactive function from those with true obstruction unless full preoperative urodynamic tests are performed;⁴⁰ hence, overall, it is not surprising that in the absence of such tests, some patients are not satisfied with their postoperative micturition performance.⁴¹ Nevertheless, some improvement is seen and the disappointment is a relative measure of the difference in postoperative flow rates between obstructive and underactive groups. The reversibility of medical therapy makes it ideal for a trial of treatment in this group, and transurethral resection may be reserved for those who are dissatisfied or who cannot tolerate blockade therapy.

PATIENTS WITH IRRITATIVE SYMPTOMS

As previously noted, overactive bladder (OAB) is common in men with both obstructed and unobstructed bladders. Although a complete diagnostic picture may be obtained by urodynamic tests on each patient, few units can afford the academic luxury of this purist approach; hence, trials of therapy are commonly practiced in elderly patients with the frequency urge syndrome (see Figure 86-9A).

Physiologic bladder contraction is mediated by a stimulation of postganglionic parasympathetic cholinergic receptors on detrusor smooth muscle, and of the forms of muscarinic receptor, the M3 subtype is thought to be the most important for bladder contraction.⁵⁴ Hence, atropine and atropine-like agents will induce a lessening of the contraction wave with corresponding decrease in detected urgency by the patient.

Early descriptions of such pharmacologic agents^{55,56} and subsequent variations in release rate⁵⁷ were precursors of a plethora of publications comparing efficacy, safety, and side-effect profiles.⁵⁸⁻⁶⁰ New-generation extended release (ER) preparations such as tolterodine ER and solifenacin have been studied, although only a minority of the patients were elderly men.⁶¹ Similar constraints applied to a systematic review of antimuscarinic therapy, and it is acknowledged that more studies are required to address urge problems in the elderly population.⁶²

Despite these laudable efforts, many will be familiar with the statement about any treatment for overactive bladder: "one is always surprised when it works."

New modalities for treatment of benign prostatic hyperplasia

Although it is accepted that transurethral resection remains the gold standard for treatment of patients with obstructive BPH,⁶³ a number of new modalities have been introduced, including prostate incision, laser therapy, stent therapy, and varieties of thermotherapy. All these techniques have their vociferous supporters, but all agree that for the patient with a significant volume of hyperplastic tissue obstructing the bladder outlet, endoscopic transurethral resection remains the treatment of choice. The need for critical evaluation of the new technology in terms of outcome measures continues to be debated in urologic circles.

Prostatic surgery in the elderly

Advances in anesthetic techniques and in some cases introduction of preoperative cardiopulmonary testing⁶⁴ have allowed a complete reappraisal of treatment options in the

elderly, and it is now rare for a patient to be refused prostatectomy on anesthetic grounds alone. Although many patients over 100 years of age have been treated satisfactorily—an unnecessary urethral catheter is undesirable at any age—the chief contraindication to operation is presently the inability of the patient mentally to appreciate what is being offered to alleviate his symptoms. Hence, apart from a few seriously compromised patients, modern anesthesia permits straightforward decisions to be made about the elderly patient, and "lesser" operative techniques such as urethral stent insertion⁶⁵ no longer require consideration under these circumstances.

Prostate cancer

Since the 1980s, prostate cancer has increasingly been recognized as a major health problem for both younger and older male patients.^{66,67} It is now the most common cancer

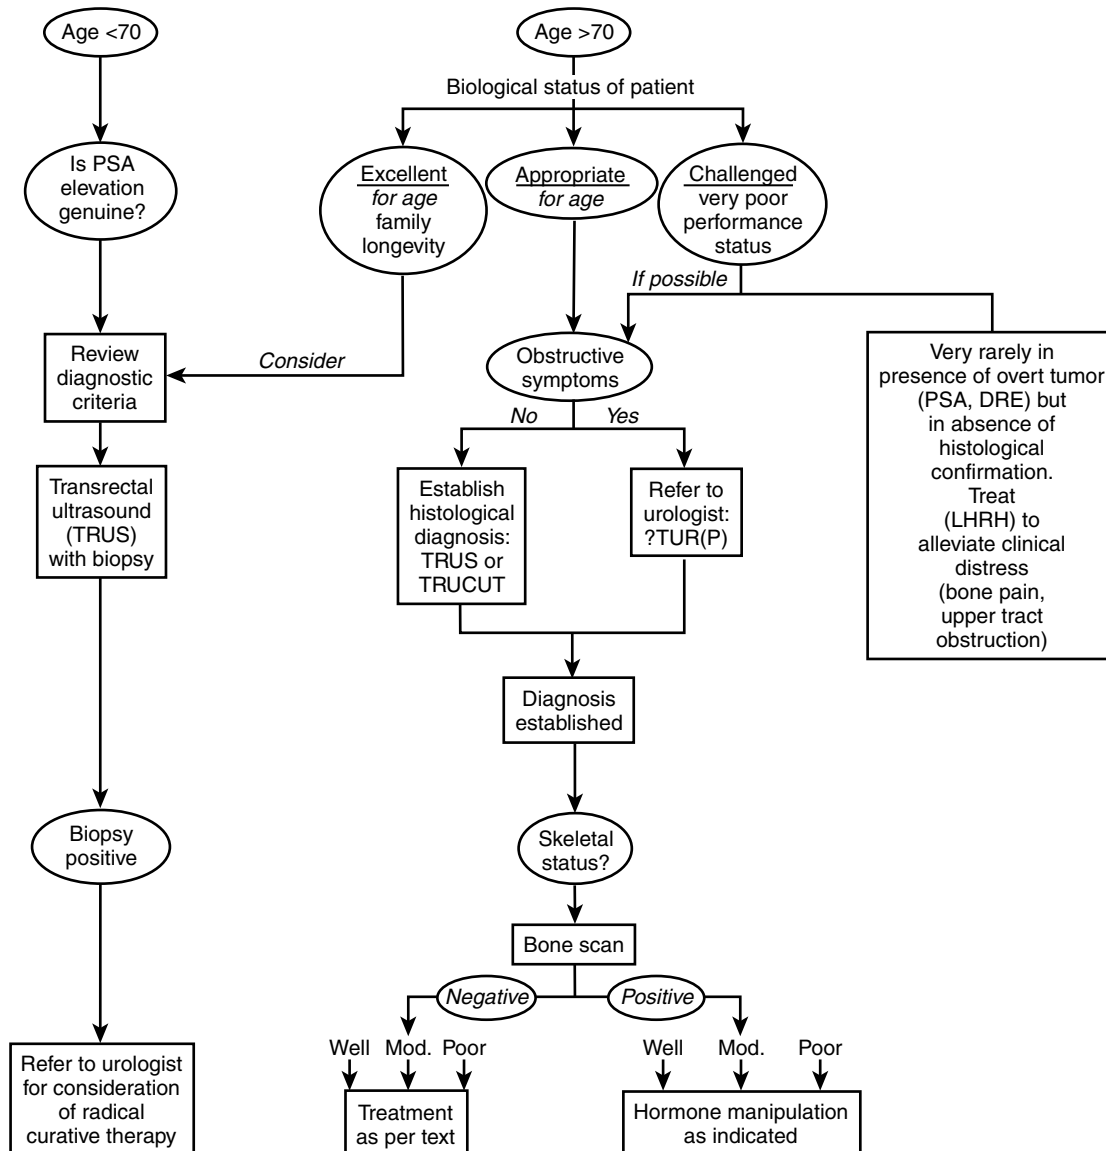

diagnosis in U.K. men, accounting for 24% of new cases,⁶⁸ 35,000 of which were diagnosed in 2004.

However, the increasing age of the population and the very slow growth of some tumors mean that, unlike many other neoplasms, not every cancer is a life-threatening event for the patient. Many older men die *with* rather than *of* their prostate cancer, but the prediction as to whether the disease as identified in any one individual patient carries a good prognosis remains extremely difficult. This overall problem is illustrated by the wide difference between the *incidence* and *mortality* of the disease in many Western countries.

In the United States in 2002, the incidence/mortality ratio was 8:1, whereas in Holland it was 2.6:1,⁶⁷ demonstrating that the diagnostic tests were detecting many more cancer cases than were later dying of the disease. The essential question relates to which of the detected cancers

Prostate cancer

WORK-UP FOR A PATIENT WITH PROSTATE CANCER
CONCENTRATING ON PATIENTS OVER 70 YEARS OF AGE

Well, Gleason ≤ 6 ; Moderate, Gleason 7; Poor, Gleason ≥ 8

are capable of progressing and leading eventually to the patient's death.

SITE OF DISEASE

Anatomically, most cancers (70% to 75%) are found in the peripheral zone of the gland (see Figure 86-2). Approximately 20% of lesions are thought to originate in the transitional zone, whereas the remainder are located in the central zone. As such, the educated finger on rectal examination should detect most nodules or palpable lesions; in a minority, the transurethral resection of the transitional zone (i.e., for an obstructive lesion thought to be BPH) may occasionally eradicate unsuspected tumor in that area.

EPIDEMIOLOGIC STUDIES

Prostatic disease is rare in the Far East, Japan, and China. Classical migratory studies have clearly shown, however, that the incidence of the disease increases as males move to a more Western lifestyle. Significant racial differences also exist; within the San Francisco Bay area, Japanese Americans are eight times less likely to suffer from the disease than African Americans.⁶⁹

PROSTATE CANCER AND THE ELDERLY

It has already been mentioned that the disease is being diagnosed at an earlier stage in younger men. At the present time, the question of whether to screen for prostate cancer and which treatment to offer for the cases so detected remains at the forefront of medical debate.⁷⁰ Views are strongly expressed because a tumor discovered at age 53, however indolent its growth pattern, is likely to carry a significant risk of death within the patient's natural life span. For the older person, however, the decision criteria are different, and it is in this context that the following variants of disease presentation are discussed.

Localized prostate cancer

Localized prostate cancer may be detected incidentally or it may be discovered as part of the investigation of a man with developing lower urinary tract symptoms. Prostate-specific, antigen-led ultrasound biopsy may reveal carcinoma (stage T¹C, Table 86-2) in a patient who merely presented with anxiety, no symptoms, and a normal rectal examination (i.e., BPH in texture). However, for the elderly patient, lower urinary tract symptoms—irritation or obstruction—are more often the reason for a first visit to his doctor.

PSA ELEVATION IN OLDER MEN

Although elevation above the age-related cutoffs will almost invariably lead to TRUS-led biopsy in younger men, the same interventional stance may not be appropriate in all older men. Biologically fit septuagenarians *may* follow the protocol pathway of their younger counterparts (discussed later), but increasingly as age progresses management will be more conservative bearing in mind the high incidence of microscopic prostate cancer found in postmortem studies of urologically asymptomatic men. Hence, the common referral of an elevated PSA in an older man (e.g., PSA 18, age 80) will demand an exquisite level of judgment from both doctor and patient, who, after full informed consent, will have to decide between biopsy and an expectant policy. The answer of course will depend on the individuals concerned, but there must be a strong argument for a careful watchful waiting approach and diagnostic/intervention only if a slowly rising (minimal doubling time) PSA enters the range (35 to 40 ng/mL) statistically associated with impending bony metastatic disease, which, as mentioned previously, must be avoided at all costs. This argument is driven by the scientific literature identifying therapy-related problems such as bone fracture associated with long-term androgen deprivation.⁷¹

Table 86-2. TNM Staging of Prostate Cancer: 1997 Revision

Primary Tumor, Clinical (T)		Primary Tumor, Pathologic (pT)		Regional Lymph Nodes (N)		Distant Metastasis (M)	
TX	Primary tumor cannot be assessed	pT2	Organ confined	NX	Regional lymph nodes cannot be assessed	MX	Distant metastasis cannot be assessed
T0	No evidence of primary tumor	pT2a	Unilateral	N0	No regional lymph node metastasis	M0	No distant metastasis
T1	Clinically inapparent tumor not palpable or visible by imaging	pT2b	Bilateral	N1	Metastasis in regional lymph node or nodes	M1	Distant metastasis
T1a	Tumor incidental histologic finding in 5% or less of tissue resected	pT3	Extraprostatic extension			M1a	Nonregional lymph nodes
T1b	Tumor incidental histologic finding in more than 5% of tissue resected	pT3a	Extraprostatic extension			M1b	Bone(s)
T1c	Tumor identified by needle biopsy (e.g., because of elevated PSA)	pT3b	Seminal vesicle invasion			M1c	Other site(s)
T2	Palpable tumor confined within prostate	pT4	Invasion of bladder, rectum				
T2a	Tumor involves one lobe						
T2b	Tumor involves both lobes						
T3	Tumor extends through the prostatic capsule						
T3a	Extracapsular extension (unilateral or bilateral)						
T3b	Tumor invades seminal vesicles						
T4	Tumor is fixed or invades adjacent structures other than seminal vesicles: bladder neck, external sphincter, rectum, levator muscles, or pelvic wall						

Following histologic confirmation, bony metastatic disease may be confirmed by isotope bone scan, but it has been suggested that PSA is a superior predictor of a negative scan if levels are less than 20 ng/mL, and thus the time-consuming and expensive scan may be avoided.⁷² Regardless of the economic arguments, however, the demonstration of a negative bone scan may be a great comfort to an older man who is likely to have widespread osteoarthritic changes in his skeleton.

TREATMENT OF LOCALIZED DISEASE

Four options are available for the treatment of older men with apparently localized disease: watchful waiting, radical radiotherapy, brachytherapy, or radical prostatectomy. The therapeutic choice will depend *inter alia* on the histologic grade of the tumor, the PSA level at diagnosis, and the biologic age of the patient.

WATCHFUL WAITING OR ACTIVE SURVEILLANCE. Since early studies from Scandinavia⁷³ and England,⁷⁴ there has been a general admission that overtreatment is common in older men who may never experience a clinical problem following discovery of the disease,⁷⁵ and hence major efforts have been made to establish safe and expectant treatment protocols for patients, particularly those with low-risk disease.^{76,77} Moderate and particularly poor-grade levels of disease have always been associated with poor survival.⁷⁴

Watchful waiting implies a low-key but persistent observation of an often elderly man who may have either histologically proven disease or nonbiopsied PSA elevation (discussed earlier); by contrast, active surveillance implies an interventional management protocol that will include rebiopsy of the gland at specified intervals to detect silent (non-PSA-detected) upgrading of histologic pattern.⁷⁸ The ideal protocol for such regimes has yet to be agreed,⁷⁹ but increasing (Internet) awareness of the overtreatment dilemma has led even younger patients (e.g., age 60 to 70) to explore the safety aspects of expectant treatment with their physicians.⁸⁰ The personal and economic importance of this debate, particularly in North America, is emphasized by the remarkable incidence/mortality data already mentioned.

CONVENTIONAL RADIOTHERAPY. Local tumor control is dependent on clinical T stage and tumor bulk. In the United Kingdom, radiotherapy was traditionally the mode of treatment for those patients with nonmetastatic (i.e., bone scan negative) disease in whom markers, grade or stage (as judged by rectal examination), pointed to the need for local primary control rather than an attempt to "cure" localized disease. In general, at that time, results of comparative trials with surgery were unfavorable, but it is generally agreed that patients entered to the radiotherapy arm of such studies were poorly staged when compared to those submitted ("selected") to radical surgery. However, centers in the United States in particular have reported more favorable outcomes when patients, accurately staged (including PSA) for localized disease, were submitted either to radical radiotherapy or radical surgery.^{81,82} Hence, for the many older men in whom watchful waiting or radical surgery is either contraindicated or not the patient's choice, radiotherapy remains an entirely acceptable method of treatment with minimal short- or long-term complications.

BRACHYTHERAPY. Brachytherapy—the implantation of an interstitial radiation source within the prostate—has gained rapid popularity in both younger and older men with localized prostate cancer. Relative simplicity, short (if any) inpatient stay, and rapid return to normal activity constitute the unarguable attractions of the technique. Within the United States it is estimated that brachytherapy, chosen by only 4% of men with localized prostate cancer in 1996, will soon be the treatment of choice for the majority, particularly elderly patients.⁸³

Selection criteria for men suitable for brachytherapy are strict. Large prostates (>60 mL), prominent median lobes, previous transurethral resection of the prostate (risk of incontinence), and significant comorbidity (previous pelvic irradiation, diabetes) are contraindications. The treatment morbidity includes irritative voiding symptoms (80%), urinary retention (13%), and late complications of radiation proctitis, stricture, and incontinence.⁸⁴

Along with external beam and surgery, brachytherapy has established itself as a safe, reliable treatment for correctly staged localized prostate cancer and is a popular choice for elderly patients in particular who wish to consider active treatment options. As always, technical expertise allied to up-to-date hard and software will be necessary to deliver optimum results.⁸⁴

RADICAL SURGERY. Radical prostatectomy has always been the first choice in the United States for the treatment of localized prostate cancer, particularly in younger men. However, enthusiasm has been taken to levels where > 90% of patients with low or moderate risk cancers elect for active therapies.⁷⁵ Such observations have confirmed the trend to overtreatment,⁸⁵ particularly in the elderly; to emphasize this point it has been noted that, in the this age group, more than 300 men would have to undergo surgery to prevent one prostate cancer death at 10 years.⁷⁶

Nevertheless, the treatment preference of biologically fit elderly men with 10-year life expectancy should be respected. Although the majority of the surgical workload will naturally involve younger men, good results can be expected with carefully selected older patients. These comments and caveats apply equally to patients choosing either open or the newly fashionable robotic assisted surgery.⁸⁶

TREATMENT SUMMARY

Observational studies, while making due allowance for pathologic stage and grade, have shown that the biologic age of the patient is the most important factor in making a decision between the treatment options. Whereas there is little doubt that the man of 55 years of age should be offered radical therapy on the basis of the 10- to 15-year predicted survival data, for men over 70 the choice widens to include more conservative approaches such as watchful waiting/active surveillance. Patient preference remains an important part of the therapeutic decision process.

Local-regional disease

The first problem with local-regional disease is to define its boundaries. Disease metastatic to bone, described later, is self-evident; more problematic is the boundary between truly localized (theoretically curable) prostate cancer and disease that has spread away from the gland so as to render

it, in all probability, an eventual candidate for palliative treatment only. Certainly in the United Kingdom, where the "PSA screening effect" has generally had a lesser impact than in the United States, patients with locoregional disease constitute the majority of new patients attending the prostate cancer clinic at the present time.

Before the PSA era, anatomic findings on DRE essentially defined "locally advanced" disease—T3 or T4 prostates with a negative bone scan. Subsequently, Partin (and others) added preoperative PSA and Gleason biopsy data to clinical stage data to produce tables capable of predicting the pathologic stage.^{87,88} Naturally, these tables were primarily designed to indicate whether curative therapy was possible for an individual patient, but the reverse and probably more important observation was to predict and define the group with locoregional disease.

Subsequently D'Amico further refined the chances of disease spread by risk stratification; "high risk" being defined as stage T2c, PSA >20 ng/mL and biopsy Gleason score \geq 8.⁸⁹ Such disease, even in the presence of apparently negative cross-sectional imaging, will have a high chance of micrometastatic locoregional spread.

Clearly, spread away from the prostate will demand treatment strategies able to contain the threat of micrometastatic disease; combinations of radiation therapy, androgen deprivation therapy (ADT), or chemotherapy remain under active investigation.

Two important randomized prospective studies have addressed the role of ADT in this patient group. In these trials Neo adjuvant⁹⁰ and adjuvant⁹¹ luteinising hormone (LHRH) therapy was found significantly to improve local control in patients treated with external beam radiotherapy. Although it might be expected that patients randomized to early hormone therapy might show an initial treatment advantage, updated reports^{92,93} have confirmed an ongoing benefit, at least in certain patient subgroups. It seems likely that these and other studies⁹⁴ will impact positively on the large number of patients presenting with nonlocalized non-(bony) metastatic disease.

Metastatic disease

Until relatively recently, a majority of patients with prostate cancer presented with bony metastases.⁷⁴ Increased public awareness and PSA "screening" since the mid-1990s have reduced this figure to 10% to 12% at presentation,⁹⁵ although great geographic variation continues to exist. Worldwide it is accepted that even with immediate treatment, the survival of such patients is approximately 50% at 2 to 2½ years and 10% to 14% at 5 years.

TREATMENT OF METASTATIC DISEASE

HORMONAL MANIPULATION. Androgen deprivation treatment (ADT) has, since 1940 when Huggins discovered the hormone-dependent nature of the tumor, been the mainstay of treatment for metastatic prostate cancer. Remission occurs for a variable period—usually 9 to 12 months—before prostate markers, which usually fall following treatment, start to rise again. Approximately 10% to 15% of patients fail to respond significantly to the hormonal manipulation, which may be achieved by either medical or surgical means. Bilateral subcapsular orchidectomy was the traditional approach to androgen deprivation, and the serum testosterone

rapidly falls into the "castrate" range. Medical therapy by LHRH analogue⁹⁶ has, however, become widely established, although the injections are expensive and the serum testosterone does not fall for 8 to 10 days, which may be of clinical importance. It has to be emphasized to the patients that the side-effect profile of these two treatments—impotence and hot flushes—is identical, a point not always well made by the manufacturers.

Diethylstilboestrol (DES) 5 mg was for many years used to achieve the required hormonal manipulation. Well-publicized cardiac toxicity, however, has led many to avoid this medication even at the lower 1 mg dose, although some continue to advocate the approach in combination with daily aspirin.

NONSTEROIDAL ANTIANDROGENS. Nonsteroidal antiandrogens have the attraction of blocking the action of testosterone peripherally without the major side effect problems associated with traditional hormonal manipulations. Each compound, however, has particular drawbacks. Flutamide leads to significant gastrointestinal upset and diarrhea, whereas bicalutamide, which has the attraction of once daily dosage,⁹⁷ also causes some breast tenderness and leads to elevation of serum testosterone because of a central agonist action effecting a rise in luteinizing hormone. Bicalutamide is licensed for the treatment of metastatic disease in conjunction with LHRH analogues.

Androgen withdrawal syndromes whereby altered expression of the androgen receptor permits an agonist response to antiandrogenic agents, particularly Flutamide, have been described.⁹⁸ Predictive factors for such a response are high baseline alkaline phosphatase and prolonged drug exposure. The literature suggests that significant PSA reductions might occur in one third of patients with a time to onward progression of 3 to 6 months, and a trial withdrawal of nonsteroidals should always be undertaken in those patients on dual therapy with PSA progression.

Maximum androgen blockade (MAB), the addition of an antiandrogen to (usually) LHRH therapy, has been intensively investigated. Although emotive arguments are frequently put forward, particularly for younger, fit patients with metastases, no significant benefit has been found to accrue from dual therapy.^{99,100} Despite this scientific conclusion, it is difficult to avoid offering dual therapy in some patients.

THE TIMING OF TREATMENT

Unusually for a neoplastic condition, the timing of treatment for androgen sensitive prostatic disease is a matter for debate; different approaches can be taken under differing circumstances. Intermittent deprivation therapy and the maintenance of the androgenous environment for cases with low-risk nonmetastatic disease are examples of this dilemma.

Intermittent androgen suppression (IAS) is a technique advanced on the Darwinian basis that the emergence of androgen independent cells might be restricted by the return of the androgenous environment; an improved quality of life (especially sexual activity) might accompany such restoration. Implicit also is the assumption that immediate is preferable to deferred treatment (discussed later). Inclusion criteria, treatment regimens, and timing protocols for IAS vary considerably;¹⁰¹ most investigators exclude patients who fail to achieve a nadir of 4 ng/mL PSA after 6 months

initial (usually combined) therapy and patients with metastatic disease in bone (TxNxM1b) at diagnosis. Ideal cases are patients with biochemical failure after surgery or radiotherapy and some men with TxN1-3 M0 disease, although it is realized that this latter group is associated with enhanced survival on conventional treatment.¹⁰²

The debate on early or delayed treatment was reignited when the Medical Research Council (MRC) initiated a trial of less than ideal construction, which was widely quoted on publication in 1997.¹⁰³ The trial showed clearly that delayed therapy in patients with metastatic disease to bone was associated with significantly worse morbidity—but not inferior prostate cancer-specific survival—and there seems little doubt that treatment should be commenced immediately in such patients even if no symptoms are present; this applies particularly to patients at risk from spinal collapse. (It had been argued previously that patients with asymptomatic bone metastases [a relatively small group] should not receive immediate ADT as they would suffer the side effects of treatment with no possibility of symptomatic improvement.)

Conclusions relating to patients with nonmetastatic disease were more controversial. Early work by the veterans research (VACURG) group when corrected for cardiovascular (estrogen associated) mortality as well as later studies involving node positive postprostatectomy patients¹⁰⁴ seemed to suggest that early ADT would be beneficial for overall survival. The MRC Mo subanalysis also supported this conclusion,¹⁰³ but later analysis of long-term follow-up data reversed this finding. EORTC 30891 subsequently reported a “modest” advantage for early ADT in terms of survival but no difference in prostate cancer mortality between the treatment arms. The reason for the reduction in non-cancer deaths, which led to the survival advantage in the immediate group, remains unexplained.¹⁰⁵

It may be concluded that, bearing in mind the prevalence of CaP in the elderly population, the case for early ADT, particularly in newly diagnosed low-risk disease in elderly patients, has yet to be made with conviction. Meticulous watchful waiting protocols would appear to be the prudent way forward for these patients.

ROLE OF ESTROGENS AND CHEMOTHERAPY

The great majority of prostate cancers eventually achieve hormone refractory status and regrowth commences. This point probably marks the most difficult therapeutic decision point for the physician and, particularly, the older patient. Estrogens (DES) may directly inhibit growth factors and may produce a PSA response for up to 6 to 9 months in some cases.¹⁰⁶ Naturally, such patients will be carefully monitored for thromboembolic events, and the estrogen will typically be prescribed with low-dose (75 mg) soluble aspirin to counter such side effects. At the time of writing, diethylstilboestrol (1 to 3 mg daily) is probably the first treatment choice for patients with newly emerging hormone-resistant prostate cancer.

Chemotherapy, certainly in the United Kingdom, has not previously been routinely associated with older men suffering from prostate cancer. Nevertheless, therapeutic advances and reduced toxicity are gradually opening the door to a treatment modality that intuitively should be the rational answer to a disease with a widespread micrometastatic profile. Modest survival advantage from Docetaxel-based

therapy in patients with bone metastases¹⁰⁷ has encouraged further work to identify ideal patient groups to undergo further trials; common and distressing side effects include fatigue, diarrhea, Alopecia, and neuropathy.

Theoretically, chemotherapeutic options with lesser toxicity should be of great interest in the nonmetastatic (e.g., postprostatectomy) setting. Slow trial recruitment, however, underscores the reluctance to submit patients—particularly older more frail patients—to chemotoxicity. Active debate continues on this question, which centers on quality of life for the elderly.

BONE PAIN

Bone pain remains the most troublesome aspect of the disease for the patient and it is often difficult to manage. Radiotherapy remains the basis of local control. Radiation should not be used in hormone-naïve disease as ADT will usually provide rapid and lengthy relief from pain. Focal treatment to local reemergent lesions (“spot welding”) is effective for pain relief and may (significantly) prevent fracture and improve quality of life. Metabolically guided therapies such as diphosphonate treatment may reduce skeletal related events, although the natural history of microfracture associated with the metastatic skeleton has always made objective assessment of benefit difficult.¹⁰⁸ Radionuclide-based therapy (Strontium⁸⁹) and hemibody radiation¹⁰⁹ are infrequently used today.

MANAGEMENT OF BONE PAIN. The management of a patient in the early stages of prostate cancer is relatively simple. Given that satisfactory exchange of information has occurred, first-line therapy is usually effective, and the patient may be seen and reassured on an infrequent basis. The emergence of resistant disease and bone morbidity in particular heralds the need for multidisciplinary team support. Apart from any medical and surgical intervention that may be required, close cooperation with a radiation – oncologist will be essential. Perhaps most important will be the integrated team of support nurses with analgesic expertise who will be crucial to the administration of palliative care at the end of the disease process.

PROSTATE CANCER IN THE ELDERLY: A PATIENT SYNOPSIS

Despite every endeavor, those patients who are destined to progress do so relentlessly, albeit at a slow, drawn-out pace. This poses particular problems as age advances.

Figure 86-11 illustrates a typical episode in an 82-year-old patient presenting with LUTS and subsequently diagnosed with well-differentiated Gleason 3+3 adenocarcinoma following TUR in 1996. PSA was stable between 20 and 25 in the years before the transurethral resection. Bone scan was negative at diagnosis, remaining so during four further tests (red dots) but converting in December 2005.

A watchful waiting policy was instituted, but slow progression led to hormonal manipulation by subcapsular orchidectomy in 1997 (a). Following a long period of remission, hormone-resistant disease gradually emerged, and bicalutamide was added in 2004 (b) but stopped 10 months later because of further progression (c). Stilbestrol was then commenced in 2005, and this was effective

Figure 86-11. Sequential PSA records in man diagnosed with low-grade prostate cancer at age 82. See text for details.

KEY POINTS

The Prostate

Anatomic knowledge of the sphincter apparatus assists understanding of continence mechanisms.

Physicians offering prostate-specific antigen (PSA) tests to patients should fully understand the implications of an abnormal result.

"Prostatic" symptoms may not be related to disease of the prostate gland.

Elderly patients with localized prostate cancer have a wide range of therapeutic options.

Elderly patients with metastatic prostate cancer should be treated, even if no symptoms are present.

for 12 months (d). Despite the final PSA rise and eventual development of bony metastases, chemotherapy was declined and the patient died on the palliative care pathway in 2006 aged 92.

Quality of life was excellent for the great majority of the patient's final years. It is to be regretted, as noted earlier, that a low-toxicity chemotherapy regime is not available to arrest disease before M1 conversion.

Oliver Milling Smith

AGE CHANGES IN THE GENITAL TRACT

The female physiologic aging process accelerates after menopause, particularly in the genital tract.

Hormone changes

In perimenopausal women the ovary becomes less responsive to gonadotrophins, which results in a gradual increase in the circulating levels of follicular stimulating hormone (FSH) and later luteinizing hormone (LH) and a subsequent decrease in estradiol concentrations. FSH levels can fluctuate markedly several years before menses cease, so is a poor diagnostic test, but eventually follicular development fails completely, estradiol production is no longer sufficient to stimulate the endometrium, amenorrhea ensues and FSH and LH levels are persistently elevated, reaching peaks 3 to 5 years after menopause. Thereafter there is a gradual decline to premenopausal levels 20 years later.¹ In the reproductive years, the ovary has three components for steroid biosynthesis: the maturing follicle, the functioning corpus luteum, and the stroma. After menopause, the stroma is the only source of estrogen.

Estrone is the major postmenopausal estrogen and it is derived from the conversion of androgens, mainly androstenedione, produced by the ovaries and adrenal glands. The efficiency of this process increases with age and estrone levels rise to four times that found in young women. This conversion also correlates with weight as fat has the ability to aromatize androstenedione to estrone.²

The other postmenopausal estrogens include estriol, which is weak and does not seem to have a significant role, and estradiol, which although secretion is minimal with blood levels being reduced by 90%, has 10 times greater biologic activity than estrone so still has an important role to play in maintaining hormone dependent tissues.³

Progesterone in the postmenopausal woman is derived mainly from the adrenal glands and levels fall steadily. Production of testosterone remains relatively unchanged and surgical oophorectomy will, therefore, result in a decrease of serum testosterone levels of up to 50%.⁴

Anatomic changes

The major change is atrophy, which results in smaller and smoother structures, flattened epithelial surfaces, and fibrous stroma with much reduced vascularization and fat content.

OVARY

The postmenopausal ovary is small and sclerotic with absence of follicular activity. The cortex involutes and germinal inclusion cysts are found. Lipid droplets may be seen in the stroma as evidence of continuing steroidogenesis.

UTERUS

There is a marked reduction in uterine size so that the uterine body to cervix ratio reverts from the 4:1 of reproductive life to the 2:1 of childhood. In the myometrium, there

is interstitial fibrosis and thickened blood vessels due to obliterative, subintimal sclerosis. The endometrium becomes a single layer of cuboidal cells with a few inactive glands, which may be dilated because of blocked ducts.

CERVIX AND VAGINA

The cervix becomes more flush with the vaginal vault and the squamocolumnar junction recedes into the endocervical canal; this can cause stenosis of the external os.

The vagina becomes thinner, atrophic, and less elastic which can make it more vulnerable to trauma. Reduction in estrogen also reduces natural defenses against infection.

VULVA

Postmenopausal changes are characterized by skin shrinkage, loss of prominent landmarks, and sparse, graying hair. The epidermis is thinner although there is increased keratinization. These features may coincide with a vulvar epithelial disorder (discussed later).

PELVIC FLOOR

Aging produces pelvic floor weakness. Damage to the nerve supply starts with parturition⁵ and progressive denervation is found in association with prolapse⁶ (discussed later). An important element of pelvic floor support is collagen, which diminishes after the climacteric.

MENOPAUSE

The cessation of ovarian function at menopause has many short- and long-term consequences. Early menopause symptoms (e.g., mood swings, hot flashes, and night sweats) affect most women to varying degrees and those who have problems may be treated effectively by hormone replacement therapy (HRT).

More relevant is the prolonged effect of estrogen deficiency postmenopausally. The average age of menopause has remained around 51 years for centuries. With female life expectancy now reaching over 80 years, there has been a massive increase in the number of postmenopausal women, and the morbidity/mortality secondary to the effects of ovarian failure becomes increasingly important. At present there is poor correlation between early symptoms and late consequences; therefore, it is not possible to select women for prophylactic HRT to obtain the most beneficial outcome.

Osteoporosis

In postmenopausal women there is accelerated bone loss so that by age 70 years 50% of bone mass is lost, whereas men lose only 25% by 80 years.⁷ This is due to increased bone resorption by osteoclasts and reduced new bone formation, leading to increased turnover. Altered calcium metabolism may be a contributory factor, but the primary defect is generalized connective tissue loss with reduced bone mineral content following breakdown of the organic collagen matrix.⁸

The resultant osteoporosis dramatically increases the elderly female fracture rate: 50% of women aged 75 years will have sustained one or more fractures at the most common sites of wrists, vertebral bodies (resulting in the classic “Dowager’s hump”), and neck of femur. The latter is the most significant consequence of osteoporosis because of its high morbidity and mortality: there is a 20% death rate within the first year, and half of survivors will fail to regain their independence.⁹

Older people are also at increased risk of falls: 35% to 40% of over 65s living at home fall at least once a year, rising to 50% for the over 80s.¹⁰ Ten percent to 15% of falls lead to serious injuries, with up to 10% resulting in fracture, 1% to 2% of these being hip fractures.¹¹

Two years of HRT results in a 66% reduction in hip fracture in the subsequent 2 years,¹² and taken for 10 years produces a 60% reduction in the overall mortality rate related to osteoporotic fractures.¹³ However, recent studies have highlighted the potential risks of HRT and it is no longer recommended as first-line prophylaxis or treatment for osteoporosis (see section on HRT).

Cardiovascular disease

Cardiovascular disease (CVD; includes coronary heart disease and stroke) is five times more common in men than in premenopausal women but by 70 years the sex difference is lost. Overall, CVD is the most common cause of death in women. In younger women, estrogen exerts cardioprotective effects through a vasodilatory effect and an alteration in lipid metabolism. Ovarian failure causes increased levels of cholesterol, triglyceride, and low-density lipoprotein (LDL), and a reduction in high-density lipoprotein (HDL). These changes contribute to an increased predisposition to ischemic heart disease.¹⁴

Theoretically therefore, estrogen therapy should reverse these effects, and previous observational data suggested a cardioprotective effect of HRT,¹⁵ but a wide variety of randomized clinical trials have observed that HRT does not reduce and indeed may slightly increase the risk of cardiac events after menopause.¹⁶

Skin and dentition

Skin changes have been attributed to the aging process, but estrogen deficiency and light exposure are significant factors. Skin thickness declines after menopause by 30% in the first 10 years, which is comparable to bone loss over the same time.¹⁷ When HRT is started early, there is maintenance of skin collagen and thickness.

Estrogen deficiency also affects teeth—one third of women over 65 in the United States are edentulous. HRT may be protective.

Hormone replacement therapy

Estrogen therapy has been widely regarded as the appropriate treatment for the consequences of ovarian failure, either for symptom relief or prevention of long-term effects. However, publication of the Women’s Health Initiative (WHI) study and Million Women Study (MWS) has led to considerable uncertainties among health professionals and women about the role of HRT.^{18,19}

Recent recommendations suggest that treatment choice should be based on up-to-date information and targeted to individual women’s needs. Currently, most women who request HRT do so for symptom relief, and duration of use

is usually less than 5 years. The merits of long-term use need to be assessed for each individual at regular intervals (e.g., annually).²⁰

HRT should currently not be prescribed solely for possible prevention of CVD and dementia, and it is no longer recommended as first line therapy for osteoporosis prevention.

If HRT is to be used, it should be in the lowest dose required to relieve symptoms. It may be given orally or parenterally (i.e., transvaginally, transdermally, or subcutaneously). There is an additional need for progesterone in nonhysterectomized women because unopposed estrogen therapy causes endometrial hyperplasia, which may lead to adenocarcinoma. Twelve to 14 days of progesterone each month reduces these risks²¹ and may be administered orally or transdermally. When HRT is given in this cyclical sequential regime, there is a withdrawal bleed at the end of each course. In women at least 1 year postmenopausal, progesterone can be given continuously which prevents endometrial proliferation, so there is no bleeding. The levonorgestrel intrauterine system (Mirena, Schering) can fulfill this role. Women who start on cyclical HRT can be changed to a continuous combined product when they reach the age of 55.

Oral estrogen

Oral administration is the most widely used route and is convenient, relatively inexpensive, and generally well tolerated. Many combinations are available commercially, both cyclical and continuous. In perimenopausal women who do not wish frequent withdrawal bleeds, a three-monthly bleed preparation can be tried. Tibolone is a synthetic steroid with estrogenic, progestogenic, and androgenic properties and acts as a continuous combined product. It also improves libido and may have less effects on breast tissue.²²

The main disadvantage of the oral route is that estrogen passes directly to the liver, where it is inactivated and partially metabolized to the less effective estrone—this is called the “first pass” effect and means that higher doses are required than with parenteral therapy. It may also result in altered hepatic metabolism with changes in clotting factors and increased renin substrate, which predisposes to hypertension.

Transdermal estrogen

Transdermal patches may be matrix or reservoir in type and require changing once or twice weekly. Combination patches with progesterone are also available. Estradiol is delivered at a controlled rate depending on surface area. The first pass effect is avoided and hepatic metabolism not affected, thus reducing the risk of thrombosis. The main problems are with adhesion, and transient skin reactions can occur in up to 30% of women; the frequency is less with matrix patches. A transdermal gel may be used instead.

Topical estrogen

Vaginal creams and pessaries are used primarily for treating atrophic vaginitis. Systemic absorption is minimal, but if use is prolonged, progesterone therapy should be considered. In general, a short course is adequate: a 14-day course should be followed by 2 nights’ application each week for up to 6 weeks. A problem with this route in the elderly is reduced acceptability and impaired manual dexterity for self-administration. A district nurse may help or a slow-release soft vaginal ring provides 3 months’ therapy. Other alternatives include a

low-dose hydrophilic vaginal tablet, which has a fine, pre-lubricated, and preloaded applicator (Vagifem)—because of its low dose and lack of systemic absorption, this product is acceptable for use in patients with a history of breast cancer.

Subcutaneous implants

Estradiol implants can be inserted in the lower abdominal wall under local anesthesia, and serum levels are sustained for several months depending on the dose. Levels tend to be higher, and symptoms tend to return more quickly despite therapeutic serum levels, requiring more frequent implants (tachyphylaxis). This method is now rarely used.

Contraindications and risks with hormone replacement therapy

There are few contraindications to HRT, which provides estrogen replacement at below the normal premenopausal plasma concentrations and those achieved with the high-dose synthetic steroids used in the combined oral contraceptive pill. The main contraindications are estrogen-dependent breast or endometrial cancers, although women with treated breast cancer and debilitating menopausal symptoms may be given HRT under specialist supervision, and there is no evidence of increased recurrence rates.²³

More recent reports have suggested a small increase in the risk of venous thromboembolism with HRT, which was not thought previously to exist.²⁴ Patients with other risk factors should therefore be treated with caution and preferably with transdermal HRT. It is not necessary to stop HRT before surgery as most patients will fall into a moderate risk category (in view of age) and receive antithrombosis prophylaxis.

HRT may be given where there are preexisting gynecologic conditions (e.g., endometriosis and fibroids), but the latter may fail to shrink and cause heavier withdrawal bleeds.

The benefits of HRT are considerable, but there are increasing concerns with the safety of long-term therapy particularly in relation to breast cancer and CVD (discussed previously). Also, although initially protective against endometrial cancer, use greater than 10 years causes a modest increase in this cancer too.²⁵ Changing to continuous combined HRT as soon as appropriate reduces the endometrial risk.²⁶

Despite extensive educational products and improved therapies such as “no bleed” continuous HRT, compliance is poor and 50% of patients do not remain on HRT 12 months after starting treatment, even when at risk of osteoporosis.²⁷

Alternatives to hormone replacement therapy

Symptomatic relief from hot flashes can be achieved with clonidine, venlafaxine (not yet licensed) and progesterone. There is also a growing trend toward “natural” products such as black cohosh, red clover, and natural progesterone cream. There are some data on the safety and efficacy of red clover²⁸ but less so with other products, and one study shows no pharmacologic activity for progesterone cream²⁹ and any benefits are likely to be a placebo effect.

VULVAR DISORDERS

Vulvar epithelial disorders are important because of the severity and chronicity of symptoms (most commonly itching, soreness, and irritation), and their association with carcinoma. Management is often difficult especially

as patients may present to a variety of specialists including gynecologists, dermatologists, geriatricians, or general practitioners. Treatment may therefore be improved by utilization of a dedicated vulvar skin clinic if available.

To accurately diagnose vulvar pathology, full examination is required because of the significant overlap of vulvar disease symptoms. Other skin and mucosal membranes should be examined and swabs taken to screen for infection. Importantly, if lesions do not respond to initial treatment or doubt exists as to their etiology, they should be biopsied to assist diagnosis and subsequent management.

There have been conflicting views about pathogenesis, diagnosis, and terminology of vulvar disorders. Lesions may be infective, inflammatory, localized variants of generalized dermatoses, premalignant, and malignant. Extensive classifications are available, but this review will focus on the general management and some specific common conditions.

Symptoms

Vulvar skin is more sensitive than other epithelium because it is subjected to increased heat, friction, and occlusion. Aging is also a factor and some chronic vulvar disorders represent an advanced stage of atrophic change. Patients with any of the myriad of diseases of the vulva may complain of symptoms such as dryness, itch, ulceration, and pain.

GENERAL MEASURES FOR VULVAR CARE

1. Avoidance of tight, restrictive, or occlusive clothing
2. Avoidance of irritants such as soaps, fragrances, or urine (if incontinent)
3. Use of emollients and soap substitutes
4. Treatment of any detected infection

Dermatologic conditions

The vulvar skin may be affected by a variety of dermatologic conditions including psoriasis, urticaria, and the bullous diseases such as pemphigus. The more common inflammatory conditions found in the elderly patient include contact dermatitis and lichen planus, which are described next.

ECZEMA/DERMATITIS

Eczema is a term used synonymously with dermatitis. This inflammatory condition affects many skin sites, classically on the flexural site of the body. Vulvar itch may, however, be attributed to eczema. The condition may be endogenous (atopic) or exogenous (contact) in nature. In the elderly population, urine is a common irritant but a history indicating a change in soap, fragrances, underwear, and so on should be sought. Management of dermatitis starts with identifying and avoiding the causative irritant and general measures of vulvar care as illustrated above. Topical steroids may relieve the itch and can be of value to try and break the “itch-scratch” cycle, which can lead to thickening with accentuated skin margins (lichenification), termed *lichen simplex*. Secondary infection may complicate dermatitis, and swabs should be taken to identify treatable infection.

LICHEN PLANUS

This inflammatory condition may also affect hair, nails, and mucosal membranes. The classic lesions are purple papules, sometimes with a lacy white surface pattern (Wickham’s striae). The usual complaint is of soreness, but

Table 87-1. Classification of VIN (International Society for the Study of Vulvar Disease, 2004)

Usual type
Warty type
Basaloid type
Mixed
Differentiated type

itch, dyspareunia, and discharge may be present. If the patient is sexually active and concern exists over vaginal narrowing, then vaginal dilators may be of benefit. A more severe presentation of lichen planus may involve an erosive vulvar lesion leading to profuse discharge and scarring. Treatment involves general vulvar care including the use of emollients and high-potency topical steroids.

Premalignant vulvar disorders

Premalignant conditions of the vulva are rare but include a spectrum of disorders such as vulvar intraepithelial neoplasia, lichen sclerosus, and Paget's disease of the vulva.

VULVAR INTRAEPITHELIAL NEOPLASIA

Although the incidence of this condition is rising in the younger population, 80% of cases occur in women over the age of 50. Vulvar intraepithelial neoplasia (VIN) represents an abnormal proliferation of epithelial cells and is almost certainly associated with exposure of the human papilloma virus (HPV), in particular subtypes 16 and 18. Smoking represents an additional strong risk factor.

Clinically the complaint may be of itch, pain or a burning sensation but around half of cases will be asymptomatic. There are no typical appearances of VIN and the lesions may be unifocal or multifocal. Assessment of malignant transformation potential is difficult, but it is generally agreed that "differentiated type" has the greatest potential for malignant change of around 30% with "usual type" around a 2% to 5% chance of transformation.³⁰ Differentiated type is often found in the elderly population and may be associated with lichen sclerosus. VIN may also be described as VIN 1, 2, or 3. The International Society for the Study of Vulvar Disease revised this classification in 2004 because of a lack of evidence of disease continuum from VIN 1 to VIN 3 (Table 87-1).

DIFFERENTIATED TYPE

Surgical treatment involves wide local excision and is often mutilating, creates anxiety, affects sexual function, and unfortunately suffers from relapse rates. For this reason, a prudent management plan may often involve watching with repeated biopsies to exclude change. No single ideal therapy for VIN exists. Surgery may be destructive and medical treatments troubled by side effects. Treatment is recognized to be difficult and referral to a specialist vulvar skin clinic is advised.

LICHEN SCLEROSUS

Lichen sclerosus (LS) is a common problem affecting the aging vulva. The etiology is uncertain, but there is an association with genetic and hormonal factors and autoimmune disease.³¹ The vulvar appearance varies but the characteristic lesions are a "figure of eight" configuration around the

vulva and anus of white plaques together with atrophy. The condition does not extend to the vagina. Loss of tissue architecture is common with fusion of tissue occurring, which may lead to introital stenosis. Chronic scratching complicates the picture, so the skin may be thickened (i.e., lichenified). Although the clinical appearance varies, there are characteristic histologic features, including an atrophic epidermis with hyalinization and areas of thickening (hyperkeratosis), and inflammation.

In the elderly, management may include investigating for the presence of autoimmune disorders such as pernicious anemia, thyroid disease, and diabetes. General vulvar care advice should be given. However, the mainstay of treatment should include topical use of a potent steroid such as dermivate. This should be applied daily at first, reducing as symptoms improve (a 30-g tube is expected to last 3 to 6 months).

Malignant change has been quoted at between 2% to 9%,³² and punch biopsies under local anesthetic should be taken of any suspicious areas to exclude atypical change. Squamous carcinoma is more likely when there is a failure to respond to topical steroid use or with the presence of ulceration, raised lesions, or lymph node involvement. These patients should report alteration in symptoms and be checked every 6 months to yearly, again ideally at a dedicated vulvar skin clinic if available.

Although the condition is associated with atrophy, topical estrogen is ineffective and should be considered only for vaginal use.

EXTRAMEDULLARY PAGET'S DISEASE

This rare condition is a neoplasm of apocrine bearing skin. It has a peak incidence at 65 years of age. Clinically it has similar symptoms to other skin conditions of the vulva. Lesions will often appear as "white islands" with bridges of hyperkeratinization. A biopsy is required to make diagnosis. Treatment is specialized and may involve surgery or radiotherapy after appropriate discussion by a multidisciplinary team. Prognosis is good if confined to epidermis, and the challenge is therefore early detection.

Vulvar discomfort

A complaint of severe pain or discomfort in the vulva for over 3 months is termed *vulvodynia*. Localized pain to light touch at the vaginal vestibule (where vaginal meets vulva) is known as localized vulvodynia (previously known as vestibulitis).

In the elderly population, vulvar pain is more commonly generalized and characterized by pain, burning, stinging, irritation, and rawness. This is often termed *dysesthetic vulvodynia* or *generalized vulvodynia*. Unlike vestibulitis, which is provoked by touch, women with dysesthetic vulvodynia have a more constant neuropathic pain. The complaint of itch is uncommon and examination is usually normal. Etiology is uncertain, but it is now recognized that both psychological and physical factors are involved.³³ Depression is a possible factor, as these patients often live alone. Assessment includes neurologic and local examinations with urethral, vaginal, and endocervical swabs to exclude infections. Pathology is rarely found.

Initial treatment should involve explanation of the condition, emphasizing this is a real condition although often no physical findings are present. General vulvar care as

previously described should be given, and in some cases use of low strength topical corticosteroids or anesthetics (e.g., 5% lidocaine) may benefit. The use of pelvic floor exercises to improve muscle tone and blood supply and vaginal retraining dilators can also be used. Some symptoms will respond to low-dose tricyclic antidepressants such as 10 mg of amitriptyline at night, increasing the dose as side effects permit to a usual dose of between 60 to 150 mg per day. The use of the neuroleptic gabapentin has also been reported as a second-line therapy.³⁴

UTEROVAGINAL PROLAPSE

Urogenital prolapse occurs when there is a weakness in the supporting structures of the pelvic floor allowing pelvic viscera to descend and ultimately fall through this anatomic defect. An increase in life expectancy has meant that prolapse has become an increasingly important problem. Although a benign condition, quality of life can be severely affected with bladder, bowel, and sexual dysfunction described. The lifetime risk for having surgery for prolapse is 11%,³⁵ and approximately 60% of elderly women have some degree of prolapse. Prolapse of the anterior and posterior vaginal walls occurs independently or together, resulting in any combination of urethrocele, cystocele, rectocele, and enterocele, which are displacements of the underlying urethra, bladder, rectum, and pouch of Douglas (and any contents), respectively. Classification of prolapse has traditionally been described as first-, second-, or third-degree prolapse depending on the relationship of the lowest part of the prolapse to the introitus.

Prolapse is most commonly related to childbirth—50% of patients with prolapse are parous³⁶—and postmenopausal hormone deficiency when lack of estrogen causes collagen loss and ligament atrophy.³⁷ Congenital weakness of sustaining structures and the natural aging process are other factors. Additionally, factors leading to increased abdominal pressure such as obesity, constipation, and chronic cough will exacerbate prolapse symptoms.

The main supports of the uterus and upper vagina are the transverse cervical, or cardinal, ligaments, the pubocervical fascia, and the uterosacral ligaments. The middle third of the vagina is supported by fascia, and the lower third of the vagina is buttressed by fibers of the pelvic floor. In the erect posture, the anterior vagina rests on the posterior wall, which is strengthened by the rectovaginal fascia and perineal body.

The patient commonly presents with a dragging or bearing down sensation of gradual onset that is worse with activity and settles with rest. A lump may be seen or felt. Urinary symptoms such as frequency, urgency, incontinence, and incomplete/slow emptying result from distortion of the prolapsed bladder and urethra, but they may also be due to atrophy, infection, or detrusor overactivity.³⁸ Digital replacement of the anterior or posterior vaginal wall is sometimes necessary before micturition or defecation may proceed.

With prolonged uterine descent, edema occurs because of the interference with venous and lymphatic drainage, leading to epithelial hyperkeratinization and decubital ulceration. Bleeding may result but carcinoma rarely develops. With severe prolapse, it is possible to cause ureteric obstruction with subsequent hydronephrosis. In the elderly patient

with complete procidentia, a degree of ureteric obstruction is likely and ultrasound investigation should be organized. Further investigation should include pelvic abdominal assessment to exclude a mass. Prolapse is assessed with the patient in the left lateral position if possible, although standing up may provide good assessment of the degree of prolapse. The practitioner may ask the patient to cough repeatedly and look for signs of stress incontinence, as this may assess urinary signs. Occult stress incontinence may occur in the elderly patient after correction of prolapse by either conservative or surgical methods. It may therefore be advisable to arrange cystometry and uroflowmetry to evaluate potential stress incontinence. If stress incontinence is discovered, then this may be addressed at the time of managing the prolapse.

Physiotherapy may have a role in the treatment of prolapse, although the evidence supporting its effectiveness is weak and in the elderly patient is less likely to benefit. Surgery offers definitive treatment, but suitability of the patient depends on the severity of symptoms, the degree of incapacity, and the patient's operative fitness. It includes, as appropriate, anterior or posterior pelvic floor repair, vaginal hysterectomy, or vault suspension if hysterectomy has already occurred. It is now standard practice to give subcutaneous heparin pre- and post operatively to reduce venous thromboembolism risk and antibiotics for surgical prophylaxis. Most patients tolerate surgery well because of improved anesthetics and minimal postoperative morbidity. The procedures lead to greater mobility and return to an independent life. Evidence suggests that surgical procedures for prolapse in the elderly do not carry any increased morbidity as compared to the younger patient.³⁹

Recurrence of prolapse will trouble about a third of patients who undergo a surgical corrective procedure.⁴⁰ The use of synthetic mesh is becoming increasingly more common in the treatment of patients with recurrent defects.⁴¹ Complications associated with the use of synthetic material may include dyspareunia or troublesome infection. The use of such procedures should therefore be reserved for specialists in this surgical field rather than the general gynecologist.

When surgery is contraindicated or declined, conservative measures may be used. It is useful to remember that it is common for women to tolerate a procidentia for years without complaint, and in general prolapse is a benign condition. However, if symptoms are troublesome, then a polyvinyl ring pessary can be inserted. The pessary should be inspected and cleaned or renewed every 4 to 6 months to prevent vaginal ulceration occurring. In this event, the ring should be removed for a few weeks to allow epithelial healing. The use of local estrogen may help healing if hypoestrogenic atrophy is present. If the ring pessary is not effective, usually because of expulsion, a shelf pessary exists to reduce prolapse. Shelf pessaries lead to a higher degree of vaginal trauma, including the possibility of rectovaginal or vesicovaginal fistulae. However, in the elderly population, because of comorbidities preventing surgery or the large degree of prolapse, they may be more suitable than the more common ring pessary. They should be inspected in the same way but are more difficult to remove and replace. Varieties of other support or space-occupying pessaries exist⁴⁰ but are less commonly used in routine practice. An awareness of their existence is useful for the elderly patient with troublesome prolapse who is difficult to treat by nonsurgical procedures.

URINARY INCONTINENCE

Lower urinary tract symptoms are common and are due to a wide variety of underlying mechanisms. Diagnosis based on history and examination alone may be correct in only 65% of women complaining of urinary tract symptoms.⁴²

Urinary incontinence is particularly disabling and distressing in the elderly, but, with modern investigation and treatment, symptoms may be alleviated if not cured. Causes of urinary incontinence can be broadly divided into overactive bladder, stress incontinence, and other causes of leakage. Continuous leakage is more likely to be associated with neurologic disorders, overflow, urethral diverticulum, or a vesicovaginal fistula.

Overactive bladder (OAB)

Detrusor overactivity is classically associated with frequency, urgency, urge incontinence, and nocturia. Uninhibited detrusor muscle contractions are usually the cause of incontinence in geriatric patients. Urodynamic investigations have shown detrusor overactivity in 80% of the elderly population. Most cases of OAB are idiopathic, but the condition is amplified in the presence of neurologic conditions such as stroke, Parkinson's disease, or multiple sclerosis.⁴³ The pathophysiology is uncertain but may occur by a reduction of functional innervation of the bladder wall.

Investigation should include a midstream urine sample to exclude infection. Simple and noninvasive tests such as daily urinary frequency/volume and incontinence charts are important. The diagnosis of detrusor overactivity is, strictly speaking, a diagnosis made at the time of urodynamic investigation. However, it is not practical for all elderly patients with symptoms of OAB to undergo this test, and often a clinical diagnosis can be made; however, if doubt exists as to the cause of urinary incontinence or if there is poor response to treatment, urodynamics are required. Ultrasonography is a useful method to check postvoid residual volumes and to exclude incontinence secondary to overflow.

Conservative treatment of OAB should include monitoring and reducing fluid intake to around 1.5 to 2 liters per day. Bladder irritants such as caffeine and alcohol should be avoided. In the elderly, the patient's medications should be reviewed to ensure there are no unnecessary diuretics or other medications. Constipation may aggravate the problem and should be treated. The use of a specialist nurse to help with behavioral therapies such as bladder retraining can improve symptoms. Many professionals advise combining this with pelvic floor exercises if the patient is capable.

Pharmacologic agents can be used when conservative measures fail. There is a large placebo effect with these agents and the difficulty is to find the right drug for the right patient. The side effects are often poorly tolerated, and this is particularly evident in the elderly patient. Anticholinergic/antimuscarinic drugs inhibit the parasympathetic action upon the bladder and hence reduce detrusor muscle contractions. They unfortunately may cause constipation, dry mouth, and dry eyes. In the older patient, reduced drug metabolism and elimination must be considered together with potential drug interactions. Oxybutynin, tolterodine, solifenacin, trospium, darifenacin, and propiverine all have level 1 evidence for their effectiveness. Trospium is made from a compound that does not cross the blood-brain barrier and may be useful in older patients on polypharmacy. The tricyclic antidepressant, imipramine

at 25 to 50 mg twice daily, can be useful in treating symptoms of nocturia and nocturnal enuresis. There is limited value in estrogen therapy for either urge or stress incontinence,⁴⁴ but it has a place when urinary symptoms are associated with significant estrogen deficiency.

Surgical options such as cystoplasty or urinary diversion for the treatment of OAB should be reserved for patients in whom all other methods of treatment have failed, and they are rarely undertaken.

Stress incontinence

Urodynamic stress incontinence is diagnosed by filling cystometry and is defined by involuntary leakage on exertion, coughing, or sneezing in the absence of detrusor activity. It is the most common cause of incontinence in women in reproductive or early postmenopausal years and is often suffered in silence despite good available treatments. It is associated with damage to the pelvic floor (usually as a result of childbirth) and causes of increased abdominal pressure such as constipation, cough, and obesity.

The treatment of genuine stress incontinence should be nonoperative initially as good results for mild/moderate leakage can be achieved with conservative measures without compromising further surgical procedures.⁴⁵ Conservative measures involve pelvic floor exercises with or without the use of biofeedback or electrical stimulation. The use of vaginal cones and weights is less common, as their effectiveness has been difficult to prove.

Surgical procedures, however, offer effective treatment. Colposuspension has traditionally been the gold standard of treatment. It is major abdominal surgery and is associated with voiding difficulties in 12% to 25% of cases and de novo overactive bladder symptoms in around 15% of cases.⁴⁶ The use of this procedure has largely been superseded by the use of tension-free vaginal tapes. A large number of variations are available for these midurethral tape procedures; however, the best body of evidence exists for the Gynecare tension free vaginal tape (TVT), which is a synthetic polypropylene, monofilamentous mesh that is inserted vaginally at the level of the midurethra into the retropubic space to provide tension-free support under the urethra. The procedure may be performed under local anesthetic and carries a low morbidity with de novo overactive bladder symptoms occurring in around 6%. The reported 2-year cure rate for the TVT is 84%, and it has been shown to be equally efficacious as colposuspension.⁴⁷ Evidence suggests that surgical procedures for incontinence in the elderly do not carry any increased morbidity as compared to the younger patient⁴⁸ and should therefore be considered to improve quality of life.

GYNECOLOGIC CANCER IN THE ELDERLY

An association has been noted between aging and cancer development, and there is a tendency for cancers to be at a more advanced stage at presentation. The management of gynecologic cancer patients is now mostly centralized in units staffed by experienced gynecologic oncologists where the care and outcome is improved. Decisions for care should be undertaken by a multidisciplinary team (MDM) involving, among others, the gynecologist, medical and radiologic oncologists, pathologists, and the patients themselves.

Female genital cancer affects five main sites.

Vulva

Vulvar carcinoma is seen most frequently in the 60-to-70-year-old age group and accounts for about 5% of genital neoplasia. Early symptoms are pruritus or an asymptomatic lump, but late presentation is more common because of embarrassment and is usually in the form of bleeding or an offensive discharge. Ninety-five percent of tumors are squamous in type, but occasionally malignant melanoma can occur. The lesion commonly arises in the labium majorum and spreads directly to the urethra, anus, and vagina and by regional lymph glands—the superficial inguinal and prefemoral nodes. Lateral tumors tend to spread to the ipsilateral nodes, but centrally placed tumors may involve the contralateral nodes. Hematologic spread is rare and a late phenomenon leading to metastases to lungs, liver, or bone. The most significant prognostic indicator is nodal status. Overall groin negative patients have a 90% 5-year survival rate.

The aim of management is to carry out the most conservative procedure likely to lead to cure. Radical vulvectomy with bilateral groin node dissections is no longer the treatment of choice, as morbidity is high. Early stage disease is often treated with wide local excision with ipsilateral nodal dissection if the tumor is greater than 1.5 cm from the midline.⁴⁹ Central tumors merit bilateral nodal dissection. Full groin node dissection is often performed if tumor is greater than 4 cm and superficial nodes are negative. Thirty percent to 70% of patients who have undergone a full node dissection will have long-term lymphedema and recurrent cellulitis.⁵⁰

Advanced disease may be treated by radical surgery sometimes necessitating exenteration. Five-year survival rates are less than 50%, and the postoperative morbidity very high.⁵⁰ Preoperative radiotherapy may be used to reduce tumor bulk and the risk of recurrence. Radiotherapy is additionally used to treat recurrence (if not previously used), and it is also helpful in the palliative setting.

If a large vulvar defect results from surgery, repair may be possible using a myocutaneous flap with rectus abdominis or gracilis muscle. Nursing management may be difficult because of increasing problems with catheterization, poor healing, and discharge, which may be infective or lymphatic in origin.

Vagina

Primary vaginal squamous cancer is rare and virtually confined to the elderly. Usually vaginal malignancy is metastatic adenocarcinoma with blood or lymphatic spread from the uterus and, rarely, kidney, breast, or colon. Direct invasion may occur from bladder, cervical or vulvar lesions. Presenting symptoms are postmenopausal bleeding, offensive discharge, and eventually fistula formation. Diagnosis is by biopsy and the treatment is usually radiotherapy, although vaginectomy can be considered for primary lesions. Other surgical measures include urinary diversion for a fistula or palliative vaginal closure (colpocleisis). Endometrial metastases show some response to high-dose progesterone.

Cervix

Worldwide, cervical carcinoma is still the most common gynecologic malignancy over all age groups. In developed countries, the incidence is falling significantly as a result of

screening programs. In the United Kingdom, screening programs stop at 60 years, but if an abnormal smear is found in a woman over this age it is 16 times more likely to lead to a diagnosis of invasive cancer compared with women younger than 30 years.⁵¹ Types 16 and 18 of the human papillomavirus (HPV) have been incriminated in the pathogenesis of invasive squamous carcinoma and are detectable in more than 90% of cases. The recent introduction of a vaccine against the high-risk HPV subtypes⁵² may change the face of cervical cancer in future generations, but vigilance is still required.

Elderly patients will present with such symptoms as offensive vaginal discharge and postmenopausal or postcoital bleeding. Pain is experienced late and related usually to diffuse pelvic infiltration or bony metastases. The first sign of this cancer may be obstructive renal failure from hydronephrosis because of advanced disease.

Diagnosis is by biopsy of suspicious areas preferably under general anesthesia so that clinical staging and evaluation of histologic tumor grade is achieved. Squamous cell cancer accounts for more than 80% of cases. Lymphatic metastases occur quickly; hence, up to 50% of early lesions have pelvic spread at presentation. Tumors confined to the cervix may be treated by radical hysterectomy and pelvic node dissection, or radiotherapy. Both treatments carry similar 5-year survival rates⁵³ in early stages. In the elderly, radiotherapy may be more commonly used because of the fear of radical surgery complications or because of the more advanced presentation of disease. However, a fit elderly patient with early stage disease will tolerate the procedure well and should not be denied it on the basis of age alone. In advanced disease, the tumor may infiltrate locally causing fistula formation to the bladder or rectum. As in other squamous carcinomas, the success of chemotherapy is limited.

Corpus uteri

Endometrial carcinoma is the most common gynecologic malignancy in the elderly. Postmenopausal bleeding is the most frequent symptom and occurs early; hence, prognosis tends to be good with an overall 5-year survival rate for all stages of around 70%.⁵⁴ There are significant associations with nulliparity, late menopause, obesity, diabetes, and hypertension (Saint triad); unopposed estrogen replacement therapy and tamoxifen use. The incidence of uterine cancer is increasing in the United Kingdom, and this has much to do with the increasing obesity rates. Eighty percent of primary endometrial cancers are adenocarcinomas arising from the glandular endothelium often on a background of atypical hyperplasia. Hyperplasia is associated with unopposed estrogen action, and when described as atypical, surgical hysterectomy is warranted as undiagnosed carcinoma may be present. Serous, clear cell, squamous, and undifferentiated carcinomas are less common but more aggressive malignancies. More rarely, sarcomatous and mixed mesodermal tumors occur, and they have a poorer prognosis.

Approximately 90% of women present with postmenopausal bleeding (PMB), and patients with this complaint have around a 10% chance of being diagnosed with endometrial cancer. The recommended initial assessment of PMB should involve a transvaginal ultrasound scan to measure endometrial thickness. A thin endometrium on ultrasound has a high negative predictive value and is reassuring.

Where a thickening is detected, an endometrial biopsy is required. Thresholds for endometrial thickness will vary between regions but commonly are between 3 and 5 mm (or greater if currently on HRT). Ultrasound assessment is of little value where tamoxifen use is present due to subendometrial cystic changes. In this situation, first-line investigation should involve hysteroscopy with endometrial biopsy.⁵⁵ However, most cases of PMB are due to benign conditions including atrophic vaginitis and simple endometrial or cervical polyps.

Endometrial tumors spread directly to cervix, vagina, and peritoneal cavity via fallopian tubes. Myometrial invasion is common and may lead to serosal involvement. Lymphatic spread involves external iliac, internal iliac, obturator, and para-aortic nodes. Hematologic spread may lead to lung metastases. The staging of endometrial cancer relies on surgical assessment of intra-abdominal disease combined with pathologic assessment of hysterectomy specimen. If tumor extends to less than 50% of myometrial depth, lymph node spread exists in fewer than 5% of cases. If endometrial biopsy suggests high-grade disease or high malignant histology or if imaging suggests deep myometrial involvement, then it is recommended that care should be provided via a dedicated gynecologic oncologist via a multidisciplinary team.

Treatment should involve as a minimum, total hysterectomy, bilateral salpingo-oophorectomy, peritoneal cytology, and upper abdominal inspection. The debate regarding the necessity of lymphadenectomy in these patients led to the Medical Research Council funded ASTEC trial. One of the study's primary aims was to assess the benefit, or otherwise, of pelvic lymphadenectomy in patients where disease is thought to be confined to the corpus. Recruitment for this trial has now closed, and the preliminary results were presented at the European Society of Gynaecological Oncology in 2005. The society suggested that there was no benefit for survival or prevention of recurrence in performing lymphadenectomy for early stage endometrial cancer.

Radiotherapy may be given when the women cannot undergo surgery for medical reasons. Postoperative radiotherapy for stage 1 disease will reduce local recurrence from 14% to 10% but has no effect on overall survival.⁵⁶ Radiotherapy is therefore given based on individual risk stratification—myometrium invasion beyond 50%, tumor grade, and age all influencing this decision. Usually radiotherapy is a combination of vaginal radiotherapy to reduce vault recurrence and external beam radiotherapy. Side effects are common, occurring in 25% of women, and include frequent bowel movements, urinary frequency, pain, and scarring. Patients with advanced disease may be suitable for surgery with adjuvant chemoradiotherapy. Treatment for advanced disease is usually palliative, involving chemotherapy to treat systemic disease and radiotherapy for problems such as vaginal bleeding or bony metastases.

Progestational agents may be used for palliation or when the patient is unfit for other treatment. Tumor deposits may regress for a time; however, high-grade tumors often lack progesterone receptors.

Vaginal vault recurrence can be successfully salvaged with either surgery or radiotherapy with 3-year survival rates of approximately 70%.

Ovary

Ovarian cancer remains the most lethal gynecologic malignancy and is currently the fifth leading cause of female cancer deaths. It affects those aged 65 years and older more frequently than younger women, with almost 50% of ovarian tumors occurring in this age group. More of the older women are likely to present with advanced disease and are less likely to be offered radical surgery and chemotherapy. The onset and progress is often insidious, so a high index of suspicion is necessary in postmenopausal women with nonspecific symptoms such as abdominal discomfort and swelling, malaise, and weight loss. In a postmenopausal woman with ascites, ovarian cancer should be the diagnosis until proven otherwise. Hereditary ovarian cancers are unlikely to represent more than 10% of all ovarian cancers. Currently there is no satisfactory screening method for ovarian neoplasia that has been shown to reduce morbidity. Screening should only be offered to high-risk individuals, with enrollment into a screening trial encouraged. Screening is therefore not advisable for the elderly population. The tumor marker CA125 is an indicator of ovarian malignancy, but it may not be elevated in all ovarian carcinomas and is often not elevated in early stage disease. However, inclusion of CA125 levels with menopausal status and ultrasound findings provides a useful algorithm termed Risk of Malignancy Index (RMI) (Table 87-2). Using RMI provides an 87% sensitivity, 89% specificity, and 75% positive predictive value.⁵⁷ The RMI's greatest value is in allowing triaging of patients to the care of a gynecologic oncologist or general gynecologists. Many postmenopausal ovarian cysts are an incidental finding, and if the RMI is low, no action is required.

All high-risk patients should be managed by a multidisciplinary team and have any surgery performed by a trained gynecologic oncologist. In advanced stage disease, operative mortality is around 1% and major morbidity about 5%.

Ninety percent of ovarian malignancies in older women are epithelial adenocarcinomas, but other ovarian components may become malignant and give rise to such histologic types as sex cord and germ cell tumors. Up to 10% of ovarian masses are metastases from elsewhere, particularly colon and breast. Granulosa cell tumor is the most common sex cord malignancy and may occur after menopause. Hormone

Table 87-2. Risk of Malignancy Index (RMI = Ultrasound Score × Menopausal Status × CA125)

Ultrasound score	0	No suspicious features	
	1	One suspicious feature	
	3	Two to five suspicious features	
Menopausal score	1	Premenopausal	
	3	Postmenopausal	
CA125		Suspicious ultrasound features are multiloculated cyst, solid areas, metastases, bilateral lesions, and ascites.	
Triaging According to RMI			
	RMI	Percentage of Women	Risk of Malignancy
Low risk	<25	40%	<3%
Moderate risk	25–250	30%	20%
High risk	>250	30%	75%

production can cause vaginal bleeding because of endometrial hyperplasia.

A complete history is essential to make diagnosis and assess fitness for surgical and nonsurgical management. Investigation includes hematologic and biochemical profiles, chest x-ray, and ultrasound screening of the pelvis, liver, and kidneys. Magnetic resonance imaging (MRI) or computed tomography (CT) scans are not routinely indicated but may assist in surgical planning and assessment of the upper abdomen.

Laparotomy establishes the diagnosis, and examination of abdominal contents provides accurate staging, which will influence treatment and prognosis. Debulking of the tumor with bilateral salpingo-oophorectomy, total hysterectomy, and infracolic omentectomy is the mainstay of treatment. Peritoneal washings and upper abdominal/diaphragmatic assessment is carried out at the time of laparotomy. Complete tumor removal may be difficult, but the greater the reduction of tumor bulk, the more effective is adjuvant therapy and ascites is better controlled. Although cytoreductive surgery is still the gold standard of care for advanced disease, results from trials of primary surgery versus neoadjuvant chemotherapy with interval surgery have suggested a benefit in advanced disease.⁵⁸ Larger trials on this question are awaited. Postoperative chemotherapy is used in all but stage 1 disease, and indeed many patients will have residual disease after surgery.

The platinum compounds, cisplatin and carboplatin, remain the agents of choice; they are toxic and side effects include myelosuppression, nephro- and neurotoxicity, and severe emetogenesis. Combination therapy of platinum drugs with paclitaxel has been shown to provide some survival benefit over cyclophosphamide/cisplatin (the previous standard of care).⁵⁹ However, this has not been demonstrated in other large trials.⁶⁰ Forty percent to 50% of patients with extensive disease will have complete remission with platinum, but the majority relapse within 2 years. A less aggressive option is the oral alkylating agent, chlorambucil, which is sometimes used in the elderly.

Failure of first-line treatment is ominous, as recurrent disease is often resistant to further therapy, but taxanes are tried in these patients with some success. Retreatment with platinum-based drugs is appropriate if the tumor was originally sensitive and a disease-free interval of greater than 1 year has occurred. Recurrent ascites is a major problem and requires repeated paracentesis; spironolactone may reduce the fluid and limit recurrence. Radiotherapy is limited to unresectable tumors and patients with symptomatic recurrence and is used only for palliation. The most common indication for palliative surgery is bowel obstruction, and referral to surgeons should be considered despite poor prognosis in order to ensure an optimized quality of life.

In knowing that most patients with ovarian cancer present late and die of the disease, although cure is the ultimate goal, it is not often achieved. Surgery and chemotherapy will have a significant impact on a patient's quality of life. Therefore, the informed patient's wishes should always be listened to in planning his or her care.

SEXUALITY AND AGING

There is a view that sexuality in the elderly is irrelevant and sexual activity unnecessary. The facts are, however, that sexual drive is not exhausted with aging, and as life expectancy

increases it is necessary to recognize that continued sexual activity is an important component of increasing age to promote satisfactory relationships, personal well-being, and quality of life. There will be an increasing demand from this age group for advice and expert help on sexual matters.⁶¹ Many older people have problems because they grew up in sexually restricted times, so that ignorance is widespread.⁶² Society has an obsession with youth and its sexuality while largely stereotyping the elderly and ignoring their difficulties in this area. In addition, as is generally the case with disabled people, the organization of institutions for the elderly does not recognize their sexuality, so their needs—for example opportunities for privacy—are ignored.⁶³

A longitudinal study⁶⁴ has shown that sexual activity remains relatively constant within a stable relationship and only declines following a negative event, particularly for the male partner—for example, the death of the spouse. Many factors contribute to changing sexuality such as age, physical appearance, self-image, culture, education, and social attitudes.

Sexual behavior and age

A steady reduction in male sexuality from early and middle years has been observed.⁶⁵ A common phenomenon in older men is erectile dysfunction due to penile arterial insufficiency, the effect of such drugs as antihypertensives, and illnesses like diabetes.⁶⁶ Brecher⁶⁷ noted that 75% of 70-year-old men continued to have some sexual activity.

Waning sexuality with age is also related to previous experience.⁶⁸ In both sexes, low activity levels in youth are associated with a greater decrease in later life.

An early study observed little change in women's capacity for sexual activity until later life.⁶⁹ However, questionnaires^{70,71} from both sexes between ages 45 and 71 were analyzed. A greater reduction was noted in sexual interest and activity in women, the most significant change being between 50 and 60 years. At 66 to 71 years, 50% and 10% of women and men, respectively, had no sexual interest.

Sexual interest also depends on the availability of a partner. Women, who tend to marry older men who die before them, are often left alone and may experience difficulty finding a new partner.⁶² Thus, masturbation may become a more regular activity. It has been found that female sexual activity was highest in those currently married and it progressively reduced in the divorced, widowed, and never married.⁷² Resumption of interest a year after widowhood is more likely when death of the partner was expected, there had been extramarital experience, and, in younger women, activity diminished when the marriage had been sexually satisfying and there was still a strong attachment to the lost partner.⁷³

A common problem following postmenopausal lack of estrogen is vaginal atrophy and dryness causing dyspareunia,⁶⁹ which leads to a loss of interest and activity. It has been observed⁷⁴ that the more sexually active women (with coitus and masturbation) had less vaginal atrophy, suggesting that activity protects the vagina by stretching and possibly stimulating hormone production. The use of HRT has been studied.⁷⁵ Estrogen, androgen, and a combination of both and placebo were compared in oophorectomized women. The results indicated a beneficial effect of androgen alone or with estrogen on sexual motivation and coital frequency. Thus, the evidence suggests that female sexuality

is affected by aging but initially less so than by menopause, and the hormones involved are estrogen and androgen. Testosterone treatment has been recommended in women where other therapeutic and counseling techniques have not helped.⁷⁶ Tibolone is an oral HRT preparation that contains androgen and has been shown to improve sexual problems including reduced libido.⁷⁷ Alternatively, a 6-week trial of testosterone undecanoate, 40 mg daily, may be used; if there is no beneficial effect, the drug should be stopped. A subcutaneous implant of 50 mg testosterone is also effective. With either treatment there is little risk of masculinizing effects, for example, hirsutism or deepening of the voice; however, if these symptoms occur, treatment should be discontinued.

Sexual response and aging

It has been noted⁷⁶ that with age, vasocongestive changes following sexual stimulation develop more slowly in both sexes; these alterations are gradual so that the couple adjusts to activity that is less intense but may be as enjoyable. Older men will develop erections more slowly and maintenance of the erection is not as good and if lost is more difficult to regain.

In women, vaginal lubrication diminishes and takes longer; there is less vaginal elasticity so that there is shrinkage in the absence of coitus. There are changes elsewhere; for example, nipple erection and breast engorgement are less marked and orgasmic capacity may be reduced⁷⁸; also the sense of touch in the genital area may be reduced or experienced as unpleasant or painful, which can further inhibit orgasm.

Management of couples with sexual problems

The management of these disorders should be guided by the same principles irrespective of age and condition of the patient, although the emphasis may vary. Both partners should take part in therapy, because although one usually presents a problem the other invariably contributes to it, and the treatment is obviously facilitated by cooperation. After an initial discussion, the couple should be seen separately so that confidential interviews are obtained including information not to be disclosed to the partner. A preliminary medical and social history may suggest contributing factor(s) and helps rapport to be established before turning to more sensitive questions.

Ignorance about sexuality is common, so there is a need for basic education and permission to experiment, for example, with different methods of stimulation and coital positions. Couples, particularly older ones, frequently have difficulty talking to each other about sexual anxieties or needs, and discussion with the therapist increases their mutual understanding and ability to communicate.

For men with psychogenic, organic, or mixed erectile dysfunction (ED), various treatments have become available in recent years. A concise account of these is available.⁷⁹ Following a full assessment to screen for conditions associated with ED, systemic treatment can be with type 5 phosphodiesterase inhibitors such as Sildenafil and Tadalafil or local intercavernosal or intraurethral prostaglandin therapy (Alprostadil).

There are currently limitations to the prescription of ED drugs in the National Health Service; they are allowed only in men who have had, for example, prostate surgery, renal failure, spinal cord injury, diabetes mellitus, multiple sclerosis, or some other specific medical condition. Those suffering severe emotional stress resulting from ED are entitled to a prescription, but many health authorities have not provided funding, so the men have to rely on a private script from their hospital clinic or general practitioner.

Mechanical devices have been tried for ED, such as vacuum cylinders and penile prostheses. The latter technique involves referral to a specialist urologist for detailed counseling and management.

KEY POINTS

Gynecologic Disorders in the Elderly

- The female aging process accelerates after menopause, particularly in the genital tract, as a consequence of cessation of ovarian estrogen production.
- Hormone replacement therapy is now only advocated for symptomatic relief, but patients should be assessed on an individual basis and fully informed of the risks and benefits.
- Diagnosis of vulvar disorders requires detailed history and examination and biopsy when indicated. Management should be by a dedicated vulvar skin clinic where available.
- Newer surgical mesh treatments for urinary stress incontinence and uterovaginal prolapse are suitable for the elderly, and some can be performed under local anesthesia.
- An elderly patient with gynecologic cancer should be offered the same surgical treatment recommended to younger women. Management should be by a multidisciplinary team.
- There is no age limit to the expression of sexuality, and the elderly should be offered a full range of counseling and treatment where appropriate.

Cancer of the Breast in the Elderly

Lodovico Balducci

INTRODUCTION

The management of breast cancer in the older woman is an increasingly common problem. The incidence and prevalence of this neoplasm increase with age, and the options available for its management have become more numerous.^{1,2} This is the consequence of the aging of the population, more wide utilization of breast cancer screening in the older woman, and the prolonged survival of breast cancer patients.

The geriatrician or the primary care provider may be involved in a number of decisions and interventions related to the management of breast cancer, including screening, referral for treatment, and management of short- and long-term treatment complications.

BREAST CANCER PRESENTATION: DIAGNOSIS AND STAGING

Diagnosis

More and more women 70 and older are undergoing mammographic screening.³ The indirect evidence of benefits supports this practice. The Surveillance Epidemiology and End Results (SEER) data indicate that women 70 to 79 who had at least two mammograms were less likely to die of breast cancer than those who were not screened, and this benefit was present even in subjects with moderate degrees of comorbidity.^{4,5} For these individuals, the most common presentation of breast cancer is an asymptomatic abnormality in the radiograph.

Other forms of presentation include an asymptomatic breast nodule, nipple discharge, and, more rarely, symptoms related to metastatic disease such as bone pain or edema of an upper extremity.⁶ Occasionally, breast cancer may manifest with metastases to the axillary lymph nodes without any sign of neoplasm in the corresponding breast.⁶

When the breast cancer is suspected because of nipple discharge or enlarged lymph nodes, radiographic examinations necessary to confirm the suspicion include simple mammography, digital mammography, ultrasound, and magnetic resonance imaging (MRI) of the breast.^{7,8,9} Although there is general agreement that digital mammography and MRI are more sensitive than regular mammography, controversy persists over the technique that is preferable in individual situations.

The cancerous nature of any abnormality found by imaging or by physical exam needs to be established by a biopsy. This may include a fine needle aspiration of a palpable mass or a core biopsy of a radiographic abnormality. Occasionally the biopsy may be avoided in women with very limited life expectancy, for whom the cancer does not appear life threatening and further management is impractical.¹⁰

Staging

The management of breast cancer is determined primarily by the stage of the disease—that is, by its extension. A discussion of the current staging systems is beyond the scope of

this chapter. As a general rule, breast cancer can present as localized, locally advanced, and metastatic disease. The tests utilized for staging include positron emission tomography (PET) scan; computed tomography (CT) (or MRI) of chest, abdomen, and brain; and radionuclide bone scan.

There is general agreement that in the presence of small tumors, without microscopic involvement of the axillary lymph nodes, these tests are unnecessary, unless the patient has specific symptoms, such as bone pain or headaches, suggesting bone and brain metastases, respectively. Likewise the majority of oncologists would perform a full staging of patients with locally advanced disease or of those in whom one or more metastases have been documented. An area of controversy is whether the staging tests are necessary for patients with local tumor and microscopically involved lymph nodes. The National Comprehensive Cancer Center (NCCC) guidelines recommend that full staging be performed in patients who are asymptomatic but have three or more microscopically involved lymph nodes.¹⁰

A number of circulating tumor markers may be useful in the management of breast cancer, including carcinoembryonic antigen (CEA), Ca15-3, and 27–29. The value of these assays is controversial.¹¹ In older patients with metastatic disease, tumor markers may be followed in lieu of imaging tests, which are more risky and expensive, to follow the disease response to treatment.

The location of metastases has important clinical implications. If untreated, brain metastases, lymphangitic lung metastases, and widespread liver metastases may be associated with a survival shorter than 1 year, whereas patients with bone and skin metastases may survive several years. Patients with metastases to long bones are at high risk of pathologic fractures and may need surgical fixation; those with metastases to the spinal cord are at risk of spinal cord compression that may lead to paraplegia and sphincter dysfunction in a period of a few hours. In the presence of vertebral metastases, the practitioner should have a high grade of suspicion for this complication. Upon diagnosis of vertebral metastases, an MRI of the spine is indicated, and this should be repeated in the presence of worsening pain or the appearance of neurologic signs, including weakness, sensory levels, and sphincter dysfunction.¹²

PATHOLOGY OF BREAST CANCER AND MOLECULAR MARKERS OF CLINICAL INTEREST

In an increasing number of cases breast cancer presents at diagnosis as “carcinoma in situ,” as a result of more widespread use of mammography. The distinction between “ductal carcinoma in situ” (DCIS) and “lobular carcinoma in situ” (LCIS) is clinically relevant, as LCIS has a high probability of recurrence both in the same and in the contralateral breast.¹³

Table 88-1. Pathologic and Molecular Markers of Breast Cancer

Marker	Prognostic Value	Predictive Value
Tumor size	Prognosis worsens with increasing tumor size	Unestablished
Tumor grade (degree of tumor differentiation)	The more undifferentiated the tumor, the poorer the prognosis	
Number of microscopically involved axillary lymph nodes	Prognosis worsens with increasing number of lymph node involvement	Unestablished
Hormone receptors	Prognosis improves with the richness in hormone receptors	Response to endocrine therapy
Ki67	Measurement of cell proliferation; the highest the value the highest the risk of recurrence	Unestablished
HER2neu	Increases risk of recurrence	Predicts response to trastuzumab and lapatinib and poor response to hormonal therapy
Genetic profile	Predicts risk of recurrence in the case of hormone receptor—rich breast cancer with uninvolved lymph nodes	May predict response to chemotherapy

A number of pathologic and molecular prognostic factors have been identified for invasive carcinoma of the breast in the early stages (Table 88-1).^{14,15} Estrogen and progesterone receptors are a harbinger of more indolent disease and predict the benefits of hormonal treatment. The overexpression of epidermal growth factor receptor II (HER2 neu) is a harbinger of very aggressive disease but, more important, predicts response to the monoclonal antibody trastuzumab¹⁶ and to the small molecule tyrosine kinase inhibitor lapatinib,¹⁶ two agents that have substantially improved the survival of patients with this aggressive form of breast cancer. The development of microarray techniques has allowed researchers to study the genetic profile of many cancers and their prognostic and predictive values. A 21-gene assay (oncotype) is now available for clinical use: it predicts those patients with hormone receptor–rich tumors and uninvolved axillary lymph nodes who are at risk of systemic recurrence and may benefit from adjuvant chemotherapy in addition to hormonal therapy.

MANAGEMENT OF BREAST CANCER

Common forms of treatment for breast cancer are listed in Table 88-2.

For the purpose of this chapter, it is useful to define some terms that will recur frequently: adjuvant and neoadjuvant therapy, breast preservation surgery, and sentinel lymph node. *Adjuvant therapy* is treatment given in addition to definitive treatment in patients with no evidence of disease with the goal of preventing tumor recurrence. *Neoadjuvant therapy* is treatment administered before definitive treatment with the goals of preventing later recurrences and of reducing tumor size making it amenable to surgery or to lesser surgery (breast preservation). *Breast preservation surgery* consists of partial mastectomy followed by radiation therapy to the breast. Although it has been in high favor since the late 1980s, the use of breast preservation has recently declined because of the discovery by MRI that a large number of patients with breast cancer harbor in the same breast small, unsuspected foci of DCIS.¹⁷ The need of postoperative irradiation of the breast in women 70 and older has been questioned, as the risk of local recurrences decreases with age¹⁸ and postoperative radiation does not appear to improve survival. External beam irradiation is particularly inconvenient for older women as it requires daily visits to the treatment center for

5 weeks. New forms of postoperative irradiation, such as brachytherapy or hypofractionation treatment, are administered over a shorter period of time and may be more compatible with the needs of older individuals.

Sentinel lymph node is the first lymph node draining the tumor and it may be identified at surgery in the majority of cases. If the tumor does not involve the sentinel lymph node, a full axillary dissection and the consequent complications (lymphedema) may be avoided.¹⁸ A disadvantage of the sentinel lymph node sampling is that it requires a two-stage surgery—that is, if the lymph node is positive for cancer, the patient needs another operation for lymph node dissection.

We will discuss treatment now by stage.

Carcinoma in situ

Surgery is still the mainstay of treatment of DCIS and LCIS. DCIS may be managed with total mastectomy or partial mastectomy, followed by radiation therapy.¹⁴ Postoperative radiation therapy after partial mastectomy reduces by half the risk of local recurrences that are further reduced by systemic treatment with the estrogen antagonist tamoxifen. Risks and benefits of tamoxifen need to be carefully assessed, as the drug does not prolong the patient's survival and the risk of local recurrence is minimal. LCIS may be treated with local excision or with bilateral mastectomy (given the risk of bilateral recurrence).

Localized diseases

Mastectomy or breast preservation surgery with sentinel lymph node sampling is the commonly used procedure. Patients with positive sentinel lymph nodes undergo axillary dissection at a later time. The choice of adjuvant treatment depends on the hormonal status and risk of systemic recurrence. In patients with cancer rich in hormone receptors, adjuvant hormonal therapy for at least 5 years reduces by 50% the risk of recurrence and by 30% the risk of mortality.²⁰ Nowadays most oncologists prefer aromatase inhibitors to estrogen antagonists. Aromatase inhibitors appear to be more effective, do not cause endometrial cancer, and have a lesser risk of deep vein thrombosis, but they may cause osteopenia and osteoporosis and have higher risk of disabling arthralgias.²¹ Current investigations explore the benefits of continuing the treatment beyond 5 years. The benefits of adjuvant chemotherapy decline with the patient's age¹⁹ and have not been conclusively demonstrated in

Table 88-2. Forms of Cancer Treatment

Form of Treatment	Specific Treatment	Clinical Considerations	Complications
Local treatment	Surgery	The most common form of treatment of localized breast cancer. Both partial and total mastectomy may be performed under local anesthesia. It may be used occasionally in the management of metastatic disease, including fixation of bones at risk for fractures and resection of brain metastases.	
	Radiation therapy	Used in combination with surgery for breast preservation. In addition it may be used for palliation of painful bony metastases and for treatment of brain metastases after total mastectomy is indicated for large tumors (more than 5cm in diameter).	
Systemic treatment	Hormonal therapy: Estrogen antagonists Aromatase inhibitors Progestins Estrogens Androgens Cytotoxic chemotherapy	Used in the management of breast cancer whose tumor is positive for hormone receptors. It may be used both in the metastatic and in the adjuvant and neoadjuvant setting.	Estrogen antagonists may cause uterine cancer and deep vein thrombosis. Aromatase inhibitors cause severe arthralgias and osteopenia.
	Targeted treatment Bevacizumab Trastuzumab Lapatinib	Used in the management of breast cancer whose tumor is poor in hormone receptors and occasionally in those who are rich in hormone receptors. It may be utilized in the metastatic and in the adjuvant and neoadjuvant setting. It enhances the activity of some chemotherapy agents. Very effective in the management of tumors who have an overexpression of HER2neu.	Older patients are at increased risk of neutropenia and cardiotoxicity and mucositis. Complications include hypertension, clotting, bleeding, and visceral perforation (postsurgical). Trastuzumab may cause reversible cardiomyopathy. Lapatinib can cause diarrhea and interactions with drugs metabolized by the CyP450 system.
	Bisphosphonates	Utilized in patients with bony metastases to delay the development of pain, fractures, and other bone complications.	

women 70 and older.¹⁹ In addition to acute complications, including alopecia, nausea and vomiting, neutropenic infections, adjuvant chemotherapy may be associated with two late complications: myelodysplasia/acute myelogenous leukemia²² and chronic cardiomyopathy (in patients treated with anthracyclines).²³ A user-friendly computer system (found at www.adjuvantonline.com) allows a fairly precise estimate of the risk of recurrence and the benefit of chemotherapy in individual situations.²⁴ In patients whose tumor overexpresses HER2neu, the addition of trastuzumab for 1 year to adjuvant treatment has further reduced the risk of recurrences by 50%.²⁵ The benefits of this compound greatly overwhelm the risks, which include reversible cardiomyopathy in older patients.

Locally advanced disease

The management of locally advanced but unresectable disease includes neoadjuvant therapy, aimed to make the tumor smaller, followed by a local form of treatment: radiation therapy, surgery, or both.²⁶ This presentation of breast is dramatic and requires aggressive treatment to prevent local complications. Fortunately, it is rare, but in older women it may result from inadequate screening and ineffective self-examination.²⁷

Metastatic disease

The management of metastatic disease is determined by the nature of the metastases, by the concentration of hormone receptors, and by the presence of HER2neu overexpression. Some general points may be made:

- Life-threatening metastases (lymphangitic lung spread or extensive liver metastases) should be treated with chemotherapy, irrespective of hormone receptor status, to achieve a rapid response and save the patient's life. These are rare in older individuals.
- Patients with hormone receptor-rich tumors should be treated with three lines of hormonal therapy, including aromatase inhibitors, estrogen antagonists, and progestins, before starting chemotherapy. The use of estrogen in high doses and androgens has become limited because of their toxicity.
- Patients whose tumors overexpress HER2neu should receive trastuzumab as part of their treatment. If this agent is contraindicated, then oral lapatinib is the treatment of choice.
- Patients who have hormone receptor-poor tumors and those whose cancer has failed three lines of hormonal treatment may receive chemotherapy. The majority of oncologists would use single agent chemotherapy

sequentially to reduce the toxicity. Particularly indicated in older individuals, because of minimal toxicity are the oral prodrug capecitabine, pegylated liposomal doxorubicin, and gemcitabine.

- Patients with bony metastases should receive a bisphosphonate in combination with other systemic treatments to delay pain and fractures.
- Patients with a single brain metastasis may benefit from surgical removal or radiosurgery. Multiple metastases require total brain irradiation.

CONCLUSIONS

The management of breast cancer in older women is predicated on individual life expectancy and disease aggressiveness. The basic treatment principles are the same as for younger women with the following considerations:

- Postoperative radiation therapy may not be indicated for breast preservation at age 70 and over.
- The risk of complications resulting from hormonal therapy and chemotherapy increases after age 70. Of particular concern are endometrial cancer and deep vein thrombosis with tamoxifen; disabling arthritis and osteoporosis with aromatase inhibitors; and neutropenic infections, mucositis, and anthracycline cardiomyopathy with cytotoxic chemotherapy.

- Long-term complications of chemotherapy in older women include myelodysplasia/acute leukemia and congestive cardiomyopathy.
- A number of chemotherapy agents are particularly suitable for the management of older women with metastatic breast cancer resistant to hormonal therapy.

KEY POINTS

Cancer of the Breast in the Elderly

- Breast cancer is in general more indolent in older than in younger women. However, the disease is lethal in women of all ages. The management should be guided by the aggressiveness of the individual cancer and the life expectancy and functional reserve of individual patients.
- Screening mammography reduces breast cancer—related mortality in women with a life expectancy of 5 years or longer. Life expectancy rather than chronologic age should direct the implementation of cancer prevention.
- Therapeutic principles are the same in women of all ages. Controversy persists about the benefits of adjuvant chemotherapy in women 70 and older with hormone receptor–positive tumors. Genomic and proteomics may help identify older women who definitely benefit from adjuvant chemotherapy.

DISORDERS OF THE ADRENAL CORTEX

The need for normal adrenal functioning continues into old age. After decades of speculation, there is now firm evidence that the patterns of basal and stimulated levels of cortisol secretion are substantially unchanged in the healthy aging population. Subtle age-related changes have been described related to the metabolism of adrenal hormones, and morphologic features such as nodules appear quite commonly in the aging adrenal glands. Their importance arises from much readier and often serendipitous recognition as advanced imaging techniques are more widely used. It is therefore relevant to open this chapter with a résumé of the physiologic and biochemical actions of adrenal steroids, mechanisms controlling their secretion, and techniques available for assessing the function and anatomy of the adrenal glands.

Physiologic responses to adrenocortical steroids

Of the multitude of steroids found in the adrenal cortex, only the secretions of cortisol and aldosterone have undisputed and vital endocrine roles. The distinction between glucocorticoid and mineralocorticoid hormone actions is based on physiologic observations, backed by differential effects on critical enzyme systems in target tissues.

Glucocorticoids. Cortisol (hydrocortisone) is the natural glucocorticoid of humans and most other mammals (but not the rat, which is unable to synthesize cortisol and uses corticosterone instead). It has long been recognized that cortisol, especially in high doses, has mineralocorticoid properties and this has led to the widespread use of dexamethasone, a synthetic glucocorticoid, effectively without mineralocorticoid properties as the benchmark glucocorticoid.¹

This practice has passed from laboratory experiments to clinical investigation, as will be discussed later. There are growing reasons to question the validity of such assumptions, although the pragmatic clinical tests have proven value. There has previously been a tendency to subdivide the actions of glucocorticoids into those seen at low doses and termed physiologic, and those seen with high doses, classically causing cushingoid side effects, as pharmacologic. There is no sound scientific basis for this differentiation as new effects are not seen with high doses, although the clinical sequelae are, of course, striking.

The term *glucocorticoid* derives from the effects on carbohydrate metabolism: antagonism of insulin action, promotion of hepatic glycogen synthesis, and participation in the defenses against hypoglycemia. It may affect resource use by virtue of tissue differences in response of the key glycolytic enzyme, phosphoenolpyruvate carboxykinase.² Glucocorticoids have many other actions, often permissive in nature. These include vascular and renal responses affecting control of blood pressure and extracellular water content. Other critical roles include actions on protein and lipid synthesis and complex interactions with the immune system. In addition there is the well-recognized but poorly characterized function that enhanced glucocorticoid secretion plays in combating stress. The stimuli recognized as stressful and capable of

evoking enhanced cortisol secretion are numerous, including: fever, trauma, hemorrhage, and plasma-volume depletion, hypoglycemia, and even psychological disturbance. A unifying hypothesis is thus hard to achieve, but with regard to inflammatory processes, it is now widely believed that the role of glucocorticoids is to curtail the effects of the rapidly responding cytokine and acute-phase protein production, which if protracted could be potentially damaging.³

Mineralocorticoids. The action of aldosterone is ostensibly simpler, operating primarily via renal mechanisms to control extracellular sodium and potassium levels with secondary consequences on fluid balance and blood pressure. The effects of mineralocorticoids on other tissues such as the colon, brain, and pituitary are documented, but their significance is much less certain. The secretion of aldosterone and its circadian rhythm are maintained in the elderly despite a decrease in tonic levels of renin, its principal regulator.⁴

Adrenal androgens. The adrenal cortex also synthesizes androgens. These include androstenedione and dehydroepiandrosterone; much of the latter is conjugated and secreted as the sulfate. The function of adrenal androgens remains obscure, although much has been made of the phenomenon in childhood of the so-called "adrenarche," when enhanced amounts are made from about the age of 7 years. By contrast with cortisol production, there is a well-documented fall in adrenal androgen production in old age, to as little as 5% of young adult levels, with decreased ACTH responsiveness, which has been termed the "adrenopause."⁵

Apart from effects on body hair, it is not at all clear what function the secretion of adrenal androgens serves in normal adults. It has been postulated that the decline in dehydroepiandrosterone levels is, in part, responsible for the increased atherogenesis and, hence, cardiovascular disease in old age, but recent evidence does not support this hypothesis.⁶ It appears more likely that dehydroepiandrosterone has an immunomodulatory, and possibly antioncogenic, action. Dehydroepiandrosterone replacement in an elderly person increases natural killer (NK) cell cytotoxicity and is claimed to dramatically improve the sense of physical and psychological well-being.⁷

Biochemical actions of steroid hormones

The effects of hormones on tissues depend on the distribution of specific receptors. Recent advances in knowledge have simultaneously clarified aspects of steroid hormone action and raised paradoxes that await definitive resolution. Steroids are lipophilic and readily enter cells: steroid receptors are intracellular. The classic model of steroid action is that steroid hormones bind to cytoplasmic receptors, forming activated complexes that are translocated to the nucleus where specific genes are activated, leading eventually to protein products as the end point of hormone influence.⁸ A similar pattern was proposed for the structurally dissimilar thyroid hormones. Molecular cloning techniques have not only revealed that all steroid hormone receptors show strong homologies to each other and the proto-oncogene *c-erb-A*, but that the latter actually appears to be a thyroid-hormone

receptor. All these receptors share homologies, both in the hormone and the DNA-binding domains, and can be regarded as constituting a superfamily of genes, whose products are transcriptional regulatory proteins evolved from a common ancestor gene.⁹ The steroid-hormone receptor is bound to a protein complex containing the heat-shock proteins hsp 90, hsp 70, and hsp 65. Exposure to steroid hormone leads to dissociation of the receptor from the complex so that the receptor is able to bind the hormone.¹⁰ Along with the classic genomic mechanisms, the cortisol-glucocorticoid receptor complex can interact with other transcription factors such as nuclear factor- κ B and also nongenomic pathways via membrane-associated receptors and second messengers.¹¹

The new complex of hormone-plus receptor adopts a different molecular conformation, exposing the DNA-binding domain of the receptor. Thus far, the generalized scheme for steroid hormones applies to glucocorticoids. When it comes to identifying the molecular basis for mineralocorticoid and glucocorticoid actions, difficulties arise. The type-1 receptor—originally considered to bind mineralocorticoids with higher affinity than glucocorticoids—shows no such distinction with more modern techniques. Indeed there is a marked kinship shown at the molecular level as well.^{12,13} A possible explanation for the failure of the great molar excess of cortisol to swamp the type-1 receptor with regard to aldosterone binding has been suggested for tissues such as kidney, gut, and salivary glands. These tissues possess a potent 11-hydroxysteroid dehydrogenase enzyme system, which rapidly converts cortisol to cortisone, and cortisone does not bind measurably to the receptor.¹⁴

Acting through the genome, glucocorticoids enhance several key metabolic enzymes, such as hepatic tyrosine aminotransferase¹⁵ and tryptophan oxygenase.¹⁶ In addition to this classic mode of action, it has also been suggested that many of the actions of glucocorticoids on the immune system are mediated by a specific protein product termed *lipocortin* (now known as *annexin A1*), which acts as a second messenger.¹⁷ This has multiple sites of action especially, inhibiting polymorphonuclear leukocyte trafficking, reduction of pro-inflammatory cytokines and stimulation of anti-inflammatory cytokines.

Regulation of adrenal function

Regulation of glucocorticoid production. Cortisol secretion is under the immediate control of pituitary ACTH secretion acting to promote the conversion of cholesterol to pregnenolone by the removal of the six-carbon fragment from the cholesterol side chain. These steps occur within the mitochondrion. A complex cascade of cytochrome-P450 variants has been implicated as steroidogenesis proceeds, shuttling from mitochondrion to endoplasmic reticulum and back. The chronic effects of ACTH affect many more steps in steroidogenesis than just cholesterol side-chain cleavage.¹⁸

Physiologic control of ACTH secretion involves three major areas: circadian rhythms, stress, and negative-feedback inhibition by cortisol. ACTH is synthesized as part of a large 31-kDa precursor polypeptide pro-opiomelanocortin.¹⁹ This is cleaved and the major fragments, including ACTH and β -endorphin, are usually cosecreted in equimolar proportions. The stimulus to ACTH release is from the

hypothalamus by way of the hypothalamopituitary portal vessels conveying corticotrophin-releasing factors.²⁰

These are a complex of polypeptides, the major constituent of which is a 41-residue moiety, corticotrophin-releasing hormone (CRH). However, this alone has less potent ACTH-releasing properties than crude hypothalamic extracts. It has been shown that vasopressin (AVP) and probably other, as yet unidentified, compounds act synergistically with CRH.²¹ The secretion of these corticotrophin-releasing factors appears to be pulsatile-driving pulses of ACTH and cortisol in turn. The circadian rhythm is composed of pulses of varying amplitudes and frequency, with a nadir reached at midnight, but the onset of activity at about 3 AM to 4 AM reaching a peak at 8 AM to 9 AM. The pulses of ACTH and cortisol decline in size and frequency thereafter, although there is often a secondary rise at about lunchtime, which seems to be related to food ingestion.²²

As mentioned earlier, there is a formidable array of apparently unrelated stressors that can stimulate the release of ACTH and cortisol. There is preliminary evidence that the relative importance of CRH, AVP, and oxytocin varies according to the stimulus.²³ Where inflammation is involved, there is growing evidence for interleukin-1, interleukin-6, and tumor necrosis factor (TNF) having the capacity to stimulate the hypothalamic-pituitary-adrenal axis, thus providing a loop to suppress their own production.²⁴

Reports suggesting extrahypothalamic production of ACTH secretagogues lack confirmation of authenticity or physiologic significance.

Negative feedback of cortisol on ACTH production constitutes a sensitive homeostatic regulatory mechanism. The sites of negative feedback include not only the ACTH-producing cells of the anterior pituitary itself, but also higher centers including the hypothalamus and CA3 field of the hippocampus.²⁵

Regulation of aldosterone production. Aldosterone is produced by the distinct outer part of the adrenal cortex, the zona glomerulosa. In humans this is found in cell clusters rather than in a distinct zone. The main regulation of aldosterone is by the renin-angiotensin system. The stimuli to renin release from the juxtaglomerular cells of the kidney are low-renal perfusion pressure, sodium depletion, and hypokalemia, although hyperkalemia acting directly on the zona glomerulosa is a more potent stimulus to aldosterone release than hypokalemia. Renin acts on renin substrate or angiotensinogen, released into the circulation from the liver, to form angiotensin-I. This decapeptide is converted to the octapeptide angiotensin-II by angiotensin-converting enzyme (ACE), which is of widespread distribution, but most importantly found in the pulmonary bed.²⁶

Angiotensin-II, apart from being a powerful arteriolar vasoconstrictor, stimulates aldosterone secretion from the adrenal cortex. Aldosterone, as mentioned earlier, acts powerfully to retain salt (and obligatorily water), but promotes kaliuresis, hence closing the homeostatic feedback loop. There are other minor influences recognized as acting on aldosterone secretion, including ACTH, dopamine, and serotonin.

Adrenocortical function in normal aging

Numerous studies indicate that basal, circadian, and stimulated cortisol secretion remains intact well into old age.^{27–33} This is particularly important with regard to the ability to

withstand stress, and the cortisol response to exogenous ACTH has been shown to be normal in elderly patients following myocardial infarction.³⁴ There are well-documented changes in the metabolism of corticosteroids with age-related decrease in the catabolism of cortisol.^{35,36} Because of the intact negative feedback mechanisms there is a commensurate reduction in cortisol production rate. Aldosterone secretion is also normally well preserved in the healthy geriatric population.³⁷ The recognized decline in adrenal androgen production^{30,38–41} has been referred to earlier.

Tests of adrenal function

Tests of adrenal function in elderly people are for the foregoing reasons largely those established for the younger adult population. The diminishing reliance on urinary collections is beneficial for practical reasons, and also means that some of the physiologically irrelevant changes alluded to earlier will not prove distracting. The key to successful and safe investigation is careful selection.

Adrenal insufficiency. To investigate possible adrenal insufficiency, the basal measurement of greatest value is the plasma cortisol, measured at the circadian peak at 8 AM to 9 AM. Measurement of midnight cortisol is uninformative. If the 9 AM cortisol is less than 150 nmol/L, the diagnosis of adrenal insufficiency is made, and if greater than 450 nmol/L, the patient is normal. For values in between, adrenal reserve should be assessed by measuring plasma cortisol before the intramuscular administration of 250 µg tetracosactrin (synthetic ACTH_{1–24}) and then 30 minutes after. If secondary adrenal insufficiency is suspected, central mechanisms need assessing. Although the insulin-induced hypoglycemia test is still the gold standard for younger patients, and indeed, has been used successfully in the elderly,⁴² there are serious hazards attending its use. If the 9 AM plasma cortisol is not greater than 180 nmol/L, if there is a history of epilepsy, or if there is a significant risk of ischemic heart disease (surely present in all elderly patients), the test is contraindicated.

Alternative tests have been suggested, including several varieties of the metyrapone (Metopirone) test. This drug blocks the 11-hydroxylase enzyme, which is a crucial step in cortisol biosynthesis. If negative-feedback mechanisms are intact, metyrapone provokes enhanced ACTH secretion, which drives adrenal synthesis of 11-desoxycortisol. In the classic version, the adrenal response is measured by urinary 17-oxogenic steroid excretion,^{43,44} but altered production of urinary metabolites in old age plus the nonstandardized assays used for the measurements diminish the value of this approach. Other investigators have proposed measurement of the plasma 11-desoxycortisol response, but this, too, has not been fully validated, especially in the elderly age group.^{45–47} Finally, it has been proposed that the ACTH level should be directly monitored, and this has been evaluated in a geriatric population.⁴⁸ The difficulties of ACTH measurements are many, standardization nonexistent, and the assay is costly and not widely available; thus as a practical test this version does not bear further consideration. Most importantly, it does not assess what one needs to know: the capacity to secrete cortisol adequately in the face of stress. It is popular in North America, but for reasons of tradition rather than sound science.

A test by which contrast has much to recommend is the glucagon stimulation test. In the most widely used version,

1 mg of glucagon is injected subcutaneously and blood samples then taken basally at 90 minutes and thereafter at 30-minute intervals up to 240 minutes. As with the insulin test, the patient fasts overnight. There is no correlation between the cortisol response (or growth hormone response, because it is a reliable test of reserve of this hormone) and blood glucose changes. The diagnostic power of the test closely approaches the insulin stress test.⁴⁹ Glucagon is, however, safe to use even in the presence of heart disease and in epilepsy. The length of sampling period is dictated by the variable time taken to reach peak cortisol secretion—this adds inconvenience and expense. The use of intramuscular glucagon has been a simpler, more reliable version requiring samples only at 0, 150, and 180 minutes.⁵⁰ It is a more reliable test than the short synacthen test when compared with the insulin tolerance test as the reference.⁵¹ As with the insulin tolerance test, a peak plasma cortisol of 550 nmol/L or higher is regarded as a satisfactory response to glucagon.

Another useful aid in distinguishing primary and secondary hypoadrenalism is the long ACTH-stimulation test using depot tetracosactrin 1 mg intramuscularly and sampling at 0, 30, and 60 minutes as with the short test, but taking further samples at 4, 8, 16, and 24 hours.⁵² The atrophied adrenals following ACTH deficiency can usually be stimulated, albeit subnormally, over this time span—in contrast to the flat response in Addison's disease.

Glucocorticoid excess. Adrenal hyperfunction usually means cortisol excess or Cushing's syndrome. Conventional methods of investigation are employed first to establish the presence of the syndrome. The 24-hour urine-free cortisol is a simple and reliable test.^{53,54} Its value derives from the fact that at normal levels of plasma, cortisol is much bound to a high-affinity cortisol-binding globulin (CBG). The free cortisol level (though thought to be the biologically active fraction) is generally small, and is readily excreted in the urine. Because the capacity of CBG is limited, and saturated with even minor degrees of cortisol hypersecretion, there tends to be a nonlinear and marked rise in urinary-free cortisol. The overnight dexamethasone suppression test is much used, but also much criticized for unacceptable error rates.⁵⁵ If a patient is genuinely thought to have Cushing's syndrome, inpatient investigation is usually required. The low-dose dexamethasone test (0.5 mg orally taken strictly every 6 hours for 48 hours) and high-dose dexamethasone test (2 mg every 6 hours for 48 hours) were originally described in terms of suppression of urinary cortisol metabolites and proved useful in the differential diagnosis of pituitary-dependent Cushing's syndrome from other causes of the syndrome, namely adrenal tumors (benign and carcinoma) and ectopic ACTH secretion from a wide variety of neoplasms.⁵⁶ More commonly, the plasma cortisol response is relied upon these days.⁵⁷ The basis of this test is that in Cushing's syndrome the pituitary lesion, most commonly a microadenoma only a few millimeters in diameter, is not truly autonomous, but shows blunted suppression of ACTH secretion, especially with high-dose dexamethasone. The plasma cortisol is an accurate index of ACTH secretion because its measurement is not affected by the concomitant presence of dexamethasone. (This useful property of dexamethasone can be used to assess adrenal reserve in seriously ill patients with suspected Addison's disease in whom glucocorticoid therapy may need to be given empirically, and the cortisol response

to tetracosactrin assessed at the same time to establish diagnosis.) There is increasing use of synthetic CRH, either of ovine or human composition.^{58,59} Though many investigators find this a helpful and safe test, as with all tests used in Cushing's syndrome it is not infallible.⁶⁰ Nevertheless, it is useful to know that there is a preservation of response in the healthy elderly population.³³

In cases of adrenal carcinoma it is not unusual to have mixed patterns of steroid excess. Virilization in women is not uncommon, and plasma testosterone is raised. A striking rise in dehydroepiandrosterone sulfate is characteristic of adrenal carcinoma,⁶¹ and this large production of a weak androgen may greatly raise the urinary 17-oxosteroid excretion.⁶²

Mineralocorticoids. The mineralocorticoid status can be monitored by measurement of plasma aldosterone and also plasma renin activity both lying and standing (if clinically possible). The latter measurement of renin requires prior consultation with the laboratory so that rapid handling can be arranged to prevent artefactual results. Primary hyperaldosteronism is very uncommon in the elderly population and is diagnosed by raised aldosterone and suppressed plasma renin activity in hypertensive patients who usually exhibit hypokalemic alkalosis. The much more frequent occurrence of secondary hyperaldosteronism is indicative of disease outside the adrenals, such as renal artery stenosis, cardiac failure, or hepatic cirrhosis leading to raised renin, driving the normal zona glomerulosa to secrete high levels of aldosterone.

Hyporeninemic hypoaldosteronism occurs predominantly in the elderly population and is characterized by hyperkalemia, a hyperchloremic metabolic acidosis, and moderate hyponatremia. It is more common in men, and is often associated with diabetes mellitus, particularly in the presence of autonomic failure or renal impairment. It is aggravated by potassium-sparing diuretics, β -blockers, and nonsteroidal anti-inflammatory drugs.⁶³

Imaging techniques in adrenal disease. The adrenal glands are readily visualized using CT scanning, especially if the patient is at all obese. Ultrasound can be useful, but is much less valuable than CT.⁶⁵ There is growing experience with magnetic resonance imaging (MRI), which may provide an indication of the likely functional status of any lesion. However, potential pitfalls arise with the exquisite sensitivity but nonspecificity of this and advanced CT scanning techniques.⁶⁴

There remains a small role for isotopic scintigraphy in the diagnosis of adrenal hyperfunction, perhaps more for extra-adrenal or bilateral pheochromocytomas using metaiodobenzylguanidine than the use of selenocholesterol or its variants in Cushing's and Conn's syndromes.⁶⁶ Angiography is invasive, but much less so with the advent of digital venous imaging (DVI), which can be useful in adrenal disease. The pituitary may require imaging in Cushing's disease—often the tiny size of the tumor defies even the latest generation CT scanners,⁶⁷ but it does seem that MRI with gadolinium enhancement offers a slight edge.⁶⁸ In cases of hypopituitarism, CT scanning may be valuable.

As a final resort, venous sampling under radiographic control may be useful in the diagnosis of adrenal, pituitary, or ectopic sites of hormone production.⁶⁹ This approach in the elderly patient should be undertaken only if, after the most careful consideration, a balance of cost-benefit factors

points inescapably in this direction. In practice this will rarely be the case.

CLINICAL PATTERNS OF ADRENAL DISORDERS

The patterns of adrenal disease do not differ greatly in the elderly population from those in younger adults. Because these are well-described in standard textbooks of clinical medicine and endocrinology, full descriptions will not be given here in all cases. Instead, emphasis will be placed on points particularly relevant to an elderly person.

Adrenal insufficiency

Primary adrenal failure (Addison's disease) characteristically begins insidiously with nonspecific symptoms, although gastrointestinal features, including weight loss, are often prominent, and in the elderly person functional status may be diminished.⁷⁰ Though the characteristic ACTH-mediated pigmentation is a useful feature if present, it is occasionally absent.⁷¹ A large survey suggested that in elderly patients Addison's disease was not only more likely to be tuberculous than in younger patients, but likely to prove fatal and the diagnosis be made at post mortem.⁷² Other rarer causes of adrenal failure, such as hemorrhage and amyloid, should be borne in mind.⁷³

Though metastases are commonly found in the adrenal glands, they only exceptionally compromise cortisol secretion.⁷⁴ The therapeutic dividend from diagnosing Addison's disease is so great that the cortisol response to tetracosactrin should be assessed at the slightest suspicion. It is emphatically not necessary for the electrolytes to be disturbed or random cortisol to be "subnormal" for the significant adrenal insufficiency to be present. Secondary adrenal insufficiency is considered later.

Cushing's syndrome and adrenal carcinomas

Cushing's syndrome is rare in elderly people. It is most frequently due to ectopic ACTH production, usually by small-cell carcinoma of the lung, but these patients typically have cachexia and profound hypokalemia, rather than the characteristic cushingoid appearance. If due to pituitary-dependent disease, transsphenoidal surgery may be considered because it causes little constitutional disturbance. Nevertheless, in mild cases medical treatment with metyrapone alone may suffice and be more appropriate. This mode of treatment is certainly appropriate with other forms of Cushing's syndrome, such as ectopic ACTH secretion. The mixed picture of Cushing's syndrome and virilization in adrenal carcinoma may be difficult to recognize: the hirsuties and thinning of capital hair may be much more prominent than the features of cortisol excess (Figure 89-1). Indeed, the main features of Cushing's syndrome may be skin atrophy and fragility with spontaneous bruising. Obesity and plethora may be conspicuously absent. In the elderly person certain features are more marked, particularly impaired cognitive function, myopathy, osteoporosis, and diabetes. Hypokalemia is common in all forms of Cushing's syndrome other than pituitary-dependent, although a patient with the nodular hyperplasia variety of Cushing's disease was diagnosed following an admission precipitated by an acute diarrheal illness in which the plasma potassium fell to 1.2 mmol/L. Subclinical Cushing's syndrome is increasingly being

Figure 89-1. Patient with a metastasizing adrenal carcinoma causing virilization and Cushing's syndrome. Note hirsuties, slight scalp recession, but absence of cushingoid facies.

recognized in cases of adrenal incidentaloma (see later discussion) and is associated with increased cardiovascular risk.^{75,76}

Adrenal carcinomas may occasionally secrete estrogen. This was retrospectively recognized in a youthful looking elderly woman with Cushing's syndrome (Figure 89-2) following removal of her large adrenal tumor (Figure 89-3) when she had a brisk vaginal blood loss. Rescue of preoperative urine specimens revealed high estrogen levels. Treatment is primarily surgical unless there are widespread metastases. The use of opDDD is probably helpful, but may be associated with severe side effects, in which case it should not be persevered with.⁷⁷

Iatrogenic glucocorticoid excess

The most common cause of Cushing's syndrome in an elderly person is the exogenous administration of steroids for a variety of medical disorders. The side effects of steroid therapy, often aggravating preexisting problems, are usually more marked in the elderly group. Particular problems include decreased cognitive function, emotional lability, and dysphoria; osteoporotic fractures; myopathy and muscle wasting with limitation of mobility; skin fragility; and impaired glucose tolerance. Furthermore, patients on maintenance steroids (>10 mg prednisolone daily or equivalent for more than 2 weeks) are at risk of adrenal insufficiency in the event of intercurrent illness, and the daily steroid dose should be doubled for at least 3 days in these circumstances.

Incidentalomas

Last, but very far from least, is the vexed problem of what to do with a patient who for usually quite unrelated reasons has an abdominal ultrasound or CT scan that reveals an

Figure 89-2. Patient with adrenal carcinoma causing Cushing's syndrome and feminization.

Figure 89-3. Intravenous pyelogram, showing large right-sided adrenal mass depressing the right kidney.

unsuspected adrenal mass.^{78,79} Because about 20% of adrenocortical carcinomas are nonfunctioning in the absence of any clinical endocrine syndrome, it is probably prudent to repeat the scans at intervals, particularly for lesions greater than 3 cm diameter, since lesions progressing to greater than 6 cm diameter are almost always malignant. However, the

problem must be kept in proportion. Adrenal cancer is rare, with an annual incidence approximately two per million.⁸⁰ Autopsy studies show that benign nodules are extremely common, especially with advancing age, and particularly in hypertensives.⁸¹ Most are microscopic, but lesions of greater than 1 cm are found in approximately 1% of patients undergoing abdominal CT.⁸² Clearly, there is a need for biochemical screening to exclude pheochromocytoma, Conn's, and also Cushing's syndrome. Hypertension and hypokalemia are particularly good indicators of functioning lesions. It has been estimated that the frequency of these conditions in 100,000 patients with an adrenal incidentaloma would be 6500 pheochromocytomas, 7000 Conn's syndrome, and only 35 Cushing's syndrome. However, subclinical cortisol hypersecretion has been reported in up to 25% of patients with adrenal tumors incidentally discovered on CT in a number of studies.^{83,84} Cumulative worldwide experience indicates that most adrenal incidentalomas are benign, but a significant number are malignant, especially large lesions, and in patients with a history of malignancy.^{85,86} Late diagnosis of genetic disorders can occur in the elderly including pheochromocytoma in the proband of a family with MEN2a, a woman aged 73,⁸⁷ and an 88-year-old woman with congenital adrenal hyperplasia, due to 21-hydroxylase deficiency, presenting with adrenal insufficiency.⁸⁸

PITUITARY DISORDERS

Pituitary tumors

Pituitary tumors are increasingly uncommon in the elderly population, with the exception of nonfunctioning (null-cell) adenomas, which increase in incidence over the age of 50. These tumors have local complications—usually due to compression of the optic chiasm causing bitemporal hemianopia, or more rarely due to invasion into surrounding structures, such as the cavernous sinus—or features of hypopituitarism (see later discussion). Functioning pituitary tumors are associated with the characteristic syndromes of hormone excess, notably, acromegaly and Cushing's disease, and behave in a similar fashion to tumors in younger patients, although it has been suggested that the somatotroph adenomas causing acromegaly are more benign in the elderly person, and thus medical therapy could be considered as a first-line option.⁸⁹ However, advances in neurosurgical techniques mean that almost all tumors can be at least debulked by the transsphenoidal approach; the relative simplicity and low morbidity and mortality of this procedure make it the treatment of choice for even the very elderly patient, especially one having visual field defects.^{90–95}

Other sellar lesions are very rare, although two occur more commonly in the elderly. Pituitary metastases may present like nonfunctioning tumors. Pituitary incidentalomas—adenomas, usually less than 1 cm in diameter, without clinical sequelae, may be identified on a CT or MRI scan performed for other indications in the same way as adrenal incidentalomas and have a prevalence of up to 10% in the over-80 age group, but intervention is not required in such cases.

Hypopituitarism

Hypopituitarism may be caused by pituitary adenoma as in younger age groups. A valuable clue in postmenopausal women is finding inappropriately low gonadotrophin levels,

although it has been reported that these can be depressed in nonspecific illness in the extremely elderly.⁴⁸ More important, because subtler and more difficult to diagnose, is idiopathic hypopituitarism, in which the pituitary fossa is normal in size. Key features may be orthostatic hypotension, hyponatremia (reflecting adrenal and thyroid insufficiency causing water overload, possibly from inappropriate ADH secretion), or hypothyroidism with inappropriately low TSH.^{96–99} Computed tomography scanning may indicate a number of abnormalities ranging from a thickened pituitary stalk to empty sella.⁹⁷ Replacement therapy with hydrocortisone and thyroxine is gratifyingly effective. As with patients on steroid therapy, those patients needing replacement hydrocortisone should be advised to double the dose of hydrocortisone for 3 days with intercurrent illnesses, and they need parenteral steroids if they cannot tolerate oral medication while unwell.

Growth hormone deficiency. Growth hormone secretion declines by about 15% per decade from a peak at about 30 years of age,¹⁰⁰ and stimulated growth hormone secretion, using both pharmacologic agents and physiologic stimuli, such as exercise, is diminished in elderly people. This fall in growth hormone secretion is due to a decline in the frequency¹⁰¹ and amplitude¹⁰² of growth hormone pulses, probably the result of an increase in somatostatinergic tone. Furthermore, there is a decrease in circulating levels of insulin-like growth factor-I (IGF-I), the peripheral mediator of the somatic effects of growth hormone—although, in contrast to young adults, the IGF-I levels do not show as strong a correlation with 24-hour growth hormone secretion.

Some of the features of aging are similar to the characteristics of adult growth hormone deficiency, such as the decrease in lean body mass and bone mineral density, the increase in fat mass,¹⁰³ and possibly, neuropsychological sequelae and increased cardiovascular mortality.¹⁰⁴ The availability of recombinant growth hormone has made the treatment of adult growth hormone deficiency possible, and recently there has been interest in its effects on the healthy elderly individual. In those with low IGF-I levels, administration of growth hormone increases lean body mass, skin thickness, lumbar spine bone density, and nitrogen retention, and decreases adipose tissue. No effect was seen on bone density at other sites or on serum cholesterol, and non-significant increases in blood pressure and fasting glucose have been reported. Side effects of fluid retention, in some cases causing bloating or carpal tunnel syndrome, arthralgia, headaches, lethargy, and gynecomastia may occur.¹⁰⁵

KEY POINTS

Adrenal and Pituitary Disorders

- Adrenal cortex produces cortisol, aldosterone, and adrenal androgens.
- Steroids act by genomic and membrane-mediated effects plus intracellular conversions.
- Clinical consequences of disordered steroid production/exposure
- Incidentally diagnosed adrenal nodules in old age
- Age-related decline in adrenal androgen and growth hormone secretion
- Diagnosis and management of pituitary disease in the elderly

At present, the only group for whom growth hormone therapy can be recommended are those with pituitary disease, requiring at least one form of pituitary hormone replacement therapy, in whom growth hormone deficiency has been demonstrated using a pharmacologic stimulation test and who have symptoms of growth hormone deficiency. Elderly patients with hypothalamic-pituitary disease and growth deficiency are distinguishable from elderly controls with respect to lipid profiles, body composition, and quality of life.¹⁰⁶ They respond as positively to growth hormone replacement as do younger patients.¹⁰⁷⁻¹¹⁰

Isolated ACTH deficiency. Less frequent is the development of isolated ACTH deficiency. This has been seen in an octogenarian who developed frequent hypoglycemic comas associated with raised insulin levels. The clue that this was not due to an insulinoma came from the equimolar secretion of insulin and C-peptide. Replacement therapy with hydrocortisone completely abolished the hypoglycemic episodes.¹¹¹

Although thyroid disorders occur over the entire age range, many appear to be increasingly common with advancing age. It is important to recognize that the clinical features of thyroid disease may be significantly altered in the aged individual, so that symptoms and physical findings typical in young persons may be modified, different, or absent in the elderly population.

The diagnosis of a thyroid disorder may be further influenced by the age of the patient as a consequence of normal aging-associated changes in thyroid physiology. Of great importance is the impact of nonthyroidal illnesses that frequently occur in the elderly person on many of the tests used to assess thyroid function.¹ Management may be influenced by the presence of the many coexistent medical disorders common in an aging population.

MORPHOLOGY

The normal aging process is accompanied by changes in the gross and microscopic appearance of the thyroid gland. Early studies based on autopsy data indicated that overall mass declines from the normal range of 15 to 25 g so that with increasing age a progressively larger proportion of individuals will have glands weighing less than 20 g.² In contrast, data obtained in recent years by ultrasound in healthy subjects reveal that aging results in little change in size of the thyroid.³

With advancing age, there is progressive fibrosis, the appearance of lymphocytes, a decrease in follicle size, and a reduction in the amount of colloid.⁴ Although these changes are common in the elderly population, they are by no means characteristic of all aged persons. More important, there does not appear to be a decline in thyroid function concomitant to the morphologic changes, and neither weight nor histologic appearance correlate with common measures of thyroid function.⁵

Hypothalamic–pituitary–thyroid regulation

The production of thyroid hormones is regulated by the hypothalamic–pituitary–thyroid axis. Thyrotropin-releasing hormone (TRH) is synthesized in the hypothalamus and functions to stimulate release of thyroid-stimulating hormone (TSH) from the anterior pituitary by binding to receptors on the cell membrane of TSH-producing thyrotropes. Thyroid-stimulating hormone is regulated by the negative feedback of the thyroid hormones thyroxine (T4) and triiodothyronine (T3) acting on the pituitary gland.

The neuroendocrine mechanisms controlling TSH release may be altered during the normal aging process. Thus, serum TSH concentration, which undergoes circadian variation, exhibits smaller fluctuations in elderly than in young men.⁶ The ability of TRH to stimulate TSH release may be affected by both the age and gender of the individual. Several studies have documented that elderly men have an impaired TSH response to TRH stimulation, with peak serum TSH values in men over the age of 60 showing approximately a 40% reduction compared with young men.^{7–12} In women,

however, there does not appear to be an effect of age on TSH responsiveness.¹³

The ability of the pituitary gland to synthesize TSH does not appear to be diminished by the aging process, as reflected by the observation that pituitary TSH content undergoes no significant change over the life span.¹⁴ The 24-hour TSH secretion has been reported to be decreased in healthy elderly men,¹⁰ but the secretion rate of TSH has also been reported to be higher in elderly subjects than in young individuals.¹⁵ However, circulating levels of TSH remain constant with advancing age, and the elevations that are commonly seen in elderly persons must be considered as evidence for failing thyroid function.¹⁶

Thyroid-stimulating hormone exerts its effects by binding to the membrane of thyroid follicular cells. The response of these cells to TSH stimulation is not impaired by aging, as reflected by T4 and T3 release into the circulation following either TRH or TSH administration.¹⁷

Within the thyroid gland, T4 and T3 synthesis results from the trapping of iodide by follicular cells, subsequent oxidation of iodide leading to iodination of tyrosine, and coupling of two iodinated tyrosines. In the normal adult, approximately 80 µg of T4 and 30 µg of T3 are produced daily.¹⁸ In elderly individuals, T4 and T3 production declines to approximately 60 and 20 µg per day, respectively. These changes may be related to the decrease in thyroidal iodide accumulation, which has been observed with aging.¹⁹

Thyroid hormone secretion and metabolism

In response to TSH stimulation, T4 and T3 stored in thyroid follicles are hydrolyzed from thyroglobulin and released into the circulation where they are bound to albumin, thyroid-binding prealbumin (TBPA), and thyroid-binding globulin (TBG), with less than 0.1% of the hormones circulating in the free form. Thyroid-binding globulin is the primary thyroid hormone transport protein, carrying about 70% of bound hormone, and its levels do not appear to differ between healthy young and old individuals.⁹ A greater T4-binding capacity of TBG has been observed in the elderly population but appears to be without clinical significance.^{20,21}

The small proportion of T4 and T3 in the free state (FT4 and FT3) is composed of the biologically active forms of the hormones and is responsible for peripheral thyroid hormone action and metabolism. Circulating levels of both FT4 and FT3 remain constant over the age span, and a decrease in concentration, especially FT3, should be considered a consequence of illness rather than as a result of normal aging.^{9,16,17,20,22} Approximately 20% to 30% of circulating T3 is directly secreted by the thyroid gland, with the remaining 70% to 80% resulting from 5'-monodeiodination of the outer ring of T4 in peripheral tissues.¹⁸ T4 degradation is decreased with advancing age so that, by age 90, the degradation rate is approximately 50% that of young subjects.^{17,23,24} This change appears to be due to an age-related reduction in the activity of monodeiodinase enzymes in peripheral tissue.²⁵ T3 degradation is less affected by

aging.^{17,25} A consequence of these changes is a decline in T4 metabolic clearance rate and an increase in the half-life of circulating T4 from approximately 6 days in young persons to over 9 days in individuals who have reached their ninth decade.^{23,24,26} Because serum T4 concentration is not affected by aging, the prolongation of T4 half-life implies that there is an aging-related decline in T4 production by the thyroid gland.

Part of T4 degradation involves 5-monodeiodination of the inner ring of the molecule and results in the generation of the biologically inactive reverse T3 (rT3).^{18,27} The outer-ring 5'-monodeiodinase is sensitive to a variety of influences including starvation, febrile illness, elevation of glucocorticoid concentration, and drugs such as propranolol, amiodarone, and iodinated contrast materials.^{18,28} As a result of inhibition of the enzyme activity, there is impaired T4 conversion to T3, with a decline in serum T3 concentration and a parallel rise in rT3 concentration. Serum rT3 is not affected by normal aging, and an increase must be considered to be a consequence of illness or drug-induced alteration in T4 degradation.^{22,25,29}

Thyroid hormone action

The primary thyroid hormone acting on peripheral tissue and responsible for the broad range of thyroid actions is FT3. FT3 and, to a lesser amount, FT4 act on peripheral tissue cells by binding to specific nuclear receptors and subsequently affect DNA transcription, RNA formation, and new protein synthesis.³⁰⁻³² There are two T3 receptor genes, located on chromosomes 17 and 3, whose product is a group of T3 receptors.³² Protein products coded for by the *c-erb-A* gene family, the cellular counterpart of the viral oncogene *v-erb-A*, have been demonstrated to be nuclear receptors for thyroid hormone.^{33,34} At the level of the pituitary, thyroid hormone action results in inhibition of synthesis and release of TSH.^{35,36}

Thyroid hormone action appears to be diminished as part of the aging process. Oxygen consumption is decreased and is reflected clinically by a decline in basal metabolic rate.³⁷ In aging animals, there is decreased ability to stimulate hepatic enzyme synthesis following exposure to thyroid hormone.³⁸ Clinical support for diminished thyroid hormone action is provided by the observation that typical features of hyperthyroidism are often absent in the elderly population of patients.

Thyroid function in advanced aging

Studies in healthy centenarians ranging in age from 100 to 110 years provide further information regarding the extent to which aging alone contributes to change in measures of thyroid function. There was no difference in serum FT4 of the centenarians as compared to both healthy elderly (aged 65 to 80 years) and healthy younger adults (aged 20 to 64 years), but serum FT3 was reduced in the centenarians. Serum TSH was also lower in the centenarians, and for the older groups as a whole there was an inverse relationship between serum TSH and age. Serum rT3 was increased in the centenarians, suggesting that there was reduced outer-ring deiodination of T4. Thus, in healthy aging persons, thyroid function was preserved into the eighth decade, whereas advanced old age was associated with reduced thyroid activity that was likely to be due to

a decrease in TSH secretion and impairment of peripheral 5'-deiodination.^{1,39}

ASSESSMENT OF THYROID FUNCTION

Circulating thyroid hormones

Screening of the secretory status of the thyroid gland can be accomplished by measurement in the blood of TSH, total circulating T4 and T3 concentrations, and FT4 and FT3 concentrations through use of radioimmunoassay or immunometric assays.¹² The development of "super sensitive" immunoassays for TSH have allowed differentiation of normal from suppressed levels of the hormone so that this single measurement can provide evidence supporting a diagnosis of primary hypothyroidism, secondary hypothyroidism, or hyperthyroidism.⁴⁰⁻⁴² It now appears that this assay may be the best initial test of thyroid function in evaluating patients for suspected under- or overactivity of the thyroid gland.⁴⁰ Although it has been suggested that the generally accepted value of 5 mU/L as the upper limit of normal for the adult population may actually be as high as 10 mU/L in individuals who have reached their eighth decade, it is more likely that TSH values between 5 and 10 mU/L indicate mild thyroid dysfunction.⁴²

Total and free concentrations of T4 and T3 are commonly used to document the status of thyroid secretory activity. It appears to be well supported that the normal range for these hormones is unaffected by aging and that deviations from normal must be considered as evidence for thyroid disease or for other illness or states that may affect hormone measurement.^{16,17,20,22,25,43}

Serum-free T4 is best measured by equilibrium dialysis^{44,45} or more easily by the use of T4-specific antibodies.^{46,47} Less reliable estimates of FT4 concentration can be obtained from the FT4 index, which involves measurement of both total T4 and a measure of thyroid hormone-binding protein capacity such as the T3 resin uptake.

Low T4 states

In addition to the expected reduction in total T4 seen in primary or secondary hypothyroidism, total T4 may be low because of a variety of other causes. Levels of TBPA may be acutely lowered in the presence of infectious disease, protein-wasting states, surgery, and malnutrition with accompanying decline in total T4. More important, TBG levels can be depressed as a result of X-linked congenital deficiency, severe catabolic illness, chronic hepatic disease, glucocorticoids, and androgen administration.⁴⁸ Binding of T4 to TBG can be inhibited by drugs such as furosemide and high-dose salicylates.⁴⁹ The anticonvulsants carbamazepine and phenytoin can reduce serum T4 by stimulating an increase in hepatic enzyme metabolizing activity.⁴⁹ In from 20% to 74% of patients with nonthyroidal illness, an inhibitor of T4 binding to TBG has been detected, which may contribute to the measurement of a low T4 in these patients.^{48,50}

The finding of a low T4 concentration in the presence of nonthyroidal illness has been termed the *euthyroid sick syndrome*.⁵¹ In mild to moderate forms, measurement of FT4 will be normal even though total T4 concentration is reduced.^{45,48} However, severe illness can result in marked reduction of both total and free T4 concentrations. When

this circumstance occurs, the prognosis of the patient is poor with a mortality rate of approximately 80% having been reported.⁵² The ability to differentiate these patients from those with hypothyroidism can be difficult.⁵³ Although serum TSH is usually in the normal range, occasionally mild to moderately elevated concentrations are found. This is especially true in the recovery phase of the illness when values can rise to as high as 20 mU/L. Within 4 to 20 weeks after clinical recovery, all measures of thyroid function usually will have returned to normal.⁵⁴

Low T3 states

The serum concentration of total T3 is easily affected by many nonthyroidal illnesses, and low values are often seen in elderly ill patients, giving rise to the "low T3 syndrome." This consequence of systemic illness is the earliest and most common of the alterations in thyroid hormone levels.^{16,17,28,43,48,53,55,56} In response to many acute illnesses, there is decreased peripheral 5'-monodeiodination of T4 to T3 with consequent reduction in serum T3 concentration and increase in serum rT3. Lowering of TBPA and TBG in the presence of acute and chronic illness further contributes to the marked fall in serum T3 characteristic of the sick elderly person. Often, the possibility of a diagnosis of hypothyroidism is raised and can usually be excluded by the absence of an increase in TSH and by the demonstration of normal or increased serum levels of rT3.

Cytokines such as interleukin-1, interleukin-6, and tumor necrosis factor (TNF) could be involved as intermediaries in the development of low T4 and T3 states. Many patients with nonthyroidal illnesses and low T4 or T3 also have elevated serum concentrations of cytokines.^{57,58} Experimental increase of TNF- α has been observed to induce low serum concentrations of T4, T3, and TSH.⁵⁹

High T4 states

Although less common than low thyroid hormone states, nonthyroidal factors can result in elevation of serum T4 concentration.^{53,60} A euthyroid increase in total T4 can occur as a result of overproduction of TBG, a disorder that may be familial.⁶¹ More commonly, TBG increases because of therapy with estrogen or tamoxifen or as a transient acute-phase reactant during acute hepatocellular injury. In these circumstances, serum-free T4 will be normal. On occasion, mild to moderate levels of illness can increase FT4 in the patient with euthyroid sick syndrome as a result of impaired T4 monodeiodination by peripheral tissues.^{48,51}

Thyrotropin-releasing hormone test

The response of serum TSH to exogenously administered TRH is a useful method of assessing the dynamics of the pituitary-thyroid axis. In the normal individual, the bolus intravenous administration of 500 μ g TRH results in a prompt rise in serum TSH, with peak values achieved in 30 minutes.^{7,8} The minimal normal response should be an increase of greater than 2 mU/L over the basal value, with many normal subjects reaching peak concentrations up to 30 mU/L.¹² As previously stated, many elderly males respond less well to TRH stimulation than do younger subjects or women at all ages.⁷⁻¹³ Failure to respond to TRH supports a diagnosis of hyperthyroidism, whereas a normal response excludes the diagnosis. Subnormal responses may be seen in

patients with severe illness, depression, or hypercortisolism as well as in euthyroid patients with thyroid adenomas or multinodular goiter. An exaggerated response of serum TSH is characteristic of primary hypothyroidism.⁴²

Measures of iodine uptake

The ability of the thyroid gland to trap iodide and other ions such as technetium (Tc) has been the basis for assessment of both thyroid gland function and morphology. The oral administration of ¹³¹I to normal individuals results in an accumulation of 5% to 25% of the dose in the gland by 24 hours.^{62,63} Because of considerable overlap between normal and hypothyroid subjects, low values for 24-hour ¹³¹I uptake are of lesser diagnostic usefulness in establishing a diagnosis of hypothyroidism. Further, exposure to increased amounts of iodide in the diet or to iodine-containing drugs or radiographic contrast media result in a marked reduction of ¹³¹I uptake. Elevated values are useful in supporting a diagnosis of hyperthyroidism, although some elderly patients with toxic nodules may have 24-hour ¹³¹I uptake values within the normal range. The 24-hour ¹³¹I uptake is usually obtained in a patient with an established diagnosis of hyperthyroidism in order to calculate the dose of ¹³¹I to be given for ablation therapy.

Thyroid scanning with ^{99m}Tc, or now more commonly with ¹²³I, is useful in the evaluation of the patient with a palpable single thyroid nodule where demonstration of activity within the nodule markedly reduces the likelihood of the nodule representing an area of malignancy. In the elderly hyperthyroid patient, scanning can be used to differentiate a diffusely overactive thyroid from the gland with single or multiple toxic nodules.⁶⁴

Other thyroid imaging procedures

Currently available imaging techniques can provide high-quality anatomic detailing of thyroid structure, including real-time ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI). These procedures can be useful in evaluating patients with single and multiple nodules by identifying cysts, areas of hemorrhage, and tissue calcification. Ultrasonography may be of value in determining which regions of the thyroid are most appropriate for fine-needle aspiration. Both CT and MRI are expensive and have few clinical indications at present, but they may be of occasional value in assessing the extent of tracheal compression by a thyroid mass, in determining the extent of substernal goiters, and in determining the extent of local invasion or metastasis by thyroid cancers.⁶⁵

Antithyroid antibodies

Many thyroid disorders, including hyperthyroidism of the Graves' disease type⁶⁶ and hypothyroidism of the Hashimoto type, are believed to be the result of autoimmune disease.^{12,67} As a consequence, high levels of serum antibodies to both thyroglobin and to microsomes are commonly found in patients with thyroid disease. Low levels of anti-thyroglobulin antibody (titer less than 1:100) may be present in patients without clinical signs of a thyroid disorder. Moderate to high titers (1:1600 to 1:25,600) can be found in patients with nonthyroid autoimmune disorders.¹²

Thyroid antibodies in the serum increase in incidence progressively with increasing age, reaching a peak

incidence of 20% to 25% in women above the age of 50 years and 5% to 10% in similarly aged men.^{68,69} However, in a highly selected population of healthy elderly individuals ranging from 65 to 110 years, the prevalence of antithyroid antibodies was low and did not differ from the prevalence in healthy young persons.¹ This finding suggests that the high incidence of antithyroid antibodies in aging populations is a reflection of disease and is not a consequence of normal aging. In many patients, the findings of high-serum antithyroglobulin or antimicrosomal antibody titers are accompanied by an elevation of basal serum TSH concentration and reduced levels of serum T₄, suggesting the presence of an autoimmune thyroiditis and a failing thyroid gland.⁷⁰

From a diagnostic standpoint, high titers of antithyroid antibodies are commonly found in patients with documented hypothyroidism and suggest a diagnosis of chronic lymphocytic or Hashimoto's thyroiditis. In patients with hyperthyroidism, elevated antithyroglobulin and antimicrosomal antibody titers are more characteristic of patients with Graves' disease than of those with toxic nodules.

Thyroid-stimulating immunoglobulins

Thyroid-stimulating activity similar to that of TSH can be found in the IgG portion of serum obtained from many patients with hyperthyroidism resulting from Graves' disease. These immunoglobulins have been demonstrated to be antibodies directed against the TSH receptor.⁶⁶ Thyroid-stimulating immunoglobulins can be detected by both radioreceptor assays utilizing radiolabeled TSH and by bioassay based on stimulation of cyclic AMP release from isolated thyroid cell cultures.⁷¹⁻⁷⁵ Both methods reveal positive tests for TSH receptor antibodies in over 85% of patients with untreated Graves' disease and in essentially 100% of patients with severe Graves' ophthalmopathy. Positive tests are infrequent in Hashimoto's disease and rare in nodular thyroid disease, including toxic nodular goiter. Monitoring of antibody levels may be useful in predicting the likelihood of sustained remission in patients with Graves' disease who are treated with antithyroid drugs.⁷⁶

Serum thyroglobulin

Thyroglobulin involved in intrathyroidal synthesis of T₄ and T₃ can gain entry to the circulation where it can be detected in normal individuals at low levels by means of immunometric assays.⁷⁷ Many elderly people have circulating antithyroglobulin antibodies, which can interfere with accurate estimation of thyroglobulin concentration. Normal individuals have been found to have serum concentrations of thyroglobulin of less than 5 µg/L and levels appear to be unaffected by age. Concentrations can be increased in patients with hyperthyroidism, benign nodules, and inflammatory disorders, such as subacute thyroiditis. High levels are found in the majority of patients with thyroid cancer.

In patients with thyroid cancer previously treated by surgical or radioiodine ablation, measurement of serum thyroglobulin appears to be a sensitive indicator of tumor recurrence, either locally or by metastases. However, caution must be observed in interpreting blood levels because elevations above normal can be found in patients whose ablation has not been complete and have been left with small remnants of nonmalignant thyroid tissue.⁷⁷

SCREENING FOR THYROID DYSFUNCTION

Disorders of thyroid function become increasingly common with advancing age and include both overt and subclinical hyperthyroidism and hypothyroidism (discussed later). As a consequence, a number of organizations have recommended that screening for thyroid dysfunction be initiated in the general population as a means of early detection of altered thyroid function. The American College of Physicians has recommended that women over the age of 50 should have serum TSH testing followed by measurement of free thyroxine if the TSH level is undetectable or greater than 10 mU/L.^{78,79} The American Academy of Family Physicians recommends that thyroid function be measured periodically in all older women. The American Thyroid Association has published guidelines for the detection of thyroid dysfunction, which recommend that all adults, both men and women, be screened with measurement of serum TSH starting at age 35 and then repeated every 5 years thereafter, with more frequent screening for individuals who may be at higher risk of developing thyroid dysfunction.⁸⁰ Other organizations have not recommended routine screening of asymptomatic persons.

HYPERTHYROIDISM

Overproduction of thyroid hormone leads to the clinical condition of hyperthyroidism. This disorder, also referred to as thyrotoxicosis, is accompanied by a broad array of symptoms and signs that can differ markedly between young and old patients.

Demography

In the past, hyperthyroidism was regarded as a disorder with preferential expression in young to middle-aged individuals, especially women. It is now clear that this disorder is also common in the elderly population.⁷⁸ The proportion of patients with hyperthyroidism who are over 60 years of age is estimated to be 15% to 20%.^{81,82-85} Many studies confirm that hyperthyroidism is far more common in women than men, with estimates of female preponderance ranging from 4:1 to as high as 10:1.^{81,84,86}

Etiology

In young persons, Graves' disease remains the most common cause of hyperthyroidism and is the consequence of thyroid receptor antibodies, which have stimulatory effects on the thyroid gland.^{66,72,74,75} With increasing age, there is a change in etiology so that more cases are due to multinodular toxic goiter and fewer to Graves' disease.^{81,87} It is estimated that more than 50% of hyperthyroid patients over the age of 60 years have thyrotoxicosis resulting from multinodular toxic goiters. Multinodular goiters are common in the elderly population and may not be clinically apparent.⁵ Many clinical observations support the concept that long-standing euthyroid multinodular goiters may undergo change to become overproductive of thyroid hormones⁸¹ (Table 90-1).

Another less common cause of hyperthyroidism in the elderly population is toxic adenoma (Plummer's disease), usually identifiable on thyroid scanning by the demonstration

Table 90-1. Etiology of Hyperthyroidism and Hypothyroidism in the Elderly Population

Hyperthyroidism	Hypothyroidism
Toxic multinodular goiter	Autoimmune disease
Graves' disease	Radioiodine or surgical thyroid ablation
Toxic adenoma	Hypothalamic/pituitary disease
Exogenous thyroid hormone	Iodine-induced
Subacute thyroiditis (early)	Iodine deficiency
Iodine-induced	Subacute thyroiditis (late)
	Inborn disorder of thyroid hormone synthesis

of a solitary hyperfunctioning nodule with suppression of activity in the remainder of the thyroid gland.^{88,89} Hyperthyroidism can occur in a previously euthyroid person following ingestion of iodide or iodine-containing substances (the Jod Basedow phenomenon). This is usually a self-limiting disorder lasting several weeks to several months.⁹⁰ Most commonly, this occurs following exposure to iodinated radiocontrast agents and to amiodarone.⁹¹ Up to 40% of persons taking amiodarone will have serum T4 levels above the normal range, but only about 5% will develop clinical hyperthyroidism.⁹² Amiodarone is fat-soluble and has a long half-life, so drug-induced hyperthyroidism can be prolonged and difficult to treat.^{93,94}

The possibility of hyperthyroidism must always be considered in the elderly person who is receiving thyroid hormone, especially if the dose is greater than 0.15 mg of L-thyroxine daily. Patients who have received such doses for many years without evidence for hyperthyroidism may insidiously develop features of hyperthyroidism as they age past 60 years because of age-associated slowing in thyroid hormone metabolism.⁹⁵

Rare causes of hyperthyroidism in the elderly population include TSH-producing pituitary tumors^{96,97} and ectopic TSH production by nonpituitary tumors. These can be recognized by the finding of unsuppressed levels of serum TSH in the presence of increased amounts of circulating thyroid hormone. An additional uncommon cause of hyperthyroidism is overproduction of thyroid hormone by metastatic follicular carcinoma.

Transient hyperthyroidism may occur in patients with subacute thyroiditis as a result of increased discharge of thyroid hormone into the circulation during the inflammatory phase of the illness.⁹⁸ In a similar fashion, radiation injury to the thyroid can be accompanied by transient increase in circulating thyroid hormone levels with associated symptoms.

T3 TOXICOSIS

In a small proportion of cases of hyperthyroidism, measurement of serum thyroid hormone concentrations result in the expected increase in serum T3, but with the finding that serum T4 is within the normal range, although often at the upper end. This circumstance has been designated as *T3 toxicosis* and can occur with any type of hyperthyroidism, but it is found more commonly in patients with toxic multinodular goiter or solitary toxic adenoma.⁸⁹ The diagnosis will not be missed if T3 is measured in patients with clinically suspected hyperthyroidism who do not demonstrate elevated levels of serum T4 or free T4.

Clinical presentation of hyperthyroidism

As with other disorders occurring in the elderly person, the clinical presentation of hyperthyroidism often differs from the classic description of the disease in younger individuals^{81,82,99–101} (Table 90-2). Presenting features may be progressive functional decline, including weakness, fatigue, changes in mental status, loss of appetite, weight loss, cardiac arrhythmia, and congestive heart failure. A symptom complex peculiar to the geriatric hyperthyroid patient is "apathetic hyperthyroidism," in which the patient lacks the hyperactivity, irritability, and restlessness common to the young patient with thyrotoxicosis and presents instead with weakness, lethargy, listlessness, depression, weight loss, and the appearance of a chronic, wasting illness. Often, the initial impression in such patients is that of depression, malignancy, or cardiovascular disease.^{102,103}

The elderly patient with Graves' disease often differs from younger patients in the nature and severity of expected classic symptoms and in physical findings. Clinically detectable thyroid enlargement, present in almost all younger patients, is absent in as many as 37% of elderly patients.⁸¹ Infiltrative ophthalmopathy with severe proptosis and exophthalmos occur infrequently in the elderly group. Thus, none of the elements of the classic triad of Graves' disease (clinical hyperthyroidism, diffuse goiter, and infiltrative ophthalmopathy) may be recognizable in the elderly patient in whom the diagnosis may be suspected only on the basis of laboratory studies.^{81,99,100}

Several reports have attempted to compare symptoms and objective physical findings in young and elderly patients with hyperthyroidism. Symptoms less commonly present in the elderly group include nervousness, increased sweating, tremor, increased appetite, and increased frequency of bowel movements. Symptoms more common include marked weight loss (present in over 80% of patients), poor appetite, worsening angina, edema, agitation, and confusion. Similarly, physical findings differ in elderly patients. In addition to absence of palpable goiter and eye signs of exophthalmos, pulse rate is slower, and reflexes are often not hyperreflexic. Cardiac arrhythmias, especially atrial fibrillation and ventricular premature beats, are more common. Lid lag and lid retraction are frequently seen.^{81,99–104}

The spectrum of symptoms and findings that result from thyroid hormone excess is broad and can involve almost all body systems. Of special concern in the elderly are the impacts of hyperthyroidism on the cardiovascular system. Thyroid hormones act on the myocardium to sensitize the heart to β -adrenergic stimulation with resultant increase in heart rate, stroke volume, cardiac output, left ventricular mass, ejection fraction and shortened left ventricular ejection time.^{104–106} These changes underlie the clinical consequences of increased systolic blood pressure, widened pulse pressure, palpitations, tachycardia, increased risk of atrial fibrillation, often with a slow ventricular response, exacerbation of angina in patients with preexisting coronary artery disease, and precipitation of congestive heart failure, which responds less readily to digoxin treatment owing to increased renal clearance of the drug.

Echocardiographic data further define the cardiac changes in hyperthyroidism. Specifically, it has been demonstrated that diastolic function is enhanced as evidenced by increased

Table 90-2. Frequency of Symptoms and Signs of Hyperthyroidism

Symptom/sign	Kawabe et al ⁹⁹ (%)		Davis and Davis ⁸¹ (%)	
	Young Elderly (n = 48)	Elderly (n = 45)	Elderly (n = 85)	
Palpitation	100	60	63	
Goiter	98	58	64	
Tremor	96	71	55	
Excessive perspiration	92	66	38	
Weight loss	73	85	69	
Eye signs	71	28	57	
Arrhythmias (atrial fibrillation and ventricular premature contractions [VPC])	4.6	16.4	62	

From Griffin MA, Solomon DH. Hyperthyroidism in the elderly. *J Am Geriatr Soc* 1986;34:887-92.

isovolumic relaxation and left ventricular filling in hyperthyroid patients.¹⁰⁷ These alterations in hemodynamic parameters may explain many of the cardiovascular signs and symptoms of hyperthyroidism and many of the cardiac complications associated with hyperthyroidism, including decreased exercise tolerance and increased risk of congestive heart failure.

Gastrointestinal consequences of hyperthyroidism in an elderly person include weight loss, poor appetite, and occasionally abdominal pain, nausea, and vomiting.^{81,82} Diarrhea and increased frequency of bowel movements resulting from thyroid hormone action on intestinal motility can occur but are often absent in the elderly in whom constipation is likely to be present. Hepatic actions of thyroid hormone can lead to alterations in liver enzymes, including elevation of alkaline phosphatase and γ -glutamyl transpeptidase levels, which return to normal following restoration of thyroid function to normal.

Weakness, especially of the proximal muscles, is a major feature of hyperthyroidism in elderly patients and is often accompanied by muscle wasting.^{81,103} As a consequence, disorders of gait, postural instability, and falls can be significant symptoms. Tremor occurs in more than 70% of elderly thyrotoxic patients, but this sign must be distinguished from other causes of tremor common in the elderly which are usually more coarse or primarily present at rest.^{99,100} A rapid relaxation phase of the deep tendon reflexes is common in young patients but is often difficult to assess in the older patient. Central nervous system manifestations may be a prominent component of the symptom complex of the elderly patient and include confusion, depression, forgetfulness, irritability, and a shortened concentration span.^{87,108} These cognitive impairments may point to a diagnosis of dementia and failure to consider the presence of hyperthyroidism.

Other clinical manifestations of hyperthyroidism in the elderly population may include glucose intolerance and, occasionally, the unmasking of latent diabetes mellitus. Mild elevations of serum calcium can occur and hyperthyroidism can contribute to the development of osteoporosis, especially when other risk factors for osteoporosis are present. Men with Graves' disease may present with gynecomastia, decreased libido, and erectile dysfunction.¹⁰⁹

Diagnosis of hyperthyroidism

Because of the altered clinical presentation of hyperthyroidism in an elderly person, suspicion must always be high and the laboratory should be used for any patient with possible symptoms. It is not uneconomical to employ screening tests for thyroid status in all geriatric patients undergoing initial clinical evaluation.^{78,104}

Serum T4 or free T4 and measurement of serum TSH by modern ultrasensitive methods are the preferable screening procedures for thyroid dysfunction.^{42,111} The findings of a normal serum T4 with suppressed serum TSH raises the possibility of T3 toxicosis and calls for measurement of serum T3.^{47,48,87} Determination of FT4 concentration by one of the direct measurement techniques may be useful when there is reason to suspect an alteration in thyroid-binding proteins.^{44,47} Demonstration of anti-TSH receptor antibodies can be helpful in making a diagnosis of Graves' disease.^{66,72,75}

The TRH stimulation test, although useful in evaluating the patient with borderline laboratory tests, is rarely performed in contemporary times.^{8,12} A significant rise in serum TSH will exclude the likelihood of hyperthyroidism, but an inadequate rise of TSH can only be considered as supportive of the diagnosis.

Thyroid scanning with ^{99m}Tc or radioiodine and measurement of ¹²³I uptake can be useful in distinguishing Graves' disease from toxic multinodular goiter.^{62,63} Scanning may demonstrate the presence of a small diffusely active goiter that could not be detected on physical examination. Very low ¹²³I uptake in a patient with elevated circulating thyroid hormone levels suggests exogenous thyroid hormone ingestion (factitious hyperthyroidism), the hyperthyroid phase of subacute thyroiditis, or iodine-induced hyperthyroidism.

Management of hyperthyroidism

The first step in management of the patient with hyperthyroidism is to determine the underlying etiology and to exclude the possibility of one of the transient forms that may require supportive therapy directed toward the primary process (hormone ingestion, iodine exposure, subacute thyroiditis). Although the vast majority of patients with either Graves' disease or toxic multinodular goiter can be treated using antithyroid drugs, radioactive iodine, or surgery, radioactive iodine ablation is the preferred treatment in the elderly patient.¹¹²⁻¹¹⁴

In the patient with suspected hyperthyroidism who is still undergoing investigation, a useful initial step in treatment is the administration of β -adrenergic blocking agents such as propranolol, metoprolol, or atenolol. These agents are especially indicated in patients who have palpitations, tachycardia, angina, or agitation as symptoms since use of the β -blockers can lead to quick symptom control. These drugs act by interfering with some peripheral actions of thyroid hormone but do not correct the hypermetabolic state. The drugs, however, do not interfere with laboratory assessment of thyroid function and can allow control of symptoms until definitive treatment can be undertaken.

Once a diagnosis of Graves' disease or a toxic nodular goiter is established, treatment should be started with one of the antithyroid drugs, propylthiouracil or methimazole.¹¹⁵ Methimazole has the advantage of often being effective when given once daily, whereas propylthiouracil is usually given in three divided doses. These agents impair biosynthesis of

thyroid hormone and lead to depletion of intrathyroidal hormone stores and consequently to decreased hormone secretion. A decline in serum T4 concentration is usually seen by 2 to 4 weeks after initiation of antithyroid drug therapy, and the dose can be tapered once thyroid hormone levels reach the normal range in order to avoid development of hypothyroidism. In 1% to 5% of patients, the antithyroid drugs may cause fever, rash, and arthralgia. Drug-induced agranulocytosis occurs in 0.1% to 0.3% of treated persons and is seen more commonly in the elderly population. It is most likely to occur within the first 3 months of treatment, especially in patients who receive more than 30 mg/day of methimazole.¹¹⁵ Routine periodic monitoring of the white blood cell count is not recommended, but measurement is called for if the patient experiences the onset of fever, sore throat, or oral ulcerations, and the drug must be discontinued if there is evidence of neutropenia. Long-term antithyroid drug administration can be used as a primary therapy in patients over the age of 60 with Graves' disease, who appear to respond more rapidly and have a greater likelihood of long-lasting remission than younger persons.^{116,117} Long-term antithyroid drugs are rarely successful in inducing sustained remission in elderly patients with toxic multinodular goiter.

The recommended definitive treatment in the elderly group is thyroid ablation through use of ¹³¹I.^{112–114} Once the patient has been rendered euthyroid by antithyroid drugs, these agents should be stopped for 3 to 5 days, following which ¹³¹I is given orally. Therapy with β -blockers can be maintained and antithyroid agents can be restarted 5 days after radiotherapy and continued for 4 to 10 weeks until the effect of radioiodine is achieved. Many therapists attempt to calculate a dose that will render the patient euthyroid without subsequent development of hypothyroidism. These calculations are based on a clinical estimate of thyroid gland size, 24-hour ¹³¹I uptake, and whether the gland is diffusely overactive or contains toxic nodules. In spite of this approach, many patients will still develop permanent hypothyroidism following ¹³¹I therapy.¹¹⁸ It is not unreasonable to treat all elderly patients with a large dose of ¹³¹I to assure ablation of thyroid tissue and avoid the possibility of recurrence of hyperthyroidism. Using this approach, patients are monitored following treatment until their serum thyroid hormone levels reach the hypothyroid range and are then put on permanent replacement therapy with exogenous thyroid hormone. Hypothyroidism may be evident as early as 4 weeks after treatment and can occur at any time after treatment. With all dosing regimens, by 12 months posttherapy 40% to 50% of patients are hypothyroid and hypothyroidism continues to occur thereafter at the rate of 2% to 3% per year.¹¹⁹ Periodic monitoring of thyroid status is a necessity for any patient treated with ¹³¹I who has not yet become hypothyroid.

Surgery is not recommended as a primary choice for treatment of hyperthyroidism in the elderly patient. The frequent accompaniment of hyperthyroidism by many coexisting disorders, including cardiac, pulmonary, and central nervous system disease, puts the patient at increased operative risk. In addition, postoperative complications of hypoparathyroidism and recurrent laryngeal nerve damage represent significant problems, especially when surgeons not highly experienced in thyroidectomy perform the surgery.¹²⁰ Surgery may be of value for the rare patient with tracheal compression secondary to a large hyperfunctioning goiter.

ATRIAL FIBRILLATION

This condition occurs in 10% to 15% of hyperthyroid patients, most of whom are elderly.^{106,121} In a retrospective study of 163 hyperthyroid patients with atrial fibrillation, approximately 60% had spontaneous reversion to sinus rhythm after becoming euthyroid. Most of these reversions occurred with 3 weeks of becoming euthyroid, whereas no patient reverted if atrial fibrillation was still present after 4 months of euthyroidism or if atrial fibrillation had been present for more than 13 months before becoming euthyroid.¹²² Thus, the patient who remains in atrial fibrillation beyond 16 weeks of return to the euthyroid state is a candidate for cardioversion.

While in the hyperthyroid state, the patient with atrial fibrillation is more sensitive to the anticoagulant effect of warfarin, resulting in a greater lowering of activity of coagulation factors II and VII and greater increase in the prothrombin ratio and partial thromboplastin time.¹²³ Many older persons with hyperthyroidism and atrial fibrillation are at increased risk for thromboembolic events, especially those with a prior history of thromboembolism, hypertension, or congestive heart failure or who have evidence of left atrial enlargement or left ventricular dysfunction.¹⁰⁶ In the absence of contraindications, anticoagulant therapy should be given with warfarin in a dose that will increase the international normalization ratio (INR) to 2.0 to 3.0. Careful monitoring of the dose of warfarin is necessary, and warfarin should be continued until euthyroidism has been achieved and a normal sinus rhythm has returned.^{105,124}

ACUTE HYPERTHYROIDISM

Acute hyperthyroidism or *thyroid storm* can occur in the patient with either known or undiagnosed hyperthyroidism who is subjected to acute stress such as an operative procedure, trauma, or infection or who is exposed to iodine-containing drugs. It can also occur in the elderly patient treated with ¹³¹I who did not receive adequate antithyroid medication before therapy.¹²⁵ In these patients, features of severe hyperthyroidism may develop over several hours and include fever, tachycardia, vomiting, diarrhea, dehydration, severe restlessness, and disorientation. Patients with cardiac disease are at especially high risk for acute heart failure or acute myocardial ischemia.

Thyroid storm is a life-threatening condition and must be treated vigorously and promptly.^{126,127} Immediate treatment involves administration of antithyroid drugs and iodide to interfere with thyroid hormone production. Propylthiouracil is given in an initial dose of 900 to 1200 mg followed in several hours with sodium iodide or oral Lugol's solution. High-dose β -blockers such as propranolol and high-dose corticosteroids are also given to blunt peripheral action of thyroid hormones and to inhibit T4 to T3 conversion in peripheral tissues. Supportive measures include sedation, fluids, antipyretics, and cooling blankets, plus antibiotics if infection is present.¹²⁶

SUBCLINICAL HYPERTHYROIDISM

The finding of suppressed or nondetectable serum TSH along with normal total and free serum T4 or T3, often in the upper end of the normal range, is defined as subclinical

hyperthyroidism. Etiology ranges from excessive thyroid hormone replacement therapy to thyroid disease, with the most common cause in the elderly person being long-standing multinodular goiter.

Demography

The finding of subnormal TSH concentrations in the elderly is not infrequent. The prevalence of subclinical hyperthyroidism appears to vary with geographic area and dietary iodine intake.¹²⁸ Individuals with low iodine intake are more commonly affected because of compensatory growth of the thyroid gland in response to low iodine and thus the tendency to develop hyperplastic nodules that may become autonomously functioning thyroid tissue. One study in Italy reported that individuals living in iodine-deficient areas had an age-related increase in subclinical hyperthyroidism from a prevalence of 0.7% in children to a prevalence of 15.4% in individuals over the age of 75.¹²⁹ Similarly, in a U.S. population of 2575 persons over the age of 60 years, 101 were found to have low TSH and, of these, 30 had no history of past or present thyroid disease. Over a 4-year follow-up period, most had normal TSH on subsequent testing, but two became overtly hyperthyroid with an increase in serum T4 to above normal values.¹³⁰ In a prospective study, persons age 85 years were followed with serum TSH and free T4 until age 89. Of 12 with subclinical hyperthyroidism at baseline, 1 became overtly hyperthyroid, 5 had persistent subclinical hyperthyroidism, 5 became euthyroid, and 1 developed subclinical hypothyroidism.¹³¹ In a study of 1210 persons in England, low TSH was found in 6.3% of women and 5.5% of men.¹³² However, repeat measurements of serum TSH 1 year later showed a return of TSH to the normal range in the majority of cases. Several studies suggest that the conversion rate to overt hyperthyroidism ranges from 1.5% to 13% within 1 year.^{130,132-135} Thus, the natural history of subclinical hyperthyroidism is variable, sometimes disappearing over time.¹³⁶

Clinical presentation

Individuals with thyroid function values indicating the presence of subclinical hyperthyroidism generally have no or only mild clinical features suggestive of hyperthyroidism.¹³³ However, persons with subclinical hyperthyroidism are at increased risk of developing atrial fibrillation as reflected by a cumulative incidence of 28% over a 10-year period in individuals over the age of 60 years, representing a 3-fold increase in risk.^{121,134} There may be other cardiac consequences of persistent subclinical hyperthyroidism including increased prevalence of atrial premature beats, increased heart rate, increased left ventricular mass, enhanced systolic function, impaired diastolic function, and reduced exercise performance (Table 90-3).^{137,138}

Many studies suggest that apparently asymptomatic individuals with subclinical hyperthyroidism have accelerated loss of bone mineral, which is benefited by treatment.¹³⁹⁻¹⁴¹ Postmenopausal women with subclinical hyperthyroidism and nodular goiter who were treated with ¹³¹I with subsequent normalization of serum TSH had an increase in bone mineral density at the spine and hip after 2 years of follow-up, whereas a similar group of women who were not treated showed progressive bone loss.¹⁴² Therefore, the finding of suppressed TSH and normal T4 in an asymptomatic elderly person calls for periodic retesting of thyroid function,

Table 90-3. Findings and Potential Adverse Effects of Subclinical Hyperthyroidism

Functional Cardiovascular Alterations
Increased cardiac contractility
Impaired left ventricular diastolic filling
Impaired systolic function during exercise
Increased left ventricular mass index
Increased intraventricular septal thickness
Increased left ventricular posterior wall thickness
Decreased large and small artery elasticity
Prolonged QTc interval
Clinical Cardiovascular Consequences
Increased heart rate and frequency of atrial premature beats
Increased incidence of atrial fibrillation
Lower serum total and low-density lipoprotein (LDL) cholesterol concentrations
Reduced exercise capacity
Increased mortality due to cardiovascular disease
Bone Loss
Osteopenia
Osteoporosis
Diminished Quality of Life

including measurement of FT4. In the presence of significant osteopenia or if there is subsequent development of clinical features of hyperthyroidism, atrial fibrillation, or increased thyroid hormone production, restoration of thyroid function to normal should be undertaken.

Impaired quality of life as assessed by questionnaire has been reported in subclinical hyperthyroidism.¹³¹ In individuals over the age of 55 years with subclinical hyperthyroidism, an increased incidence of dementia and Alzheimer's disease has been reported, especially in those who have circulating antithyroid antibodies detected.¹⁴³ Long-term studies of patients with untreated subclinical hyperthyroidism have demonstrated an increase in both cardiovascular and all-cause mortality.^{132,144}

Treatment

Treatment of subclinical hyperthyroidism is controversial because of the low rate of progression to overt hyperthyroidism. A long-term study of patients with untreated subclinical hyperthyroidism demonstrated an increase in both cardiovascular and all-cause mortality.¹⁴⁵ When these data are coupled with the findings of diminished self-reported ratings of quality of life and a higher rate of osteopenia in persons with subclinical hyperthyroidism, it is reasonable to consider earlier, more aggressive treatment, especially in individuals who already manifest these changes.¹⁴⁶⁻¹⁴⁸

Although there have been no randomized prospective trials evaluating the treatment of subclinical hyperthyroidism, there is a consensus that therapy should be initiated in elderly individuals with heart disease or evidence of other problems, such as bone loss, that may be impacted by this entity and who have serum TSH levels less than 0.1 mU/L. A consensus panel of endocrinologists has recommended treatment for those with TSH suppression of <0.1 mU/L but recommends periodic retesting of thyroid function in patients with partial TSH suppression of 0.1 to 0.4 mU/L.^{149,150} It has been suggested that all postmenopausal women, individuals over age 60, and those with a history of heart disease, osteoporosis, or symptoms be treated if the TSH is less than

0.1 mU/L and that a similar approach be considered if the TSH is between 0.1 and 4 mU/L in this same population.^{151,152} Treatment leading to the return of serum TSH to normal has been associated with significant improvement in cardiovascular function including a decrease in the heart rate, total number of beats during 24 hours, number of atrial and ventricular premature beats, and reduction in left ventricular mass index, interventricular septum thickness, and left ventricular posterior wall thickness at diastole.¹⁵³

HYPOTHYROIDISM

Hypothyroidism is the clinical state that results from inadequate peripheral tissue response to thyroid hormone action. Most commonly, this occurs as a consequence of decreased thyroid hormone production from the thyroid gland,^{154,155} but in rare instances can result from tissue unresponsiveness to the presence of adequate amounts of thyroid hormone in the circulation.^{156,157} Deficient thyroid hormone release most commonly is the result of disease or dysfunction of the thyroid gland itself and is referred to as "primary hypothyroidism." In some patients, pituitary TSH release is inadequate, leading to failure of the thyroid gland and "secondary hypothyroidism." Rare cases of "tertiary hypothyroidism" have been identified in which the underlying mechanism is failure of synthesis or release of hypothalamic TRH.

Demography

Hypothyroidism is relatively common in the general population and shows a clear sex and age relationship.^{78,83} The Wickham, England, study identified hypothyroidism, based on measurement of serum TSH, in 19 per 1000 women with a mean age at diagnosis of 57 years and a prevalence 10-fold more common in women than in men. The incidence rate of elevated serum TSH showed a direct relationship to age in women, increasing from 4% to 5.7% of women under age 45 to 17.4% of women over the age of 75 years. In men, elevated serum TSH was present in 1.6% to 3.5% of those under age 65 and increased to 3.5% to 6.9% in persons over the age of 65 years.⁸⁴ Similarly, study of the Framingham population in the United States revealed clear elevation of serum TSH in 5.9% of women between the ages of 60 and 89 years and borderline elevation in an additional 7.7%. Men of the same age had elevated serum TSH in 2.4% of subjects, with another 3.3% showing borderline levels.¹⁵⁸

Many population studies carried out in Great Britain, Sweden, Switzerland, West Germany, Japan, and the United States confirm the high frequency of hypothyroidism in the population, its predominance in women, and its progressive increase with advancing age.^{78,85,110,159–165} Based on the clear influence of age on the risk of development of hypothyroidism, it is reasonable to screen all elderly individuals for the possible presence of the disorder through measurement of serum TSH.⁷⁸

Etiology

Hypothyroidism can arise as a consequence of inborn or acquired disorders/diseases of the thyroid gland, from exposure to agents affecting thyroid-hormone synthesis, and from disease or disturbance of hypothalamic–pituitary production of TRH and TSH (see Table 90-1). In the elderly population, the most common cause of thyroid failure is Hashimoto's

disease.¹⁵⁵ This autoimmune disorder is characterized histologically by continuous replacement of normal thyroid tissue with lymphocytic and fibrous tissue, ultimately leading to a reduced mass of functional thyroid elements and decline in hormone production.⁴ Many patients can be identified by demonstrating the presence of antithyroglobulin and antimicrosomal antibodies in their serum.^{67,68,71} Much evidence has accumulated for the presence of another family of immunoglobulins that are capable of blocking the action of TSH on thyroid cells either by interfering with TSH binding to its receptor or by blocking both pre- and postreceptor processes.^{67,166}

There is a question over whether or not the presence of antithyroid antibodies in the serum can predict the subsequent development of hypothyroidism.¹⁶⁷ In a study of subjects with demonstrated thyroid antibodies, hypothyroidism developed at a rate of 5% per year. Other reports do not support the predictive value of antithyroid antibodies, although they document the strong association of the antibodies with the presence of increased serum TSH and clinical hypothyroidism.¹⁶⁸

Some patients with previously diagnosed Graves' disease may go on to develop an autoimmune hypothyroidism.¹⁶⁹ This consequence may be related to the presence of TSH-blocking antibodies. Other forms of thyroiditis, such as subacute and silent thyroiditis, may progress from a transient hyperthyroid state to euthyroidism, and finally, to permanent hypothyroidism.

A major cause of hypothyroidism is the prior treatment of hyperthyroidism, especially Graves' disease, by either radioiodine^{118,119} or subtotal thyroidectomy.¹⁷⁰ Both treatments have been demonstrated to be followed by a continuous, life-long risk of developing hypothyroidism, with a rate 1 year after initial treatment of 20% to 40% and an annual incidence of 2% to 4% each year thereafter. Any patient with a prior history of surgical or radioiodine treatment of hyperthyroidism should have yearly monitoring of thyroid status with serum TSH and/or T4.

Iodide and iodine-containing drugs can result in inhibition of thyroid-hormone synthesis (Wolff-Chaikoff effect) with ensuing hypothyroidism, which is usually reversible when the source of exogenous iodine or iodide is removed.¹⁷¹ Common sources of iodine ingestion are expectorants (potassium iodide), topical antifungal or antiseptic agents (betadine), iodine-containing radiographic contrast agents, and the antiarrhythmic agent, amiodarone.¹⁷² Long-term lithium therapy can also lead to impaired thyroid hormone synthesis and to inhibition of thyroid hormone release. As many as 20% of patients taking lithium may develop hypothyroidism.⁴⁹

Impairment of production or release of TSH from the anterior pituitary or of TRH from the hypothalamus leads to secondary and tertiary hypothyroidism, respectively. These alterations can be the consequence of pituitary or hypothalamic tumors, surgical or traumatic injury, radiotherapy, or infiltrative diseases such as histiocytosis, sarcoidosis, tuberculosis, or amyloidosis. These patients may have isolated abnormalities of the TRH–TSH–thyroid axis or, more commonly, other associated disorders of hypothalamic, anterior, and posterior pituitary function.

Iodine deficiency in the past accounted for many cases of hypothyroidism, usually with an accompanying goiter. With

the routine use of iodized salt and common exposure to many iodine-containing agents in the diet, this is now a rare cause of hypothyroidism in the United States. However, in many underdeveloped parts of the world, iodine deficiency remains as a common cause of failure of thyroid hormone production.

Clinical presentation of hypothyroidism

Hypothyroidism, particularly in the elderly population, is a disorder with insidious onset characterized by the emergence of symptoms and signs over many years, so that neither the patient nor close associates may be aware of the process.^{173,174} Consequently, the manifestations of hypothyroidism are often attributed to "old age" or to other disorders common in the elderly person. Depending on recognition of the "classic" clinical features of hypothyroidism will invariably result in failure to make the diagnosis in many symptomatic patients.¹⁷⁵ In one study, only 10% of patients with a laboratory-confirmed diagnosis were recognized as being hypothyroid on clinical examination.¹⁷⁶ Similar results have been found in other investigations.^{158,159,161,177}

Central nervous system manifestations are a significant consequence of hypothyroidism in the elderly population. Mental slowing is common, along with complaints of fatigue and excessive sleepiness. The possibility of psychiatric disorder is raised by patients who present with depression, delirium, or paranoid ideation.^{159,178,179} So-called myxedema madness with psychotic behavior is infrequent. Alterations in level of consciousness can occur with confusion and coma. An acute decline in mental status may be precipitated by the stress of infection or trauma, exposure to the cold, or exposure to drugs such as sedatives and narcotics.¹⁸⁰ Seizures can occasionally be due to severe hypothyroidism. The possibility that hypothyroidism may be a cause of reversible dementia has led to much study of patients undergoing dementia evaluation. Most reports confirm that whereas hypothyroidism is common in patients with dementia, only rarely is the dementia truly reversible with thyroid hormone therapy, although there may be overall improvement in the patients' functional state.¹⁵⁹

Classic cold intolerance and diminished sweating are often present in the elderly hypothyroid patient, but these symptoms are also common in euthyroid elderly. Hypothermia may be found. Dry skin, puffiness of the face, periorbital edema, coarsened and thinned hair, thinning of the outer parts of the eyebrows, brittle nails, and yellowing of the skin are common features of the patient, but these also occur with great frequency in patients of advanced age whose thyroid function appears normal.

Coarsening of the voice with slow and sometimes slurred speech should increase the awareness of possible hypothyroidism. Hearing impairment may be due to thyroid insufficiency, or, more commonly, hypothyroidism may aggravate a hearing disorder of other cause.

An important feature of thyroid deficiency in the elderly group is physical slowing with accompanying symptoms of fatigue, weakness, and occasionally muscle stiffness. Arthralgia can also lead to physical slowing. Entrapment neuropathy with paresthesias can occur, especially involving the carpal tunnel.¹⁸¹ Other aspects of neurologic involvement in hypothyroidism include impairment of reflex function, leading to the classic delayed or "hung-up" relaxation phase of

the reflex. Not infrequently, there may be hyporeflexia or complete loss of reflexes, especially of the Achilles tendon.

In the elderly patient, assessment of changes in weight may give little insight into a possible diagnosis of hypothyroidism. Weight gain may occur, but decrease in appetite may be sufficient to result in weight loss. Bowel motility may be slowed with resultant constipation, but here again, this is a common complaint of the nonhypothyroid elderly.

The myocardium is affected by thyroid-hormone deficiency, with the most common changes being bradycardia and narrowed pulse pressure. Reduced cardiac output is the consequence of slowed heart rate, decreased ventricular filling, and a decrease in ventricular contractility.^{106,182} The myocardium may undergo myxedematous infiltration with resultant cardiac enlargement, symptoms of ischemic heart disease, and development of pericardial effusion.¹⁸³ Reduced cardiac output results in decrease of glomerular filtration rate and consequent renal retention of sodium and water, so that peripheral edema may develop even in the absence of overt congestive heart failure.

Alterations in peripheral vascular resistance can lead to hypertension. Pulse wave analysis from recordings at the radial artery in patients with hypothyroidism demonstrates increased augmentation of central aortic pressures and central arterial stiffness. These changes, along with increased cardiac afterload and with hypothyroid-associated endothelial dysfunction, contribute to increased cardiovascular risk. These abnormalities are reversed by appropriate thyroid hormone replacement.¹⁸⁴ Other cardiovascular risk factors for patients with hypothyroidism include smoking, elevated levels of homocysteine, elevated C-reactive protein, coagulation abnormalities, and insulin resistance.¹⁸⁵

Electrocardiographic abnormalities may be seen including slow heart rate, low voltage of the QRS complex, flattening or inversion of T waves, prolonged QT interval, and ventricular arrhythmias.¹⁰⁶ The echocardiogram often demonstrates features of decreased left ventricular contractility with increased systolic time interval and prolongation of isovolumic relaxation time. Small pericardial effusions may be present in as many as 50% of hypothyroid patients but usually do not affect cardiac function.^{186,187}

Hematologic, metabolic, and other systemic impacts of hypothyroidism are more likely to be detected by laboratory evaluation than by clinical examination.¹⁸⁸ Anemia of the normocytic or macrocytic type can be found in about one third of patients,¹⁵⁹ appears to be mediated by insufficient production of erythropoietin, and is directly attributable to the lack of thyroid hormone. Serum iron may be low in some patients, but serum levels of folic acid and B₁₂ are usually normal. Pernicious anemia occurs frequently in association with autoimmune forms of hypothyroidism and should be looked for in hypothyroid patients with persistent anemia after hormonal treatment or in patients with macrocytosis and low serum B₁₂.

Changes in blood lipoprotein composition are common in hypothyroidism and have implications for atherogenesis. Short-term hypothyroidism is associated with an increase in plasma lipoprotein (a) and T3 therapy rapidly lowers lipoprotein (a) together with apolipoprotein B and low-density lipoprotein (LDL) cholesterol, supporting the hypothesis that thyroid hormone is capable of regulating plasma lipoprotein (a) and apolipoprotein B in a parallel manner. Elevated

concentrations of lipoprotein (a) in combination with LDL cholesterol may be involved in the increased risk of cardiovascular disease, which is associated with hypothyroidism.¹⁸⁹ Changes in LDL receptor activity are significantly correlated with changes in LDL cholesterol, but not changes in lipoprotein (a). The LDL receptor pathway appears to be involved in the catabolism of lipoprotein (a) to a limited extent.¹⁹⁰ Hypothyroidism has been associated with elevated levels of total and high-density lipoprotein (HDL) cholesterol, total/HDL cholesterol ratio, apolipoprotein AI, and apolipoprotein E. The increase in apolipoprotein AI without a concomitant increase in apolipoprotein AII suggests a selective elevation of HDL2. These effects were found to be reversible with treatment of the hypothyroidism.¹⁹¹

Hyponatremia may be found in elderly patients with hypothyroidism. The clinical picture is that of the syndrome of inappropriate antidiuretic hormone secretion—that is, dilutional hyponatremia, concentrated urine, normal or expanded intravascular volume, and sodium excretion in the urine. The mechanism appears to be an increased release of antidiuretic hormone as well as altered renal blood flow with increased tubular reabsorption of sodium and water.

Evidence suggestive of myopathy is provided by elevated levels of serum creatine phosphokinase (CPK), which may be very high. Decreased renal clearance of the enzyme largely contributes to these increased levels.

MYXEDEMA COMA

This condition is an extreme, life-threatening form of hypothyroidism that occurs almost exclusively in the elderly population. Presentation is that of an elderly person with rapid development of stupor, seizures, or coma, often in association with infection, stress, exposure to the cold, or following administration of sedatives, tranquilizers, or narcotics.¹⁸⁰ History or symptoms of hypothyroidism may have been present for a long time. Hypothermia of profound degree is often present along with more common signs of hypothyroidism. Respiratory depression with hypoxia and carbon dioxide retention is commonly present and may necessitate intubation and ventilatory assistance. Blood pressure may be low, along with bradycardia and features of shock. Laboratory data will reveal, in addition to marked hypothyroxinemia, hyponatremia, hypoglycemia, elevation of serum CPK, anemia, and evidence of respiratory acidosis with increase in PCO_2 . Chest X-ray often reveals cardiomegaly, because of either dilated myocardium or pericardial effusion. Electrocardiogram typically shows low voltage. Recognition of the syndrome and prompt initiation of therapy is essential, because the mortality rate is probably in excess of 50%.

Laboratory diagnosis of hypothyroidism

The findings of low total and free serum T4 concentration along with elevation of serum TSH clearly establish a diagnosis of primary hypothyroidism, and these two findings require no further investigation.⁴² Measurement of serum T3 in an elderly patient is of little diagnostic value because many disorders or drugs common in this age group lead to reduced concentrations of T3.²⁸ Conversely, in some patients with hypothyroidism, serum T3 levels may remain in the normal range.

The failure to find elevation of serum TSH in a patient with reduced serum T4 or T3 concentrations and clinical

features suspicious for hypothyroidism requires that more extensive laboratory evaluation be carried out. The differentiation between secondary or tertiary hypothyroidism and the various “sick euthyroid” syndromes may be difficult. Normal values of FT4 point against hypothyroidism, but low FT4 may be seen in both conditions. Measurement of rT3 may be useful because its concentration will be low in true hypothyroidism and is generally normal or increased in non-thyroidal illness.²⁸

The TRH test may occasionally be of value because patients with secondary hypothyroidism will show blunted or absent rise in TSH, whereas sick euthyroid individuals usually will respond to TRH with a rise. The measurement of antithyroid antibodies may indirectly support a diagnosis of hypothyroidism if the titers are high, but the levels themselves cannot indicate the functional state of the thyroid gland.

Therapy for hypothyroidism

The establishment of a diagnosis of hypothyroidism generally calls for initiation of thyroid hormone replacement. In the vast majority of patients, the preferred form of treatment is with synthetic L-thyroxine. There is little role for treatment with T3 because peripheral conversion of T4 to T3 is capable of providing adequate amounts of T3.

It is now well established that the usual replacement dose of T4 is lower in the elderly than in the young patient, largely as a result of an age-related reduction in the rate of T4 clearance.^{192–196} The mean daily dose of T4 for patients over the age of 65 years has been estimated to be 0.110 mg (1.6 $\mu\text{g}/\text{kg}$), but it varies in individual patients from 0.05 to 0.2 mg. Determination of the optimum T4 dose is based on monitoring of serum TSH and is defined as the dose of T4 that will reduce serum TSH into the normal range.¹⁹⁷ There is a suggestion that the magnitude of initial serum TSH elevation correlates with the final T4 replacement dose.¹⁹⁶

Excessive thyroid hormone replacement should be avoided. Elderly patients treated with L-thyroxine in standard doses and with serum T4 in the normal range have often been found to have suppressed serum TSH. Even though clinically evident features of hyperthyroidism are not detectable, metabolic effects of increased thyroid hormone can occur and include increased nocturnal heart rate, shortened systolic time interval, increased urinary sodium excretion, and increased hepatic and muscle enzyme activity.^{198,199} Of even greater consequence is the observation that patients on thyroid hormone replacement who have suppressed serum TSH also have evidence for increased bone resorption with consequent risk of accelerated rate of osteoporosis and, possibly, increased risk of fracture.^{199–201}

In the elderly patient, initiation of hormone replacement should be with small doses, which are then slowly increased until full replacement has been achieved.^{192,193} For most older patients, a dose of 0.025 mg daily of L-thyroxine is an appropriate starting amount. Subsequent increases can be in increments of 0.025 mg daily at 4- to 8-week intervals until the serum TSH has been normalized. It is not usual for the decline in TSH to lag behind the attainment of normal values for serum T4. This approach to treatment minimizes the risk of possible adverse effects of thyroid therapy, which include provocation of anginal pain, myocardial infarction, congestive heart failure, and arrhythmias.

Special attention must be given to the patient who, in addition to hypothyroidism, has an established diagnosis of ischemic heart disease. In this circumstance, it may be difficult to achieve full hormone replacement without provoking cardiac symptoms. An attempt should be made to maximize the antianginal regimen, including administration of β -blockers, vasodilator agents, and calcium-channel blockers.^{202,203} Should this approach fail, the patient should undergo evaluation for the possibility of angioplasty or coronary artery bypass surgery.²⁰⁴

In the patient who is thought to have secondary or tertiary hypothyroidism, consideration must be given to the possibility that there may be coexistent ACTH deficiency with resultant hypoadrenalism. Because the increased metabolic state resulting from thyroid replacement can precipitate the clinical picture of adrenal insufficiency, glucocorticoid replacement should be started concomitantly with thyroid hormone if there is any likelihood that ACTH deficiency is present. Some patients with long-standing, severe primary hypothyroidism may also develop signs of adrenal insufficiency following the initiation of thyroid hormone, owing to metabolic impairment of adrenal hormone production from the hypothyroidism itself. Should any features of hypoadrenalism be suspected, prompt treatment with physiologic doses of glucocorticoids should begin. After a euthyroid state has been achieved, the steroid dose may be tapered and discontinued. In some patients, it may be prudent to start treatment with both thyroid and glucocorticoid hormones and discontinue the latter as the patient approaches euthyroidism.

The treatment of myxedema coma warrants special consideration. The patient should be cared for in an intensive-care setting.^{126,205–207} If the diagnosis is suspected, therapy must be started at once, even though laboratory confirmation has not yet been obtained.^{126,205–207} Treatment with thyroxine is necessary to correct the hypothyroid state with an initial dose of 300 to 500 μg given intravenously, because both intestinal and intramuscular absorption are likely to be unreliable.^{205,206} In a review of 87 patients with myxedema coma, initial thyroxine doses greater than 500 μg were associated with a mortality rate of 53%, whereas the mortality rate in patients treated with an initial dose less than 500 μg was 9%. Mortality was highest in patients over the age of 65 years.²⁰⁸ Once there is evidence of a clinical response such as rise in body temperature and heart rate, the daily dose of thyroxine should be reduced to 50 to 100 μg , given orally as soon as possible, and adjusted further as necessary by monitoring of serum TSH.²⁰⁶ T3 or combinations of T4 and T3 are not recommended in an elderly patient because the acute metabolic impact of T3 can lead to cardiac arrhythmia or myocardial infarction.

Adrenal insufficiency can be present in patients with myxedema coma. In life-threatening situations, blood for measurement of cortisol should be drawn and intravenous stress doses of glucocorticoids should be given and continued until there is laboratory confirmation of status of adrenal function. A decision can then be made to either continue treatment for adrenal insufficiency or to taper and discontinue the glucocorticoid.

Supportive therapy must be promptly initiated and may include ventilatory support for respiratory failure, antibiotics for infection, external rewarming for hypothermia, and

correction of hypotension by fluid replacement or dopamine. Hyponatremia, if severe, should be treated.

SUBCLINICAL HYPOTHYROIDISM

As a result of a number of large laboratory survey studies, a significant population of individuals has been identified who have serum levels of TSH above the accepted upper limits of normal, but in whom serum concentrations of total and free T4 and T3 are normal, and symptoms of hypothyroidism are usually mild or lacking.^{78,83,177,209,210} This syndrome has been termed *subclinical hypothyroidism* and is most commonly found in women above the age of 60 years.^{211–214} It is thought that the failing thyroid gland responds with an increase in TSH secretion, which, in turn, is capable of further driving the thyroid to maintain normal levels of T4 and T3 until true thyroid failure ensues. Antithyroid antibodies are often present, suggesting an autoimmune etiology.

Demography

In the Framingham study, 5.9% of subjects over the age of 60 years had clearly elevated serum-TSH concentrations (>10 mU/L) with normal serum T4 levels, and an additional 14.4% had slightly elevated serum TSH (5 to 10 mU/L) with normal serum T4.¹⁵⁸ A thyroid screening survey of 1149 community-residing women with mean age of 69 ± 7.5 years identified 10.8% as having subclinical hypothyroidism.²¹⁴ Other studies have established a prevalence rate of between 25 and 104 per 1000 persons with the highest rate occurring in women over age 55 years. The incidence in women between 40 and 60 years of age may be as high as 10%. Data from the Whickham study indicate that 60% of subjects with serum TSH values greater than 6 mU/L and 80% of those with TSH values greater than 10 mU/L had demonstrable antithyroid antibodies in their serum. Of the entire population of women, 5% had both elevated TSH levels and antithyroid antibodies.⁸⁴

Of clinical importance is the question of what is the likelihood that the person with laboratory criteria for subclinical hypothyroidism will go on to develop clinical hypothyroidism. In a long-term follow-up study, women who initially had antithyroglobulin and antimicrosomal antibodies along with a serum TSH of greater than 6 mU/L developed overt hypothyroidism at the rate of 5% per year. No cases developed in women with borderline elevation of TSH only (6 to 10 mU/L), and only one case developed in the 67 women who had antithyroid antibodies with normal TSH levels.²¹² Other studies support progression to overt hypothyroidism at the rate of 7% per year in women with elevated serum TSH and high titers of antithyroid antibodies with ranges from 1% to 20% per year.^{76,215,216} There is a relationship between the degree of elevation of TSH and the long-term risk of progression to overt hypothyroidism. An initial TSH greater than 12 mU/L resulted in a 77% incidence of overt hypothyroidism by 10 years of follow-up.^{217,218} It is clear that the presence of antithyroid antibodies, which indicate the presence of chronic autoimmune thyroiditis, constitutes a significant risk factor for the development of clinically apparent hypothyroidism in women who are found to have isolated elevated values of serum TSH.^{84,166}

Clinical manifestations

Subclinical hypothyroidism has been associated with a number of potentially adverse clinical findings, particularly those affecting the cardiovascular system (Table 90-4). There is evidence that systolic contractility on effort and left ventricular diastolic contractility at rest are decreased in patients with subclinical hypothyroidism.²¹⁹ These changes may have little functional significance in the resting state, but symptoms can develop during cardiopulmonary exercise. The altered contractility and clinical response to exercise are corrected with thyroid hormone treatment.^{220–222} Although subclinical hypothyroidism has been associated with a prolongation of the QT interval, little has been reported regarding its clinical consequences.

The relationship between subclinical hypothyroidism and cardiovascular disease has been the subject of many clinical studies, which have yielded conflicting results. A study of 1922 patients indicated that subclinical hypothyroidism was not associated with an adverse cardiovascular risk profile.²²³ This observation was further supported by data from several large longitudinal studies of community-residing persons.^{121,224}

Contrarily, a number of studies suggest that subclinical hypothyroidism is a risk factor for cardiovascular disease. The relationship between subclinical hypothyroidism or autoimmune thyroid disease and coronary heart disease (CHD) was evaluated in a Japanese study of patients diagnosed as having CHD by coronary angiogram (the CHD group) and healthy subjects matched for age, sex, and body mass index (the control group). Thyroid function, thyroid autoantibodies, and serum lipid concentrations were measured in the CHD and control groups. The CHD group exhibited significantly decreased levels of serum free T3 and free T4 and significantly increased serum TSH levels as compared with the control group, indicating a significant decrease in thyroid function in the CHD patients. Serum HDL cholesterol levels were significantly decreased in the CHD group.²²⁵ Another Japanese study of men and women of mean age 58.5 years found 10.2% to have subclinical hypothyroidism. Men with subclinical hypothyroidism had a prevalence of ischemic heart disease four times greater than euthyroid men but no increase in intracranial hemorrhage or cerebral infarction. Over 12 years of follow-up, there was a significant increase in all-cause mortality in the subclinical hypothyroid men but not in women.²²⁶ Another longitudinal study of men and women with a mean age of 50 years found a significant increase in prevalence of coronary heart disease in both men and women with subclinical hypothyroidism who had a TSH level greater than 10 mU/L.²²⁷ Similarly, a study of 2730 men and women age 70 to 79 years who were followed for a period of 4 years revealed an increased risk for congestive heart failure in persons with subclinical hypothyroidism who had TSH levels of 7 mU/L or greater.²²⁸ In this population, subclinical hypothyroidism was not associated with an increased risk for coronary heart disease, stroke, peripheral arterial disease, or cardiovascular-related or total mortality.

Among elderly residents of a nursing home, 6% were found to have subclinical hypothyroidism, and of these, 83% had dyslipidemia and 56% had evidence of coronary artery disease in contrast to a 16% incidence of coronary artery

Table 90-4. Findings and Potential Adverse Effects of Subclinical Hypothyroidism

Ventricular Function
Impaired systolic function on effort
Impaired left ventricular diastolic function at rest/delayed relaxation time
Right ventricular systolic and diastolic dysfunction
Increased risk of congestive heart failure
Peripheral Vasculature
Increased systemic vascular resistance
Impaired vasodilatation
Increased carotid artery intima-media thickness
Increased arterial stiffness
Increased pulse wave velocity
Increased diastolic blood pressure
Increased peripheral vascular disease
Dyslipidemia
Increased total cholesterol
Increased low-density lipoprotein (LDL) cholesterol
Increased apolipoprotein B
Increased lipoprotein A
Atherosclerosis
Increased ischemic/coronary heart disease
Increased risk of myocardial infarction
Increased aortic atherosclerosis
Coagulation
Increased factor VII activity
Central Nervous System
Depressed mood, fatigue, decreased energy
Memory impairment
Dementia
Mortality
Increased cardiac mortality
Increased all-cause mortality

disease in euthyroid residents.²²⁹ A possible contributing factor for the increased risk of vascular occlusive disease is the finding of an increase in factor VII activity, which may result in a hypercoagulable state with increased risk of thromboembolism.²³⁰

There have been many reports indicating that subclinical hypothyroidism is associated with alterations in circulating concentrations of lipids that may enhance the risk for development of vascular disease.^{222,231–237} A study of 2108 community-residing persons demonstrated that in the 119 person subgroup (5.6%) with subclinical hypothyroidism, there was a significant increase in total serum cholesterol and in LDL cholesterol with no change in HDL cholesterol.²²⁷ In other studies, decreased HDL and increased lipoprotein (a) and apolipoprotein B have been described, along with an accompanying higher prevalence of ischemic heart disease.^{236,238,239}

Women with hypercholesterolemia have an increased likelihood of having coexisting subclinical hypothyroidism.²⁴⁰ Patients with subclinical hypothyroidism have been noted to have a relative increase in low-density lipoprotein and decrease in high-density lipoprotein with a higher prevalence of ischemic heart disease.²⁴¹ In a large group of elderly women with evidence of aortic atherosclerosis, 13.9% were found to have subclinical hypothyroidism; and in those women with a history of myocardial infarction, 21.5% had subclinical hypothyroidism.²¹⁴ Similarly, the presence of

subclinical hypothyroidism was accompanied by a high prevalence of both aortic atherosclerosis and myocardial infarction, with an even higher prevalence in those who also had detectable antimicrosomal antibodies.

As in patients with overt hypothyroidism, those with subclinical hypothyroidism have been shown to have alterations in peripheral vasculature. Both diastolic blood pressure and pulse wave velocity were significantly increased in patients with subclinical hypothyroidism as compared to euthyroid persons.²³¹ Pulse wave analysis has also demonstrated increased arterial stiffness in patients with subclinical hypothyroidism, which improved after thyroid hormone treatment.²³² Carotid intima-media thickness, a recognized risk factor for cardiovascular disease, has been found by high-resolution ultrasonography to be increased and positively related to age, TSH, and LDL cholesterol levels.²³⁹ In a nursing home population with mean age 79 years, 78% of persons identified with subclinical hypothyroidism were found to have symptomatic peripheral vascular disease.²⁴²

Subclinical hypothyroidism also can affect central nervous system function with patients reporting memory impairment, depressed mood, anxiety, and a variety of somatic complaints. Thyroxine treatment has been reported to improve these symptoms as well as to improve sense of well-being and performance on psychometric testing.^{222,243–245}

Treatment

Thus, attention must be given to the question of whether or not the detection of subclinical hypothyroidism warrants treatment—a topic of considerable controversy. Treatment with L-thyroxine has resulted in improved systolic and diastolic functioning, improvement in left ventricular ejection fraction with exercise, and a decrease in systemic vascular resistance.^{235,246,247} Several studies have reported that treatment with L-thyroxine results in a decrease in total and LDL cholesterol, an increase in serum high-density lipoproteins, and a decrease in low-density lipoproteins and apolipoprotein B.^{236–238,241,248–251} There are no substantive data as yet to indicate that early treatment of subclinical hypothyroidism with thyroid hormone replacement is effective in reducing the risk for subsequent development of atherosclerosis or coronary artery disease.

Several publications have dealt with the divergent opinions on treatment for subclinical thyroid dysfunction.^{149,150,152,252,253} Two reports on subclinical thyroid disease were prepared by a panel of experts appointed by the American Association of Clinical Endocrinologists, the American Thyroid Association, and the Endocrine Society, who carried out an exhaustive review of the literature using principles of evidence-based medicine. These reports addressed issues of screening, evaluation, and management of patients with subclinical thyroid disease and culminated in a consensus statement of conclusions and recommendations prepared by the panel members, which was published in 2004.^{149,152} Subsequently, a response document from representatives of three organizations was prepared and published in 2005, pointing out areas where there was disagreement with the consensus conference recommendations.¹⁵⁰

The consensus panel concluded that routine treatment of patients with subclinical hypothyroidism with serum TSH levels of 4.5 to 10 mU/L was not warranted but indicated that treatment is reasonable for patients with TSH levels greater

than 10 mU/L. This recommendation was based on data from patients with a TSH level above 10 mU/L regarding the projected rate of progression from subclinical to overt hypothyroidism and the effects of thyroxine treatment on symptoms, depression, lipid profiles, and cardiac function.¹⁴⁹

The three sponsoring societies disagreed with some of the consensus panel's conclusions. Thus, the three societies recommend routine screening for subclinical thyroid disease according to previously published guidelines. Further, they recommend routine treatment of patients with subclinical hypothyroidism who have TSH levels between 4.5 to 10 mU/L.¹⁵⁰

At present, a conservative approach is to monitor patients identified with the syndrome with serum TSH and T4 at 6- to 12-month intervals. Replacement therapy with thyroxine should be given to those patients with serum TSH greater than 10 mU/L and to those with TSH between 4.5 and 10 mU/L who have either high levels of antimicrosomal antibodies or symptoms consistent with mild hypothyroidism.

NODULAR THYROID DISEASE AND NEOPLASIA

The development of thyroid nodules is an age-related process that occurs more commonly in women than in men.^{84,254–256} Autopsy studies have demonstrated that thyroid nodules are frequently found in the elderly population, even when clinical examination of the neck has failed to reveal abnormality.^{254,256} Autopsy data reveal that an increase in frequency of nodules is evident in women and men over age 30 with a progressive increase to a frequency of 90% in women and 50% in men aged over 70 years. These observations are supported by ultrasound data, which have found thyroid nodules in approximately 50% of women over the age of 50 years.²⁵⁷

Clinical presentations

Thyroid nodules most commonly are asymptomatic; the patient may discover them accidentally, or the physician may find them during the course of a physical examination or as an incidental finding on CT or MRI of the head, neck, or chest. Of greatest concern is the finding of a single palpable nodule, which raises the possibility of thyroid malignancy. In many such patients, further evaluation will reveal the presence of multiple nodules. Although a single nodule is more likely to harbor a malignancy than a multinodular thyroid, only approximately 10% of clinical single nodules will, in fact, be malignant.

Patients with thyroid nodules should be questioned for the history of external radiation exposure of the head, neck, and upper thorax. It is well established that radiation of the thyroid results in a marked increase in risk of developing thyroid malignancy. In the United States, it was common practice for many years, up to the 1950s, to treat facial acne, tonsillar enlargement, cervical adenitis, and thymic enlargement with external radiation. It is estimated that several million people were irradiated, many of whom are now in the over-60 age group. Although a history of irradiation in a patient with nodular thyroid increases the likelihood of malignancy, it is important to note that irradiation also increases the development of benign nodules. Of individuals who as children received low-dose head and neck irradiation, 87%

Table 90-5. Risk Factors for Malignancy in a Thyroid Nodule

- Male
- Age greater than 60
- History of irradiation of head or neck area
- Family history of thyroid cancer
- Solitary on clinical examination
- Increase in size
- Hard on palpation
- Hoarse voice
- Suspicious ultrasound characteristics
 - Size greater than 1 cm
 - Solid rather than cystic
 - Hypoechoogenicity
 - Central hypervascularity
 - Presence of microcalcifications
 - Irregular borders

have ultrasound-detectable nodules, from 16% to 29% will develop palpable thyroid nodules, and of these, approximately one third will be malignant.^{258,259} Nodules are apparent after a latency of 10 to 20 years, and the incidence of malignant nodules reaches a peak 20 to 30 years after exposure.^{255,258}

Occasionally, a thyroid nodule will be associated with acute onset of neck pain and tenderness. This circumstance may be the result of acute or subacute thyroiditis or hemorrhage into a preexisting nodule.

The finding of multinodular thyroid increases in areas of iodine deficiency. Often there is a history of goiter dating back to childhood or young adult years. Very large multinodular goiter, particularly those with a sizable substernal component, may compress the trachea and lead to complaints of dyspnea. Disturbances of swallowing may also occur. This presentation is most common in older women. A large substernal goiter sometimes is first recognized when the patient has had a chest radiogram and is noted to have compression or deviation of the trachea or a superior mediastinal mass.²⁶⁰

Differential diagnosis

The entities that present as thyroid nodules are many. Most are the result of benign thyroid lesions and include follicular and colloid adenomas, acute and subacute thyroiditis, Hashimoto's thyroiditis, and thyroid cysts. Malignant thyroid neoplasms include papillary, follicular, medullary, and anaplastic carcinomas, as well as thyroid lymphoma and metastases to the thyroid. Nonthyroid lesions may also present as apparent thyroid nodules and include lymph nodes, aneurysms, parathyroid adenomas and cysts, and thyroglossal duct cysts.²⁶¹

The likelihood that a single nodule is malignant increases if there is a history of radiation exposure, if it occurs in a man, has been observed to undergo increase in size, is accompanied by hoarseness of the voice suggestive of impingement on the recurrent laryngeal nerve, and is stony hard on palpation (Table 90-5).

Age appears to be a risk factor for the development of thyroid cancer. The National Cancer Data Base of 53,856 patients with thyroid cancer indicates that approximately 25% of all thyroid cancers are first diagnosed in individuals who are older than 60 years.^{262,263} The overall

Table 90-6. Occurrence of Thyroid Malignancy in the Older Patient, and 10-Year Survival

Cancer Type	Percentage of Cancer Patients		Percentage 10-Year Survival*
	>Age 40	>Age 64	
Papillary/mixed	79	60–67	<65
Follicular	13	20–25	<57
Medullary	3	5	<63
Anaplastic	2	6	0
Lymphoma	3	5	≤100

*Age at diagnosis >60 years.

histologic distribution of thyroid cancer is 79% papillary, 13% follicular, 3% Hurthle cell, 3.5% medullary, and 1.7% anaplastic.²⁶² Age is a factor in predicting histologic type of malignancy^{262,264} (Table 90-6). In patients over the age of 60 years, papillary carcinoma accounts for approximately 67% of thyroid cancers. Follicular carcinoma, the next most common histologic type, has a peak frequency in both the fourth and sixth decades of life with a mean age at diagnosis of 44 years. It, along with Hurthle-cell carcinoma, makes up approximately 23% of the thyroid malignancies in the over-60 age group. Medullary carcinoma has a peak incidence in the fifth and sixth decades and accounts for 5% of thyroid cancers in the elderly population.^{262,265}

Anaplastic carcinoma of the thyroid is almost exclusively a disease of older persons and accounts for approximately 6% of thyroid cancers in this age group. It is invariably fatal in a short period of time from its first diagnosis, especially when greater than 5 cm in diameter.²⁶⁶ Clinically, it often arises in an area of previous thyroid disease and is recognized by its rapid growth, rocklike consistency, and local invasiveness with recurrent laryngeal nerve involvement and tracheal compression.

Lymphoma and metastatic cancers make up the remaining thyroid malignancies in elderly people. Lymphoma is characterized by a rapidly enlarging painless neck mass, which may cause compressive symptoms and initially may be difficult to differentiate from anaplastic carcinoma on clinical appearance alone. Hashimoto's thyroiditis is commonly present in patients with lymphoma.²⁷⁶

The rapid onset of a painful, tender thyroid mass with an accompanying fever and leukocytosis is highly suggestive of acute suppurative thyroiditis. Similarly, the development of a painful, tender, firm thyroid mass without fever and leukocytosis points toward a diagnosis of subacute or granulomatous thyroiditis. A history of an antecedent upper-respiratory tract infection with a sore throat further supports the diagnosis. This disorder may be accompanied in its acute phase by transient hyperthyroidism as a result of leakage of thyroid hormones from damaged follicular cells. Another consideration in the patient with acute onset of a painful, tender neck mass is hemorrhage into a previously asymptomatic thyroid cyst or adenoma.

Evaluation of a thyroid nodule

The major objective of evaluation in the patient who is found to have a thyroid nodule, especially an apparently single nodule, is to determine if the nodule is benign or malignant. A number of diagnostic modalities are available.

Blood tests of thyroid function will usually give normal results, with the exception of the patient with a hyperfunctioning adenoma or toxic multinodular goiter. In some patients with nodular disease secondary to Hashimoto's thyroiditis, serum TSH may be increased. Several reports have shown that serum TSH may be an independent predictor of thyroid malignancy with the risk of malignancy in a thyroid nodule increasing with higher levels of TSH, even within the normal range, so that the likelihood of malignancy was 52% when TSH was 5 mU/L or greater.^{268,269} Measurement of serum thyroglobulin is often elevated in patients with thyroid cancer but cannot reliably differentiate malignancy from benign adenoma or thyroiditis.⁷⁷ Its major usefulness is in the early recognition of recurrence or metastasis in patients with papillary or follicular carcinoma who had previously undergone total thyroidectomy. Elevation of serum calcitonin concentration greatly supports a diagnosis of medullary carcinoma.²⁷⁰

Determination of functional status of a nodule by isotope imaging is useful. Malignant tissue rarely is able to take up iodine, so that identification of a nodule as "warm" or "hot" by ¹²³I or technetium scanning makes the likelihood of malignancy in the nodule remote. In addition, scanning may reveal that an apparent single nodule is, in fact, part of a multinodular thyroid, again decreasing the risk of malignancy. The finding of a nonfunctioning or "cold" nodule does not establish a diagnosis of malignancy because 95% of thyroid nodules are cold, and of these, the incidence of malignancy is 5%.²⁷¹ For this reason, isotopic scanning is no longer considered as an initial diagnostic test.

High-resolution ultrasonography can detect lesions as small as 2 mm and can permit classification of a nodule as solid, cystic, or mixed solid-cystic.²⁷² The technique often demonstrates multinodularity in a gland with a single palpable nodule. The value of ultrasonography in establishing a diagnosis of malignancy is limited because there is considerable overlap in the ultrasound characteristics of benign and malignant nodules. The following ultrasound features increase the probability of malignancy: (1) size greater than 1 cm, (2) solid rather than cystic, (3) hypoechogenicity, (4) central hypervascularity, (5) presence of microcalcifications, and (6) irregular borders (see Table 90-5).²⁷³ The procedure may be useful for detecting recurrent or residual thyroid cancer and for screening individuals who have had a history of irradiation exposure. It may also be of value in the patient suspected of having thyroid lymphoma, because this malignancy often produces a characteristic asymmetrical pseudocystic pattern.²⁷⁴

Computed tomography and MRI can provide detailed information on thyroid anatomy. These procedures are expensive and appear to add little to initial clinical assessment for malignancy.⁶⁵ However, they may be useful in determining the extent of disease in patients with anaplastic carcinoma or lymphoma of the thyroid. Additionally, CT and MRI can provide information about the size and substernal extent of large goiters and compression of neck structures.

In patients with nontoxic nodular goiter, thyroid hormone has been used to suppress TSH on the assumption that benign lesions were more likely to be TSH-dependent and, therefore, likely to decrease in size. The procedure involves giving L-thyroxine in a dose sufficient to suppress serum

TSH and monitoring the size of the thyroid nodule for a period of 3 to 6 months. Because of the subjective nature of assessment of thyroid nodular size and the demonstration that suppressive therapy had little significant effect on goiter or nodule size during several well-controlled trials of L-thyroxine, there does not appear to be justification for future use of this procedure.^{275,276} In addition, the administration of suppressive doses of L-thyroxine to elderly patients carries substantial risk for precipitation or aggravation of ischemic heart disease and for acceleration of bone loss.

Fine-needle aspiration (FNA) of the thyroid to obtain tissue for cytologic or histologic examination appears to be the most reliable and accurate method of separating benign from malignant disease.²⁷⁷⁻²⁷⁹ FNA is indicated in any patient with a solitary nodule and when there is suspicion of thyroid malignancy from clinical, ultrasound, or scanning findings. In skilled hands, the procedure is safe, inexpensive, and capable of determining the presence or absence of malignancy with 95% accuracy. The reliability of FNA can be further increased if done in conjunction with real-time sonographic guidance. The cytopathologic findings from FNA are assigned to four categories: positive for malignancy, suspicious for malignancy, negative for malignancy, and nondiagnostic. In the case of a nondiagnostic aspirate, repeat FNA is recommended. Surgery is recommended for all patients with a malignant cytologic diagnosis. For patients with a suspicious interpretation of the FNA, thyroid scanning is recommended with surgical excision to follow if the lesion is hypofunctioning. The patient with benign cytology can be managed subsequently by observation. The patient with clinical or FNA features suggestive of lymphoma should have a large-needle or surgical biopsy done to confirm the diagnosis.²⁷⁴

Management of thyroid nodules

The management of thyroid nodules largely depends on the results of the diagnostic evaluation, especially the determination as to whether the nodule has a high risk of being malignant based on ultrasound characteristics and FNA results.²⁸⁰ Nodules identified as being "warm" and with associated normal thyroid hormone production and no compressive symptoms warrant only observation with examination at intervals of 6 to 12 months. "Hot" nodules are managed similarly as long as thyroid function is normal. If evidence for hyperthyroidism is found, then appropriate treatment for this condition should be initiated.

Management of the "cold" nodule is more complex.²⁸¹ When possible, FNA biopsy should be performed.²⁷⁷⁻²⁷⁹ Demonstration of benign cytology in either a solid or a cystic nodule indicates that the patient can be managed subsequently by observation. The combination of suspicious cytology by FNA and cold appearance on scanning should lead to a recommendation of surgical excision. If FNA reveals malignant cells, operation is recommended with little need for further study.

Only a surgeon experienced in the procedure should perform surgery for thyroid carcinoma. If a diagnosis of malignancy has not been firmly established preoperatively, the nodule should be removed with a wide margin of uninvolved tissue and examined by frozen section. If a diagnosis of papillary or follicular carcinoma is confirmed or has been made before surgery, near-total thyroidectomy should be

carried out because of the high frequency of multicentricity of malignancy and the need to remove functional thyroid tissue in order to monitor the patient with whole-body radioiodine scanning in the future.^{263,280,282-284} Regional lymph nodes should be explored and removed if there is evidence of metastatic involvement. Postoperatively, attention must be paid to the possible complications of recurrent laryngeal nerve injury and hypoparathyroidism, which may be transient or permanent. Almost certainly, patients will become hypothyroid following surgery and will require hormone replacement, which should be in a dose sufficient to suppress serum TSH to levels below normal, if clinically tolerated.

Postoperatively, and at 6- to 12-month intervals thereafter, it will be necessary to discontinue thyroid replacement for a period of up to 6 weeks to allow endogenous serum TSH levels to rise sufficiently high (>30 mU/L) to promote tissue uptake of ¹³¹I. Alternatively, replacement thyroid hormone can be continued and recombinant human TSH (rhTSH) can be given intramuscularly at 24-hour intervals for two doses.²⁸⁵ Twenty-four hours after the second dose of rhTSH or after the period of thyroid hormone withdrawal, blood is obtained for measurement of thyroglobulin and then large scanning doses of ¹²³I are administered and neck and total-body scans are performed at 24, 48, and 72 hours. If serum thyroglobulin is elevated or if areas of uptake are found, large ablative doses of ¹³¹I are then administered and replacement therapy reinstated 48 hours later. This approach reduces the recurrence rate of both papillary and follicular carcinoma and prolongs survival.^{263,283,284,286} In the patient whose initial surveillance thyroid scan shows no areas of uptake and in whom the serum thyroglobulin levels are below 0.1 ng/mL, subsequent monitoring can be done by periodic measurement of serum thyroglobulin while continuing on thyroid hormone replacement without the need for thyroid hormone withdrawal.²⁸⁷ As long as the serum thyroglobulin remains below 0.1 ng/mL, the risk of thyroid cancer recurrence is very low. Patients followed in this way should also have periodic neck ultrasonography performed.

The 10-year survival rate when initial diagnosis is made over the age of 60 years is estimated to be less than 65% for patients with papillary carcinoma, whereas 10-year survival falls to less than 57% in older patients with follicular carcinoma and is lower yet for patients with medullary carcinoma.^{264,288} In patients with follicular carcinoma, increased size (greater than 3 cm) was associated with increased recurrence, and distant metastases at time of diagnosis predicted a high risk of subsequent death.²⁶⁵ Patients with radioiodine-resistant differentiated thyroid cancer have shown a positive

response to treatment with motesanib diphosphate, an orally active inhibitor of vascular endothelial growth factor receptors.²⁸⁹ For medullary carcinoma, the operative procedure of choice is total thyroidectomy because the disease is often multicentric. Routine dissection of the lymph nodes is also recommended. The majority of medullary carcinomas do not respond to ¹³¹I therapy so that patients with inoperable residual or recurrent disease are treated palliatively with external irradiation. The survival declines with increase in age at time of initial diagnosis, being substantially lower in patients over age 60 years. Approximately two thirds of patients in their seventh decade will have persistent disease after surgery.²⁹⁰ The efficacy of surgery can be monitored postoperatively by measurement of blood calcitonin concentration, both in the basal state and after stimulation.²⁷⁰ Survival rates for thyroid malignancy initially diagnosed in patients over the age of 60 years are given in Table 90-6.

The management of anaplastic carcinoma of the thyroid remains unsatisfactory.²⁸⁶ Relief of symptoms of compression can sometimes be achieved by surgery followed by high-dose (45 to 60 Gy) external irradiation.²⁹¹ Chemotherapy with doxorubicin may be beneficial in combination with surgery and external irradiation.^{266,292}

Patients with thyroid lymphoma should have clinical staging carried out by means of CT or MRI. The survival rate can approach 100% in response to aggressive external irradiation in combination with CHOP (cytoxan, Adriamycin, vincristine, prednisone) chemotherapy.²⁷⁴

Subtotal thyroidectomy has been the traditional therapy for compressive goiter.²⁹³ However, large compressive goiters can respond to ablation doses of ¹³¹I (25 to 125 mCi) with significant shrinkage of the thyroid and accompanying relief of compressive symptoms such as stridor, dyspnea, and dysphagia.^{260,276,294,295} Improvement in the response to ¹³¹I has been observed when patients were given rhTSH before radioiodine administration.²⁹⁶ In these patients, replacement doses of L-thyroxine sufficient to keep serum TSH within the normal range should be given following either surgery or radioiodine treatment to maintain suppression of thyroid tissue and to avoid the late development of hypothyroidism.

If acute, suppurative thyroiditis is suspected, treatment with antibiotics is called for. The microorganisms most commonly responsible are *Staphylococcus aureus*, *Streptococcus hemolyticus*, *Escherichia coli*, *Pneumococcus*, and *Salmonella*. Rarely, surgical drainage of a fluctuant mass will be necessary. Nodules found in association with subacute thyroiditis require no special care and may diminish in size as the disease resolves.

Summary of Management Algorithm

Hyperthyroidism

- Use β -blockers for rate control of tachyarrhythmias.
- ^{131}I ablation is preferred treatment.
- If atrial fibrillation is present:
 - Use anticoagulants
 - Use cardioversion if normal sinus rhythm has not occurred by 16 weeks after normalization of thyroid function
- Use high-dose antithyroid drugs plus iodide for thyroid storm.

Subclinical Hyperthyroidism²⁹⁷

- Normalize thyroid function with antithyroid drugs or ^{131}I if:
 - There are clinical features of hyperthyroidism
 - Atrial fibrillation occurs
 - There is evidence for osteopenia or osteoporosis
 - TSH is suppressed <0.1 mU/L
 - There is an increase in T4, free T4, T3, or free T3 during follow-up
- Monitor TSH/free T4 at 6- to 12-month intervals in asymptomatic patients with TSH 0.1 to 0.4 mU/L.

Hypothyroidism

- Treat with L-thyroxine:
 - Start with low-dose 12.5 to 25 μg daily
 - Increase by 12.5 to 25 μg at 2- to 4-week intervals
- Monitor treatment response with serum TSH.
- If coronary artery disease and angina are present, start β -blocker along with L-thyroxine.
- For myxedema coma:
 - Provide supportive care in intensive-care setting
 - Treat immediately with IV L-thyroxine 300 to 500 μg
 - Give IV glucocorticoids until adrenal status is determined

Subclinical Hypothyroidism²⁹⁷

- Initiate treatment with L-thyroxine if:
 - TSH is >10 mU/L
 - TSH is 4.5–10 mU/L and
 - Antithyroid antibody titers are $>1:1600$.
 - Dyslipidemia is present.
 - Coronary artery disease is present.
 - Symptoms suggestive of mild hypothyroidism are present.
- Monitor TSH/free T4 at 6- to 12-month intervals in patients with TSH 4.5 to 10 mU/L, negative antithyroid antibodies, and no evident symptoms of hypothyroidism.

Thyroid Nodules/Malignancy

- If suspicious nodule is present, do FNA biopsy.
- If positive diagnosis is made of differentiated thyroid cancer:
 - Treat with near-total thyroidectomy
 - Follow with ^{131}I ablation of any thyroid remnant
 - Subsequent yearly follow-up with ^{123}I scans and serum thyroglobulin

KEY POINTS

Disorders of the Thyroid

- Both disease states and drugs commonly used in the elderly can affect measures of thyroid function.
- Disorders of thyroid function increase in prevalence with increasing age.
- Because aging can alter the clinical presentation of both hyperthyroidism and hypothyroidism, screening for thyroid dysfunction is warranted for all persons over the age of 50 years.
- Treatment of both subclinical hyperthyroidism and subclinical hypothyroidism may prevent the later occurrence of significant adverse clinical events.
- Treatment of both hyperthyroidism and hypothyroidism in elderly people differs from the approach to treatment in younger persons.
- Thyroid malignancy increases in prevalence with increasing age, and initial diagnosis in the older person carries higher risk of subsequent recurrence or decreased survival.

Disorders of the Parathyroid Glands

Jane Turton
Michael Stone
Duncan S. Cole

INTRODUCTION

Most individuals have only four parathyroid glands, which are usually located at the superior and inferior poles of the thyroid gland and which arise from the second and fourth branchial arches during fetal development¹ (Figure 91-1).

A parathyroid gland is oval, yellow in color, measures about 5 mm across, and usually weighs less than 35 mg. Within a gland, there are four cell types: chief cells, clear cells, oxyphil cells, and adipose cells.²

PHYSIOLOGY OF PARATHYROID HORMONE

Parathyroid hormone (PTH) is produced by the chief cells and is an 84 amino acid polypeptide with biologic activity in the N-terminal portion of the molecule. It is synthesized as pre-pro-PTH and is then sequentially processed to pro-PTH and finally to intact PTH (1-84). PTH is secreted as intact PTH and also in the cleaved C-terminal PTH form (C-PTH). The proportion of C-PTH secreted relative to intact PTH changes in response to circulating free calcium concentration.

Intact PTH has a half-life of less than 5 minutes. It is metabolized by Kupfer cells in the liver, resulting in cleavage of its N-terminal portion and the intracellular degradation of the N-terminal fragment. C-terminal fragments are released back into the circulation from the liver. These fragments are cleared by the kidneys and may be elevated in renal failure. C-terminal fragments have a longer half-life than the intact hormone and constitute the majority of circulating PTH forms.

PTH secretion exhibits both a circadian rhythm, with a peak in the early hours of the morning and nadir in late morning/early afternoon,³ and a seasonal variation that is highest in the winter and lowest in the summer.⁴

The secretion of PTH occurs predominantly in response to a fall in extracellular free calcium concentration, which is sensed by the calcium sensing receptor (CaSR) on parathyroid chief cells. The CaSR is a G-protein coupled receptor found in the intestine, kidney, thyroid C-cells, brain, and bone, where it is involved in local calcium homeostatic processes.⁵ The gene mutation of the CaSR in familial benign hypocalciuric hypercalcemia results in an alteration of the calcium homeostatic set point.⁶

The secretion of PTH is also influenced by circulating levels of 1,25-dihydroxyvitamin D ($1,25(\text{OH})_2\text{D}_3$) phosphate and magnesium. $1,25(\text{OH})_2\text{D}_3$ suppresses PTH secretion by inhibiting gene transcription. Hyperphosphatemia increases PTH synthesis and secretion; the converse holds for hypophosphatemia. In states of significant chronic magnesium deficiency, PTH secretion is impaired. An acute magnesium deficiency may, however, increase PTH secretion.

In the kidney, PTH stimulates 1α -hydroxylation of 25-hydroxyvitamin D₃ ($25(\text{OH})\text{D}_3$) to produce the biologically

active $1,25(\text{OH})_2\text{D}_3$, promotes calcium reabsorption in the distal convoluted tubule, and inhibits the reabsorption of phosphate from the proximal tubule.

In the small intestine, PTH has a small direct local effect, and circulating $1,25(\text{OH})_2\text{D}_3$ produced in the kidney promotes gastrointestinal absorption of calcium and phosphate.⁷

PTH increases osteoclastic resorption of bone at cortical surfaces and causes the release of calcium into the extracellular fluid. The net result of PTH action is an increase in extracellular calcium levels and a reduction in phosphate levels.

CALCIUM HOMEOSTASIS AND CHANGES WITH AGE

In the elderly, average PTH levels can be up to 35% higher than those measured in a young adult population.^{8,9} The cause of this is multifactorial and is the result of the following conditions:

- A fall in $1,25(\text{OH})_2\text{D}_3$ production by the aging kidney as the glomerulofiltration rate falls from 125 mL/min at age 20 years to 60 mL/min at age 80.¹⁰
- A reduction in the responsiveness of renal 1α -hydroxylase to circulating PTH.¹¹
- A reduction in dietary intake and absorption of calcium and vitamin D.¹²
- A reduction in vitamin D production in the skin as a result of less frequent and efficient sunlight exposure. Individuals who are housebound or living in nursing

 X-rays and isotope bone scan
 Sestamibi and ultrasound scan for preoperative assessment of primary hyperparathyroidism

Table 91-2. PTH Assay, Calcium, and Vitamin D Assays**PTH Assay**

Blood for PTH assay should be collected into tubes containing EDTA, as PTH is more stable in EDTA.¹⁴ Intact PTH is measured by noncompetitive immunoassay, which recognizes the C-terminal region. Specificity for the intact PTH is achieved by using a signal antibody that binds to the N-terminal (1-34) region.

Calcium and Vitamin D Assay

Total calcium is usually measured using dye-binding spectrophotometric techniques. Forty percent of calcium in blood is bound to albumin, so changes in serum albumin may alter the total calcium result. Laboratories correct for this by reporting an "adjusted calcium" result.

The more physiologically relevant ionized calcium fraction (by direct ion-specific electrode) may be measured using electrochemical methods.

Nutritional vitamin D status is assessed using an assay for serum 25-hydroxyvitamin D (25(OH)D), which has a physiological half-life of 3 weeks.

homes are at particular risk of developing abnormal PTH secretion secondary to vitamin D deficiency¹³ (Tables 91-1 and 91-2).¹⁴⁻¹⁶

SECONDARY HYPERPARATHYROIDISM

Secondary hyperparathyroidism is the most common disorder of calcium homeostasis in the elderly and has a prevalence of 20% to 60% in the population aged over 75 years.¹⁷ It occurs when there is vitamin D deficiency or insufficiency, and the resultant decrease in serum calcium causes parathyroid gland hyperplasia, which in turn causes a physiologic increase in PTH production.

The combination of vitamin D deficiency and secondary hyperparathyroidism is associated with an increased risk of fracture.^{17,18} There is an associated increase in mortality from cardiovascular disease¹⁹ independent of bone mass, serum 25(OH)D, and renal function.²⁰⁻²²

The first-line treatment for secondary hyperparathyroidism is a combined preparation of elemental calcium 1000 to 1200 mg and vitamin D₃ 20 micrograms (800 IU) daily. Chapuy et al showed that reducing PTH levels and improving serum 25(OH)D₃ levels using this combination could reduce risk of hip fracture by 30% at 18 months and that this efficacy was maintained out to 3 years.²³

If for any reason a patient cannot or will not adhere to this regime, vitamin D₂ or D₃ alone, 1 α -hydroxycalciferol,

or 1,25-dihydroxycalciferol can be used. 1,25-dihydroxycalciferol is particularly useful for patients with renal failure although careful monitoring of serum calcium is required.

Case Report: Secondary Hyperparathyroidism

A female Caucasian nonsmoker age 81 years presented to our clinic with a history of falls and a past history of wrist fracture, osteoarthritis, hypertension and hypercholesterolaemia. She was independent in her activities of daily living and mobile with a walking stick but lacked confidence to go outside alone. Her diet was low in calcium. She was referred for a bone density scan and diagnosed osteoporotic (Neck of Femur T score -3.0). She was taking a statin and mild opiate analgesia for arthritic pain. A biochemical screen for secondary causes of osteoporosis was performed, which revealed a profound vitamin D deficiency, secondary hyperparathyroidism, and mild hypocalcaemia. She was treated with a combined preparation of calcium 1000 mg and 800 IU ergocalciferol daily, which normalized her biochemistry (see below).

Treatment of Secondary Hyperparathyroidism**PRIMARY HYPERPARATHYROIDISM**

The biochemical presentation of primary hyperparathyroidism (HPT) is a raised plasma PTH and hypercalcemia. The peak incidence occurs between ages 55 to 64 years at 1:1000. The prevalence is 2% in persons aged over 75 years, and it is three times as common in women as in men.²⁴ Primary HPT is caused by a single adenoma in 80% of cases, four-gland hyperplasia in 15% of cases, and carcinoma in fewer than 1% of cases.²⁵ A rare but notable form of hypercalcemia, which can mimic primary hyperparathyroidism, is benign familial hypocalcaemic hypercalcemia.

Changes in the levels of circulating PTH have been shown to have an effect in the bone and in the brain. There is an increase in the bone remodeling space, and in trabecular bone, high levels of PTH increase bone formation. However, in cortical bone, high levels of PTH increase bone loss, cause a fall in bone mineral density (BMD), and increase the risk of fracture independent of 25(OH)D₃ levels.^{26,27}

In the brain, high levels of PTH can cause mood disturbance and memory loss secondary to the action of PTH on the PTH₂ receptor.²⁸

Case Report: Primary Hyperparathyroidism

A female Caucasian age 75 years presented with a history of bone and muscle pain, low mood, indigestion, and a BMI of 18.5. She was referred for bone densitometry, which confirmed severe osteoporosis. Screening for secondary causes of osteoporosis revealed hypercalcemia (corrected calcium 2.68 mmol/L), normal 25(OH)D₃, a raised PTH of 6.8 pmol/L, and raised urinary calcium excretion. She had no vertebral fractures. She was prescribed regular vitamin D₂ and an oral bisphosphonate. She was referred for parathyroidectomy. At surgery, she had a solitary right lower parathyroid adenoma measuring 20 × 3 × 2 mm removed. Since her surgery, her PTH and calcium have remained in the normal range. Her mood has improved, and the muscle and bone pains have eased. Bone mineral densities have increased by 7.5% in the 12 months since her surgery.

A common presentation of primary hyperparathyroidism follows measurement of serum calcium and the identification of individuals with asymptomatic hypercalcemia. The very elderly can present with an acute disequilibrium hypercalcemia as their renal function progressively declines or if they become acutely dehydrated²⁹ (Table 91-3).

Although most patients are now identified while asymptomatic, they can present with symptoms of lassitude, fatigue, mood swings, muscle pain, generalized weakness, and memory loss.²⁵ The classical presentation of primary hyperparathyroidism comprising bone cysts, pathologic fractures, and renal calculi as described by Von Recklinghausen in 1891 is very rare.³⁰

The treatment of primary hyperparathyroidism can be conservative or surgical. The conservative management involves regular monitoring (serum calcium, BMD, and PTH) and the use of oral or intravenous bisphosphonates. Although the effects on serum calcium are limited and transient,³¹ they are effective in treating the associated loss of bone.³² The use of calcium and vitamin D supplements with bisphosphonates is accepted practice in postmenopausal osteoporosis; however, in primary hyperparathyroidism, calcium supplementation should not be used. It is, however, safe to prescribe regular vitamin D₃ alone to these individuals to ensure that serum vitamin D levels remain normal.

The use of surgery as treatment is becoming more acceptable, even for very elderly patients, because improvements in imaging have led to successful minimally invasive surgical techniques.³³ The indications for surgery are detailed in Table 91-4. The usual imaging and localization techniques are sestamibi and ultrasound scanning (Figures 91-2 and 91-3), and during surgery intraoperative sampling of parathyroid hormone³⁴ is performed, which confirms when the hyperfunctioning tissue has been removed (Figure 91-4).

After parathyroidectomy, patients can have increases of up to 12% in bone mineral density in the first year, even without further treatment,³⁵ and the dilemma regarding the use of calcium and vitamin D supplementation is removed. The mood disturbance and memory loss associated with hyperparathyroidism has also been shown to improve after surgery.^{36,37}

Table 91-3. Symptoms and Signs of Acute Hypercalcemia

Differential Diagnosis of Hypercalcemia in the Elderly

Primary hyperparathyroidism
Malignancy
Renal failure
Addison's disease
Hyperthyroidism
Immobilization
Medications: thiazide diuretics, calcium supplements, lithium
Milk alkali syndrome
Paget's disease (when immobilized)
Sarcoidosis
Tuberculosis
Vitamin D or vitamin A intoxication

Symptoms of Acute Hypercalcemia

Neurological: drowsiness, confusion, irritability hypotonia, coma
Gastrointestinal: anorexia, nausea, vomiting, acute pancreatitis
Cardiovascular: arrhythmias
Renal: polyuria, polydipsia, dehydration

Table 91-4. Indications for Parathyroidectomy: National Institutes of Health Consensus Conference on Primary Hyperparathyroidism 1991 and 2002 Recommendations for Surgery³³

1991 Recommendations

Typical bone, renal, gastrointestinal, or neuromuscular symptoms
Life-threatening hypercalcemia
Calcium level 11.4–12.0 mg/dL (2.9–3.0 mmol/L)
Urine calcium level >400 mg/day (10 mmol/day)
Renal stones
BMD 2 SDs <age, sex-matched controls (z score)
Reduced creatinine clearance <30%
Age <50 y
Patient request;
Adequate follow-up unlikely

2002 Additional Recommendations

Calcium level >1 mg/dL (0.25 mmol/L) above normal for each laboratory
BMD T score < -2.5 at any site (WHO definition of osteoporosis)

Figure 91-2. Sestamibi scan showing increased uptake at lower right lobe of thyroid.

Figure 91-3. Ultrasound showing a hyperechoic region behind right lower lobe of thyroid.

Calcimimetic medications initially developed for the treatment of hyperparathyroidism related to renal disease and for the treatment of hypercalcemia of malignancy may now be used to treat primary hyperparathyroidism. These medications alter the sensitivity of the calcium sensing receptor in the parathyroid glands, thus reducing the levels of circulating PTH and calcium.³⁸

LITHIUM

Hypercalcemia and hyperparathyroidism is common in patients treated with lithium. It has an incidence of 6.3% to 50%, and it can mimic primary hyperparathyroidism.^{39,40} However, there are subtle differences between primary HPT

Figure 91-4. Graph of changes in PTH when hyperfunctioning parathyroid tissue is removed. Intraoperative PTH assay is carried out rapidly during the operation and takes 10 to 12 minutes. A drop in PTH of >50% indicates complete removal of the hyperfunctioning tissue.

and lithium-induced HPT. In lithium-induced disease, there is usually a normal serum phosphate, severe hypercalcemia is rare, 24-hour urinary calcium excretion is low or normal, and there is no adenoma. However, there is a hyperplasia of the parathyroid glands, and the condition is reversible on withdrawing lithium.⁴¹

Hypercalcemia can occur many years after initiation of lithium therapy, but it is also a recognized effect of a single dosing with lithium, which causes an acute elevation of serum PTH by direct stimulation of the parathyroid gland.⁴² Surgical treatment of hypercalcemia with subtotal parathyroidectomy is usually unsuccessful when it is a result of lithium administration, and the hypercalcemia can recur if lithium therapy is continued.⁴³

TERTIARY HYPERPARATHYROIDISM

In individuals who have prolonged secondary hyperparathyroidism as a result of renal failure, there is severe hyperplasia of the parathyroid glands, and the set point for normal inhibition of PTH secretion by calcium is altered. The hyperplastic parathyroid glands show a reduction in CaSR expression, and unlike secondary hyperparathyroidism, patients have high serum calcium and high PTH.

There are indications for parathyroid surgery in this condition, including severe bone pain, fractures, hypercalcemia,

Case Report: Lithium-Induced Hyperparathyroidism

A 65-year-old female presented to clinic with hypercalcemia and osteoporosis identified by screening in a gastroenterology clinic (corrected serum calcium 2.78, total spine T score -4.4, total hip T score -1.9). She had clinical risk factors for osteoporosis, namely smoking, a history of thyrotoxicosis, and celiac disease. She was being treated for bipolar disorder with oral lithium. She was adherent to a gluten-free diet and was taking 1000-mg calcium with 400 IU ergocalciferol and oral bisphosphonates as treatment for her osteoporosis at the time of presentation. Her PTH was raised; vitamin D was normal, and her 24-hour urinary calcium was low (see table). She had preoperative imaging for primary hyperparathyroidism, which did not identify an adenoma and she was not offered surgery. Her calcium and ergocalciferol were replaced with calciferol, and since then serum calcium has remained within normal limits. She continues to be treated with oral bisphosphonate for her osteoporosis.

PTH (0.9–5.4 pmol/L)	Calcium (2.20–2.60 mmol/L)	25(OH)D (8–50 ng/ml)	Phosphate (0.8–1.45 mmol/L)	24-Hour Urinary Calcium (<7.0 mmol)
6.6	2.78	25.8	1.34	0.7

Case Report: Tertiary Hyperparathyroidism

A 74-year-old male, who had received a renal transplant at age 58 years presented with osteoporosis (total spine T score -2.2 , NOFT score -2.8 , total hip T score -2.2), gross heterotopic calcification with chalky discharge, cardiovascular disease, and multiple falls.

Biochemically he had a vitamin D deficiency (25(OH)D 12.5 mcg/L), hyperparathyroidism (PTH 29.0 pmol/L), and a raised calcium x phosphate product (calcium 2.57 , phosphate 1.81). He had CKD stage 4 disease with a creatinine of 350 micromol/L. He was managed conservatively with intermittent oral etidronate, phosphate binders, and low-dose alfacalcidol as he was unfit for parathyroid surgery. He subsequently died after suffering a hip fracture.

Figure 91-5. Heterotopic tissue calcification in a periarticular distribution.

heterotopic calcification, and bone cysts; however, if this condition is treated surgically, there is a risk that some patients will subsequently develop adynamic bone disease (Figure 91-5).

HYPOPARATHYROIDISM

Hypoparathyroidism is much less common than hyperparathyroidism. It is unusual for it to present for the first time in the elderly. It presents clinically as hypocalcaemia and is a result of insufficiency or resistance to PTH. It can occur after surgery for thyroid or parathyroid disease or reflect autoimmune disease. The reduction in PTH leads to an increase in renal calcium loss and reduced absorption of calcium in the gut because of a fall in $1,25(\text{OH})\text{D}_3$ production. Treatment is with hydroxylated products of vitamin D, Ca supplementation, and thiazide diuretics to reduce renal calcium loss.

KEY POINTS

Disorders of the Parathyroid Glands

- Vitamin D deficiency and secondary hyperparathyroidism is common in the elderly.
- Treatment of frail elderly people with simple calcium and vitamin D supplementation significantly reduces the risk of fractures.
- Acute disequilibrium hypercalcaemia is an important, life-threatening cause of confusion in the elderly.
- The differential diagnosis of raised serum calcium and raised parathyroid hormone includes primary hyperparathyroidism, lithium-induced hyperparathyroidism, familial hypocalcaemic hypercalcaemia, and tertiary hyperparathyroidism.
- More elderly patients are now being considered for parathyroid surgery because of improvements in preoperative imaging and the use of minimally invasive surgical techniques.

Diabetes mellitus remains a significant personal and public health burden with unmeasured socioeconomic implications.¹⁻⁴ Although detailed and focused studies in older people need to be planned, there is the recognition that as a common disabling disorder, diabetes requires interventional strategies at an early stage and the involvement of both patients and caregivers in defining goals of care and treatment plans.^{5,6}

During the last decade, a number of factors suggest that care delivery has been enhanced and attitudes have changed.⁷ In particular, there is more recognition that older patients with diabetes may be different from younger counterparts⁸; for example, they have a high degree of comorbidity, an age-related impairment of functional ability, and an increased vulnerability to hypoglycemia and its consequences. They may also require a different approach to care, which involves a greater focus on managing disability and functional impairment.⁹ This chapter provides an account of the scientific and clinical basis of managing older people with diabetes, which should be a basis for enhancing the quality of diabetes care delivered. Although this is a large topic, the chapter should be read in conjunction with the European guidelines on diabetes in older people, which are currently being updated.¹⁰ Modern aims of care have been identified and should form the basis of any care package (Table 92-1).

DIABETES DEFINITION, CLASSIFICATION, AND DIAGNOSIS

Diabetes is defined by hyperglycemia and the tendency to develop specific complications, particularly retinopathy; indeed, the gold standard test for diabetes would be to leave the subject untreated for several years after which the presence of retinopathy is diagnostic.¹¹⁻¹³ The diagnostic criteria were developed to diagnose type 2 diabetes mellitus (previously known as non-insulin-dependent diabetes mellitus), since type 1 diabetes (previously known as insulin-dependent diabetes mellitus) is generally obvious clinically. A venous plasma glucose level equal to or exceeding 11.1 mmol/L (200 mg/dL)^{14,15} following glucose challenge identifies those subjects who have a dramatically increased risk of retinopathy.^{11-13,16} The cutoff value of 11.1 mmol/L does actually separate normoglycemic and diabetic populations (each with a gaussian distribution of 2-hour values) in different age groups, suggesting that the World Health Organization (WHO) criteria (see later discussion) apply in both elderly and young people.

Table 92-1. Aims in Managing the Elderly Diabetic Person

- Maintain an optimal level of well-being and quality of life
- Avoid hyperglycemic malaise and optimize nutritional status
- Assess comorbidity state
- Avoid adverse drug events, particularly hypoglycemia
- Maintain lower limb strength
- Recognize disability and limit handicap

The majority of elderly diabetic people have type 2 diabetes, but type 1 does occur¹⁷ and the age-specific incidence of type 1 is the same from 30 to 80 years of age.¹⁸ Type 1 diabetes in the elderly population may have a very insidious onset, when it is termed "latent autoimmune diabetes of the aged" (LADA). LADA has been shown to be quite common in some series (e.g., 10% to 15% of diabetic adults and 50% of the nonobese type 2 diabetic subjects¹⁹); the autoantibody screen is not used in routine clinical practice in elderly people because it is not particularly predictive. Diabetes may also be secondary to or exacerbated by other conditions such as pancreatic disease, endocrine disease such as Cushing's syndrome, acromegaly, or thyrotoxicosis, and (most commonly) drug therapy with high-dose thiazide diuretics, oral glucocorticosteroids, and oral β -blockers. A comprehensive list of diabetogenic drugs is given in the National Diabetes Data Group criteria.¹⁴ The majority of subjects with secondary diabetes are elderly.²⁰ A simple classification of diabetes mellitus in the elderly population is given in Table 92-2.

Recently, the diagnostic criteria were revised by both the American Diabetes Association (ADA)²¹ and the WHO²²—see Table 92-3 and www.diabetes.org.uk/info/carerec/newdiagnostic.html. These revisions have attempted to make screening for diabetes easier, but the ADA criteria have created pitfalls for the unwary. Both sets of criteria lower the threshold for an abnormal fasting plasma glucose (FPG) from 7.8 to 7.0 mmol/L, which addresses the low sensitivity of the fasting plasma glucose to detect an elevated 2-hour postchallenge glucose. Many studies have shown that this decrease in FPG increases the sensitivity of the FPG (e.g., from 65% to 81% in Bristol, U.K.), but the test still misses diabetic subjects with elevated 2-hour plasma glucose levels.²³ Isolated postchallenge hyperglycemia is not a benign mild condition; it carries increased risk of death.²⁴ Finally, the ADA reintroduced the concept of impaired fasting glucose (IFG) for subjects with a fasting glucose of 6.0 to 6.9 mmol/L. It is true that the risk of macrovascular disease increases once the FPG exceeds 6.0 mmol/L, but these IFG subjects have 2-hour postchallenge glucose levels, putting them clearly into normal, IFG, or diabetic categories, which require different management. In the predominantly European population of Bristol,²³ one third of IFG subjects have each category of glucose tolerance, whereas in the high-risk Gujarati population of Leicester, U.K., all IFG subjects have either diabetes

Table 92-2. Classification of Diabetes in Elderly People

Primary

- Type 1
- Type 2
- Obese
- Nonobese
- Maturity-onset diabetes of the young

Secondary

- Pancreatic disease
- Drugs (e.g., steroids)
- Other endocrine conditions (e.g., Cushing's syndrome, acromegaly, thyrotoxicosis)

Table 92-3. WHO Values for Diagnosis of Diabetes Mellitus and Other Categories of Hyperglycemia²²

	GLUCOSE CONCENTRATION (mmol/L)		
	WHOLE BLOOD		
	Venous	Capillary	Plasma (Venous)*
Diabetes mellitus:			
Fasting <i>or</i>	≥ 6.1	≥ 6.1	≥ 7.0
2 hours after glucose load	≥ 10.0	≥ 11.1	≥ 11.1
Impaired glucose tolerance (IGT):			
Fasting (if measured) <i>and</i>	<6.1 <i>and</i>	<6.1 <i>and</i>	<7.0 <i>and</i>
2 hours after glucose load	6.7–9.9	7.8–11.0	7.8–11.0
Impaired fasting glycemia (IFG):			
Fasting <i>and</i> (if measured)	5.6 <i>and</i> <6.1	5.6 <i>and</i> <6.1	6.1 <i>and</i> <7.0
2 hours after glucose load	<6.7	<7.8	<7.8

*Corresponding values for capillary plasma are:

For diabetes mellitus: fasting, 7.0; 2 hr, 12.2.

For impaired glucose tolerance: fasting, <7.0; and 2 hr, 8.9 and <12.2.

For impaired fasting glycemia: 6.1 and <7.0, and if measured, 2 hr, <8.9.

For clinical purposes, the diagnosis of diabetes should always be confirmed by repeating the test on another day unless there is unequivocal hyperglycemia with acute metabolic decompensation or obvious symptoms.

or IGT on the 2-hour PG.²⁵ These facts are important if the FPG is used for diagnosing diabetes.

The latest WHO and International Diabetes Federation (IDF) criteria simplify matters greatly by introducing the term *intermediate hyperglycemia* as somewhere between normal glucose tolerance (fasting venous plasma glucose <6.1 mmol/L and 2-hours postchallenge of <7.8) and diabetes (fasting venous plasma glucose = 7.0 mmol/L and 2-hour postchallenge of 11.1 mmol/L).²⁶

IMPAIRMENT OF GLUCOSE TOLERANCE WITH AGING

The prevalence of diabetes mellitus increases with advancing age and is predominantly type 2. This age-related impairment has been confirmed by more recent studies indicating that glucose intolerance begins in the third decade and continues throughout adulthood.^{27–30} The magnitude of the rise has been estimated to be 0.33 to 0.72 mmol/L (5.9 to 13.0 mg/dL) per decade in 1- and 2-hour postglucose ingestion samples. The rise is more pronounced in women (about 0.55 mmol/L [9.9 mg/dL] higher than in men).³⁰ The National Health and Nutrition Examination Survey (NHANES III) of U.S. residents found a rise in prevalence of impaired glucose tolerance (IGT) of 11.9% in those aged 40 to 49 years to 20.7% in those aged 60 to 74 years;³¹ this survey also demonstrated increasing prevalence rates of diabetes with age from 3.4% to 24.4% (Figure 92-1).

Several possible mechanisms may contribute to glucose intolerance during aging and these are listed in Table 92-4. The impairment is clearly multifactorial, being characterized by delays in glucose-mediated insulin secretion, insulin-induced suppression of hepatic glucose output, and a rise in insulin-mediated glucose uptake.

EPIDEMIOLOGY OF DIABETES MELLITUS IN THE ELDERLY POPULATION

To promote rational health care planning involving an accurate assessment of the public health burden of diabetes and a needs assessment, we require better ways of identifying

Figure 92-1. Data from NHANES III: rising abnormalities of glucose tolerance with age. (From Harris MI, Flegal KM, Cowie CC et al. Prevalence of diabetes, impaired fasting glucose, and impaired glucose tolerance in U.S. adults: the Third National Health and Nutrition Examination Survey, 1988–1994. *Diabetes Care* 1998;21:518–24.)

individuals with the disease since approximately 50% may be undiagnosed.³² However, even studies of subjects with previously diagnosed diabetes can provide useful information. For instance, the surveys of Poole, Oxford, and Southall (U.K.) of European subjects with diagnosed diabetes³³ reveals that 60% of known diabetic subjects are aged 60 years or more.

The prevalence of diabetes rises from youth to old age (Figure 92-1). However, the Melton (U.K.) screening survey,³⁴ the East and West Finland screening survey,³⁵ and a survey of Pima Indians³⁶ found static prevalences from age 65 to 85, suggesting that the age-related increase in diabetes prevalence levels off after age 65. Most developed countries have a prevalence of approximately 17% in their elderly white population and around 25% in nonwhite populations.^{15,31,35–47} The prevalence in white British elderly people is only around 9%,^{34,48} although the prevalence in nonwhite British elderly people is still approximately 25%,⁴⁹ and the prevalence in care-home residents is 25%.⁵⁰

The prevalence of previously diagnosed diabetes in the United Kingdom elderly population has increased over the last few decades and one could argue that this is because of a higher rate of ascertainment, rather than a true increase. Evidence from screening in Glostrup, Denmark, shows an increased true prevalence in the Danes because of increased obesity and decreased exercise,⁵¹ and NHANES III has shown a true increase in prevalence³¹ from NHANES II³² (Table 92-5).

The risk of developing type 2 diabetes is increased by parental history,^{32,47,52} obesity,^{32,45,47,51,52} hypertension,^{45,52} lack of exercise,^{45,52} and nonwhite race.^{31,32} In subjects with these risk factors, exercise seems to protect against the development of diabetes.⁵² This is important when advising the offspring of patients who are told to stay slim, avoid refined carbohydrates, exercise more (climb 15 flights of stairs per day), and be aware of their risk of diabetes and hypertension.⁵² Targeted screening of at-risk individuals is now also advised (e.g., fasting venous plasma glucose every 3 years for offspring of diabetic patients, after the age of 40 years),²¹ remembering to advise the subjects to buy life insurance before the test rather than after.

Table 92-4. Mechanisms of Decreased Glucose Tolerance in Old Age

- Delayed/decreased glucose-induced insulin secretion
- Impaired insulin-mediated glucose uptake in skeletal muscle and adipose tissue because of predominantly postreceptor defect
- Other factors:
 - Increased body fat
 - Decreased physical activity
 - Reduced dietary carbohydrate
 - Impaired renal function
 - Hypokalemia
 - Increased sympathetic nervous system activity
 - Diabetogenic drugs

IMPACT OF DIABETES MELLITUS IN THE ELDERLY POPULATION

Overview

Diabetes places a significant vascular burden on older patients with diabetes, which is partly explained by the traditional risk factors present and also by the effect of aging, itself. Older patients appear to have 2 to 3 times more need for hospital care than the general population⁵³ for various conditions such as heart failure, stroke, and coronary heart disease. This increase occurs from middle age onwards.⁵⁴ Older people with diabetes also use primary care services 2 to 3 times more than nondiabetic controls.^{54,55}

Several studies have defined the prevalence of elderly patients in hospital diabetic populations. In a study from the Edinburgh Royal Infirmary, elderly patients aged 65 years and over with diabetes accounted for 60% of the overall bed-occupancy because of diabetes, giving a mean hospital prevalence of 4.6%.² A Cardiff-based study of three district general hospitals found a hospital prevalence (pooled data) of 8.4% with a mean age of 65 years.⁵⁸

Diabetes in older subjects is associated with considerable morbidity, mainly because of the long-term complications.⁴⁸⁻⁵¹ A population-based study from Oxford⁵⁹ measured the incidence of complications over a median period of 6 years in 188 patients aged 60 years and over by using a structured questionnaire and clinical examination. Incidence rates of ischemic heart disease, stroke, and peripheral vascular disease were 56, 22, and 146 per 1000 person-years, which are slightly higher than found in the Framingham study,⁶³ since the Oxford study involved an older age group. Retinopathy occurred at a rate of 60 and cataract at 29 per 1000 person-years, whereas proteinuria (albumin concentration greater than 300 mg/L) was 19 per 1000 person-years. Incidence rates appeared to be unrelated to sex or duration of diabetes, but stroke and peripheral vascular disease rose significantly with age.

Table 92-5. Prevalence of Diabetes in Different Screened Elderly Populations

Study	Year	Ref.	Age	Sex	Ethnic Origin	DIABETES IGT RATE

Abbreviations: F, FBG-based survey; D, recruitment details scanty; pm gtt, testing performed in afternoon, which may increase diabetes prevalence; U, previously undiagnosed diabetic subjects only recorded.

In Poole, a coastal town in southern England, the prevalence of diabetic neuropathy, an important cause of foot ulceration and amputation, was determined in 1077 diabetic subjects,⁶⁰ who comprised 94% of the known diabetic population. Neuropathy was diagnosed by the presence of neuropathic symptoms plus one or more physical findings, such as loss of light touch or impairment of pain sensation. The overall prevalence of neuropathy was 16.3% (compared with 2.9% in nondiabetic controls) with similar values in both type 1 and type 2 diabetes patients.

A community survey from Nottingham, U.K.,⁶¹ of 98 elderly diabetic patients (mean age 73 years) registered with two inner-city general practices, studied the impact of diabetes in terms of complications and frequency of hospital and general practice contacts. Figure 92-2 shows that diabetic subjects had significantly higher prevalences of stroke, cognitive impairment, diminished leg pulses, visual impairment, and absent vibration senses (vibration perception threshold greater than 50 V at one or more sites, as a marker of neuropathy) compared with nondiabetic controls. Disability was present in four out of five patients. Cataract was the most common cause of disability associated with visual impairment.

Visual loss

Diabetic retinopathy was the third main cause of blindness and partial sight registration in one epidemiologic study in Avon, U.K.⁶⁴ However, the diabetic person also has a greater risk of cataract, glaucoma, retinal artery thrombosis, and retinal vein thrombosis. Thus it is no surprise that blind registrations for diabetic subjects in Nottingham, U.K., are eight times higher than the subjects not known to have diabetes,⁶⁰ with 16% of elderly diabetic subjects having blind or partial-sight registrations. The diabetic blind registration is predominantly due to maculopathy, which is treatable, unlike most forms of age-related macular degeneration, the main cause of blind registration in the elderly population.

Many cross-sectional studies show that good glycaemic control is associated with less chance of developing

retinopathy.^{80,81} The U.K. Prospective Diabetes Study has now shown, in a prospective randomized controlled trial of aggressive versus conventional (when the trial was started) treatments, that both blood glucose lowering and blood pressure lowering decrease the risk of retinopathy.⁶⁷⁻⁷⁰ Duration of disease is also associated with increased risk of retinopathy. Because the elderly diabetic subject has often had type 2 diabetes for at least 5 to 7 years before diagnosis,⁷¹ it is not surprising that diabetic retinopathy is already present at diagnosis in 10.5% of elderly subjects in whom only one pupil was dilated⁷²; 23.8% of subjects of all ages in the U.K. Prospective Diabetes Study had retinopathy at presentation.⁷³

Laser photocoagulation can preserve vision in edematous and exudative maculopathies if visual acuity is 6/9 or better,^{74,75} and it has been calculated that screening and treating diabetic retinopathy would prevent 56% of blind registrations that are caused by the retinopathy.⁷⁶ Interestingly, the EURODIAB controlled trial of lisinopril in insulin-dependent diabetes (EUCLID) showed a 50% reduction in progression of retinopathy in type 1 diabetic subjects randomized to ACE inhibitor.⁷⁷

Cataract has been shown to be more common in diabetic subjects^{78,79} even at the time of diagnosis,⁸⁰ and its presence predicts increased mortality.⁸¹ However, The U.K. Prospective Diabetes Study showed that aggressive blood glucose reduction decreased the rate of cataract extraction.⁶⁷

Although some studies show an association of diabetes with open-angle glaucoma,⁸² other studies do not.⁸³⁻⁸⁵ There is some evidence that glaucoma is associated with worse retinopathy⁸⁶ and neovascularization is associated with glaucoma,⁸⁷ particularly if there is rubeosis iridis. It is well accepted that retinal venous thrombosis is a complication of diabetes,⁸⁸ and there is some evidence that retinal artery thrombosis is associated with diabetes.^{80,89}

Age-related macular degeneration seems very common in diabetic patients; the theoretical reasons for this are discussed in the paper by Klein et al.⁹⁰ However, most studies show no such association,⁹¹⁻⁹³ and only one study has shown such an association in men aged 75 or more.⁹⁰

The gold standard ophthalmologic assessment is slit-lamp examination by an experienced user,⁹⁴ but this is often not practicable. Mydriatic retinal photography has a sensitivity of detection of eye disease of 89%, which is significantly better than the sensitivity of direct ophthalmoscopy of 65%.⁹⁴ If photography is not available, subjects need measurements of visual acuity and dilated fundoscopy by experienced observers each year; this is probably worth doing opportunistically anyway because even photography misses 11% of retinopathy. Although exudative maculopathy is easy to spot in the dilated eye (exudates around or within one disk's diameter of the macula), macular edema is practically impossible to distinguish from a normal eye by ophthalmoscopy; hence, the importance of measuring the corrected visual acuity. Reasons for referral to an ophthalmologist are set out in Table 92-6.

Foot disease

Limb amputation remains an important health problem in the diabetic population, with the rate of lower limb amputation being 15 times higher than for nondiabetic patients.⁹⁵

Figure 92-2. Comparison of morbidity between diabetic and nondiabetic individuals. P values are shown in parentheses. (From Doman TL, Peck GM, Dow JDC, et al. A community survey of diabetes in the elderly. *Diab Med* 1992;9:860-5.)

It is three times higher in diabetic men than in women.⁹⁶ Elderly people are particularly affected.⁹⁷

In 1986 the total annual cost of major leg amputations in diabetic patients in the United Kingdom was estimated to be in excess of £13 million⁹⁸; in the United States, the direct medical care costs for all amputations in the diabetic populations, not including rehabilitation, exceeded \$500 million.⁹⁹ A recent study from the Netherlands¹⁰⁰ estimated the direct costs associated with diabetes-related lower limb amputations and found it to be more than £10,000 per hospitalization, with a mean inpatient stay of 42 days. This study identified increasing age and a higher level of amputation as important factors leading to increases in both the period of hospitalization and the associated costs (Table 92-7).

The mortality rate for amputees is high. Recent evidence indicates that the 3-year survival following lower extremity amputation is about 50%,¹⁰¹ with a median life expectancy after amputation of less than 2 years.⁹⁶ Only 5% of elderly amputees become fully independent postoperatively.¹⁰²

In about 70% of cases, amputation is precipitated by foot ulceration^{103,104} whose principal antecedents include peripheral vascular disease and peripheral neuropathy, both of which increase with age. Other at-risk groups include those with limited joint mobility, bony abnormalities, diabetic nephropathy, excess alcohol intake, visual impairment, and patients living alone.⁹⁷

Various risk factors that increase the likelihood of foot ulceration have been identified (Table 92-8). Peripheral sensorimotor neuropathy is the primary cause or contributory factor in 90% of cases.^{105,106} Both small (often unmyelinated) and large (usually myelinated) nerve fibers are affected, which leads to the common symptoms of numbness, lancinating and burning pain, "pins and needles," and hyperesthesia, which is typically worse at night.⁹⁷ Physical examination reveals a glove and stocking loss of pain, fine touch, and thermal sensation (small

fibers), with coexisting vibration and proprioceptive loss (large fibers). Small muscle atrophy in the foot can also occur because of motor fiber loss, which can cause flexor/extensor muscle imbalance resulting in clawed toes, prominent metatarsal heads, and forward displacement of the metatarsal foot pads.¹⁰⁷ This can lead to abnormally high foot pressures developing, which can increase the risk of foot ulceration and lead to gait disturbances. In elderly patients with peripheral neuropathy, this may give rise to further foot injuries and falls. The presence of visual loss may exacerbate the situation.¹⁰⁸ A trivial foot injury in a patient with severe neuropathy can eventually lead to the development of a Charcot joint, which is a chronic neuroarthropathy whose prevalence varies from 0.15% to 7% depending on the study population.⁹⁷ The majority of subjects have had diabetes for at least 10 years, and most are elderly people.

Peripheral blood flow in patients with diabetes is disturbed, with loss of blood flow autoregulation, increased arteriovenous shunting, and changes in capillary blood flow. Some of these abnormalities may be reversible or ameliorated by improved glycemic control.¹⁰⁹ Risk factors for peripheral vascular disease include smoking, hypertension, and hypercholesterolemia, with prevalence increasing with both advancing age and duration of diabetes. Symptoms include intermittent claudication and/or rest pain with lower limb ulceration or gangrene being important clinical outcomes. Radiologic investigation may show medial arterial calcification, which has been reported to be associated with both diabetic peripheral somatosensory and autonomic neuropathy.¹¹⁰ Objective assessment of limb blood flow by Doppler ultrasound can be affected by extensive medial calcification, giving rise to a misleadingly high ankle-pressure index.¹¹¹

It seems logical that interventions designed to prevent diabetic foot disease and amputations in patients with diabetes should be directed to the prevention of peripheral neuropathy and peripheral vascular disease and the prevention, early detection, and treatment of foot lesions. Several studies using staff and patient education and a multidisciplinary approach to foot care have demonstrated a reduction in diabetes-related amputations.^{112,113} However, elderly people require more assistance than the young because they have difficulty perceiving foot problems and touching their feet.¹¹⁴ By incorporating an intensive multidisciplinary approach in a diabetes foot clinic,¹¹² a London-based study demonstrated a 44% decline in amputation rate after 2 years. By use of suitable-fitting shoes, the recurrence rate of foot ulcers was reduced from 83% to 26%. At the University Hospital of Geneva, an 85% reduction in the rate of below-knee

Table 92-6. Reasons for Referral to an Ophthalmologist

- Cataract either obscuring examiner's view of fundus or impairing patient's vision
- Diabetic maculopathy as evidenced by exudates within 1 disk diameter of macula or any unexplained loss of visual acuity
- Proliferative changes, such as intraretinal microvascular abnormalities, venous changes (beading, loops, dilation), six cotton wool spots in one quadrant, large blot hemorrhages, arteries replaced by white lines
- Proliferative changes, such as new vessels visible or vitreous hemorrhage
- To complete blind registration

Table 92-7. Duration of Hospitalization for Lower-Extremity Amputations, and Mean Costs of Hospitalization (Including Hospital Stay and Surgery) by Age Group in the Diabetic Population

Age Group	Duration of Hospitalization*	Mean Costs of Hospitalization (£)	Number of Cases

amputations was seen over a 4-year observation period by a combination of education and training in foot care in patients with diabetes.

With many elderly patients having great difficulty in performing the most routine foot care,¹¹⁴ often as a result of poor vision and reduced mobility, it becomes very important to design strategies that enable partners and other caregivers to have a role in prevention and treatment of foot lesions. Educational material needs to be concise and repeated regularly,⁹⁷ and video presentations may also be helpful. The accompanying box on foot care education provides general principles of foot care reflecting a positive approach that can be adapted to many patients in clinical settings.

General Principles of Foot Care Education

- Target the level of information to the needs of the patient. Those not at risk may require only general advice about foot hygiene and shoes.
- Assess the ability of the patient to understand and perform the necessary components of foot care. If this is limited, then the spouse or caregiver should be involved at the beginning of the process.
- Suggest a positive approach to foot care with “do’s” rather than “don’ts”—the principle of active rather than passive foot care is more likely to be successful and acceptable to the patient.
 - Do inspect the feet daily.
 - Do report any problems immediately.
 - Do have your feet measured every time new shoes are bought.
 - Do buy shoes with a square toe box and laces.
 - Do inspect the inside of shoes for foreign objects every day before putting them on.
 - Do attend a fully trained chiropodist regularly.
 - Do cut your nails straight across and not rounded.
 - Do keep your feet away from heat (fires, radiators, and hot water bottles) and check the bath water before stepping into it.
 - Do wear something on your feet to protect them at all times and never walk barefoot.
- Repeat the advice at regular intervals and check that it is being followed.
- Disseminate advice to other family members and other health care professionals involved in the care of a patient.

Figure 92-3. Mortality of elderly subjects in Melton Mowbray, according to glucose tolerance status. (From Crosson SCM, Price D, Burden M et al. Mortality of elderly people with diabetes. *Diab Med* 1994;11:250–2.)

Mortality

It is a widely held belief that diabetes mellitus confers little or no excess mortality risk in older patients, with life expectancy being similar to nondiabetic risk after age 70 to 75 years.^{115–117} This apparent finding was explained by a shorter life in elderly subjects with other competing causes of death minimizing the effect of diabetes.¹¹⁸ In line with this, most early reports indicated that the ratio of death rates in diabetics to rates in the general population falls progressively with age, especially in those aged 65 years and over, though it remains above unity up to age 80 years.¹¹⁸ More recently, one study actually found a significantly lower mortality in patients aged 75 years and over (mortality ratio 0.88) compared with the general population,¹¹⁹ and these contradictory findings have created uncertainty about the true impact of this metabolic disorder on the older diabetic population.

It is important to determine whether premature death because of diabetes is observable in elderly patients because this evidence would provide guidance to those responsible for providing health services on how best to focus their resources. An unequivocal finding of increased mortality would argue for a more sustained commitment to diabetic health care provision and research. Alternatively, the absence of excess mortality could redirect care strategies toward reducing morbidity and disability only.

A recent literature review by the authors has confirmed that diabetes in later life imposes an excess mortality risk¹²¹ associated with a reduction in life expectancy in both sexes, even in patients aged 75 years and over. The pattern of excess mortality is relatively consistent, even though the duration of follow-up varied between studies. In the Melton study by Crosson et al¹²⁰ a substantial increase in excess mortality was seen in diabetic subjects aged 65 years and over (Figure 92-3), and impaired glucose tolerance was found to be associated with a relative risk of death of 1.7 (95% confidence interval 0.8 to 3.5). Most studies report a higher mortality in female diabetics and in both sexes; excess mortality is predominantly because of macrovascular disease.

Dementia

There is now better evidence that diabetes may be associated with decreases in psychomotor speed, frontal lobe/executive function, verbal memory, processing speed, complex motor

functioning, working memory, immediate and delayed recall, verbal fluency, visual retention, and attention.¹²² Earlier studies had shown that elderly diabetic subjects have impaired cognitive function,^{123–126} but these studies were generally not population-based, excluded subjects with dementia,^{123–126} and generally used a large battery of tests to show the deficit.^{124–126} Worse cognitive function in these tests was associated with worse glycemic control.^{123–126}

There are several possible explanations for the lower cognitive function in the known diabetic subjects, apart from abnormal plasma glucose levels. First, depression has been found to be associated with known diabetes.^{129,130} Second, hypertension is associated with diabetes and insulin resistance¹³¹ and is itself associated with decreased cognitive function;¹³² there is even evidence to suggest that among hypertensive subjects, hyperinsulinemia is associated with worse cognitive function.¹³³ Third, cerebrovascular disease is 2 to 3 times more common in people with known diabetes,^{61,134} which again might be associated with cognitive impairment. Fourth, there is evidence that cortical atrophy is associated with diabetes. Some studies suggest that the excess dementia is because of vascular disease,¹²⁸ whereas others suggest an excess of Alzheimer type of dementia.¹²⁷ It is likely that the current diagnosis and classification of dementia in diabetic subjects is inaccurate owing to the multiple risk factors present.¹³⁵ However, it is vitally important to exclude iatrogenic hypoglycemia (e.g., from long-acting sulfonylureas) as a cause of confusion because it is eminently treatable, although the authors have seen patients rendered permanently confused by a single episode of profound hypoglycemia.

Glycemic control appears to play a role in altering cognitive function. In one study, patients with a HbA_{1c} of greater than 7.0% had a fourfold increase in developing cognitive impairment.¹³⁶ A study in type 1 diabetes has shown that cognitive impairment is worsened by increasing duration of diabetes and may also be associated with recurrent hypoglycemia.¹³⁷

Whatever the reason, known diabetic subjects appear to have poorer cognitive function than subjects not known to have diabetes. It is interesting to note the two studies that suggest that improving glycemic control improves cognitive function.^{138–140} Impaired cognitive function should be borne in mind when treating elderly diabetic subjects because it has implications for their safe treatment. It may cause difficulty with glycemic control as a result of erratic taking of diet and medication. This may occur with hypoglycemia where patients forget that they have taken medication and repeat the dose. One should enlist the help of family and services to optimize glycemic control to see if this makes any difference; if it does not, accept that one has to change glycemic targets to less strict, but safer control.¹⁴¹ It is important to consider screening for other treatable causes of cognitive impairment.

Several recommendations relating to best practice in this area are derived from the European guidelines¹⁰:

- Each functional assessment must include a measure of the three domains of function: global/physical, cognitive and affective (grade of recommendation A). *Specific assessment of cognitive dysfunction and depressive illness by screening methods are an essential part of this process and can be undertaken by either medical and/or nursing and therapy staff.*

- Optimal glucose regulation may help to maintain cognitive performance and improve learning and memory. Evidence level 2+; grade of recommendation C.

RESIDENTIAL CARE AND THE HOUSEBOUND

Greater numbers of older people are now living within care homes and other forms of residential care. Several studies have shown that diabetes is an independent risk factor for admission to a care home.^{142,143} Again, the number of diabetic residents identified is just the tip of the iceberg. These were prevalences of 12% diagnosed and 15% undiagnosed diabetes in a study of Birmingham residential care homes,⁵⁰ and in Canada a routine screening program led to 30% of residents being diagnosed as diabetic.¹⁴⁴ Residence of nursing home is a risk factor for hyperosmolar nonketotic coma and carries increased mortality.¹⁴⁵ Compared with nondiabetic residents, diabetic residents have increased rates of stroke, peripheral vascular disease, amputation, urinary catheter, foot ulcer, renal impairment, and dementia.^{50,146} They suffer poor nutrition, with 20% of residents being at least 20% underweight¹⁴⁷ but recent trends in obesity in the West suggest that the proportion of obese residents being admitted to nursing homes in the United States has risen from 15% to 25% over a decade.¹⁴⁸ Diabetes is a risk factor for pressure sores, although this is less of a problem in rural American nursing homes,¹⁴⁹ so it may be preventable.

It is very clear that the residents of care homes receive inadequate diabetes care compared with their noninstitutionalized peers^{146,150,151}; (Table 92-9). Various common problems make diabetes management more complex in these patients.¹⁵² The following are some of the problems:

- There may be irregular oral intake owing to: (1) confusion and/or a poor appetite because of concurrent illness; or (2) dysphagia because of stroke or other neurologic or gastroenterologic disorders. Lack of regular calorific intake can be particularly troublesome for insulin-treated patients.
- Recurrent urinary, chest, and other infections can render the diabetic person liable to hyperglycemia, and possibly ketosis with poor metabolic control.
- Leg ulcers and pressure sores may deteriorate rapidly.
- There can be an increased vulnerability to hypoglycemia (especially in those taking sulfonylureas or insulin) owing to poor appetite and difficulties in ensuring sufficient and regular caloric intake.
- There may be inadequate facilities to cater for the dietary needs of residents with diabetes, and inadequate knowledge on the part of catering staff—including the need for snacks outside main meals.
- Adequate arrangements for regular diabetes review may be lacking, particularly for those discharged from hospital clinics and who are unable to visit their primary care physician.
- There may be insufficient provision of health professional input, particularly of specialist nurses, dietitians, dental surgeons, opticians, and state-registered chiropodists and doctors, including hospital specialists.

Table 92-9. Care Received by Diabetic Subjects in Care Home or Free Living¹⁵¹

	Care Home (%)	Free Living (%)
Annual review	44*	84
Chiropody	60*	96
Optician	36*	76
Dietitian	48	60†

* $P < 0.05$ care home resident versus free living elder.

†Not significant.

Some time ago, the British Geriatrics Society (Special Interest Group in Diabetes)¹⁵³ and the British Diabetic Association¹⁵⁴ published guidelines. In particular the BDA monograph is an excellent reference work on the subject and an incentive to improve care, and this document is being updated by Diabetes UK and is available in 2009. The European guidelines have a section devoted to Care Home diabetes and several of their recommendations are given below:

- At the time of admission to a care home, each resident requires screening for the presence of diabetes. Level of evidence 2++, grade of recommendation B.
- Each resident should have an annual screen for diabetes. Level of evidence 2+, grade of recommendation C.
- Each resident with diabetes should have an individualized diabetes care plan with the following minimum details: dietary plan, medication list, glycemic targets, weight, and nursing plan. Level of evidence 2+, grade of recommendation C.

See the accompanying box on improving care.

Improving Care Within Residential Nursing Home Settings

- Each resident should have an individual diabetes care plan agreed between patient (or relative), doctor (who is responsible for diabetic care), and home care staff.
- There should be increased community support from experienced health professionals, such as diabetes specialist nurses and dietitians.
- Diabetic patients living in residential and nursing homes should have ready access to other specialist health professionals.
- Each resident with diabetes should be reviewed by either the family doctor or a hospital consultant physician/geriatrician at least once a year.
- Patients in residential and nursing homes should be included in any local audit of diabetic care.

GLUCOSE CONTROL IN DIABETES MELLITUS

Overview

A major trial to guide the clinician is the U.K. Prospective Diabetes Study (UKPDS). The initial outcomes of intensive blood glucose control⁶⁸ were disappointing, with sulfonylurea

or insulin use reducing microvascular end points from 11.4% to 8.6% (i.e., by approximately one quarter) at 10 years. A 1% decrease in HbA_{1c},⁶⁷ was associated with a significant reduction in any diabetes end point (21% decrease), diabetes-related death (21% decrease), all-cause mortality (14% decrease), any myocardial infarction (MI) (14% decrease), any stroke (12% decrease), microvascular end points (37% decrease), cataract extraction (19% decrease), amputation or peripheral vascular disease death (43% decrease), and heart failure (16% decrease). The U.K. study looked at intensive control from time of diagnosis; however, the recent Kumamoto intervention study in middle-aged Japanese subjects with type 2 diabetes for 6 to 10 years found that intensive insulin treatment with good control delayed the onset and progression of specific diabetic complications¹⁵⁵; that study suggests that the thresholds for developing specific complications are: HbA_{1c} 7%, fasting plasma glucose 6.7 mmol/L, and postprandial plasma glucose 10 mmol/L.

The main concern is that striving for normoglycemia using insulin or sulfonylurea drugs might result in hypoglycemia. Compared with younger subjects, aging individuals perceive fewer symptoms of hypoglycemia, need a lower plasma glucose level to elicit symptoms, exhibit a reduced counter-regulatory response to hypoglycemia, and recover more slowly from the hypoglycemic insult.^{157–160} Thus the elderly person may have few symptoms of hypoglycemia until developing neuroglycopenia,¹⁶¹ when nothing can be done about it. Hypoglycemia may be missed entirely or misdiagnosed, especially as one third of hypoglycemic events in the elderly have nonspecific symptoms.¹⁶² Although age is an independent risk factor for drug-induced hypoglycemia,¹⁶³ elderly people are taught very little about it.¹⁶⁴ In the Diabetes Control and Complications Trial and Kumamoto studies,^{155,165} the risk of hypoglycemia increased dramatically, as the HbA_{1c} decreased below the upper normal limit. However, the usual control of the elderly diabetic person's glycemia is poor.⁶¹

Sensible and appropriate diabetic care requires a considered judgment of the risks and benefits of treatment. A framework for this management is assisted by the aims of care, which are:

- Achieve metabolic targets at lowest daily doses of therapeutic agents
- Prevent hypoglycemia
- Reduce and limit other associated adverse drug reactions
- Limit weight gain on sulfonylureas and insulin therapy
- Ameliorate microvascular complications
- Attend to macrovascular risk factors and disease

Unless there are other reasons to treat the elderly diabetic individual differently from the younger diabetic person, aim for an HbA_{1c} level less than 7%, fasting plasma glucose 5.0 to 7.0 mmol/L, and random plasma glucose less than 11.1 mmol/L. See the accompanying box on "Treatments to Improve Glucose Control."

Pathologic basis for the treatment of type 2 diabetes

Type 2 diabetes mellitus accounts for more than 90% of cases of diabetes in old age,¹⁶⁶ with the remainder being predominantly type 1. Type 2 diabetes has been characterized

Treatments to Improve Glucose Control

Improve β -cell dysfunction by:

- Stimulating pancreatic β -cells to secrete more insulin; for example, by the use of sulfonylureas or other insulin secretagogues
- Lowering circulating levels of glucose, for example, by dietary modification
- Introducing exogenous insulin to replace the function of the failing β -cell

Decrease insulin resistance by:

- Using drugs that decrease insulin resistance (e.g., metformin, peroxisome proliferator-activated receptor γ agonists, and probably a minor effect of some sulfonylureas)
- Directly reducing hyperglycemia, for example, by dietary modification
- Limit the dietary intake of monosaccharides, for example, by:
 - Diet
 - Drugs that delay the absorption of monosaccharides by inhibiting breakdown of polysaccharides (e.g., α -glucosidase inhibitors such as acarbose)

Initial Care Plan for the Older Adult With Diabetes

- Set realistic glycemic goals.
- Agree upon the frequency of diabetic follow-up by primary or secondary health care team.
- Organize monitoring of glycemic control by the patient and/or caregiver; for example, by home urine or blood glucose monitoring or, if the patient cannot manage this, by regular review.
- Advise on stopping smoking, on exercise (ideally a minimum of 3 weekly brisk walks of 30–45 min duration), and on alcohol intake.
- Refer to social or community services as appropriate.

by a combination of insulin resistance (at both hepatic and peripheral tissue levels) because of a potentially decreased number of insulin receptors and a postreceptor defect, and β -cell dysfunction characterized by defective insulin secretion.¹⁶⁷ Other disturbances are often associated with hyperglycemia, including hypertension, dyslipidemia, and obesity; this is referred to as Syndrome X, Reaven's syndrome, or the Deadly Quartet.¹⁶⁸ Syndrome X is associated with increased risk of large vessel disease, and further abnormalities associated with this syndrome and increased vascular risk are being described (e.g., microalbuminuria, abnormal plasminogen activator inhibitor-1 levels).

Treatments for glucose control

Specific treatments aim to reverse or ameliorate the previously discussed defects of glucose control in one or more of the following ways: improvement of β -cell dysfunction; decrease of insulin resistance; and limitation of dietary intake of monosaccharides (see box on "Treatments to Improve Glucose Control").

Table 92-10. Risk Factors for Hypoglycemia^{174,175}

- Choice of sulfonylurea/insulin
- Tight glycemic control
- Increasing age
- Male gender
- Recent discharge from hospital
- Polypharmacy
- Change of or new hypoglycemic treatment
- Impaired renal function
- Excess alcohol
- Hepatic impairment
- Cardiac failure

DIETARY TREATMENT

The foundation of any treatment in diabetes is diet.¹⁶⁹ Complex carbohydrates should comprise 50% to 55% of the energy intake, and come from food high in fiber (bread, pasta, rice, and potatoes). Up to 25 to 50 g of added sucrose is allowed, but one would generally not advertise this since refined carbohydrate is very prevalent in the Western diet. The diet should contain as much fiber as possible, but realistically one is looking at a maximum of 30 g per day. Fat intake should be limited to 30% to 35% of energy intake.

Although diet is vitally important, it is unlikely to achieve glycemic targets when used alone. In the U.K. Prospective Diabetes Study, only 6% of subjects were controlled on diet at the end of the second year.¹⁷⁰

In most cases, diet alone will fail, and most patients will need oral hypoglycemic drugs. Although there are many hypoglycemic drugs available, the mainstays are metformin and sulfonylureas as these are relatively cheap.

SULFONYLUREAS

Sulfonylureas bind to a specific sulfonylurea receptor on the pancreatic β -islet cell, which blocks ATP-sensitive potassium channels and hence stimulates insulin release.¹⁷¹

Hypoglycemia is the main side-effect of note, and risk factors for hypoglycemia are given in Table 92-10.

Glibenclamide appears particularly likely to cause hypoglycemia and death, more so than other sulfonylureas^{174–177} including chlorpropamide^{68,177} and metformin.¹⁷⁸ The deaths of elderly patients from hypoglycemia in a Swedish study,¹⁷⁹ and the finding that some elderly subjects experience a prolonged hypoglycemic effect from it,¹⁸⁰ has placed a question mark over glipizide. Gliclazide has a low (but not zero) risk of hypoglycemia^{181–186}; it may be less likely to cause weight gain, the other common problem with sulfonylureas,^{181,183–186} and achieves glycemic targets with low rates of secondary failure.¹⁸⁴ If hypoglycemia is a major worry, then tolbutamide has the lowest risk^{175,176} and can be used if the patient's creatinine is over 200 $\mu\text{mol/L}$.¹⁷² Several longer-acting or slow-release preparations are now on the market, including gliclazide MR, and these may aid compliance.

METFORMIN

Metformin reduces insulin resistance particularly in the liver, and so decreases hepatic glucose output by decreasing gluconeogenesis.¹⁸⁷ Metformin decreases gluconeogenesis from lactate, but plasma lactate levels stay stable since metformin increases oxidation of lactate.¹⁸⁷ However, older biguanides

Table 92-11. Contraindications to Metformin

- Renal impairment (creatinine >120 $\mu\text{mol/L}$)
- Hepatic impairment (including alcohol abuse) as indicated by abnormal liver function tests
- Cardiac failure, even if treated
- Critical limb ischemia
- Any acute illness
- Use of intravenous radiologic contrast media

decreased oxidation of lactate, hence the unpredictable high risk of lactic acidosis. Lactic acidosis is a condition of the elderly group.¹⁸⁸ Metformin is predictable and safe if used correctly.¹⁷⁸ The contraindications^{172,173} are given in Table 92-11 and they must be observed. Advantages of metformin are that it does not cause hypoglycemia on its own, it does not cause weight gain, and it is inexpensive. It probably decreases HbA_{1c} by about 1% to 1.5%, and fasting plasma glucose by 4 to 5 mmol/L,^{189–192} which is similar to sulfonylureas. In the U.K. Prospective Diabetes Study, metformin was used in obese subjects; all-cause mortality, and any diabetes-related end points were significantly lower on intensive treatment with metformin than with insulin or a sulfonylurea.¹⁹¹ Metformin is now available as a slow-release preparation and in combination with either pioglitazone or rosiglitazone.

Apart from lactic acidosis, other side effects include gastrointestinal disturbance, which may be minimized by gradual introduction of the agent. Metformin may also cause vitamin B₁₂ malabsorption, so it is wise to check B₁₂ levels every 5 years, and particularly if the subject has neuropathy.

ACARBOSE

This is an α -glucosidase inhibitor that inhibits the breakdown of polysaccharides in the small bowel, which are then digested or fermented more distally. This leads to lower but more sustained postprandial glucose levels and flatulence, which is the main limiting factor in the use of acarbose. Its advantages are low risk of hypoglycemia on its own (though if the patient is rendered hypoglycemic by co-prescription of a sulfonylurea, polysaccharides will be slower to correct this) and little weight gain.

Although acarbose can be successfully combined with metformin, sulfonylureas, or insulin, its use in many older people with diabetes may be limited because of gastrointestinal side effects and the need for frequent dosing.

THIAZOLIDINEDIONES (TZDS)

These agents are generally well tolerated in older people and can produce a lowering of HbA_{1c} of up to 1.5%. Their use in patients with diabetes has recently come under scrutiny because of evidence that suggests an increased risk of cardiovascular events in patients on thiazolidinediones with the risk apparently confined to rosiglitazone.¹⁹³ Further analysis of data from ongoing studies is taking place but inevitably there has been restricted use by some clinicians.

Thiazolidinediones reduce insulin resistance by activating the peroxisome proliferator-activated receptor γ (PPAR γ).¹⁹³ They do not cause hypoglycemia but because they cause fluid retention and may increase the risk of heart failure, they are contraindicated in this latter condition and in those with a history of heart failure. Rosiglitazone should

also not be used in those with acute coronary syndrome or in those with ischemic heart disease or peripheral arterial disease. There has also been recent concern that TZDs are associated with an increased risk of bony fractures due to bone loss. This needs further investigation but may warrant clinicians considering the overall fracture risk of patients with diabetes before they decide on treatment with a TZD.

They are safe in mild-to-moderate renal impairment, and pioglitazone is safe even with creatinine clearance as low as 2 mL/min. They can be used as monotherapy (although not all countries have a monotherapy license),¹⁹⁴ combined with metformin^{195,196} or a sulfonylurea,¹⁹⁷ or combined with insulin (pioglitazone only) but treatment must be stopped if significant fluid retention develops. A TZD can be added (triple license) to existing treatment with metformin and a sulfonylurea, if human insulin is likely to be unacceptable. It takes 6 weeks at least to achieve the full effect on plasma glucose levels. Both drugs are available in combination with metformin.

Prandial glucose regulators, the meglitinides, and amino acid derivatives

Repaglinide acts on the β -cell for a short time to rapidly and potently stimulate insulin release. Therefore it is taken just before each meal. It is predominantly metabolized to inactive metabolites by the liver, and is safe in mild-to-moderate renal impairment. In a comprehensive review,¹⁹⁸ it appears that repaglinide is as effective as sulfonylureas at reducing HbA_{1c}, but with better postprandial glucose levels, and slightly less risk of symptomatic hypoglycemia. It cannot be used with sulfonylureas. However, its use with metformin has been studied in a crossover study with three arms, which found that metformin plus repaglinide (mean HbA_{1c} decrease 1.41%) exerted a greater hypoglycemic effect than monotherapy with metformin (0.33%) or repaglinide (0.38%) without significant hypoglycemia.¹⁹⁹ Similarly, it can be used effectively in combination with a thiazolidinedione.

Nateglinide is safe in mild-to-moderate renal impairment, and very usefully safe in mild-to-moderate hepatic impairment.²⁰⁰ It has a modest hypoglycemic effect as monotherapy, but is licensed only in the United Kingdom for use with metformin, with which it works well.²⁰¹

Newer therapies are becoming available that offer greater choice in the management of type diabetes. These are represented by incretin-based treatments. Exenatide that is a GLP-1 (glucagon-like peptide-1) is an effective glucose-lowering agent and is often considered when oral agents fail to achieve glycaemic targets and the patient is unwilling to accept a thiazolidinedione or insulin. It lowers HbA_{1c} by about 0.9% when used at a dose of 10 μg twice daily given subcutaneously. It also lowers weight by an average of 1.4 kg. Treatment may be complicated by nausea. A once-daily analogue, liraglutide, is also now available. The combination of reduced risk of hypoglycaemia (unless used with a sulphonylurea) and weight loss may be advantageous in older patients unless they are very frail where the impact of nausea and weight loss would not be desirable.

Other new treatments are stagliptin and vildagliptin which are oral DPP-IV inhibitors that can decrease HbA_{1c} by 0.7–1.0% as monotherapy but can be used with other oral agents. These are weight neutral compounds and have a low risk of hypoglycaemia unless used with a sulphonylurea.

Table 92-12. Indications for Insulin

- Type 1 diabetes
- Type 2 diabetes, inadequately controlled by oral means
- Type 2 diabetes, with an intercurrent illness and associated hyperglycemia
- Type 2 diabetes, with other illnesses contraindicating oral therapy (e.g., liver disease)
- Type 2 diabetes during prolonged surgery
- Hyperglycemic coma

INSULIN

This is the required therapy for type 1 diabetes, and in view of the progressive deterioration of glucose homeostasis it is commonly needed in type 2 diabetic individuals.

There is often a reluctance to start an elderly diabetic patient on insulin, but given the wide range of insulin and injection devices available, and the benefits of improved glycemic control discussed previously, this attitude is generally inappropriate. Indications for insulin treatment are given in [Table 92-12](#).

There are several advantages to short-acting insulin analogues. They are more convenient for the patient, being given as the meal arrives. They cause fewer hypoglycemic reactions, particularly overnight, and because patients need fewer snacks between meals to prevent hypoglycemia, weight gain may be less problematic.²⁰² They can also be given after a meal,²⁰³ which is very useful if one does not know whether the patient is going to eat until he or she has eaten, as in subjects with dementia or where there is intermittent vomiting as in diabetic gastroparesis.

A twice-daily (bid) regimen is the most common. For the older type 1 diabetic subjects, twice-daily premixed insulins seem to work well. For the older type 2 diabetic person going on to insulin, one would generally use a twice-daily isophane regimen²⁰⁴ since it gives good control with low risk of hypoglycemia^{156,205}; one can add soluble insulin later if required.

The more intensive "basal bolus" regimen uses a daily intermediate- or long-acting insulin (isophane- or zinc-based) given before bed or before an evening meal, and a bolus quick-acting insulin (either soluble or quick-acting analogue) given before each meal.

One combines insulin with an oral agent in a regimen of daytime oral agent plus bedtime insulin regime, or when trying to limit weight gain on the insulin. Limiting the weight gain associated with insulin has been noted with sulfonylureas,^{206,207} but is particularly effective with metformin co-prescription.^{208,209} The main side effect of insulin is hypoglycemia, and one should be aware that 3 AM hypoglycemia is quite common. If this occurs on a regime with the isophane before teatime, moving the isophane to bedtime generally helps. Patients who are frail or who have poor vision may still be able to dial the dose by counting audible clicks, or using the preset preloaded Optiset pen (Aventis), or have someone else prepare the pen for them to use at the correct time. However, sometimes it is necessary to have caregivers or district nurses give the insulin, in which case a once-daily regime is generally necessary. The diabetes specialist nurses are vital for high-quality, safe insulin treatment, particularly initiation.

Choice of treatment strategy

The first step is to identify the rare elderly-onset type 1 diabetic individuals who need insulin treatment. For the other subjects, the initial treatment is a trial of diet for 6 to 12 weeks

with instruction by a trained dietitian. Patients and caregivers should be educated about the indications for referral to hospital as an outpatient and when admission is likely to be required. Oral agents are likely to be needed to get to target HbA_{1c} and we would recommend the following:

For normal weight (body mass index 20 to 25 kg/m²) and overweight patients (body mass index >26 kg/m²), metformin should be considered first and titrated to 1.5 to 3 g per day according to gastrointestinal tolerability if there are no contraindications (see [Table 92-11](#)). If there are contraindications, or if metformin fails, then a sulfonylurea should be considered as monotherapy or combination therapy, respectively. A thiazolidinedione should be used if the patient is on either metformin or a sulfonylurea and cannot take the alternative agent; commonly this will be an individual on a sulfonylurea who cannot take metformin owing to renal impairment, when a thiazolidinedione will probably be suitable.

For underweight patients (body mass index <20 kg/m²), one should question the diagnosis of type 2 diabetes. Does this patient have type 1 diabetes needing insulin, or diabetes secondary to chronic pancreatic disease (also probably needing insulin), thyrotoxicosis, or coexistent underlying malignancy? In thin type 2 diabetic subjects, sulfonylureas should be taken as first-line therapy; unless there is a dramatic long-lasting effect, insulin treatment should be used if the sulfonylurea fails to achieve control quickly.

For demented patients or people with a chaotic lifestyle who cannot be relied upon to eat regularly, hypoglycemia is a major worry. Metformin is the first choice, particularly if the once-daily long-acting formulation is available to allow supervision of once-daily medication. If the person is still poorly controlled, and cannot be adequately supervised, a thiazolidinedione is a safe next agent. If the problem is just a chaotic lifestyle, then one of the prandial glucose regulators is sensible.

For people with diabetes secondary to steroid use, the plasma glucose is raised over the afternoon and evening. Intermediate-acting sulfonylureas cause hypoglycemia before breakfast.²¹⁰ A short-acting insulin secretagogue, such as tolbutamide or repaglinide, before midday and evening meals works quite well or, if insulin is needed, a rapid-acting analogue before midday and evening meals is a good start—although it may need converting to a complete basal bolus regimen. Hypoglycemic medication must be decreased as the steroid dose is decreased.

The European guidelines have provided a series of glycemic targets to guide treatment and these are as follows¹⁰:

For older patients with type 2 diabetes, with single system involvement (free of other major comorbidities), a target HbA_{1c} (DCCT aligned) range of greater than 7% should be aimed for. Evidence level 2++; grade of recommendation B. The precise target agreed upon will depend on existing cardiovascular risk, presence of microvascular complications, and ability of individual to self-manage.

For older patients with type 2 diabetes, with single system involvement (free of other major comorbidities), a target HbA_{1c} (DCCT aligned) with a range of 6.5–7% should be aimed for. Evidence level 2++; grade of recommendation B. The precise target agreed will depend on existing cardiovascular risk, presence of microvascular complications, and ability of individual to self-manage.

HOME MONITORING OF DIABETIC CONTROL

Blood glucose monitoring is recommended for insulin-treated patients on at least two occasions per day for those who are in poor metabolic control, but for stable patients a four-point profile once per week is adequate. Blood glucose estimations should be done before meals and at bedtime. Blood glucose monitoring is also valuable for patients with poor metabolic control (e.g., if considering insulin treatment) or who are at risk of hypoglycemia.

For patients with type 2 diabetes who are taking oral agents, home blood glucose monitoring should be offered, although it is not essential. Monitoring is only of value when a patient or caregiver or doctor is able to interpret and act upon the results.

HYPOGLYCEMIA IN THE ELDERLY PATIENT

Sulfonylurea-induced hypoglycemia is a problem, if severe, owing to the prolonged nature of the event. It is frequently misdiagnosed as a cerebrovascular event, or classified as "confusion query cause." Glibenclamide and chlorpropamide are very long-acting, but other sulfonylureas can have a prolonged effect in the setting of renal or hepatic impairment. Diazoxide, which has a direct inhibitory effect on insulin secretion, may be used as an adjunct to treatment. In the unconscious patient, diazoxide can be given as a slow intravenous infusion of 300 mg over 30 minutes, and can be repeated every 4 hours if necessary. Glucagon can be used in insulin-treated patients to good effect and is valuable since one does not need venous access. However, it should not be used in sulfonylurea-induced hypoglycemia since it stimulates the remaining β -cell activity (upon which the sulfonylureas depend for their efficacy) to release further insulin.

Insulin-induced hypoglycemia is more common, and nocturnal hypoglycemia may present as morning headaches or disturbed sleep. Any subject taking more than 1 unit of insulin per kilogram bodyweight should be closely questioned for unrecognized hypoglycemia.

HYPERGLYCEMIC COMA

Immediate Management of Hyperglycemic Comas

- Be aware of hyperglycemic coma as a possibility.
- Test for hyperglycemia, ketosis, and acidosis.
- Screen for any precipitating illness (e.g., infection, cerebral or myocardial infarction, inadequate treatment).
- Institute a slow insulin infusion guided by frequent bedside blood glucose monitoring to halve glucose level over 4 hours.
- Arrange prompt, adequate fluid replacement with 0.9% saline (if Na less than 155 mmol/L) or 0.45% saline (if Na greater than 155 mmol/L) at 500 mL/hr over first 4 hours.

Diabetic ketoacidosis (DKA) may occur at any age, whereas hyperglycemic hyperosmolar nonketotic (HONK) coma occurs predominantly in subjects aged over 50 years.²¹² The tendency to hyperosmolality in HONK coma may be worse in elderly people who may not appreciate thirst well, may have difficulty drinking enough to compensate for their osmotic diuresis,^{212,214} and may also be on diuretics.²¹⁵ It also appears that hyperosmolality not only worsens insulin resistance, but may also inhibit lipolysis.²¹⁴

Diabetic ketoacidosis may be defined as hyperglycemia occurring in conjunction with ketoacidosis as evidenced by significant ketosis (3+ Ketostix in urine or plasma) and significant acidosis (venous plasma bicarbonate less than 15 mmol/L or arterial pH below 7.2). HONK comas may be defined as hyperglycemia occurring in conjunction with raised plasma osmolality (greater than 350 mmol/L) with no evidence of ketoacidosis. The osmolality may be measured directly in the laboratory using a freezing-point depression technique, or can be estimated approximately by calculating the sum of $2 \times (\text{Na}^+ + \text{K}^+) + \text{urea} + \text{glucose}$, concentrations in mmol/L.

All studies of hyperglycemic comas show a progressive increase in mortality with age.^{213,216,217} In Birmingham, the mortality due to DKA rose from 5% in the age range 60 to 69 to 100% at age 90,²¹³ although the number of 90-year-olds was small. Most studies suggest that death is primarily because of acute illnesses, such as pneumonia and myocardial infarction.^{213,216,217} There has been no apparent decrease in mortality over the past 20 years.^{213,216}

The cause of the hyperglycemia may be infection, myocardial infarction, inadequate hypoglycemic treatment, or inappropriate drug treatment. Often, a particular cause cannot be identified^{213,216}; for instance, there was no apparent cause in 354 out of 929 admissions with DKA in Birmingham.²¹³ Thiazide diuretics and steroids are known to increase blood glucose levels and may precipitate DKA; thiazide diuretics and furosemide may be particularly likely to precipitate HONK coma.²¹⁵

Management of hyperglycemic coma

This is covered in greater detail elsewhere.²¹¹ The history and examination should pay special attention to previous diabetic symptoms and treatment, any precipitating infection, infarction or medication, evidence of heart failure, and the degree of dehydration (see box on "Immediate Management of Hyperglycemic Comas"). Blood should be tested for glucose, urea, electrolytes, creatinine, cardiac enzymes, and cultures. Urine and sputum should also be cultured and an electrocardiogram and chest x-ray obtained.

Acidosis should be identified by measurement of either venous bicarbonate or arterial blood gas pH. Urine (or plasma from blood in a lithium heparin tube left to stand) should be dipstick-tested for ketone bodies. Intravenous (IV) fluid replacement should be at a rate of 500 mL/hr over the initial 4 hours, reducing to 250 mL/hr. The patient needs more rapid infusion where there is shock due to hypovolemia, and here a central line is invaluable to monitor aggressive infusions, particularly in the presence of cardiac failure or recent MI. There is a wide choice of IV fluid depending on the condition of the patient. In DKA or a HONK coma with plasma sodium level less than 155 mmol/L, use 0.9% saline. If the plasma sodium level rises above 155 mmol/L, then use 0.45% saline,^{211,212,214} although if the plasma glucose level is less than 15 mmol/L, 5% dextrose could be used. If the

patient is shocked because of hypovolemia, then a plasma volume expander may be needed.

An insulin pump (50 units human soluble insulin in 50 mL of 0.9% saline) is undoubtedly the easiest way to deliver the required insulin, and syringe pumps are now very reliable. The dose of insulin infused is varied according to the result of blood glucose testing, which is initially performed hourly, and then less frequently as the readings stabilize.

Subjects with a HONK coma may need very small doses of insulin to reduce plasma glucose levels; however, if the patient is in hypercatabolic state or has marked insulin resistance, as in obesity or in some subjects with type 2 diabetes, larger doses of insulin may be required. The plasma glucose should halve over 4 hours; if it does not, check that the insulin is actually being given, and increase the insulin infusion rate as necessary—for example, initially by 25%, aiming to reduce the plasma glucose level by 5 to 10 mmol/L per hour.

The potassium level needs to be checked 2 hours after starting treatment, and then 4-hourly until stable; if the level is 4.0 to 5.0 mmol/L, add 20 mmol/L of KCl to each liter of IV fluid, and add 40 mmol/L if the potassium level is below 4.0 mmol/L.

Thrombotic complications may occur or may well have occurred before hospitalization in subjects with a HONK coma. Most authors recommend prophylaxis against deep venous thrombosis with heparin 5000 units tds subcutaneously.^{211,212,214} If there is decreased consciousness, pay particular attention to pressure areas and use pressure-relieving mattresses and booties because heels in particular are very prone to ulceration. Unconscious diabetic subjects with hyperglycemia should have a nasogastric tube passed. As the subject improves and the plasma glucose falls below 15 mmol/L, one can either change to 5% dextrose, or feed the patient, to further reduce ketone bodies in DKA. The immediate management of these comas is summarized in the accompanying box on "Immediate Management of Hyperglycemic Comas." Please note that lactic acidosis will not be covered in this chapter.

BLOOD PRESSURE CONTROL IN DIABETES MELLITUS

Hypertension is very common in elderly people with type 2 diabetes (up to 50% prevalence in some studies, and becoming more prevalent as the target blood pressure decreases). The U.K. Prospective Diabetes Study⁶⁹ showed that a 10 mm Hg systolic BP reduction led to significant reductions in any diabetes end point (12% reduction), diabetes-related death (17%), all-cause mortality (12%), MI (12%), stroke (19%), microvascular end points (13%), amputation or death from peripheral vascular disease (16%), and heart failure (12%). The U.K. study used either ACE-inhibitor-based or β -blocker-based regimens to similar effect, although the ACE inhibitor was better tolerated.

Which agent should be used? Given the HOPE, United Kingdom, Syst-Eur, and SHEP studies, one could make a case for ACE inhibitor, long-acting dihydropyridine calcium channel blocker or thiazide diuretic as first-line agents of choice, or a combination if necessary²¹⁸ (e.g., use of an ACE inhibitor plus either a diuretic or a generic calcium channel antagonist in subjects of African-Caribbean descent). If the systolic pressure is more than 10 mm Hg from target, then 98% of patients will need at least two agents to control their

blood pressure, so the question is academic: patients will be taking as many as they can tolerate. One worry is the diabetogenic effect of thiazide diuretics; in SHEP the whole thiazide group's mean glucose rose 1 mmol/L, but we do not know how many needed an escalation of their hypoglycemic medication. If glycemic control is borderline, we generally use indapamide instead of a thiazide since indapamide is said to be metabolically inactive. The main worry about ACE inhibitors (and sartans) is atheromatous renal artery stenosis, which is common in diabetic people with peripheral vascular disease.²¹⁹ In practice we look at the peripheral circulation and creatinine and, if worried, request Doppler ultrasound of renal arteries.²²⁰

The European guidelines offer a series of recommendations relating to blood pressure lowering in older patients with diabetes¹⁰:

- The threshold for treatment of high blood pressure in older subjects with type 2 diabetes should be 140/80 mm Hg or higher for more than 3 months and measured on at least three separate occasions during a period of lifestyle management advice (behavioral: exercise, weight reduction, smoking advice, nutrition/dietary advice). Level of evidence 2++; grade of recommendation B.

This decision is based on the likelihood of reducing cardiovascular risk in older subjects balanced with issues relating to tolerability, clinical factors and disease severity, and targets likely to be achievable with monotherapy and/or combination therapy, and with agreement with primary care colleagues.

As most subjects aged 70 years and over with type 2 diabetes and hypertension will already by definition have a high CV risk, no additional weighting for extent of CV risk has been applied. A lower value of blood pressure should be aimed for in those who are able to tolerate the therapy and self-manage, and/or those with concomitant renal disease.

- Optimal blood pressure regulation should be aimed for to help to maintain cognitive performance and improve learning and memory. Evidence base 2++, grade of recommendation B.

LIPID CONTROL IN DIABETES MELLITUS

Coronary heart disease (CHD) is the most common cause of mortality in type 2 diabetes and remains the principal challenge for older people with this metabolic disorder. Elevated levels of blood lipids is an independent risk factor for CHD and there is published evidence of cardiovascular benefit using a lipid lowering regimen, although this is limited in older subjects. As part of a multifaceted approach to the metabolic consequences of diabetes, effective management of blood lipids is essential to optimize vascular outcomes. Attention to risk factors such as smoking and other metabolic derangements such as blood pressure are also of paramount importance.

Diabetic dyslipidemia is characterized by high triglycerides, low HDL-cholesterol, and an LDL-cholesterol that is rich in highly atherogenic, small, dense LDL particles, which contribute to cardiovascular risk.²²¹ Can we alter this? The Scandinavian Simvastatin Survival Study (4S)²²² included 2282 subjects with angina or previous myocardial infarction aged 60 to 70 years with hypercholesterolemia (total cholesterol >5.5 mmol/L) randomized to a placebo or simvastatin

to achieve total cholesterol below 5.2 mmol/L; this resulted in a 27% lowering of risk of death and a 29% lowering of risk of a coronary end point (nonfatal MI or CHD death). Subgroup analysis examined the diabetic subjects of all ages, and showed a much greater absolute risk reduction in diabetic than in nondiabetic people,²²³ with very similar relative risk reductions—emphasizing the much greater benefit of addressing vascular risk in the diabetic than the nondiabetic subject.

The Cholesterol And Recurrent Events (CARE) study²²⁴ took subjects with an acute myocardial infarction in the preceding 3 to 20 months with total cholesterol below 6.2 mmol/L (mean 5.4 mmol/L) who were randomized to placebo or pravastatin 40 mg per day. In 2129 subjects aged 60 to 75 years, pravastatin resulted in a 27% relative risk reduction of major coronary events over the 5-year follow-up. The elderly subgroup benefited more than average from the pravastatin.

Thus it appears that lipid reduction benefits the elderly diabetic person. In secondary prevention, a total cholesterol level more than 5.0 mmol/L indicates the need for treatment. In primary prevention, risk assessment is based on age, gender, blood pressure, and microalbuminuria using the color charts.²²⁵

We would not measure lipids in subjects aged more than 80 years because there is at present no evidence that dyslipidemia has an adverse effect at that age. However, a more recent study provides convincing evidence of benefit irrespective of age. The Heart Protection Study²²⁶ included adults with diabetes aged 40 to 80 years treated with simvastatin 40 mg or a placebo over a 5-year period. Treatment led to an average fall in LDL-cholesterol of 1.0 mmol/L and resulted in a highly significant reduction of 27% in the incidence in first nonfatal myocardial infarction or coronary death and a 25% reduction in first nonfatal stroke or fatal stroke. Evidence of benefit was observed after as early as 12 months of treatment.

One should also attend to other cardiovascular risk factors and consider whether the dyslipidemia is secondary to thyroid, hepatic, or renal disease.

VASCULAR PROPHYLAXIS

Diabetic patients have a twofold to threefold increase in the rate of cerebrovascular accidents or myocardial infarctions, and have a worse outcome than nondiabetic people from either myocardial infarction or stroke.²²⁷

Aspirin should be used as secondary prophylaxis in all diabetic people with evidence of macrovascular disease, and it should be strongly considered as primary prevention in diabetic subjects with other risk factors for macrovascular disease, such as hypertension, cigarette smoking, dyslipidemia, obesity, and albuminuria (macro or micro).²²⁸ Because of the platelet defects associated with diabetes, it is recommended that the dose of aspirin should be 300 mg per day,^{228–230} although the American Diabetes Association's position statement (<http://www.diabetes.org/DiabetesCare/supplement198/s45.htm>) advocates a dose of 81 to 325 mg enteric-coated aspirin per day. If the patient cannot tolerate aspirin, then clopidogrel²³¹ can be used.

The elderly diabetic person is at increased risk of atrial fibrillation (odds ratio: 1.4 for men and 1.6 for women)²³² and at twofold increased risk of thromboembolism from

atrial fibrillation.^{233,234} We can find no subgroup analysis of the major atrial fibrillation trials to examine the benefits of warfarin specifically in older diabetic subjects. It appears that the adverse event rate in diabetic people drops from 8.6 events per 100 patients per year to 2.8 events with warfarin use.²³⁴ It is important to check for retinal new vessels when diabetic subjects are placed on warfarin, although the Early Treatment Diabetic Retinopathy Study²³⁵ showed no excess vitreous or preretinal hemorrhages in subjects given aspirin for vascular prophylaxis.

Despite our efforts, patients are still likely to suffer myocardial infarction. The Diabetes mellitus, Insulin Glucose infusion in Acute Myocardial Infarction (DIGAMI) study^{236,237} reported on treating subjects with acute myocardial infarction and either diabetes or raised random plasma glucose (i.e., not necessarily diabetic) with either an intensive insulin infusion and then a four-times daily insulin regimen or conventional treatment. Over a mean follow-up of 3.4 years, there was a 33% death rate in the treatment group compared with a 44% death rate in the control group, an absolute reduction in mortality of 11%. The effect was greatest among the subgroup without previous insulin treatment and at a low cardiovascular risk. Evidence is continuing to accumulate that the diabetic person should have a glucose/insulin infusion after a myocardial infarction.

CARE ISSUES AND FUTURE INITIATIVES

Diabetes mellitus in old age is increasingly recognized to be a specialist area. It demands skills and commitment often not available to hard-pressed general physicians attempting to cope with the dramatic increase in scientific knowledge and the escalation of clinical involvement required by most employers, whether in hospital or primary care settings. This final section explores several topical themes within the emerging discipline of "geriatric diabetology," which focuses on service delivery.²³⁸

Models of care

Four models of care are usually defined in relation to managing older adults with diabetes.²³⁹ In the first, where there is effectively a breakdown in patient and doctor education and communication, the patient is essentially self-caring. This model should be avoided. A primary care-based approach is a common and often an acceptable model as long as there is an enthusiastic and informed commitment to diabetes care. It has several advantages, including increased convenience for both patients and relatives, familiarity with practice staff, and continuity of care. Disadvantages such as lack of on-site specialist input and unstructured follow-up practices may lead to suboptimal care.

Hospital service-based care is a third model and has the advantage of regular specialist input, but has two main disadvantages. These are the lack of clinic time to deal with the vast numbers of patients needed to be seen, and the fact that junior medical staff are often expected to provide this "expert" opinion. The extra inconvenience for patients traveling large distances and the excessive waiting times discourage many patients from being involved in this practice. Primary care physicians should always be involved.

The fourth model is the favored one and consists of a "shared care" approach between the hospital (diabetologist

or geriatrician) and primary care. Joint management policies are essential for this to be a worthwhile and effective partnership, with an emphasis on early referral to secondary care when problems develop. Good communication is important and a common diabetes record card is mandatory. Clear boundaries of responsibility need to be established, and educational strategies should form the basis of a common approach to management.

Diabetes specialist nurses for elderly people

Diabetes specialist nurses are an invaluable addition to a diabetes service and can act as a link between primary and secondary care sectors.²⁴⁰ They have many other roles (see box on "Roles of the Diabetic Specialist Nurse for Elderly People") and we feel strongly that some of these specialist nurses should be appointed specifically to manage older

Roles of the Diabetic Specialist Nurse for Elderly People

- To teach, advise, and counsel patients and caregivers both in the clinic and in the patient's home.
- Where possible, to educate patients to achieve self-care.
- To teach self-monitoring of blood glucose (or urinalysis, if appropriate) and instruct in the use of special monitoring techniques for patients with physical problems, partial-sightedness, or blindness.
- Teaching and advising on insulin administration.
- To liaise with and refer to other health professionals, chiropodists, community nurses, general practitioners, etc.
- To commence insulin treatment in the patient's home.
- To advise and guide residential and nursing home staff to manage patients with diabetes.
- To provide continuing support and advice to patients and health care providers when specific problems arise relating to diabetes.

Roles of the Geriatrician in Elderly Diabetic Care

- To assess coexisting disease that impacts on diabetes management
- To manage increasing dependency and disability
- To recognize and manage cognitive impairment
- To assess and treat urinary incontinence
- To liaise between hospital and community support services
- To provide respite programs for spouses and caregivers
- To be a member of a hospital diabetic clinic team

diabetic patients. In conjunction with the primary care physician, community dietitian, social worker, chiropodist, geriatric liaison sister, and geriatrician (or diabetologist), they should constitute a "Community Diabetes Team" that will provide multiprofessional diabetes health care.

Special considerations

Providing specialist care for older patients with diabetes requires an up-to-date approach to implementing research findings or at least questioning them and deciding if they are applicable. Recent evidence suggests that examining older patients admitted to the hospital with diabetes for the presence of depression may be a valuable aid to improving outcomes.²⁴¹

The recent introduction of amylin analogues (e.g., pramlintide) and dipeptidyl peptidase-IV inhibitors (sitagliptin and vildagliptin) create new opportunities for treatment in aging subjects but their use needs to be defined from both an efficacy approach but also from a safety standpoint. The emergence of an increased risk of fractures (especially of the hip and wrist) in subjects treated with TZDs²⁴² has more recently been of concern prompting clinicians to consider fracture risk generally in patients before starting a TZD. There remains a great deal to achieve in enhancing diabetes care for older inpatients but recent work by the National Diabetes Support Team (U.K.) has provided a series of recommendations, some of which deal specifically with older people which may bring about an improvement in outcomes.²⁴³ (See box on "Roles of the Geriatrician in Elderly Diabetic Care.")

Diabetes mellitus remains an exciting challenge for all health professionals involved in clinical geriatrics, and progress is being made in improving all aspects of the care of this common and serious condition.

KEY POINTS Diabetes Mellitus

- Diabetes is very common in elderly people, and is frequently undiagnosed.
- Type 2 predominates, but type 1 and secondary diabetes also occur.
- Diabetes has considerable associated morbidity (predominantly macrovascular disease and conditions with mixed etiology, such as dementia and foot ulcers) and increased mortality.
- Glycemic targets are a compromise between improved cognition and quality of life with a lower plasma glucose level, and risks of drug side effects with still lower target levels.
- Control of vascular risk factors using hypotensive and lipid-lowering drugs and antiplatelet and anticoagulant drugs is vitally important.
- There must be secondary amelioration of complications, such as eye and foot disease.

Blood Disorders in the Elderly

Bindu Kanapuru
William B. Ershler

There is the old maxim "Hematology is the study of blood, and the organs it perfuses." With such perspective it would seem impossible to adequately provide a comprehensive review in a single chapter. Instead, we provide broad strokes of the key topics of modern hematology with particular focus on geriatric issues of clinical relevance.

Most circulating cells are derived from a single hematopoietic stem cell. The life span of blood cells is genetically predetermined. Therefore, hematopoiesis is a lifelong continuous process. Stem cells lack the surface molecules, which are associated with differentiation (maturation), but they do express the CD34 molecule on their surface, a feature that has important clinical implications. Hematopoietic stem cells give rise to unipotent progenitor cells, which then divide and differentiate into recognizable cells of a specific lineage. This differentiation process is considered to be random. Once a specific cell line is determined (leukocyte, erythrocyte, etc.), the progenitor cells go through further differentiation to manifest their ultimate predestined phenotype. This is accomplished by upregulation of specific receptors under the influence of multiple cytokines and growth factors. Certain of these cytokines, for example erythropoietin and granulocyte-colony stimulating factor, have, in recent years, become important clinical tools.

With aging, there is a notable reduction in the capacity to produce new blood cells. Yet unless there is substantial physiologic stress, the number of circulating cells remains fairly constant. Quantitative deficiencies are only apparent when stress produces a demand that exceeds reserve proliferative capacity. Such might occur during an acute infection or after cytotoxic chemotherapy. Significant qualitative deficiencies in blood cell function are not thought to be a consequence of aging but may be associated with age-associated chronic diseases.

Acknowledging that the discipline of hematology extends way beyond what is presented, we attempt in the pages that follow to provide an overview of blood disorders of particular relevance to older people. We focus primarily on the hematologic problems that will be encountered by the practicing geriatrician. These include anemia, myelodysplasia, myeloproliferative disorders, hematologic malignancies, and disorders of hemostasis.

ANEMIA

Anemia is a significant health problem in the elderly because of both a high prevalence and significant associated morbidity (Table 93-1).¹ Although there is a long-established perspective that anemia in the elderly is of little consequence, studies have shown that even mild decreases in hemoglobin levels are associated with reduced quality of life, clinical depression, falls, functional impairment, slower walking speed, reduced grip strength, loss of mobility, worsening comorbidities, and mortality and have called for a greater focus on this problem.² Currently, screening for anemia is

not generally practiced, and thus it is typically discovered during a workup for other conditions, at a time when many of its deleterious effects may have already occurred.

The World Health Organization (WHO) defines anemia as a hemoglobin level of less than 13g/dL in adult males and less than 12g/dL in adult females.³ In older men and women, anemia by this definition is associated with an increase in mortality.⁴⁻⁹ It has been pointed out the WHO criteria do not take into account inherent racial variations, particularly with respect to African Americans who may have lower levels of hemoglobin without significant adverse outcomes.^{10,11} In a study that analyzed 1018 black and 1583 white adults aged 71 to 82 years, anemia was associated with increased mortality in whites but not blacks.^{10,11} The issue of defining criteria for the diagnosis of anemia is quite relevant in the context of age as well. Older women, for example, have better physical performance and function at hemoglobin values between 13 and 15 g/dL than between 12 and 12.9 g/dL,¹² suggesting perhaps that a cutoff level of 12 g/dL is too low. Nevertheless, the WHO definition remains the current standard utilized in most current epidemiologic surveys and many clinical laboratories.

Prevalence of Anemia

Guralnik and colleagues examined the third National Health and Nutrition Examination Survey (NHANES III) database, a nationally representative sample of community-dwelling persons and determined age- and sex-specific prevalence rates of anemia in the total U.S. population.¹³ For those over the age of 65 years, by WHO criteria, approximately 11% were anemic (see Table 93-1). The prevalence of anemia was lowest (1.5%) among males between 17 and 49 years of age and highest (26.1%) in males over 85 years. Among those 65 years and older, the prevalence rate was notably higher in African Americans as compared to whites and Hispanics. Prevalence rates of anemia in the elderly vary in community-dwelling and institutionalized populations. It is also quite clear that anemia is more common among frail elderly. In the

Table 93-1. Anemia Prevalence in the Elderly Using the WHO Criteria

Study (ref)	Age	Population	Prevalence
Gurlanik (13)	≥65 years	Community-dwelling elderly Americans	10.6%
Ferruci (256)	>70 years	Community-dwelling elderly Italians	11%
Denny (257)	≥71	Community-dwelling	24%
Joosten (258)	≥65 years	Hospitalized	24% (defined as Hb < 11.5 g/dL)
Artz (43)	Most ≥65 years	Nursing-home	48%
Robinson (17)	Most >65 years	Nursing home	53%

nursing home, for example, anemia prevalence approaches 50% or higher.^{14–17}

Pathogenesis

In younger adults with anemia, the cause is usually readily apparent. In older patients, however, discerning the cause of anemia can oftentimes be challenging (Table 93-2). Inflammation, nutritional deficiencies, and renal insufficiency are commonly observed, but for as many as one third of elderly anemic individuals (and almost 50% for those residing in nursing homes), the anemia cannot be attributed to conventional causes, a condition now termed *unexplained anemia*.¹⁸

ANEMIA OF INFLAMMATION

Chronic diseases, such as atherosclerosis, diabetes, arthritis, infection, and malignancy, increase in prevalence with age and each is characterized by inflammatory processes. Although there are several ways in which inflammation can negatively influence erythropoiesis, disordered iron kinetics is a common feature.¹⁹ During inflammation, there is reduced iron absorption from the gastrointestinal tract and defective reutilization of iron sequestered in reticuloendothelial cells. Hepcidin, a 25 amino acid polypeptide produced in the liver in response to inflammatory stimuli, down-regulates intestinal iron absorption as well as macrophage and monocyte iron release, thereby creating functional iron deficiency and resultant hypoproliferative anemia.^{20–24} Reduced secretion of erythropoietin due to the action of inflammatory cytokines is also known to play a role in the anemia of chronic inflammation.²⁵

IRON DEFICIENCY ANEMIA

The prevalence of iron deficiency in the elderly may range from 2.5% to as high as 30% in some studies. Iron deficiency is usually secondary to iron loss rather than inadequate intake and is important to identify because it may be a manifestation of an occult malignancy. For example, in one study, of 114 outpatients referred to a gastroenterologist for investigation of iron deficiency, 45 had upper gastrointestinal and 18 had colonic sources of bleeding.²⁶ In an older study of 100 patients in whom the site of bleeding could not be established by any means other than laparotomy, a malignancy was found to be the cause in 10%.²⁷ In a survey of 1388 patients over 65 years of age, 25% were anemic and approximately one third were iron deficient. Of those with iron deficiency, gastrointestinal endoscopy found 57%

to have an upper gastrointestinal lesion and 27% to have colonic lesions. In total, gastrointestinal malignancy was found in 15% of those with iron deficiency anemia.²⁸

Iron deficiency may be the result of gastrointestinal malabsorption, particularly in patients who have had bowel resection, inflammatory bowel disease, or who are on chronic antacid therapy. Furthermore, malabsorption of iron may be an early manifestation of celiac disease.^{29,30}

For patients who present with anemia and microcytic red blood cell indices, serum levels of iron, ferritin, and transferrin saturation are typically low and total iron-binding capacity is elevated. The coexistence of chronic inflammatory disease may complicate analysis. To determine whether patients with chronic inflammation and anemia are iron deficient, measurement of the soluble transferrin receptor is frequently useful. Under conditions of iron deficiency, transferrin receptor is upregulated and increased levels are found in the serum. An index, derived by dividing the serum level of soluble transferrin receptor by the log of the ferritin level, has been shown to be helpful.³¹ A ratio of less than 2 denotes anemia of chronic inflammation, whereas values greater than 2 identify patients with either uncomplicated iron deficiency anemia or a combination of both iron deficiency and inflammation.

B₁₂ AND FOLATE

Since the implementation of the Food and Drug Administration's policy of folic acid fortification of cereal grain products in 1998, there has been a dramatic reduction in measurable folate deficiency. Just 2 years after implementation, examination of the NHANES cohort IV (1999–2000) compared with cohort III (1988–1994) revealed the prevalence of low-serum folate concentrations (<6.8 nmol/L) decreased from 16% before to 0.5% after fortification.³² Thus, folic acid deficiency is currently an uncommon cause of anemia. Vitamin B₁₂ deficiency, however, remains a problem, particularly in geriatric populations.³³ The great majority of B₁₂ deficiency in the elderly is due to food cobalamin malabsorption with true dietary deficiency or pernicious anemia being significantly less common. An age-associated atrophic gastritis with or without antacid therapy is a frequent antecedent. Macrocytic indices, the hallmark of B₁₂ deficiency, may not be apparent because of concomitant inflammatory disease or iron deficiency. In addition to red cell changes, patients with B₁₂ deficiency may also present with a myriad of hematologic abnormalities including leukopenia, thrombocytopenia, and pancytopenia,

Table 93-2. Features of Anemia by Classification

	MCV	Iron/TIBC	Ferritin	ESR/CRP	EPO	CrCl	Misc
IDA	Small	Low/hi	Low	wnl	High	wnl	
ACI	Small	Low/low	Low to High	High	High	wnl	
CKD	wnl	wnl	wnl	wnl	Low	<30 cc/min	
B ₁₂ /Folate	Large	wnl	wnl	wnl	High	wnl	levels
Hypo-thyroid	Large	wnl	wnl	wnl	High	wnl	TSH up
MDS	wnl - Large	wnl	wnl	wnl	High	wnl	marrow
UA	wnl	wnl	wnl	wnl	Low	>30 cc/min	

Abbreviations: IDA, iron deficiency anemia; ACI, anemia of chronic inflammation; CKD, chronic kidney disease; B₁₂, vitamin B₁₂; MDS, myelodysplastic syndrome; UA, unexplained anemia; TIBC, total iron binding capacity; ESR, erythrocyte sedimentation rate; CRP, c-reactive protein; EPO, serum erythropoietin; CrCl, creatinine clearance.

occasionally requiring the diagnosis of myelodysplasia or aplastic anemia. B₁₂ deficiency is usually suspected by the finding of an elevated mean corpuscular volume (MCV) either on routine screening or for evaluation of the cause for anemia. However, other causes for macrocytosis are more common, and these include excessive alcohol intake, drug intake (particularly antineoplastic agents), reticulocytosis, myelodysplasia, and hypothyroidism. Levels of B₁₂ below 200 pg/mL quite reliably indicate vitamin B₁₂ deficiency; however, measurement of *methylmalonic acid levels and homocysteine (which are elevated)* may be necessary to establish the diagnosis for those with higher serum B₁₂ levels. Treatment with both intramuscular B₁₂ and crystalline oral B₁₂ are effective in the elderly, even in patients with cobalamin food malabsorption.

RENAL INSUFFICIENCY

Chronic kidney disease (CKD) is an important cause of anemia in the elderly.^{34,35} Reduced renal erythropoietin (EPO) production is the primary factor leading to anemia in CKD. Serum EPO levels have been shown to be inappropriately low at a creatinine clearance of < 40 mL/min.³⁶ The precise degree of renal dysfunction sufficient to cause anemia remains controversial. Mild hemoglobin decreases in adults may be detected at a creatinine clearance of 40 to 60 mL/min.^{37,38}

A study among community-dwelling elderly suggested anemia and low EPO levels independent of age and other factors at a creatinine clearance < 30 mL/min.³⁹ In a nursing home of 6200 residents, 59% were found to be anemic and 43% had calculated creatinine clearances of < 60 mL/min. Their analysis indicated that renal impairment, even at mild levels increased the risk of anemia.¹⁷

UNEXPLAINED ANEMIA

Increasingly, it has become recognized that approximately *one third of older adults* with anemia do not have an obviously discernible cause upon routine evaluation (Table 93-3). Typically, this anemia is generally mild (hemoglobin concentration in the 10 to 12 g/dL range), normocytic, and hypoproliferative (low reticulocyte count). It has been postulated that the cause relates to a number of factors including testosterone,⁴⁰ occult inflammation,⁴¹ reduced hematopoietic reserve with advancing age,⁴² inappropriately low-serum erythropoietin level,⁴³ and myelodysplastic syndromes (discussed later). It is clear that this anemia is associated with a low-serum erythropoietin level for the degree of anemia. The EPO level usually falls within the normal reference range. However, this is abnormal because serum EPO should rise with falling hemoglobin concentration. The diagnosis of "unexplained anemia" assumes the clinician has excluded

serious causes. The threshold to pursue a bone marrow examination to exclude myelodysplastic syndromes remains unknown. However, we advocate considering a bone marrow examination in all patients requiring red cell transfusion who otherwise have an unexplained anemia. Macrocytosis, thrombocytopenia, neutropenia, splenomegaly or unexplained constitutional symptoms of fever, chills, early satiety, bone pain, or weight loss should prompt consideration of a bone marrow examination.

MYELODYSPLASIA

Myelodysplastic syndromes (MDS) include a heterogeneous group of disorders characterized by dysplastic changes within the bone marrow and impaired proliferation in one or more cell lines (erythroid, myeloid, or megakaryocytic).⁴⁴ As such, peripheral cytopenias and symptoms related to anemia, leukopenia, or thrombocytopenia are common manifestations of the disease. MDS occurs primarily in older males with a median age of 76 years. Each year approximately 15,000 patients will be diagnosed with this disorder, although this might be an underestimate.⁴⁵

Classification

The long-established French-American-British (FAB) classification⁴⁶ defined five distinct types of MDS: refractory anemia (RA), refractory anemia with ringed sideroblasts (RARS), refractory anemia with excess blasts (RAEB), refractory anemia with excess blasts in transformation (RAEB-T), and chronic myelomonocytic leukemia (CMML). The WHO has modified this general classification based on salient bone marrow cytogenetic features (e.g., deletion of the short arm of the fifth chromosome [5q-]) and other histopathologic or clinical features (Table 93-4).⁴⁷ Thus, RAEB is divided into two groups based on the number of blasts and the RA and RARS into those with only anemia or those with multilineage involvement. These modifications have enabled a more accurate estimation of prognosis.⁴⁸

Pathogenesis

Although in a majority of cases, no distinct cause for MDS can be identified, in many there is an association with prior chemotherapy, particularly with alkylating agents or topoisomerase inhibitors, and with prior radiation therapy.^{49,50} Treatment-related MDS patients are usually younger and have a worse prognosis than de novo MDS patients.⁴⁹ Prolonged exposure to high concentrations of benzene and pesticides appear to increase the risk of MDS possibly by inducing chromosomal abnormalities.⁵¹ Carcinogens present in cigarette smoke appear to have a similar effect in increasing the risk of MDS, especially of the type associated with deletions of chromosome 5 and 7.⁵² A familial etiology for MDS has also been postulated.⁵¹ Chromosomal abnormalities are frequently seen in MDS, and they are very similar to those in acute myelogenous leukemia (AML) including complex karyotypes.⁴⁹ Several mechanisms may be involved in the pathogenesis of MDS, including alteration in apoptotic pathways, cytokine regulation, bone marrow microenvironment, mitochondrial enzymes, and immune regulation.⁵³ Furthermore, there is evolving evidence that some MDS cases have an autoimmune basis because clinically MDS may be associated with other autoimmune disorders and

Table 93-3. Features of Unexplained Anemia

Hemoglobin	10.5 to 12 g/dL
Reticulocyte index	Low
MCV	80 to 95 fL
Serum iron	Mildly low normal
TIBC	Normal
% Iron saturation	Mildly low normal
B ₁₂ , folate, ESR, TSH	Normal
Platelet and white blood counts	Normal
Creatinine clearance	<90 to >30 mL/min

Table 93-4. WHO Classification and Criteria for the Myelodysplastic Syndromes

Disease	Blood Findings	Bone Marrow Findings
Refractory anemia (RA)	Anemia	Erythroid dysplasia only < 5% blasts
Refractory anemia with ringed sideroblasts (RARS)	Anemia	< 15% ringed sideroblasts Erythroid dysplasia only < 5% blasts
Refractory cytopenia with multilineage dysplasia (RCMD)	Cytopenias (bicytopenia or pancytopenia) No or rare blasts No Auer rods <1 × 10 ⁹ /L monocytes	≥ 15% ringed sideroblasts Dysplasia in ≥10% of cells in two or more myeloid cell lines < 5% blasts in marrow No Auer rods
Refractory cytopenia with multilineage dysplasia and ringed sideroblasts (RCMD-RS)	Cytopenias (bicytopenia or pancytopenia) No or rare blasts No Auer rods <1 × 10 ⁹ /L monocytes	< 15% ringed sideroblasts Dysplasia in ≥10% of cells in two or more myeloid cell lines ≥ 15% ringed sideroblasts < 5% blasts No Auer rods
Refractory anemia with excess blasts-1 (RAEB-1)	Cytopenias < 5% blasts No Auer rods <1 × 10 ⁹ /L monocytes	Unilineage or multilineage dysplasia 5% to 9% blasts No Auer rods
Refractory anemia with excess blasts-2 (RAEB-2)	Cytopenias 5% to 19% blasts Auer rods ± <1 × 10 ⁹ /L monocytes	Unilineage or multilineage dysplasia 10% to 19% blasts Auer rods ±
Myelodysplastic syndrome, unclassified (MDS-U)	Cytopenias No or rare blasts No Auer rods	Unilineage dysplasia in granulocytes or megakaryocytes < 5% blasts No Auer rods
MDS associated with isolated del(5q)	Anemia < 5% blasts Platelets normal or increased	Normal to increased megakaryocytes with hypolobated nuclei < 5% blasts No Auer rods Isolated del(5q)

laboratory evidence has documented oligoclonal T-cell patterns in up to 50% of cases.⁵⁴

Clinical and laboratory features

Patients with MDS may be asymptomatic or present with symptoms and signs related to qualitative or quantitative defects of erythrocytes, leukocytes, and platelets.⁵⁵ Fatigue, which significantly affects quality of life,⁵⁶ exertional dyspnea, fever, and infections are some of the reasons for consulting a physician. Complete blood count usually reveals anemia with normocytic or macrocytic indices. Moderate leukopenia and thrombocytopenia or thrombocytosis may be present. Bone marrow examination may reveal a normal or hypercellular pattern with dysplastic features identified in erythroid, myeloid, and megakaryocytic cell lines, or in all three (trilinear). Commonly seen changes in peripheral blood and bone marrow include anisocytosis, macrocytosis, basophilic stippling, ringed sideroblasts, pseudo-Pelger Huët abnormality, blast cells, and hypersegmented neutrophils, micromegakaryocytes, and large platelets.⁵⁵

PROGNOSIS

The International Prognostic Scoring System (IPSS)⁵⁷ divides patients into low, intermediate-1 (INT-1), intermediate-2 (INT-2), and high categories (Table 93-5). It is based on the number of cytopenias (hemoglobin level of less than 10 g/dL, an absolute neutrophil count of less than 1500/μL, and a platelet count of less than 100,000/μL), chromosomal abnormalities, and percentage of bone marrow blasts and is used

to estimate overall survival and predict progression to AML. Median survival ranges from less than 3 months regardless of age in the high-risk groups to almost 12 years in those less than 60 years in the low-risk group. In the low-risk group, patients over 70 years seem to have a worse prognosis than younger patients, but age does not seem to significantly change prognosis in the high-risk category. Other factors found to be of prognostic importance include WHO subtypes⁵⁸ and transfusion dependence. Older age did not influence prognosis in the refractory anemia group, which is usually associated with good prognosis.⁵⁸ Also, MDS associated with 5q deletion is associated with a good prognosis.⁵⁹

Treatment

Supportive care in the form of transfusions, iron chelating therapy, and adequate treatment of infections is the backbone of treatment in MDS. In the low and INT-1 groups, treatment is deferred unless significant cytopenias are present. Patients with deletion 5q have a relatively good prognosis and experience an excellent response to the thalidomide analog lenalidomide. In one series, 67% of patients became transfusion independent after treatment with 10 mg of daily lenalidomide and continued to remain so for more than 2 years.⁶⁰ Recombinant erythropoietin with or without granulocyte-stimulating factor is used to treat symptomatic anemia in those with low-serum erythropoietin levels and symptomatic anemia.⁶¹ Older patients in the low INT-1 category but with neutropenia or thrombocytopenia and inpatients in the INT-2 and high-risk group who are ineligible

Table 93-5. Myelodysplastic Syndrome (MDS) International Prognostic Scoring System (IPSS): Prognostic Variables

IPSS Score	0	0.5	1.0	1.5	2.0
Marrow blasts %	<5	5–10	—	11–20	21–30
Karyotype	Good*	Intermediate*	Poor*	—	—
Cytopenias	0/1	2/3	—	—	—

*Good = normal, -y, del(5q), del(20q); poor = complex (>3 abnormalities) or chromosome 7 anomalies; intermediate = any other abnormalities.

for transplantation are best treated with DNA methyltransferase inhibitors, such as decitabine⁶² or azacytidine,⁶³ as both have been shown to improve quality of life. Although intensive therapy with allogeneic stem cell transplantation has been traditionally reserved for younger patients, reduced intensity conditioning regimens have extended this therapy to selected older patients with favorable results. Assessment with the Hematopoietic Cell Transplantation Comorbidity Index (HCT-CI) has been used in elderly MDS patients and may help select patients for whom the risk-benefit ratio is favorable for this form of aggressive therapy.⁶⁴

MYELOPROLIFERATIVE DISORDERS

Myeloproliferative disorders (MPDs) are characterized by clonal proliferation of hematopoietic stem cells. They include polycythemia vera (PV), essential thrombocythemia (ET), chronic idiopathic myelofibrosis (CIF), and chronic myelogenous leukemia (CML). CML is identified by the presence of the translocated *bcr-abl* gene and typically has three phases: a chronic phase, seen in more than 80% of patients, a blastic phase, and an intermediate, accelerated phase.

The 2008 WHO classification has replaced the term *disease* in MPD with *neoplasm* to indicate the possibly malignant nature of these disorders.^{47,65} The myeloproliferative neoplasm (MPN) group includes mast cell disease, chronic eosinophilic and neutrophilic leukemia, hypereosinophilic syndrome, and other previously unclassified bone marrow disorders in addition to CML, PV, CIF, and ET. The common feature of these disorders is evident clonal proliferation without dysplasia.

Epidemiology

PV and CIF are more often diagnosed in the elderly⁴⁵ and equally in both genders, with a median age of 70 years. Incidence rates for all age groups have ranged between 0.7 to 2.6/100,000 for PV and 0.3 to 1.5/100,000 in CIF, but rates as high as 23.5/100,000 have been reported for those between 70 and 79 years for age in PV. An increased incidence among Ashkenazi Jews has been reported. Incidence for ET ranged between 0.59 and 2.53/100,000 with almost twofold higher rates seen among females than males. Unlike PV, ET is diagnosed at a younger age and is often seen in association with pregnancy. A significant trend toward an increase in ET incidence has been observed, especially among men, although the trends for PV and CIF do not show any change.⁴⁵ Familial studies have shown an almost fivefold increased risk for PV and sevenfold risk for ET in first-degree relatives with myeloproliferative disorders.⁶⁶

Etiology

Identification of a specific (V617F) mutation in the Janus Kinase-2 (*JAK2*) gene improved our understanding of the pathogenesis of myeloproliferative disease.⁶⁷ *JAK2* V617F can be identified in almost 95% of PV patients⁶⁸ and in more than 50% of ET and CIF patients.⁶⁹ Increased activity of this gene enhances the sensitivity of the mutated stem cells to hematopoietic growth factors like erythropoietin, thrombopoietin, stem cell factor, and granulocyte-stimulating factor, causing clonal trilinear proliferation of myeloid precursors. Additionally a mutation in the *mpl* gene, which involves the thrombopoietin receptor, is also thought to play a minor role in the pathogenesis.⁷⁰ The *bcr-abl* fusion gene formed as a result of translocation of the *abl* gene from chromosome 9 to the *bcr* region on chromosome 22 causes transcription of proteins with abnormal tyrosine kinase activity resulting in clonal proliferation recognized most commonly in CML.⁷¹ Clonal evolution with additional chromosomal abnormalities frequently involving the 17th are seen in more than 50% of patients in accelerated phases of the disease.⁷²

Production of growth factors by cytokines secreted from megakaryocytes and monocytes are hypothesized to play a role in proliferation of fibroblasts, changes in extracellular matrix, and angiogenesis seen in CIF.⁷³ Abnormal homing of stem cells and endothelial progenitor cells CD34+ to peripheral hematopoietic organs are also known to play a role in the extramedullary hematopoiesis of myelofibrosis.⁷⁴ Secondary myelofibrosis can result as progression of PV and ET, although progression of true ET has been highly debated.

Clinical features and diagnosis

The characteristic clinical features vary by specific myeloproliferative disorder. In ET, they are related to abnormalities in platelet number and function, and this is manifest predominantly as thrombotic episodes, although hemorrhagic episodes are also encountered.⁷⁵ Thrombotic events can precede the diagnosis of the disease and can involve both microvascular and large vessel arterial circulation causing ischemic strokes, peripheral vascular disease, and myocardial infarction in addition to venous thrombosis.⁷⁶ Erythromelalgia, a specific microvascular condition seen in ET, typically presents with erythemic, burning sensation of the extremities and ulceration of the toes.⁷⁷ The risk of thrombosis increases with age in both PV and ET.⁷⁸ Higher incidence of cardiovascular complications is also seen in those older than 65 years who had history of thrombosis.⁷⁹ It appears that the presence of *JAK2* mutation⁸⁰ and leukocytosis⁸¹ may be additional risk factors for thrombosis in MPN patients. Hemorrhagic complications usually occur in patients with very high platelet counts (>1500 × 10⁹/L), and clinical presentation can vary from minor bruising or epistaxis to life-threatening gastrointestinal bleeding.⁷⁸ CIF may be asymptomatic in more than 30% of the patients, and diagnosis may be suspected on the basis of a leukoerythroblastic blood picture, presence of classic tear drop cells, or an enlarged spleen usually in the prefibrotic stage.⁸² Presentation in CML is similar to that seen in other MPNs with constitutional symptoms and hemorrhagic manifestations. A finding of low leukocyte alkaline phosphatase (LAP) scores characterizes CML as compared to PV, ET, and CIF, which typically have normal LAP scores.

General signs and symptoms in patients with myeloproliferative disorders include splenomegaly, which can run the spectrum of mild and of little concern to uncomfortable and even life threatening if rupture occurs. Pruritus may be present in more than 50% of the patients. Patients with MPD also have a high incidence of fatigue, which may substantially decrease the quality of life.⁸³ Weight loss, night sweats, fever, and bone pain are also seen.

Diagnosis

The diagnosis of MPN has undergone a radical change with the identification of the JAK2 mutation. Previously standard criteria included physical signs and parameters based on peripheral blood counts, oxygen saturation, bone marrow findings, red cell mass, and the presence of splenomegaly. The new WHO criteria, an update of the previous 2001 criteria, include detection of JAK2 mutation along with bone marrow biopsy in the diagnosis of *bcr-abl* negative MPNs. Important changes also include lowering the platelet threshold number for diagnosis of ET from 600 to $450 \times 10^9/L$ and establishing a 2g/dL increase of hemoglobin from normal levels as criteria for PV.⁸⁴ Different algorithms using serum EPO levels, morphology of bone marrow megakaryocytes, bone marrow reticulin staining, and use of fluorescence in situ hybridization (FISH) for *bcr-abl* have been proposed to enable differentiation of MPNs from one another.⁸⁴ It is especially important to differentiate the cause of isolated thrombocytosis because the prognosis of ET is very different from thrombocytosis seen in early prefibrotic CIF and that resulting from CML. The diagnosis of ET also may require exclusion of reactive thrombocytoses like cancer, iron deficiency anemia, and inflammatory conditions.⁸⁵ The diagnosis of CML is straightforward by identification of the Philadelphia chromosome by cytogenetics or *bcr-abl* gene by FISH technique.

Prognosis

As mentioned previously, survival times vary markedly in each of the described myeloproliferative diseases. One study shows 3-year survivals as high as 92% for ET and 88% for PV. However, older age was associated with lower overall survival for myeloproliferative diseases as a group⁹⁰ in <50 years and 66% in those >80 years of age).⁴⁵ ET and PV are associated with reduction in life expectancy, significant morbidity related to thrombosis, hemorrhage, and a small but definite risk for either leukemogenic transformation or marrow fibrosis, especially in the elderly.⁸⁶ Fatigue present in more than 80% of these patients has significant negative effect on quality of life.⁸³ It is now recognized that those with JAK2 mutation,⁸⁰ especially those with higher allelic burden and higher leukocyte counts, have a tendency to higher rates of thrombosis. Age >60 years, a previous history of thrombosis,⁷⁹ and a high platelet count ($>1,500 \times 10^9/L$) have been previously identified as important prognostic factors for thrombosis in these patients. Patients in the prefibrotic stage of CIF have relatively good prognosis, with survival of almost 12 years. However, for those with high-risk CIF, life expectancy is significantly reduced.⁸⁷ The median length of survival can be as short as 1 year for those at highest risk. AML occurring in patients with primary myelofibrosis carries the worst prognosis with a dismal median survival of less than 3 months. Numerous scoring systems in CIF using

hemoglobin levels, age, and white blood cell count have been described to predict prognosis,⁸⁸ and older age appears to be a common negative prognostic factor.⁸⁹

Treatment

Treatment in PV and ET is generally recommended to reduce morbidity associated with qualitative and quantitative changes in blood cells. Phlebotomy to reduce hematocrit to less than 45% is the mainstay of treatment in PV, as this has reduced the incidence of thrombosis.⁷⁵ Low-dose aspirin has been shown to reduce the risk of micro- and macrovascular complications and is recommended for treatment in all patients with PV.⁹⁰ In the European Collaboration on Low-dose Aspirin in Polycythemia vera (ECLAP) study, which randomized predominantly asymptomatic low-risk PV patients, cardiovascular death, nonfatal myocardial infarction, nonfatal stroke, and major venous thromboembolism were fewer among those treated with 100 mg aspirin daily as compared to placebo-treated controls (relative risk = 0.4 [95% CI 0.18 – 0.91], $p = 0.0277$).⁹¹ Total and cardiovascular mortality were also reduced by 46% and 59%, respectively. There was no significant increase in the risk of bleeding. In younger, low-risk ET patients, treatment is generally not required although low-dose aspirin can be used to reduce microvascular symptoms.⁹² However, in elderly patients, aspirin may be recommended based on the ECLAP study, especially if other traditional risk factors for vascular disease are also present.⁹²

The evidence for benefit with treatment with hydroxyurea (HU) in high-risk ET patients has been clearly demonstrated, particularly with reference to reduced thrombosis (1.6%) compared to no treatment (10.6%).^{93,94} Superior benefit was also seen when HU was compared to other cytoreductive agents including anagrelide.⁹³ Studies with HU in PV have not been as consistent, and a higher risk of leukemic transformation has been observed in treated patients. However, in high-risk PV and ET patients, HU is considered the standard of care.⁷⁵

Primary myelofibrosis is a potentially fatal disease, and allogeneic hematopoietic stem cell transplantation is the only potentially curative therapy currently available. However, age and increasing comorbidity are strong negative prognostic factors for survival, even in these patients, and only 14% of myelofibrosis transplant patients older than 45 years survived 5 years after an allogeneic hematopoietic stem cell transplant (HSCT), as compared to 62% of younger patients.⁹⁵ In that same series, those with a Charlson comorbidity index of 4 to 6 had a greater than twofold risk of mortality. Reduced-intensity conditioning (RIC) regimens have increased response rates and event-free survival (EFS) in older patients, but in most of these studies, patients are considered old at age 60. It can be said that for patients younger than 70 years of age with low comorbidity, RIC regimen and allogeneic transplantation is a reasonable option worthy of clinical investigation.⁹⁶ Optimum treatment for those 70 years and older remains investigational and outside of a clinical trial may be supportive management alone. Control of symptomatic anemia, elevated leukocytes, or platelets may require pharmacologic intervention, but treatment is primarily palliative.

Erythropoietin and danazol were commonly employed to correct anemia, but a recent retrospective study⁹⁷ found an increase in risk of transformation to leukemia with the

use of these agents in myelofibrosis, and thus enthusiasm for this approach has been tempered. High response rates for patients with anemia and splenomegaly with lenalidomide have been observed in those with the del (5q) group of myelofibrosis.⁹⁸

The management of CML has changed dramatically since the late 1990s. Survival in CML patients depends on the phase of the disease, with median survival ranging from 5 years in those who present with chronic phase to less than 3 months for the blastic phase.⁹⁹ Prognostic classification developed by Social and Hasford incorporating variables like percent blasts, spleen size, platelet count, basophil and eosinophil counts, and age distinguishes three groups: low, intermediate, and high risk with good correlation with survival.¹⁰⁰ With the introduction of the oral tyrosine kinase inhibitor, imatinib, treatment of CML has improved considerably, and it appears that response rates and overall survival for older patients is comparable to that observed for younger patients.¹⁰¹ Although no prognostic models are currently available for imatinib, complete cytogenetic response to treatment (i.e., disappearance of the Philadelphia chromosome on samples from bone marrow) identifies patients with favorable prognosis.

Current projections are for those treated in chronic phase with imatinib 400 mg daily,¹⁰² overall survival rates exceed 75% at 6 years. Resistance to imatinib may occur and is usually associated with the presence of mutation in the kinase domain of *abl*. Newer drugs that bind to both active and inactive domains, such as dasatinib and nilotinib,¹⁰³ have enhanced survival in patients with imatinib refractory patients. Unless under investigational circumstances, the current role for hematopoietic stem cell transplantation is currently restricted to patients who are refractory to imatinib treatment.¹⁰⁴ The tyrosine kinase inhibitor drugs as a whole are well tolerated, and even the initial grade III and IV adverse effects of myelosuppression and liver toxicity experienced with imatinib are reduced to less than 2% at 5 years. Because these drugs are metabolized by CYP3A4 enzymes, which also are involved in the metabolism of drugs commonly used in the elderly, care to minimize drug-drug interactions are important, and attention to the potential for cardiac conduction delays (prolonged QTc) is of particular concern for those with preexisting cardiac disease.¹⁰⁴

OTHER HEMATOLOGIC MALIGNANCIES COMMON TO OLDER PATIENTS

Multiple myeloma

Multiple myeloma (MM), the second most common hematologic malignancy diagnosed in the United States, is a disorder characterized by monoclonal proliferation of plasma cells (>10%) within the bone marrow. Typically, in MM, abnormal amounts of monoclonal immunoglobulin or light chains (kappa or lambda) are present in the serum or urine. Manifestations related to involvement of the bone predominate, but symptoms resulting from the extramedullary effects of the circulating abnormal protein or hypercalcemia are also frequently observed. The median age of myeloma diagnosis is 70 years, and it occurs more frequently in African Americans and in males. The annual incidence in the United States is 4.4/100,000. Curiously, MM incidence and mortality rates

are decreasing. However, the 5-year relative survival rates continue to be less than 20% for patients 65 years and older.

ETIOLOGY

Lower socioeconomic status, education, and dietary habits seem to account for the difference in incidence between African Americans and whites in the United States.^{105,106} Familial studies have shown the risk of myeloma is higher in patients with a family history of hematologic malignancy, possibly implicating genetic predisposition.¹⁰⁷ Risk is also known to be higher after radiation or exposure to pesticides, certain chemicals, and asbestos¹⁰⁸ and also in those with a history of inflammatory disease¹⁰⁹ or allergies.¹¹⁰ High levels of human herpes virus-8 (HHV-8) virus have been reported in bone marrow stromal cells of myeloma patients, indicating a possible viral etiology for the disease in selected cases.¹¹¹

PATHOGENESIS

Bone pain is the primary symptom in approximately 70% of patients. Radiographs reveal either localized punched-out lytic bone lesions or diffuse osteoporosis, usually in bones with active hematopoietic tissue. The discrete lytic lesions are characterized by large and numerous osteoclasts on the bone-reabsorbing surface. Excess of osteoclast activating factors like RANKL, MIP-1 α , and IL-6 coupled with a decrease in osteoblast activity caused by the presence of inhibitors such as Dickkopf-1 (DKK-1) contribute to the characteristic osteolytic bone lesions. With bone demineralization and with decreased activity because of pain, hypercalcemia may be expected. The symptoms of hypercalcemia (drowsiness, confusion, nausea, and thirst) are nonspecific, but their occurrence should alert the physician to investigate this possibility. Cardiac arrhythmias, renal insufficiency, and profound central nervous system (CNS) depression can develop as hypercalcemia progresses.

The circulating monoclonal protein at high levels can cause increased whole blood viscosity. This occurs most frequently with IgM (see Waldenström's disease, discussed later in the chapter) but may also occur with IgA, or even IgG myeloma. Increased viscosity compromises circulation including that to the brain, kidney and heart, and thus symptoms of confusion, light-headedness, or chest pain may result. The myeloma protein itself may cause tubular damage within the kidney, and renal insufficiency is a major consequence of uncontrolled myeloma.

CLINICAL FEATURES

It is important to differentiate myeloma from other plasma cell dyscrasias that occur with increasing frequency with age. Monoclonal gammopathy of undetermined significance (MGUS) is considered a benign disorder secondary to age-associated immune dysregulation.¹¹² The features of MGUS (Table 93-6) include a marrow with less than 10% plasma cells (and without dysplastic features characteristic of myeloma plasma cells), less than 3 g/dL monoclonal protein in the serum, and no end organ damage. Patients with MGUS will have stable, not increasing, levels of paraprotein. It is important to recognize MGUS and to follow closely, as some patients with early MM will present with features of MGUS only to progress to the more aggressive myeloma. About 1% of patients considered to have MGUS progress to MM per year.^{113,114} MGUS patients who have >1.5 g/dL of

Table 93-6. Early Myeloma versus MGUS

	Early Multiple Myeloma	Monoclonal Gammopathy of Undetermined Significance (MGUS)
Pathogenesis	Neoplastic plasma cell disorder (malignant)	Disordered immunoregulation or possibly benign B cell neoplasm
Bone marrow	Frequently >10% plasma cells with many dysplastic features (myeloma cells)	Usually, 10% normal appearing plasma cells
Bone	Lytic bone lesions or diffuse osteoporosis	Usually no bone disease
Symptoms	Bone pain, constitutional symptoms (fatigue, weight loss), or those associated with kidney failure or hyperviscosity	Usually no symptoms
Serum spike	Progressively rising	Stable

monoclonal protein other than IgG and an abnormal urinary light chain ratio are at a greater risk of progression to MM. Follow-up every 3 months is recommended for patients with two or more of these conditions present, as opposed to less frequent intervals in those patients without.¹¹⁵

Smoldering myeloma has the same laboratory features as MM but without end organ damage. Solitary plasmacytoma is an isolated tumor consisting of plasma cells either in bones (solitary myeloma of bone) or soft tissue (extramedullary plasmacytoma) without systemic involvement.¹¹⁶ In 1% to 2% of patients, MM can progress to plasma cell leukemia, which is more common in younger patients, has more than 20% plasma cells, and is more aggressive than MM.

Renal dysfunction is seen in more than 20% of myeloma patients at the time of diagnosis.¹¹⁷ The pathogenesis of the renal disease is frequently multifactorial with contributions from paraproteins, tubular damage, tissue deposition of light chains, amyloidosis, hyperuricemia, or infection.¹¹⁸⁻¹²⁰

Pathologic fractures are also common. Fatigue related to anemia occurs in 30% to 60% and usually occurs in patients with hemoglobin levels less than 10g/dL.¹²¹ Signs of amyloidosis (present in up to 30% of myeloma patients) like macroglossia may also be present. Although constitutional symptoms can occur because of anemia, hyperviscosity, hypercalcemia, renal insufficiency, or infection, it should be remembered that in the elderly these symptoms might be less pronounced. The clinical presentation of MM has changed over the years with a lower percentage of patients presenting with end organ damage.¹²² Especially in the elderly, MM is usually suspected by the presence of normocytic normochromic anemia and mild renal failure or hypergammaglobulinemia. Because of the catabolic effects of myeloma-associated cytokines, older patients may present with normocytic anemia and a drop in serum cholesterol, even before other signs or symptoms of the disease appear.

LABORATORY DATA AND DIAGNOSIS

Complete blood count, metabolic profile with liver function tests, serum LDH level, serum beta-2 microglobulin, serum-free light chain assay, serum and 24-hour urine protein, electrophoresis and immunofixation, a skeletal survey, and bone marrow are all important in the initial workup of MM patients.¹²³ Hypercalcemia, renal insufficiency, anemia, and bony abnormalities, which are the hallmarks of end organ damage in MM, are usually identified with the preceding evaluation. Other laboratory abnormalities include hypoalbuminemia, elevated LDH and beta-2 microglobulin, and platelet and coagulation abnormalities as well as rouleaux formation (stacking of red cells) apparent on the peripheral blood smear.¹²¹

Protein electrophoresis detects a monoclonal protein in approximately 80% of the patients in the serum and in 75% in the urine. Immunofixation (or immunoelectrophoresis) allows identification of the isotype, and this is usually IgG (60%) or IgA (20%). Of the 20% without detectable monoclonal protein by serum protein electrophoresis, most will have either kappa or lambda light chains detected in the urine (light chain myeloma). Only about 1% of myeloma will be truly "nonsecretors".¹²¹ In the absence of monoclonal protein, the diagnosis of MM is established by finding of >30% plasma cells in the marrow.

PROGNOSIS

Traditionally the Durie-Salmon staging (predominantly clinical features and amount of paraprotein) has been used to identify patients at higher risk of death, as it is a good indicator of tumor burden in MM. However, the international staging system (ISS) has been shown to more accurately provide prognostic information. This staging system is based on the levels of serum beta-2 microglobulin and albumin, as well as other measures. In one survey, in stage I or low-risk MM (serum beta-2 microglobulin <3.5 g/dL and serum albumin >3.5 g/dL), median survival was 62 months. In contrast, for stage III (serum beta-2 microglobulin >5.5 g/dL), median survival was 29 months, and for the intermediate stage (stage II), the median survival was 44 months.¹²⁴ Certain cytogenetic abnormalities including those detected by fluorescence in situ hybridization (FISH) such as deletion of chromosome 13, hypoploidy, t(4;14), t(4;16), 17p-, when combined with a plasma cell labeling index >3% and selected laboratory data (LDH and CRP) have been shown to improve prognostic accuracy.¹²⁵

Although most prior studies have not distinguished significant differences in clinical features of myeloma in young versus older patients, two reports are notable. The first compared those above and below the age of 70 years, and the second compared those above and below 50 years. Both showed that older patients presented with more advanced stage, poorer performance, and more adverse clinical features including lower hemoglobin, and higher creatinine, and in both reports the response rates and survival were less for the older group.^{126,127}

TREATMENT

Older patients with MGUS and smoldering or asymptomatic myeloma need careful follow-up in an effort to detect and intervene if evidence for progression to more aggressive disease occurs. In patients with symptomatic myeloma, treatment includes two components, one to manage the disease and the second to provide supportive treatment to control

complications or end organ damage. In older patients, treatment is especially difficult as improvements in progression-free survival and overall survival may come at an expense of increased toxicity and poor quality of life. Proper selection of patients using geriatric assessment may reduce the possibility of these adverse outcomes.

Previously, vincristine, doxorubicin, and dexamethasone were used as initial aggressive therapy, although it was difficult to prove that this was more effective than oral melphalan and prednisone (MP) in terms of overall survival. Recently, thalidomide and dexamethasone have become the agents of first-line therapy and are even used as induction therapy before transplantation. Bortezomib (a reversible inhibitor of 26S proteasome) alone or in combination has also been used for myeloma with excellent results.¹²⁸ Retrospective studies have shown similar toxicity profiles and survival outcomes in both younger and older patients despite the elderly receiving reduced chemotherapy doses.¹²⁹

Currently the standard of care in elderly myeloma patients is treatment with melphalan, prednisone, and thalidomide (MPT). In patients between 65 and 75 years of age, median overall survival was 51.6 months for MPT compared to 33.2 months for MP and 38.3 months for autologous transplantation with reduced intensity melphalan conditioning regimen.¹³⁰ The complications from MPT include an increased risk of venous thromboembolism, especially when administered with high-dose dexamethasone and erythropoietic stimulating agents as well as peripheral neuropathy, infection, and constipation. Other combinations, which have shown benefit in older patients, include bortezomib or lenalidomide in combination with dexamethasone. Objective response rates as high as 90% have been seen with both these regimens.^{131,132} The efficacy of maintenance therapy is not currently established and should not be offered outside of a clinical trial.

Treatment with bisphosphonates has benefit with regard to lytic bone disease, bone pain, and osteopenia.^{133,134} Radiation is used as a palliative measure to reduce bone pain and along with dexamethasone to stabilize tumors of the spine to prevent spinal cord compression and compression fractures. Newer surgical techniques like vertebroplasty and kyphoplasty have improved the care of patients with bony complications in MM. Appropriate use of erythropoietic agents for management of anemia, aggressive management of infections including prophylactic antibiotics, immunoglobulin use, and management of hyperviscosity and hypercalcemia are all important for reducing morbidity in MM patients.

Lymphoma

Lymphomas are neoplastic disorders of B and T lymphocytes, which predominantly involve lymphoid organs. They are made up of a heterogeneous group of disorders, each with distinct etiology, histology, and clinical and prognostic features. Broadly, they can be classified as Hodgkin's, which make up less than 10% of the lymphoid neoplasm and non-Hodgkin's lymphoma.¹³⁵ Hodgkin's lymphoma, characterized by an owl eye–like inclusion in the nucleus referred to as Reed Sternberg cells on histology, usually has a predictable pattern of spread and predominantly involves lymphoid organs (lymph nodes, spleen, and liver), whereas non-Hodgkin's lymphoma (NHL) may involve extranodal tissues and can have widespread systemic involvement at presentation.

Classification of lymphoma has undergone numerous changes. The World Health Organization classification is the current accepted and widely used classification. B lymphomas, as the name implies, primarily arise from lymphocyte of B cell lineage and constitute more than 90% of NHL as compared to T-cell lymphomas.¹³⁵ B-cell and T-cell lymphoma subtypes are further subclassified based on the maturation level of the cells. Categories under mature B- and T-cell lymphomas include distinct morphologic, immunophenotypic, and clinical subtypes.¹³⁶

EPIDEMIOLOGY

NHL is a disease that affects all age groups with almost 50% of incident cases occurring in those over 65 years of age. Age-adjusted incidence in those over 65 years of age for 2001–2005 was as high as 88.4/100,000 compared to 9.4/100,000 in those younger than 65 years. Diffuse B-cell lymphoma is the most common B-cell subtype in all ages including those above 75 years. Anaplastic large cell lymphoma, lymphoblastic cell, and Burkitt's lymphoma are less frequently encountered in the elderly.¹²⁵ White males have the greatest incidence of all lymphomas with the exception of peripheral T-cell lymphoma and mycosis fungoides, which are more common in African Americans. Asians have the lowest incidence of lymphoma.¹³⁵ There is an equal distribution of lymphoma subtypes between sexes, although a lower incidence of follicular lymphoma and higher incidence of mycosis fungoides lymphomas have been observed among black females.¹³⁵ A decreasing trend in the incidence of lymphomas has been seen in younger but not older age groups. The incidence of mantle cell and Burkett's lymphoma has increased in those over 75 years of age.¹³⁵ The reason for these trends in the elderly, particularly among certain NHL subtypes, is not known, although age-related changes in immune function may be contributing.

ETIOLOGY

Environmental, infectious, genetic factors, and certain diseases are all known to play a role in the genesis of NHL, mostly by altering or activating immune processes.¹³⁷ Immunodeficiency is associated with a greatly increased risk of NHL. It is estimated that human immunodeficiency virus (HIV) patients have an almost 100-fold increased risk for NHL. An increase in NHL has also been reported in association with transplantation, rheumatoid arthritis, Sjögren's syndrome, and systemic lupus erythematosus, especially for diffuse follicular lymphoma and marginal cell lymphomas. NHL has been associated with the use of pesticides, especially in those with t(14;18) subtype, and with use of permanent dark hair dyes in women.¹³⁸ Obesity and a diet high in animal fat and protein are also known to increase the risk of NHL.¹³⁹ Hepatitis C, Epstein-Barr virus, *Helicobacter pylori*, *Campylobacter jejuni*, and *Plasmodium falciparum* are all known to be associated with specific subtypes of lymphoma.¹⁴⁰ Chromosomal translocations, for example, t(14;18) involving the *bcl-2* proto-oncogene in 85% to 90% of follicular lymphoma¹⁴¹ and the t(8;14) and other translocations involving the *c-myc* proto-oncogene in 100% of Burkett's lymphoma, can promote lymphoma development.

DIAGNOSIS AND WORKUP

The diagnosis hinges on a tissue diagnosis, usually obtained by lymph node biopsy. A comprehensive evaluation starts with a complete physical examination to document all

involved areas as well as pattern of spread. Further diagnostic procedures include imaging studies to determine occult areas of involvement. These would include computed tomography, magnetic resonance imaging, and positron emission tomography (PET), either alone or in combination. Bone marrow biopsy is often recommended to rule out extranodal involvement.

CLINICAL FEATURES, PROGNOSIS, AND MANAGEMENT

AGGRESSIVE LYMPHOMAS. Diffuse large B-cell lymphoma (DLBCL) is the most common lymphoma subtype seen in the elderly.¹⁴² Although characterized by an aggressive course without treatment, DLBCL has a high chance of cure with therapy. DLBCL may present as localized disease, but this is very unusual. More commonly, the disease manifests in an advanced stage and with extranodal involvement (e.g., the gastrointestinal tract or bone marrow).¹⁴³ Patients may also present with severe systemic systems and sometimes with rapidly progressive organ failure. Immunophenotyping reveals subtypes based on their derivation from germinal center or activated B cells. *bcl-2*, *bcl-6*, *p53*, CD10, and *mum1* expression also may recognize distinct clinical types of diseases with different presentation and prognosis. Cytogenetic analysis reveals a deletion of 18q as the most frequent abnormality (20% of cases) as well as a number of other nonrandom alterations. Mantle cell lymphoma—identified by the presence of B-cell markers (CD19, CD20, and CD22), the T-cell marker CD5, and the lack of CD23 and CD10¹⁴⁴ antigens—is an aggressive type of lymphoma that presents in more than 75% of the cases at an advanced stage.¹⁴³ It is a disease of elderly males with a median age at presentation of 68 years and a 2:1 male-to-female ratio.¹⁴³ Despite intensive treatment, the 5-year survival is less than 40%. Lymphadenopathy and bone marrow involvement are common, and splenomegaly is present in more than 60% at diagnosis. Leukemic expression (peripheral blood involvement) is also common in mantle cell lymphoma. Cytogenetic analysis typically reveals *t*(11;14)(q13;q32) in more than 85% of patients involving the *bcl-1* oncogene and the overexpression of cyclin D1.¹⁴⁴

The International Prognostic Index (IPI), which risk-stratifies patients based on age, tumor stage, LDH level, number of extranodal sites, and performance status, is useful in determining treatment.¹⁴⁵

TREATMENT

Although many studies have shown no definite age difference in clinical presentation,¹²⁵ treatment of lymphomas in the elderly is associated with significant bias, which may account for some of the observed poorer outcomes.^{142,146} More than 60% of elderly lymphoma patients have at least one comorbidity,¹²⁵ and physiologic changes in the key organ reserve may render an older patient more vulnerable to chemotherapy toxicity. As mentioned earlier, a careful comprehensive assessment of comorbidities, functional status, and social factors are likely to improve outcomes.

Randomized studies have shown that the standard regimen of cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) is safe, well tolerated, and comparably effective in young and old patients.¹⁴⁷ However, complete response is still seen in only 40% of elderly patients. The

introduction of rituximab, a monoclonal antibody to the lymphocyte cell surface antigen CD20, has greatly improved response rates and survival for patients of all ages with NHL. In previously untreated 60- to 80-year-old patients with DLBCL, Rituximab-CHOP (R-CHOP) resulted in a 76% complete remission rates with relapse-free survival of 70% at 2 years—a considerable improvement from CHOP alone and without any increase in toxicity.¹⁴⁸ Thus, R-CHOP is currently the standard of care for elderly patients with DLBCL. The use of Granulocyte-Colony Stimulating Factor (G-CSF) has also been recommended in the elderly if neutropenia is the only limiting factor to treat patients with CHOP regimens.¹⁴⁹ Standard treatment for mantle cell lymphoma, such as R-CHOP, results in better remission rates and time to treatment failure but does not significantly improve survival, and for this histology, more aggressive treatment might be required.¹⁵⁰ In the elderly, hyper-fractionated cyclophosphamide, vincristine, doxorubicin, dexamethasone (hyper-CVAD) regimens alternating with high-dose methotrexate and cytarabine have shown response rates as high as 90%.¹⁵¹ Yet when rituximab was added to this regimen, a high rate of toxicity and shorter failure-free survival was seen in those over 65 years of age (50% vs. 73%).¹⁵¹ However, rituximab used alone for 2 years as maintenance therapy after a modified hyper-CVAD regimen without methotrexate and cytarabine showed a complete remission rate of 64% with acceptable toxicity and has been recommended in patients over 65 years of age.¹⁵² Rituximab in combination with fludarabine, cyclophosphamide, and mitoxantrone in relapsed patients is associated with improved survival in relapsed or recurrent mantle cell lymphoma as compared to standard chemotherapy.¹⁵³

INDOLENT LYMPHOMAS. Follicular lymphoma (FL) accounts for 20% of lymphomas in the elderly population. Small painless lymphadenopathy without other symptoms may be the most common presentation.¹⁵⁴ Bone marrow involvement may be present in up to 60% of patients but usually does not signify poor prognosis unless infiltration is extensive and associated with peripheral cytopenias.¹⁴³ Sometimes fever and weight loss may be present with lymphadenopathy and warrant immediate investigation. Translocation *t*(14;18) juxtaposing the *bcl-2* oncogene with the Ig heavy chain promoter may be detected in more than 90% of follicular lymphomas.¹⁵⁵ Follicular lymphomas are graded from I to III based on the number of large cells in the malignant nodules. Initially, grade III FL was thought to be associated with worse clinical outcomes, but subsequent studies have shown this not to be the case.¹⁵⁶ Historically, FL has been considered an indolent lymphoma with a median survival of 8 to 10 years but generally not curable with standard chemotherapy. The follicular lymphoma International Prognostic Index (FLIPI) was established, which is a modification of the IPI¹⁵⁷; five adverse prognostic factors were selected: age >60 years, advanced stage, hemoglobin level (<120 g/L), number of nodal areas (more than four vs. four or fewer), and serum LDH level (above normal vs. normal or below). Three risk groups were defined: low risk (zero to one adverse factor), intermediate risk (two factors), and poor risk (three or more adverse factors), and this system effectively predicts prognosis. Transformation to an aggressive type of lymphoma may occur, especially in those with high-risk FLIPI, and portends poor prognosis.^{157,158}

In older patients where maintaining quality of life is an important end point, treatment is commonly deferred unless symptoms or signs of progressive disease develop. Under carefully monitored circumstances, this delay in treatment initiation has been shown to not significantly influence survival.¹⁵⁹ The decision to start radiotherapy, a potentially curative treatment in early stage disease, is highly individualized, and age >60 years is found to be an adverse factor with regard to the effectiveness of localized approaches such as these.¹⁶⁰ No standard chemotherapy regimens are currently available for treatment of FL. Rituximab-based therapy combined with traditional chemotherapy regimens including CHOP¹⁶¹ and fludarabine¹⁶² have shown durable response rates as high as 90%.¹⁶³ For elderly patients with comorbidities or functional impairment, rituximab as a single agent is both well tolerated and an effective treatment.¹⁶⁴

Marginal cell lymphoma includes three categories: mucosa-associated lymphoid tissue (MALT) lymphoma (typically located in the gastrointestinal tract), splenic marginal zone lymphoma (SZL), and nodal zone lymphoma (NZL).¹⁶⁵ Gastrointestinal MALT is the most common extranodal presentation of MALT lymphoma, and the stomach is the most common organ involved.¹⁶⁶ Pathogenesis is mainly related to the presence of infection with *Helicobacter pylori*,¹⁶⁷ which is seen in almost all cases and investigations to identify this organism is mandatory in MALT lymphomas.¹⁶⁸ Other commonly involved regions include salivary gland, ocular adnexa, lung, skin, and Waldeyer's ring.¹⁶⁶ Patients with gastric MALT typically present with symptoms of dyspepsia or abdominal pain, and upper endoscopy and biopsy will reveal a tumor with the characteristic histology.¹⁶⁸ Although prognosis of low-grade MALT (86%, 5-year survival) is excellent,¹⁶⁹ those who present with advanced disease and poor IPI scores do not fare well. Eradication of *H. pylori* with antibiotics has been very effective in treatment of localized gastric MALT and is the standard treatment when *H. pylori* is identified. Initial treatment in those who have *H. pylori* negative disease or t(11;18) translocation (associated with resistance to *H. pylori* treatment),¹⁷⁰ radiotherapy, or rituximab is usually employed.¹⁷¹ Treatment of MALT in other sites involves locoregional radiotherapy or surgery, although individualized treatment taking into consideration the patient's functional status and preferences is the preferred approach. Splenic marginal zone lymphoma and nodal zone lymphoma are primarily seen in women. An association with hepatitis C infection is seen in some SZL and NZL. The spleen is commonly involved in SZL as is the bone marrow.¹⁷² M-protein (paraprotein) and immunologic abnormalities may be seen in a high percentage of patients and are associated with a poor prognosis.¹⁷³ As with indolent lymphomas, asymptomatic or elderly patients may be frequently followed for development of symptoms or progression to aggressive lymphoma. Hepatitis C patients may be successfully treated with appropriate therapy,¹⁶⁶ but splenectomy is the preferred treatment for hepatitis C–negative patients.¹⁷³ Nodal zone lymphoma primarily presents with extensive peripheral and central lymphadenopathy. Survival is lower than the other NZLs and treatment is not defined, but rituximab-based therapies have been used with varying success.¹⁶⁶

Waldenström macroglobulinemia (WM) (lymphoplasmacytic lymphoma) is a low-grade lymphoma identified by IgM monoclonal protein in serum and presence of characteristic intertrabecular infiltration of bone marrow with plasmacytoid lymphocytes. Immunophenotyping reveals surface IgM+, CD10–, CD19+, CD20+, CD22+, CD23–, CD25+, CD27+, FMC7+, CD103–, and CD138 cells.¹⁷⁴ The median age of diagnosis is 63 years, and the disease occurs more commonly in the white population. Symptoms in WM are primarily related to direct tumor infiltration or with the effects of IgM protein. Infiltration can occur within any organ causing hepatomegaly, splenomegaly, and lymphadenopathy, and the bone marrow is almost always involved.¹⁷⁵ Hypercalcemia secondary to lytic bone lesions may be seen. Hyperviscosity due to presence of pentameric IgM molecules can give rise to headaches, ocular symptoms epistaxis and even altered consciousness.¹⁷⁵ Primary amyloidosis can occur in WM and typically involves the heart and peripheral nerves leading to cardiac failure and severe peripheral neuropathy. The lung may also be involved. Cardiomyopathy is more common in the elderly and is a primary cause of death in WM.¹⁷⁶ Renal dysfunction can be related to glomerulonephritis secondary to tissue infiltration with tumor, cryoglobulin deposition, or the result of IgM antibody against glomerular basement membrane. Cold agglutinin disease resulting from IgM antibody directed at the red cell antigens can lead to chronic immune hemolytic anemia. Cytopenias may also occur because of bone marrow infiltration of the tumor. Twenty percent of patients may have no symptoms at diagnosis.

Asymptomatic WM patients usually do not require treatment and may be followed by observation alone.¹⁷⁷ A close watch, especially to monitor symptoms of hyperviscosity, is imperative, especially in those with serum monoclonal levels greater than 5 g/L.¹⁷⁸ Measurement of serum viscosity is usually not helpful although symptoms rarely occur at levels less than 4 cp. Plasmapheresis is the treatment of choice in reducing hyperviscosity in these patients.¹⁷⁹ Treatment is usually recommended for symptomatic patients and those with a hemoglobin level less than 10g/dL and platelet count less than $100 \times 10^9/L$.¹⁷⁷ Median survival is about 5 to 10 years in WM¹⁷⁸ and older age; high serum β_2 microglobulin, poor performance status, and cytopenias predict a poor prognosis.¹⁸⁰ Especially in older people, survival may be affected by concomitant comorbidities, as only 50% of deaths in WM patients have been attributable to the disease. Options when cytoreductive treatment is required include single-agent therapy with chlorambucil, fludarabine, or rituximab with reported median response duration as high as 60 months¹⁸¹ and combination therapy with CHOP and cyclophosphamide and prednisone (CP),¹⁸¹ although their specific activity in people over 65 years is not known.

T-CELL LYMPHOMAS. Peripheral T-cell lymphoma and angioimmunoblastic lymphoma (AIBL) are the two most common T-cell lymphomas encountered in the elderly. Derived from post-thymic lymphocytes, they can identify by expression of T-cell receptor $\alpha\beta$ or $\gamma\delta$ chains and CD3+, CD4+, or CD8+ cells. Median age of presentation is generally greater than 60 years with a male preponderance. Clinically they present in advanced stages with higher rate of "B" symptoms, worse performance scores and a higher IPI.¹⁸² Involvement of the skin is common in peripheral T-cell lymphoma

(PTCL), and allergic manifestations and symptoms related to proteinuria are typically seen in AIBL as well as a high seropositivity for Epstein-Barr virus.¹⁸³ Molecular cytogenetics reveal a high rate of chromosomal abnormalities and T-cell receptor (TCR) clonality in β or γ genes. Peripheral T-cell lymphoma and AIBL generally have a poor prognosis when compared with B-cell lymphomas.¹⁸⁴ IPI is useful in predicting prognosis, with survival less than 1.5 years in the high-risk group and longer than 10 years in the low-risk group,¹⁸⁵ although other molecular findings like *p53* expression¹⁸⁶ have also been shown to correlate with poor survival. Treatment with six to eight cycles of standard CHOP or more aggressive regimens for patients with AIBL are all reasonable approaches but should be individualized based on acceptable toxicity and a goal to maintain quality of life in the elderly.

HODGKIN'S LYMPHOMA

Hodgkin's lymphoma (HL) constitutes about 8%¹³⁵ of total lymphomas in the population. Incidence of HL at 2.5% is relatively low and typically demonstrates a bimodal pattern of distribution with highest rates seen between 20 to 30 years of age (4.3%) and between 70 to 84 years of age (4.4%). In the younger age groups, HL is more often diagnosed in females than males, whereas the reverse is true in the elderly.

The characteristic feature of HL is the presence of lymphadenopathy, which develops in a contiguous fashion, and the presence or absence of systemic symptoms, which provide useful prognostic information. Of the histologic variants of HL, the nodular sclerosing variety is most common, but the mixed cellularity type appears more frequently in older patients than in younger patients. Elderly patients with Hodgkin's present in more advanced stages and with more constitutional ("B") symptoms (fever, weight loss, night sweats) but with less bulky disease than younger patients.¹⁸⁷ Accurate staging is imperative such that curative therapy can be effectively prescribed. Positron emission tomography/computed tomography (PET/CT) has become an excellent method to assist in staging.

Traditionally, stage I and II in the absence of B symptoms have been considered to have a good outcomes. Additional prognostic factors have come to light in both early stage and advanced disease, which further define survival and necessitate treatment modification. In early stage disease, bulky disease (mediastinal mass on chest x-ray greater than one third of the intrathoracic diameter, or mass greater than 35% of the thoracic diameter at T5-6, or any other mass greater than 10 cm) identifies a subset of patients with less favorable disease especially associated with resistance to radiation. The international prognostic score,¹⁸⁸ which awards one point each for albumin <4 g/dL, hemoglobin <10.5 g/dL, male, age >45 years, stage IV disease, leukocytosis (white blood cell count at least 15,000/mm³), lymphocytopenia (lymphocyte count less than 8% of white blood cell count or lymphocyte count less than 600/mm³), can predict freedom from disease progression (FFP) and overall survival and has proven a useful adjunct to staging in assessing the type of therapy to be undertaken. Those who had none of the above had 84% rate of FFP compared to 42% for the presence of five or more.

A treatment of doxorubicin, bleomycin, vinblastine, and dacarbazine (ABVD) has become the standard of care for HL. In early stage disease, four to six cycles are administered depending on the presence of bulky disease. In the presence

of favorable factors, two cycles may be sufficient. Involved field radiation after completion of chemotherapy and complete response may reduce relapse rate in these patients,¹⁸⁹ but the long-term risk of second malignancy is of concern for younger patients. Reports have been inconsistent regarding outcomes of elderly patients following chemotherapy. Doxorubicin-based regimens and involved field radiation have been shown to be equally effective in the elderly¹⁹⁰ who have been selected appropriately. Nonetheless, treatment regimens should be chosen with an eye on potential toxicity in older patients. A retrospective analysis of elderly patients from the German Hodgkin's group¹⁹¹ showed that with the exception of minor reactions like nausea and pain, frequency of adverse effects were greater in elderly (>60 years) than younger patients. This excessive toxicity resulted in a reduction of the treatment dose and number of cycles, and early termination of treatment. As a result, lower response rates and overall survival were observed. Although Hodgkin's disease was still the most common cause of death in the elderly and younger patients, mortality resulting from treatment-related toxicity and second malignancies was more common in older patients. Appropriate assessment in the elderly to individualize treatment programs based on a comprehensive pretreatment evaluation may minimize toxicity, treatment reductions, and less favorable outcomes. Currently, elderly Hodgkin's lymphoma patients are more likely to experience treatment-related cardiovascular disease, second malignancy, and death.^{192,193} Age-appropriate cancer screening, annual chest imaging, thyroid function tests, and tests to detect cardiovascular risk factors are essential in all treated patients to identify and prevent late toxicities associated with therapy for HL.

Chronic lymphocytic leukemia

Chronic lymphocytic leukemia (CLL)/small lymphocytic leukemia is a disorder classified as a mature (peripheral) B cell neoplasm according to the WHO classification.¹⁹⁴ There are almost no reported cases under the age of 30 years and only about 10% of the cases occur in those below 55 years of age. Although not significant, there has been a trend toward a slight decrease in the incidence rates of CLL, including in those aged 75 years and above.¹³⁵ It is a disease predominantly seen in the white population occurring slightly more frequently in males and the incidence is very low among Asians and Pacific Islanders.¹³⁵ An increased risk of CLL has been observed in patients with pernicious anemia,¹⁹⁵ chronic sinusitis, recurrent pneumonia, and herpes simplex and zoster viral infections.^{196,197} Interestingly, there is a decreased incidence of CLL in patients with chronic rheumatic as well as nonrheumatic valvular heart disease. Population and family studies have highlighted the importance of genetic factors in the etiology of B-cell CLL (B-CLL). The relative risk of CLL in first-degree family members can be eightfold higher than in controls.^{198,199} Some have suggested the risk increases with the degree of relationship between the affected member and the family members,¹⁹⁸ and it is apparent that the age at onset of disease occurs earlier in successive generations—a phenomenon termed *anticipation*.²⁰⁰

CLINICAL FEATURES AND DIAGNOSIS

A rapid proliferation in the use of automated meters to evaluate peripheral blood counts have caused an increase in diagnosis of asymptomatic individuals with elevated lymphocyte

counts and those in early stage CLL.^{201,202} The median age of patients diagnosed in early stage also is increasing. Lymphadenopathy is the most common feature in symptomatic patients, and the lymph nodes are usually painless and mobile on examination.²⁰³ Inguinal lymphadenopathy is uncommon. Nonspecific symptoms such as malaise, fatigue, and weight loss also predominate in symptomatic CLL patients. Other findings include anemia, hepatomegaly, and splenomegaly.²⁰⁴ Bruising secondary to thrombocytopenia may also occur in these patients. Cytopenia seen in CLL may result from bone marrow failure (more common) or secondary to autoimmune disease.²⁰⁵ Clinical features are similar in younger and older patients,²⁰⁶ except that younger patients (<50 years) usually present with a higher hemoglobin level.²⁰⁷ Autoimmune hemolytic anemia can occur in CLL as a presenting feature or during the course of the disease with a prevalence of approximately 4%. Older males appear to have a higher rate of autoimmune hemolytic anemia.²⁰⁸ Treatment with steroids for this condition is frequently successful²⁰⁸ but can significantly increase the morbidity and mortality if prolonged treatment is required by elderly patients. Other autoimmune disorders like immune thrombocytopenic purpura and pure red cell aplasia occur but are uncommon. Infections secondary to hypogammaglobulinemia may precede the diagnosis of CLL but more commonly occur during the course of the disease especially following CLL treatment. Although bacterial infections with encapsulated organisms are the most common, fungal and viral infections are also fairly frequent.²⁰⁹ Transformation to diffuse B-cell lymphoma (Richter's) also occurs in CLL patients with a 10-year incidence of 16.5%,²¹⁰ and older people appear to be at an increased risk.²¹¹ This can occur even in early stage disease and is heralded by the development of systemic symptoms and rapidly growing lymphadenopathy.

CLL cells contain either unmutated or mutated immunoglobulin heavy chain variable (IGHV) genes. ZAP-(zeta chain associated protein) 70 is a 70 kDa intracellular tyrosine kinase involved in T-cell receptor signaling.²¹² By gene expression analyses, it was discovered that CLL cells with unmutated IGHV differed from CLL cells with mutated IGHV in the expression levels of a small subset of genes, one of which encodes ZAP-70. It has been established that patients with CLL cells that have unmutated IGHV have more aggressive disease, and that measurement of ZAP-70 may be used as a surrogate marker for the expression of unmutated IGHV.²¹³ Furthermore, the expression of the cell surface marker CD38 on CLL cells also defines those with more aggressive disease,²¹⁴ but the two markers (ZAP-70 and CD38) do not always coincide.²¹⁵ Using both markers, clinicians are now better prepared to determine which patients at presentation are likely to be best served by aggressive treatment (those positive for ZAP-70 or CD38) and those for whom specific therapy can be delayed.

DIAGNOSIS AND MANAGEMENT

The international working group recently updated CLL guidelines²¹⁶ for diagnosis and management. CLL is usually diagnosed by the presence of lymphocytosis in the peripheral blood $>5 \times 10^9/L$ present at least for 3 months, with $<55\%$ of atypical cells (prolymphocytes or lymphoblasts). Flow cytometry is essential in the diagnosis of CLL and reveals the characteristic immunophenotype with CD5+, CD23+, FMC7-, weak expression of surface Ig (sIg), and weak or

absent expression of membrane CD22 and CD79b.²¹⁷ Bone marrow usually has $\geq 30\%$ lymphocytes, although bone marrow examination is not required for diagnosis.

Clinical staging using Rai²¹⁸ or Binet^{219,220} classification is used both to provide prognosis and guide therapy. It is well known that CLL is a heterogeneous disease with survival for some only 2 years and for others, 2 decades. However, it is also appreciated that more than 30% of the patients show progression from an early to more advanced stages within 3 years of diagnosis.²²¹ Numerous prognostic indicators have been identified that can detect these individuals at high risk of progression and that also correlate with survival.

Features associated with poor prognosis include older age,²²² absolute lymphocyte count $> 50 \times 10^9/L$, diffuse bone marrow involvement, low platelet count, lymphadenopathy, low hemoglobin, and the presence of fever.^{223,224} A diagnosis of CLL has significant effects on psychological quality of life (more so in the elderly), and this aspect should be considered in decision making.²²⁵

Currently the guidelines do not recommend treatment for early asymptomatic disease (Stage 0 Rai and Stage A Binet),²¹⁶ as more than 50% of these patients are alive at 10 years, and treatment for indolent disease did not improve outcome. For all stages, more than 65% of patients >80 years old did not receive treatment at the time of initial diagnosis as compared to $<45\%$ in those less than 40 years. However, analysis of relative survival from the National Cancer Database²²⁶ revealed that elderly patients do succumb to CLL more often than from existing comorbid diseases.

TREATMENT OF CLL

Treatment in the early and intermediate stages is offered only for those with CLL-attributable symptoms. Chlorambucil with or without prednisone was initially the drug of choice, but this has been largely replaced by fludarabine, either alone or in combination with cyclophosphamide or rituximab.²²⁷ However, the incidence of autoimmune hemolytic anemias is increased in patients treated with fludarabine, and hematologic toxicity does appear to increase in those over 70 years of age. Pentostatin, cyclophosphamide, and rituximab has also been found to be effective treatment of CLL with no significant differences in overall response (83% vs. 93%) or complete response rate (39% vs. 41%) when older (70 years) were compared with younger patients (<70 years).²²⁸ In patients with 17p deletion (associated with p53 mutations and poor prognosis), alemtuzumab, a humanized anti-CD52 monoclonal antibody, achieved objective response rates as high as 40%.²²⁹ Curiously, older patients appeared to do better than younger patients, and currently this agent is recommended as frontline therapy for those over 70 years with 17p deletion or refractory CLL. There is an increased risk of infections with alemtuzumab, and appropriate prophylaxis should be administered. Reduced intensity allogeneic stem cell transplantation may be considered for younger patients (<65 years) with good performance status after first remission or refractory disease, but supportive care and observation may be best for older patients in that setting.

ACUTE MYELOGENOUS LEUKEMIA

Acute myelogenous leukemia (AML) is primarily a disease of the elderly. The median age at diagnosis is 67 years and according to the National Cancer Institute's Surveillance,

Epidemiology and End Results (SEER) registry, the age-adjusted incidence rates for people aged 65 years and older is 16.4/100,000 as compared to 1.7/100,000 for those under 65 years.²³⁰ Furthermore, there is a progressive increase in the incidence of AML with age up to 85 years with the highest incidence and mortality in those 74 to 85 years old. Although in the earlier years incidence of AML has shown to increase with each year, the annual percentage change in the age groups 65 to 74 years and >75 years has shown a significant downward trend for the years 2001–2005. However, the mortality rates continue to increase in those over 75 years. There is a slight gender difference, with males being more affected, and this difference becomes more pronounced with age.

AML diagnosis is made by the demonstration by a minimum of 20% myeloblasts in a bone marrow sample. Environmental, genetic, and iatrogenic factors have been implicated in its etiology.²³¹ AML may arise *de novo* or, as commonly the case with older patients, as a progression of MDS or after treatment for a primary malignancy (secondary, or treatment-related AML).²³² In people over 60 years of age, cigarette smoking (number of cigarettes and duration of smoking) is associated with an increased risk, particularly of the M2 subtype of FAB AML classification.²³³ A higher carrier rate of Human T-cell lymphotropic virus-1 (HTLV-1) type virus has been observed in patients with acute promyelocytic (FAB M3) leukemia.²³⁴

As with most of the hematologic malignancies, classification schemes have recently been revised in consideration of new molecular and genetic understandings of disease pathogenesis. Thus, the classic French American British (FAB) system has been replaced by the WHO classification of acute leukemia (Table 93-7).

Clinical features in AML are related to uncontrolled proliferation of leukemic blasts in the bone marrow and infiltration into body tissues. Anemia and thrombocytopenia are frequently seen. CNS infiltration, which is more often seen in those with initial white blood counts >100,000/mm³ and in those with monocytic leukemia, may manifest as meningeal

involvement, bleeding, or as distinct mass (chloromas). Lumbar puncture should be considered in patients with neurologic features if imaging studies do not reveal pathology. Chloromas may also present as a space-occupying mass when present on the spine. In the elderly, more subtle symptoms like weakness, fatigue, or generalized malaise may be initial presenting features. Acute promyelocytic leukemia may manifest with disseminated intravascular coagulation (DIC) and bleeding manifestations. Elderly patients with AML typically present with a worse performance status and a greater percentage of complex and high-risk karyotypic abnormalities but lower numbers of peripheral and bone marrow blasts.²³⁵ Cytogenetic evaluation and immunophenotyping are absolutely essential in the initial workup of leukemia to classify subtypes and determine prognosis.²³⁶ Although age itself is a poor prognostic factor in AML, the demonstration of high-risk karyotypes or immunophenotypes might portend an even greater risk of standard therapy failure.²³⁷

Acute promyelocytic leukemia (FAB M3) is usually associated with favorable cytogenetic alterations and is also effectively treated by the use of all-trans retinoic acid and daunorubicin or arsenic trioxide.²³⁸ Studies have shown that standard induction therapy is associated with better outcomes in those over 60 years with low-risk features compared to best supportive care.²³⁹ Although the rate of hospitalization is greater in these patients, treatment is often quite gratifying with a return to a baseline level of functioning after discharge. For those younger than 75 years with good performance status and favorable cytogenetics,²⁴⁰ cytosine arabinoside combined with an anthracycline followed by consolidation therapy is still considered the standard of care. Reduced intensity conditioning regimens followed by stem cell transplantation can be effective curative therapy for older patients with excellent performance status once in remission. However, this approach is still considered investigational and should be performed in the setting of a clinical trial. New treatment approaches may also be relevant for older patients. For example, treatment with gemtuzumab, an ozogamicin calicheamicin conjugated to monoclonal antibody specific for the CD33 receptor, was associated with improved median survival in older patients with relapsed disease.²⁴¹ For patients with significant comorbidities or over the age of 75 years and with unfavorable cytogenetics or other high-risk factors, the standard induction therapy (cytosine arabinoside and an anthracycline, such as daunorubicin) often results in poor outcomes, and these patients may best be managed by low-intensity therapy or supportive care. However, involvement of the patient in decision making and consideration of available psychosocial support are important in all decisions regarding AML management. Support with granulocyte colony-stimulating factor (G-CSF) after chemotherapy may be considered in older patients, as it has been shown to improve remission rates and reduce hospitalizations.²⁴²

The elderly are susceptible to tumor lysis syndrome, which should be considered in all patients, particularly those who present with very high white counts. Also, the elderly are particularly susceptible to the cerebellar toxicity of certain drugs, most notably cytosine arabinoside. When this drug is used in higher doses, such as during remission consolidation, careful neurologic checks should be performed before each dose of drug.

Table 93-7. WHO and FAB AML Classifications

WHO	FAB
I	
AML with recurrent genetic abnormalities <i>t</i> (8;21)(q22,q22);(AML1/ETO) <i>inv</i> (16)(p13;q22) or <i>t</i> (16;16)(p13;q22); (CBFB/MYH11) <i>t</i> (15;17)(q22;q12)(PML/RAR α) 11q23(MLL) abnormalities	
II	
AML and MDS, therapy related Alkylating agent related Topoisomerase type II inhibitor related	
III	
AML with multilineage dysplasia Following MDS Without antecedent MDS	
IV	
AML not otherwise categorized AML without maturation	M1
AML, minimally differentiated	M2
AML with maturation	M3
Acute monocytic leukemia	M4
Acute myelomonocytic leukemia (AMMoL)	M5
Acute monoblastic leukemia AMMoL with eosinophilia	M5e
Acute erythroid leukemia	M6
Acute megakaryoblastic leukemia	M7
V	
Acute leukemia of ambiguous lineage	

DISORDERS OF HEMOSTASIS

Hemostasis is maintained by intricate and complex interactions involving vascular, platelet, and coagulation components. With advancing age, alterations in function of at least one of these components is likely, and there is a tendency for either bleeding or clotting to result. This may be a consequence of aging, but it is equally likely to be associated with use of one or many prescription drugs that can influence coagulation or platelet function. However, as a general rule, coagulation defects in elderly people may be treated just as they are in other age groups.

Senile purpura

Senile purpura occurs mainly on the extensor surfaces of the forearms and hands and may be seen in many otherwise normal older people. Loss of subcutaneous fat and changes in aging connective tissue permit undue mobility of older skin, and shearing forces result in rupture of small vessels. Platelets are typically normal both qualitatively and quantitatively in patients with senile purpura, and no correlation has been shown with ascorbic acid deficiency.

Purpura resulting from platelet defects

Thrombocytopenia may occur as a primary (idiopathic) disorder or a secondary phenomenon (drug-induced or associated with other blood diseases, infections, neoplasia, or various other conditions). Occasionally thrombocytopenia, thrombasthenia, or combined defects may be present.

AUTOIMMUNE (IDIOPATHIC) THROMBOCYTOPENIC PURPURA

Autoimmune (idiopathic) thrombocytopenic purpura (ITP) is usually secondary to IgG auto antibodies against platelets that sensitizes the platelets for destruction²⁴³ and has a higher incidence in the elderly as compared to the younger population.²⁴⁴ Antibody to platelet antigens may be observed in a number of medical conditions including in the setting of systemic lupus erythematosus, HIV, immunodeficiency disorders, or B-cell lymphoproliferative syndromes (e.g., CLL). In older people, the onset is usually insidious and is not clearly related to another illness. More than two thirds may present with signs of mucosal or visceral bleed (e.g., hematuria). The course is usually chronic and intermittent. An association of chronic ITP with current or past infection with *H. pylori* infection suggests an association that might be very relevant in older patients.²⁴⁵

Few platelets are seen in the peripheral blood smear, and those present are large ("megathrombocytes"). The bone marrow typically reveals an increase in megakaryocytes. There is usually no splenomegaly. Diagnosis is primarily clinical; testing for the presence of antibodies on platelet surfaces is, however, associated with many false positive results, and the assay has not proven of great value under most circumstances.²⁴⁶ Treatment is usually initiated if bleeding occurs or prophylactically in the setting of a very low platelet count (usually less than 10,000/ μ L) or before surgery. Therapy usually involves corticosteroids (prednisone 1 to 2 mg/kg per day), which results in improvement in about 80%, but sometimes only after 2 or more weeks of treatment.²⁴⁷ Other approved treatment options include intravenous immunoglobulin and danazol. Anti-CD20 antibody

(rituximab)²⁴⁸ and the new thrombopoietin (TPO) receptor agonist eltrombopag²⁴⁹ are currently being evaluated. Splenectomy is usually considered only for refractory cases but provides excellent cure rates with complete remission in more than 60% of the cases.²⁵⁰

Secondary thrombocytopenia

Drugs are an important cause of thrombocytopenia. They may be direct marrow toxins or cause idiosyncratic, hypersensitivity reactions or immune-mediated platelet destruction. Some drugs are known to cause selective thrombocytopenia only by decreasing megakaryocytes. Commonly used drugs associated with thrombocytopenia include sulfonamides, penicillin, tetracycline, desipramine, chlorothiazide, digoxin, insulin, cimetidine, and myelosuppressive drugs used as chemotherapeutic agents.²⁵¹ Secondary thrombocytopenia is seen with acute and chronic leukemia, lymphoma, infection, myelodysplastic syndromes and myeloproliferative disorders, chemotherapy treatment, collagen vascular diseases, splenomegaly, paraproteinemia, cirrhosis of the liver, and hypersensitivity reactions.

Heparin-induced thrombocytopenia results from antibodies against heparin, which bind to and activate platelet Fc receptors.²⁵² Patients are at risk of severe bleeding from the thrombocytopenia, as well as arterial thrombosis, and one or the other can be lethal. Management includes immediate discontinuation all heparin-related products including low-molecular weight heparin and warfarin and use of alternative antithrombotics like argatroban and hirudin before restarting warfarin.²⁵² Although the incidence of this complication is low, the widespread use of heparin in clinical practice makes it a familiar problem.

Thrombotic thrombocytopenic purpura

Thrombotic thrombocytopenic purpura (TTP) is a disseminated thrombotic microangiopathy that can be triggered by infection, drugs (e.g., clopidogrel), autoimmune disease, or without a known risk factor. The syndrome is due to deficiency of the ADAMTS-13 protein. ADAMTS-13 is a protease discovered in normal plasma that cleaves von Willebrand factor and prevents platelet aggregation and clot formation.²⁵³ TTP has a rapid onset, with widespread manifestations appearing over the course of 1 or 2 days. In the classic case, fever, thrombocytopenia with bleeding, microvascular hemolytic anemia, acute renal failure, and CNS disturbances are seen. Elevated LDH, bilirubin, and low haptoglobin are often present, and schistocytes or fragmented red blood cells may be seen on the peripheral blood smear. Other clotting studies are usually normal, fibrinogen levels are normal or increased, and split products are usually absent.

TTP is usually treated by large-volume plasma exchanges. Cryodepleted (vWF poor) plasma can be used in combination with steroids. This form of therapy has decreased the mortality rate of TTP from 90% to less than 50%. In patients with TTP who do not respond to plasma exchange, a combination of steroids, antiplatelet agents, and emergency splenectomy has been used with some success.

Coagulation defects in the elderly

Survival with congenital coagulation disorders in later life is possible, especially in von Willebrand's disease. Acquired disorders include vitamin K deficiency, which leads to a

reduction in prothrombin (factor II) and in factors VII, IX, and X. This condition may occur in malabsorption syndromes, liver disease, prolonged obstructive jaundice, and biliary fistula and with oral broad-spectrum antibiotic therapy. Renal failure, extracorporeal circuits, and acquired inhibitors may result in significant blood coagulation defects.

Anticoagulant therapy with warfarin reduces hepatic synthesis of the same four factors. Although warfarin has been associated with increased risk of hemorrhagic complications, particularly intracranial hemorrhage,²⁵⁴ maintaining INR values between 2.0 to 3.0 remains appropriate in the elderly²⁵⁴ to derive adequate benefit. Levels of D-dimer, fibrinogen, factor VIII, and thrombin are known to increase with age and may explain the high incidence of vascular disorders in the elderly. These have also been shown to predict adverse outcomes including hospitalization, mortality, and poor functional outcomes.

Disseminated intravascular coagulation

A syndrome of diffuse intravascular coagulation (DIC) may be seen in elderly people in an acute, subacute, or chronic form. There is typically a serious underlying disease process leading to thromboplastic substances entering the circulation or directly injuring endothelial cells. Liver disease, acute pancreatitis, incompatible transfusions, cancer, and nonbacterial thrombotic endocarditis have also been associated with the occurrence of DIC.²⁵⁵ DIC may also complicate the clinical course in acute promyelocytic leukemia in the elderly. Criteria for diagnosis are not well defined; the most useful are a low platelet count, prolonged prothrombin time, positive plasma protamine test for fibrin, monomer–fibrinogen complexes, D dimers, and levels of fibrinogen and fibrin

degradation products related to the clinical condition. Primary treatment should include control of underlying disease.

Therapy may include restoration of depleted blood components with platelet and fresh frozen plasma infusions in bleeding patients. The use of heparin in the treatment of DIC remains controversial. Most studies have found heparin to be of little or no value and may, in fact, result in exaggerated thrombocytopenia or thrombosis. Even in complex situations such as promyelocytic leukemia, the routine use of heparin remains controversial.

ACKNOWLEDGMENT

This work was supported in full by the Intramural Research Program, National Institute on Aging, National Institutes of Health.

KEY POINTS

Blood Disorders in the Elderly

- Aging without disease is associated with minor changes in hematologic functions.
- Anemia in older persons is of clinical importance. It is important to find the cause and treat it when possible.
- Older patients with lymphoma, myeloma, chronic leukemia, or myelodysplasia can be effectively managed with standard or new agents, but a pretreatment comprehensive assessment is needed to tailor treatment and avoid toxicity.

Cancer is a major cause of death and morbidity in elderly patients. Within England and Wales, there were 138,454 cancer deaths in 2005; of these, 51% (70,647) were 75 years or older.¹ Although total U.K. death rates fell between 1999 and 2005, the total number of older people dying from cancer has increased. In the United States, cancer incidence rates increased from the mid-1970s through to 1992 and then decreased from 1992 to 1995, although since then the incidence rates have been essentially stable. The rates of breast cancer in women and prostate cancer in men have increased, but a compensatory fall in lung cancer in men has resulted in a stable total population.² As the incidence and prevalence of cancer increases, coupled with improved diagnostic certainty and life expectancy, many doctors will be faced with caring for elderly patients with cancer. It is estimated that over 5% of National Health Service (NHS) expenditure is used in cancer care, with elderly patients responsible for a large proportion of this expenditure. A European study found that Britain ranked 10th for men and 11th for women, when considering 5-year cancer survival. This is despite the fact that Britain spends more on cancer than other major European countries.

Although cancer was chosen as a key area in the "Health of the Nation"³ document, elderly people were not specifically targeted, and in the Department of Health document, "A Policy Framework for Commissioning Cancer Services,"⁴ which provides guidance for purchasers and providers of cancer services, there is no mention of involvement of geriatricians in the acute care or rehabilitation of elderly patients with cancer. The Cancer Reform Strategy launched on December 3, 2007, although setting a clear direction for development of cancer services in England over the following 5 years, does little to focus on the needs of older cancer patients.⁵ The National Service Framework for older people and Living Well in Later Life (March 2006) do not highlight cancer as a particular problem in old age.^{6,7}

The true impact of cancer in older people is unknown because of poor histologic verification; often the first registration of cancer is at death certification. In the United States, in an attempt to focus attention on geriatric oncology, the American Cancer Society, the American Society of Clinical Oncology, and other research groups have formed subgroups specifically to deal with the problem of geriatric oncology. In the Netherlands, age-specific cancer mortality rates have increased with increasing age for both males and females during 1991–1995,⁸ and this may reflect better identification of cases, worse survival, or a combination of both.

It is clear from work by Grulich et al that there is a change in cancer mortality with age.⁹ Between 1970 and 1990 for males and females aged 75 to 84, there was a 16% and 18% respective increase in cancer mortality. This is in contrast to males and females aged 45 to 54 who have had a 19% and 17% decrease in cancer mortality.

It should, however, be remembered that cancer mortality is influenced by a variety of factors that are closely associated with age. In the United States between 1980 and 1988, there was a large increase in breast cancer incidence as a result of an increase in uptake of mammography. However,

despite this substantially higher incidence rate, particularly for women age 50 and older, the mortality rate fell as a result of improved treatment and early detection.¹⁰

CANCER AND AGING

There is no doubt that older people are more likely to develop cancer and differences in tumor growth and spread occur as a result of aging. The relationship between cancer and aging is complex, and various factors, including changes in host tumor defenses and exposure to carcinogens, have roles to play in the etiology of tumors. Although there are several distinct theories of cancer causation in older people, including decreased ability to repair DNA, oncogene activation or amplification, tumor suppressor gene loss, decreased immune surveillance, prolonged duration of carcinogenic exposure, or increased susceptibility of aged cells to carcinogens, no one theory has universal backing.¹¹

There is debate as to whether carcinogenesis and aging are related phenomena. Many believe such a relationship exists,^{12,13} with some postulating that cancer develops because of normal processes occurring during aging¹⁴ and others favoring a common etiologic origin for both cancer and aging.¹⁵ There is a relationship between chromosomal alterations and malignancy.¹⁶ Several inherited disorders, featuring both chromosomal breakage and an increased frequency of malignant disease, show abnormalities of DNA repair or recombination,¹⁷ and many genetically determined syndromes have both an accelerated progression of biologic aging and a high frequency of malignant disease.¹⁸

The increased incidence of cancer with age can be interpreted by the two major theories of aging.^{11,19} The first, the damage or error theory, holds that over time there is an accumulation of damage to vital areas of cellular or organ function, which culminates in the manifestations of the aging process. Mutations may occur in certain key genes or in many individual genes on a random basis. The multistep model of carcinogenesis fits with this theory as successive cancer-causing mutations accumulate during the aging process.²⁰ The alternative or program theory considers aging as a latter stage of a program that proceeds through embryogenesis to growth development and maturation. During aging, certain genes become expressed and others are shut down.

In 1858, Virchow²¹ stated that each tissue present in the body has a limited response to injury. Since then, further work has described how various tissues of the body respond to damage. Those tissues having continuously mitotic cells, such as the gut and marrow, develop tumors, whereas those with intermittently mitotic cells, such as endothelial or smooth muscle, develop degenerative diseases such as atherosclerosis, but only rarely malignant change. Nonmitotic cells such as the neurone virtually never develop tumors but are associated with disorders such as Alzheimer's or Parkinson's disease, illustrating that frequent cell turnover is required for tumor development.²²

Alterations in DNA methylation in some genes is more common in older subjects and results in an increase in cancer.²³ The formation of DNA adducts in a variety of tissues

is seen in chemical carcinogenesis,²⁴ and, in certain animal models, adduct-like compounds (L-compounds) accumulate with age.²⁵ These compounds do have the capability to carry mutations, DNA chain breaks, and gene rearrangements.²⁵ Further evidence for the role of altered DNA repair in cancer causation is provided by the increased susceptibility of cells from older persons to chromosomal damage by ³H-thymidine and to the toxic consequences of irradiation.²⁶

When comparing young and aged rats, the activity of DNA repair and metabolic activation enzymes was found to decline in the aged group, and the accumulation of spontaneous DNA damage may affect vital functions.²⁷

In considering cancer in elderly people, the role of factors that increase life span (geroprotectors) and their effects on tumor development must be noted. Geroprotectors are of three types. First are those that decrease the mortality of a long-living subpopulation, are effective in inhibiting carcinogenesis, prolong tumor latency, and decrease the incidence of cancers (e.g., calorie-restricted diet). Second are those that increase the survival in a short-living subpopulation without a change in the maximum life span and may increase tumor incidence in an exposed population (e.g., tocopherol). Finally, there are geroprotectors that prolong the life span equally in all members of the population, postpone the beginning of population aging, and in general do not influence the incidence of tumors but do prolong tumor latency (e.g., β -mercaptoethylamine).²⁸

A large body of literature describes the gradual alteration of immune function that occurs with advancing age and that may contribute to the increase in malignancy. Many of these changes occur with the onset of thymic involution, which begins at puberty and results in only 10% of thymic function remaining by the age of 45. Although the total population of T lymphocytes does not decline, the number of suppressor and killer cells decreases, the helper-suppressor ratio reverses, and there is an increase in the number of immature lymphocytes in the peripheral blood. Immune surveillance depends on the integrity of lymphocytes, and thymic function is critical for monitoring and disposing of cells that harbor replicative aggregations. Thymic hormones decline with age and have also been shown to be significantly lower in age-matched patients with malignant disease.²⁹ The role of thymic factors in the improvement of immunocompetence, in both viral infections and cancer, is still developing.³⁰ Although reduction in immune surveillance may play a role in the development of cancer in older people, if it were to result in tumor development as seen in immunosuppressed patients, a lack of tumor diversity would be expected, which is not the case.³¹

Administration of L-arginine acts directly on the pituitary to increase thymulin levels and, thus, the number of lymphocyte peripheral subsets.²⁹ However, there are no data on the use of L-arginine in immune activation in elderly patients with cancer.

There is conflicting opinion regarding the growth and spread of cancer in older patients, and although some evidence shows death to be earlier in older subjects, coexisting diseases have obvious effects on morbidity and mortality. Some experimental work has demonstrated slower tumor growth, fewer metastases, and longer survival in older rodents and others have shown decreased tumor growth associated with impaired T-cell function.³² Cultures from melanoma cell lines have demonstrated that T cells from young, but not old, donors stimulate the growth of tumor cells, and T cells

from young, but not old, mice produce angiogenic factors resulting in a richer vascular supply that may be responsible for increased growth and metastases. The therapeutic implications of angiogenic factors produced by T cells have yet to be explored. Additionally, a relationship between energy and cancer mortality, although not statistically significant, has been noted in older patients.³³

Many elderly subjects have been exposed to carcinogenic agents as a result of their occupation (asbestos; inorganic chemicals such as arsenic or nickel; and plant products such as aflatoxin, polycyclic hydrocarbons, and dyes). Lifestyle and diet are dominated in older subjects by tobacco consumption and atmospheric pollution, and although studies have shown an increased incidence of cancer of the endometrium and breast associated with diet, other dietary factors such as fiber does protect against the development of carcinoma of the bowel.

The relationship between cancer and aging is clearly complex and various factors, including exposure to carcinogens and changes in the host defense, have roles to play in the etiology of tumors. With further understanding of normal aging, its relationship to carcinogenesis should be further understood.³⁴

CANCER PREVENTION

There are two main approaches to cancer prevention: *primary prevention*, which may be less applicable to older people, relates to changes in lifestyle, exercise, and diet to preclude the development of cancer; and *secondary prevention*, which involves screening tests and examinations to aid early detection of tumors, thereby decreasing morbidity and mortality, increasing the chance of cure, and prolonging the disease-free interval following therapy.

Cancer becomes 100 times more common in men and 30 times more common in women between the ages of 25 and 75 years.³⁵ Therefore, secondary prevention should perhaps be targeted at older people rather than the young.³⁶

PREVENTION STRATEGIES

Prevention has been classified into three types.³⁷ Primary prevention aims to prevent the onset of a disease, and secondary prevention aims to halt progression of a disease once it has been established. By identifying the disease early, often while the patient is still asymptomatic, prompt and effective treatment may be given to stop the disease. Tertiary prevention aims to rehabilitate people with an established disease to minimize residual disabilities and complications.

The focus of many cancer studies is in both primary and secondary prevention. Approximately 80% of all cancers are potentially preventable, and many public health strategies have been aimed at behavior modification such as smoking cessation, healthy diet, and protection from sunlight.³⁸

Primary prevention and health promotion for older people are important issues not only for cancer but other common causes of morbidity and mortality, such as stroke and cardiovascular disease. With regard to cancer, primary prevention may include elimination of environmental carcinogens through chemoprevention (i.e., estrogen antagonists for breast cancer).³⁹ Primary prevention, even at extreme old age, may result in a decreased incidence of heart disease, colon cancer, and hypertension.⁴⁰

For screening to be applicable, a disease must be common, curable if diagnosed early, and the test involved must be highly sensitive. Screening in the United Kingdom is almost exclusively for tumors of the breast, cervix, and colon and is more commonly performed in younger people. Older subjects are less likely than those from younger age groups to participate in screening and cancer detection behaviors,⁴¹ and this may be due to inadequate knowledge about cancer,^{42–44} lower educational level,⁴⁵ perceived susceptibility,⁴⁶ and ethnic background.⁴⁷ Other factors such as fear of cancer⁴⁸ and its treatment, difficulty differentiating between normal physiologic changes and early symptoms or signs of cancer^{49,50} and fatalism^{51,52} have also been implicated. Men participate less than women in screening procedures,^{53,54} although the role of ethnicity, marital status, availability of screening test, and physician attitude are all known to have effects on this gender inequality. It has been found that elderly people who scored highly in a health perception questionnaire which measured current health, prior health, health outlook, health worry/concern, resistance or susceptibility to illness, and rejection of the sick role, were also more likely to have participated in cancer screening programs.⁵³ This perception of health by older people playing an important role in cancer prevention has been reported by others.^{55–57}

Older subjects involved in health promotion have significant improvement in their quality of life, and therefore this should be advocated.⁵⁸

If screening of older subjects is to increase, the involvement of health care providers will be important.^{59,60} Many exploratory studies have found that individuals failing to undertake cancer screening tests have cited lack of involvement with the health care providers in the previous year, as well as in some countries the financial implications of undertaking such screening. Ageist attitudes must not prevent physicians from recommending screening, nurses must not remove patient's autonomy, and screening services must not exclude those most at risk.⁶¹ Education of health care practitioners, instilling confidence in their ability to teach certain self-examination techniques to patients and increasing the education of patients, is essential.⁶²

To improve the early detection of cancer, several questions, including the attitudes of older people toward screening and the barriers perceived by the patient, especially for skin, breast, and cervical cancer, need to be explored.^{63–65} Elderly people must be encouraged to take all "red flag" symptoms seriously and not delay seeking a medical opinion. In addition, they should be educated about self-examination, access to screening, and the good outlook of a cancer diagnosis, if treated early.

Breast cancer studies have shown a positive relationship between stage of disease and age at diagnosis,⁶⁶ which has not improved with time.⁶⁷ However, older women are less likely to participate in screening programs for breast cancer than are younger women.⁶⁸ In the United Kingdom in 1988, screening by mammography of women aged 50 to 64 on a triennial basis was recommended by the Forrest Report, and national coverage was achieved by the mid-1990s.⁶⁹ Evidence from Hendry and Entwistle,⁷⁰ in a study involving 1500 women aged 65 to 69 years, which achieved a screening uptake of 74.6% and a cancer detection rate of 9.3/1000, suggests that the extension of screening to women aged 70 years would be both beneficial and cost-effective. The extension

of screening to this age group appears to have been well received. On March 31, 2007, 76% of women aged 53 to 64 years resident in England had been screened at least once in the previous 3 years. In addition, at that point the overall screening of women aged 65 to 70 years had achieved a rate of 67.7%, which was an 8.7% increase from March 2006.⁷¹

Mammography reveals more tumors in older patients than in younger subjects,⁷² increases the proportion of early cancers detected,⁷³ and thereby reduces mortality.^{74–78} Only 16% of all mammographies performed in the 1980s were on women aged over 60 years.⁷⁹ Factors that previously reduced the number of elderly women attending for mammography, considering themselves less at risk for developing breast cancer⁸⁰ and considering self-examination to be adequate are still seen but less commonly. Haigney et al assessed the views of both older women and hospital doctors on the performance of clinical breast examination.⁸¹ Despite older women stating they would accept clinical breast examination if it was offered by their doctor, only 7% of doctors said that they would routinely perform such an examination on women over 50 years of age. Previous assumptions that older women will not attend for routine screening have been inaccurate. An overall predicted uptake of previous non-attendees was found to be 50%, and when studied by age group, 67% of patients aged 65 to 69 years, 53% of patients aged 70 to 99 years, and 27% of patients aged ≥ 85 years attended for mammographic screening.⁸² This, however, is now reflected in the age groups included within screening but is difficult to extrapolate to those who are not invited by letter.

The American Cancer Society (ACS) recommends that women begin monthly breast self-examination at the age of 20 and between 20 and 39 years have a clinical breast examination every 3 years. The society then recommends that from age 40 onward women should have an annual mammogram and a clinical breast examination. Unlike the United Kingdom's National Screening Programme, there was no upper age limit to the 1997 ACS recommendations as long as the women are in good health.⁸³

In 2003, the ACS reviewed its recommendations in a number of key clinical groups. A group of experts considered the screening of older women and women with comorbid conditions. They recommended that screening decisions should be individualized, and as long as the woman was in reasonably good health and fit enough to be a candidate for treatment, she should continue to be screened with mammography. However, if the individual had a life expectancy of less than 3 to 5 years, severe functional limitations, or multiple or severe comorbidities likely to limit life expectancy, it may be appropriate to consider cessation of screening.⁸⁴ The argument for the extension of screening to older women focused on the aging population, the finding that 45% of all new breast cancer cases were in women aged 65 and older,⁸⁵ and that 45% of all cancer deaths occur in women aged 65 years or older.⁸⁶ Data obtained from the Surveillance, Epidemiology and End Results (SEER) program showed a life extension of 178 days for those over 85 years and 617 days for those aged 65 to 69 years old⁸⁷ if screening was extended. Hughes and colleagues studied individuals below or above the age of 70 years diagnosed with breast cancer between the years 1980 and 2000. When considering two 10-year cohorts and after adjustment for clinical stage, there was no significant improvement in survival in any age group. However, when compared with

an age-matched group in the general population, the elderly breast cancer patients had a 62% increased risk of death.⁸⁸

Unfortunately, despite well-documented evidence of the benefits of screening for colorectal cancer (CRC), there is a relatively low participation rate, particularly when comparing the screening programs that exist for breast or cervical cancer.⁸⁹ Colorectal screening uses fecal occult blood, digital rectal examination, and either sigmoidoscopy or colonoscopy. Although well accepted in the United States, until recently it was not commonly performed in the United Kingdom.^{90,91} Colon cancer is related to the presence of premalignant adenomas, which are more common in elderly people.^{92,93} There is controversy about some of the earlier studies, which showed no increased survival following screening.⁹⁴ More recent studies have sufficient evidence to suggest that population screening of people aged over 50 years can reduce mortality rates from bowel cancer.^{95,96}

The U.K. NHS Bowel Screening Programme currently offers screening every 2 years to all men and women aged 60 to 69 years. Although individuals aged over 70 years can request a kit, they are not sent one automatically. Controversy exists about the upper age limit of 69 years, as Hardcastle et al⁹⁵ and Kronborg et al⁹⁶ suggested an upper age limit of 74 years. It is expected that for every 100 patients screened, 98% will get a normal result and be returned to routine screening and the remaining 2% will be offered a colonoscopy. For every 20 individuals offered colonoscopy, 16 will accept the invitation and of them, half are likely to have nothing abnormal detected, 38% are likely to have one or more polyps detected, and 12% are likely to have colorectal cancer detected.⁹⁷ The third arm of the U.K. Bowel Cancer Screening pilot study concluded in 2008. Goodyear et al reported a 49% reduction in presentation with a symptomatic cancer and a proportionate rise in the number of asymptomatic colorectal cancers that were detected by screening. In the screened population, there was a significant increase in early Dukes A tumors and an odds ratio of 0.27 for Dukes D cancers.⁹⁸ However, there is no evidence yet that colorectal cancer screening will be recommended routinely in individuals 70 years or above.

Despite good screening methodologies, nonattenders will always give a variety of reasons for nonparticipation, including time-related or priority-related, not noticing a test in the mailbox, or forgetting. Much work is required to ensure that individual decision making is not hampered by poor communication or failing to address specific concerns.⁹⁹

In 1997, the U.K. government accepted the advice of the National Screening Committee not to introduce a population screening program for prostate cancer because it would be neither cost-effective nor acceptable.¹⁰⁰ The main reasons against such an introduction were that prostate specific antigen (PSA) has a low specificity and that it cannot reliably distinguish males with prostate cancer from males without the disease. It must, however, be remembered that despite its dubious role in screening, both PSA and C-reactive protein (CRP) are significant predictors of cancer-specific survival in prostate cancer.¹⁰¹ A U.S. study that followed a representative sample of 7889 men found evidence of 32% undergoing PSA screening. The authors found that this was higher than the number who were undertaking fecal occult blood screening (22.8%) and comparable with the numbers of women aged 75 years or older (29%) undergoing cervical

cancer screening. In this population, the majority reported that their doctor first suggested screening and within these, at least two thirds reported that the risks and benefits of screening were fully discussed with them before commencement.¹⁰² The role of screening may become more important, as further evidence becomes available around the efficacy of specific treatments for colorectal cancer.

Although PSA testing is widespread in the United States, the impact of screening remains controversial and may also result in treatment costs in largely asymptomatic patients who will die from unrelated causes.¹⁰³

Although lung cancer is common, it is generally considered that survival is not improved by screening programs. Despite physicians considering that older subjects have little or no benefit from smoking cessation, there is evidence that elderly smokers have no less ability to stop smoking with increasing age¹⁰⁴ and innovative clinics may increase the rate of smoking cessation in an elderly population.¹⁰⁵ It has been known for some time that immediately after cessation of smoking, a decline in the risk of developing lung cancer is seen and by 15 years the risk is that of a lifelong nonsmoker.¹⁰⁶ Using modeling data from a meta-analysis of epidemiologic studies, it has been predicted that 18 million deaths from lung cancer will occur in China before 2033. If, however, there were a complete but gradual cessation of both smoking and solid-fuel use by 2033, there would be 6.5 million fewer deaths from lung cancer (i.e., a reduction of 8% to 26% would occur).¹⁰⁷ The absolute reduction in the number of smoking-related cancers in some studies has been less significant, however.¹⁰⁸

The role of spiral computed tomography and positron emission tomography in the detection of early stage lung cancer in individuals considered to be at higher risk has been well described. In an Italian study with patients (mean age 58 years) of whom a number were up to the age of 84 years, there was little evidence for the routine use of screening.¹⁰⁹ In 2008, there was a U.K. call for a randomized trial initiated by the Health Technology Assessment to address this question in a systematic way.

The screening for cervical cancer has been aimed particularly at young women. Data from the late 1980s suggested that fewer than one half of all women aged 65 years or older had had a Papanicolaou screen in the previous 3 years.¹¹⁰ It is known that individuals assessed by their postcode of residence show that the most deprived patients are at increased risk of cervical cancer. In the United Kingdom, the regional differences in the socioeconomic gradients are greatest for lung and cervical cancer in the north of England.¹¹¹ Although there is some evidence that cancer screening behavior with regard to breast and cervical cancer is not affected by disability status, the quality of the experience during cancer screening does increase the likelihood of the individual undertaking future routine screening.¹¹² Fahs et al,¹¹³ using a Markov computer model, found that the early detection of cervical cancer through screening programs may improve survival rates regardless of the patient's age. In addition, screening older women for cervical cancer remained cost-effective although for women aged over 64 years with a history of regular negative smears, regular screening becomes inefficient and the cost increases. Most studies of the cost benefit of screening women for cervical cancer using a Papanicolaou test only recruit women up to the age of 64 years,

and this coupled with the increasing use of human papillomavirus DNA testing as well as vaccination of younger individuals should reduce the incidence of cervical cancer in older women in the future.¹¹⁴ Various methods of improving participation in cervical screening, including the availability of testing in older persons accommodation¹¹⁵ and creating educational interventions, have been recommended.¹¹⁶

INCIDENCE

Overall cancer incidence rates are higher for males than for females, and males have a greater probability of dying from cancer compared with females.^{117–119}

Malignant disease has a rising incidence with age, particularly for tumors of the prostate, stomach, colorectum, pancreas, and esophagus.^{120–123} The most common cancer site for adult males (aged 25 years or older) is the lung, and for adult females it is the breast.^{124,125} In the case of primary lung and breast tumors, although there is a similar rise in incidence with age, this reduces in the very old group, which may be due to poorer standards of diagnosis and certification or due to an increase in deaths from other causes. In 1996, Smith¹²⁶ found that although mortality rates increase with age, the relative frequency of cancer deaths declined. Almost 40% of all deaths between the ages of 50 and 69 years, but only 4% of deaths in those aged 100 years or older, were due to malignant disease. Of the 524 patients aged 100 years or older who died from malignant disease in the United States in 1990, the most common single site was the breast in 70 women, with 45 men dying of carcinoma of the prostate.¹²⁶ Similar studies in England and Wales looking at patients aged over 100 at the time of death showed a decreased mortality rate for males but a slow nonexponential increasing mortality rate in females.¹²⁷ This, however, has not been a consistent finding, since de Rijke and colleagues found in a Netherlands study that the total cancer incidence rates in both men and women were highest in the age group 85 to 94 years. Within middle-aged groups, there was a stable rate of the most common tumors, but increasing rates in the oldest age groups. Although they speculated that it might be due to a real increase as a result of changes in mortality from other diseases, they also suggested that it was caused by an artifactual increase resulting from increased cancer detection rates in the very elderly group.¹²² With increasing interest in older patients with malignant disease, the latter rather than the former seems more likely.

DIAGNOSIS

For many patients, early diagnosis is the key to improved survival. There is evidence that stage of disease varies in older subjects at presentation. In breast cancer, it has been found to be earlier in these subjects when screening is utilized and the number of cancer cases diagnosed, and confirmed by mammography in older women appears to be increasing.¹²⁸ However, many older patients delay seeking medical advice, and this may result in cancer being diagnosed at an advanced stage. The delay in diagnosis may have the same cause as the failure to participate in screening, namely a general lack of awareness of possible signs and symptoms of malignancy. Older people may still view cancer to be untreatable and to be invariably fatal. Some studies have found that elderly patients may have

difficulty accessing diagnostic interventions.¹²⁹ It must be realized that this factor is now being superseded by factors such as race, poverty, and, in some countries, insurance status.¹³⁰ Older people are significantly less likely to have their cancer verified histologically compared with younger patients.^{131–133} Death certificate only diagnosis in older patients with cancer may occur, although with better cancer registry data, this trend should reduce in all age groups.¹³⁴

The diagnostic tests offered to older patients are influenced by the medical specialty to which they are referred. Fleming and Fleming found that geriatricians were less likely to recommend mammography when compared to general physicians,¹³⁵ and older people with suspected lung cancer are less likely to be investigated by geriatricians than by chest physicians.¹³⁶ There is controversy as to whether the patient's age alone influences the method and the thoroughness of diagnostic investigations. Mulcahy et al concluded that the patient's age did not influence the method of detecting colorectal cancer.¹³⁷ However, they did find that significantly more older patients with colorectal cancer were likely to present as emergency cases with advanced disease when compared with younger patients. These emergency cases are often referred to medicine or geriatric medicine rather than surgical units, and this may be partly explained by atypical presentation and the general frailty of the patient.¹³⁸ The relative lack of investigations that are undertaken in an elderly person may be partly due to the oncologist's lack of understanding about normal aging. Geriatricians are experienced in assessing preexisting disability and concurrent disease and in understanding functional status, level of dependency, and psychological adjustment. This enables joint decisions with regard to further therapy before the rehabilitation and, it is hoped, recovery of the elderly patient with cancer.¹³⁹

With improved screening and diagnostic tests, older patients should present with an earlier stage cancer. The knowledge of and ability to treat comorbidity should ensure that older patients are just as likely to be investigated as their younger counterparts. This should be particularly encouraged in patients with tumors, where low-risk elective surgery can be undertaken and found to have similar morbidity and mortality in all age groups.¹⁴⁰

STAGE OF DISEASE

Cancer staging is an important component of management. There is little doubt that both histology and stage of the cancer are independent predictors of survival.¹⁴¹ There is a clear relationship between age and stage at diagnosis and between age at diagnosis and treatment received by the patient with cancer.^{142,143} In general, older patients are more likely to have advanced or unstaged disease when compared to younger patients,¹⁴⁴ although other factors, including greater material deprivation, also affect the age at diagnosis.¹⁴⁵ It must therefore be remembered that those older patients living in increased poverty may present later with their tumors. Although data from the 1990s¹⁴⁶ found that patients over 74 years of age were more likely to have unstaged tumors, the discrepancy between unstaged stomach cancer (26.9%) and breast cancer (2.4%) is more likely to be due to the diagnostic techniques available at this time, rather than chronologic age alone. Older patients are also more likely to have "unknown" stage at diagnosis. Bergman et al¹⁴⁷ and Martin et al¹⁴⁸ found

that older women with breast cancer were more likely to be diagnosed as stage unknown or stage 3 when compared with younger women. In contrast, Busch et al found a lower proportion of older women (≥ 75 years) with breast cancer stage 2 or unknown when compared to younger women (13.7% vs. 8.3%),¹⁴⁹ although for stages 1, 3, and 4 there were comparable proportions for both age groups.

Older women with ovarian cancer have a higher proportion of advanced disease (stages 3 and 4) than younger women, and age remains a prognostic indicator.^{150,151} As with breast cancer, there are reports that older women have the highest proportion of unstaged ovarian cancer.¹⁵²

Although there have been some conflicting data regarding colorectal cancer stage at presentation, in a study of more than 172,000 patients with colorectal cancer, unstaged tumors were more likely to be found in the older group. Ironically, survival was significantly higher in the unstaged group, except for patients who were aged 65 years or older.¹⁵³

TREATMENT

Elderly patients should receive therapy comparable to their younger counterparts, although this may not always have been the case. In the 1980s and 1990s, older people with cancer were less likely to receive definitive treatment than younger patients.¹⁵⁴ With the increasing inclusion of older individuals (although often not over 70 years of age) in cancer screening, there are few patients who should not, following assessment of comorbidity, be considered for active curative treatment. There is, however, an issue regarding the inclusion of older individuals in clinical trials. When a comparison of the 1990 incidence data from the National Cancer Institute (NCI) Surveillance, Epidemiology and End Results (SEER) program¹⁵⁵ was made to the NCI Treatment Trials, which included more than 8000 elderly patients, a significant discrepancy between the incidence of cancer and participation in cancer treatment protocols was found. Only 39% of males and 25.9% of the women involved in the trials were 65 years or older; as a result, the United States, under the auspices of the NCI, has sponsored a number of trials specifically targeting older patients. Unfortunately, cancer data from the United States including years 1995–2002 suggested that cancer treatment is not always consistent with evidence-based guidelines and pointed out that there are economic, racial, geographic, and age-related disparities in cancer treatment.¹⁵⁶ U.S. data comparing 1996–1998 with 2000–2002, showed an increase in the total number of trial participants, with only 1.3% of 65-to-74-year-old patients and 0.5% of patients aged over 75 years being represented. With increasing age participation becomes reduced.¹⁵⁷ During the 1980s and 1990s, there was evidence that age affected decision making regarding curative cancer therapy,¹⁵⁸ and many of the older drugs caused a number of adverse drug reactions, particularly in older individuals. However, when side effects of chemotherapeutic agents are considered, there is some evidence that younger patients report more nausea, fatigue, and vomiting than do their older counterparts.

The reasons behind the underrepresentation of older subjects in treatment figures are complex. The patient may not have full investigation and staging and therefore not be eligible to enter into a trial. Some argue that older patients are more likely to suffer from toxicity with chemotherapy,

although newer drugs have reduced toxicity and allow good palliation for most cancers.¹⁵⁹

As noted earlier, when side effects of chemotherapeutic agents are considered, studies have documented that younger patients report more nausea, fatigue, and vomiting than do their older counterparts.¹⁶⁰ However, Dibble et al found that vomiting immediately after chemotherapy for breast cancer was equally prevalent in younger and older age groups and delayed vomiting occurred more frequently in younger women with a larger body mass index.¹⁶¹ One possible explanation for the reduction in nausea and vomiting in older people is that younger patients have higher anxiety levels and a greater expectation of being sick.¹⁶² Other studies have confirmed that nausea expectation and younger age are risk factors for chemotherapy-induced nausea and vomiting.¹⁶³

Putative problems with compliance in older people has been cited as a reason for their nontreatment, and elderly women with breast cancer have been found not to follow the prescribed adjuvant chemotherapy, although the reasons for this were not clear.¹⁶⁴ Further planning with regard to patient education is required as more elderly people undergo complex oral chemotherapeutic regimens at home. Other studies have shown, in contrast, that older patients are more compliant with therapeutic regimens than are younger patients.¹⁶⁵

Other reasons given for the nontreatment of elderly subjects with cancer have included advanced disease at presentation, and although there is some evidence that patients over 55 years of age have more advanced disease, at presentation this is not universal.^{66,142,143,166–168}

Some doctors caring for elderly patients with cancer consider that they are less likely to wish to receive treatment than their younger counterparts. This was not the finding of Yellen and colleagues,¹⁶⁹ who used structured scenarios to assess patients' willingness to accept toxic chemotherapy to enhance survival and found that older patients were as willing to choose chemotherapy as were younger patients, though the former required a greater survival advantage before they would choose a toxic regime over a less toxic alternative.

Myths about cancer may affect treatment. If older patients believe that cancer treatments are worse than the disease itself¹⁷⁰ or they have a greater fear of cancer than younger patients do,¹⁷¹ they may decline treatment. If adequate information is given to older patients, they are likely to accept treatment in a similar fashion to younger patients^{172,173} and indeed may experience less emotional distress following the diagnosis of cancer.¹⁷⁴

Poor life expectancy in elderly subjects has been cited as a further reason for nontreatment; however, life expectancy tables should not be used to gauge who should receive therapy.

Unfortunately, many patients with cancer, irrespective of their age, consider that they have not fully participated during the treatment decision-making process. There is evidence that if patients perceive that they have been poorly involved, they have increased anxiety, which impacts on their quality of life.¹⁷⁵ However, Bilodeau and Degner found that older women with breast cancer preferred to assume a passive role in treatment decision making.¹⁷⁶ Whereas most younger women felt that stage of disease, likelihood of cure, and treatment options were the most important aspects of the information they received, older women considered that self-care issues were more important.^{176,177} The attitudes of physicians with regard to informing older people about a

cancer diagnosis may also influence the treatment that they receive. Although anecdotal evidence suggests that older people do not wish to receive a diagnosis of cancer, 80% of respondents aged 65 to 94 years wanted to be informed of a cancer diagnosis, with 70% of the respondents wanting their relatives also to be informed when the diagnosis was made.¹⁷⁸ This is in contrast to the feelings of relatives of patients with cancer, when 66% did not want the diagnosis to be disclosed.¹⁷⁹ It must, however, be remembered that collusion and nondisclosure to patients have a negative effect on those caring for the patient.¹⁸⁰

The presence of comorbidity is associated with less treatment for cancer. Following an interview of 800 patients aged 65 years or older with newly diagnosed cancer of the breast, prostate, colon, or rectum, logistic regression was used to assess factors potentially influencing the receipt of definitive treatment by each individual. The study showed that for breast and prostate cancer, there was a clear increase in the percentage of patients not receiving definitive treatment with increasing age,¹⁸¹ and in colorectal cancer, men were more likely to receive definitive therapy than women.¹⁸¹ Other studies have found factors determining nontreatment with chemotherapy to include impaired ability to perform activities of daily living, access to transportation, being unmarried, low income, and low educational achievement.¹⁸¹ Surprisingly, the presence of other medical disorders, although reducing definitive treatment, was not statistically significant in the analysis. In contrast, advanced age, impaired access to transportation, and poor functional and cognitive status showed little influence on receipt of surgical therapy.

Coexisting diseases are well documented in older patients with cancer. Approximately 25% of patients over the age of 75 years with cancer have vascular disease, and almost 10% have coexisting chronic obstructive pulmonary disease or diabetes mellitus.¹⁸² Unfortunately, patients with some coexisting diseases, irrespective of age, are less likely to receive curative treatment for their cancer.¹⁸³ It is important that such patients are included in clinical trials to determine the effect of comorbidity on treatment tolerance and survival,^{184,185} although many exclusion criteria are derived from a desire to study "pure" patients rather than the pragmatic approach, which often characterizes the specialty of geriatric medicine.

SURGERY

Surgery is considered to be the treatment of choice for most cancers, and patients should not be denied surgery on the basis of chronologic age.¹⁸⁶ Nonetheless, mortality and morbidity rates are often increased in older patients who undergo surgery for a variety of difficult cancers. Consultation and teamwork can, however, minimize mortality and morbidity.¹⁸⁷ In a review of 105 patients aged 75 years or older with a variety of recurrent solid tumors, postoperative mortality was 3.8% with a 5-year survival rate of over 40% for selected patients.¹⁸⁸ This figure is continuing to improve, and it is essential that a full assessment of patient suitability for surgery is undertaken.¹⁸⁹

Advanced age per se is often used by either the patient's family or the physician to justify not proceeding with surgery. This ageist attitude is, however, fortunately declining. Surgery for octogenarians now obtains better clinical outcomes in both cancer and noncancer patients.¹⁹⁰

In older women with breast cancer, age is often independently negatively associated with the surgery being performed.¹⁹¹ Unfortunately, primary surgical therapy varies significantly with age.¹⁹² Elderly women are less likely to receive breast reconstruction surgery than are younger women, and ageist attitudes do unfortunately continue to prevail.¹⁹²

Surgery is the treatment of choice for patients with colorectal cancer. Chronologic age should not be a reason to withhold surgery from such patients.^{187,193–195} Although postoperative morbidity may be similar in young and older patients, mortality may be up to three times higher and both cancer-specific survival and disease-free survival significantly worse in older groups, after rectal cancer surgery. The role of additional comorbidity in individuals aged over 65 may have been the cause of the long-term cancer-related survival being worse in contrast to the short-term prognosis.¹⁹⁶ Unfortunately, older patients with colorectal cancer are more likely to present with advanced disease, twice as likely to have emergency surgery, and less likely to undergo curative surgery.¹⁹⁷ Although the proportion of older patients undergoing curative surgery for colorectal cancer has increased,¹⁹⁸ this may be because surgery is performed on most patients regardless of age.¹⁹⁹

Some patients with colorectal cancer will have solitary hepatic metastases, which are usually resected in younger individuals. When analyzing data from the resection of metastases in individuals aged 75 years or older, the overall survival at 1, 3, and 5 years was 90%, 64%, and 33%, respectively, and the disease-free survival was much lower at 1 and 3 years (74% and 42%). Although the authors suggest that this may affect those selected for liver resection, many older individuals would consider a 42%, 3-year, disease-free survival as being an adequate benefit, when compared to a hospital morbidity and mortality of 10% and 3%, respectively. Older individuals wish to be actively involved in such difficult decision making and may at times surprise medical practitioners in the risks that they are prepared to take.²⁰⁰

DRUG THERAPY

The normal physiologic changes of aging affect drug absorption, distribution, metabolism, and elimination; thus, when prescribing any drug for an elderly person, drug pharmacokinetics must be considered. Elderly patients with cancer may receive a wide range of drugs including chemotherapeutic agents, analgesics, antiemetics, antibiotics, and others, in addition to drug therapy that was previously prescribed for coexisting medical disorders.²⁰¹

Although absorption is not significantly altered by age per se, some normal changes of aging do affect drug absorption. Oral drugs are modified by gastric motility and emptying time, whereas the absorption of parenterally administered drugs is dependent on local blood flow in muscles and fatty tissue. Drug distribution is affected by the decrease in total body water and albumin and the change in the ratio of lean body weight to fat. The reduction in albumin results in a greater concentration of unbound highly lipophilic drugs in the circulation able to exert their effects.

Drug metabolism is affected by decreased liver mass and hepatic blood flow as well as decreased microsomal enzymatic activity in the liver.²⁰² Elimination is affected by the

reduction in glomerular filtration rate, decreased renal blood flow, and renal tubular function, and it is particularly important with cyclophosphamide and methotrexate, which are both excreted renally.

Unfortunately, as with younger patients with cancer, many older individuals will have multiple medications, which will increase the risk of adverse drug reactions, drug-to-drug interactions, and nonadherence. Many clinical trials do little to select "typical" geriatric medicine type patients; as a result, our progress in the understanding of many of the pharmacologic issues in treating older individuals with cancer are yet to be addressed.²⁰³

CHEMOTHERAPY

Chemotherapy, often a primary systemic form of treatment for cancer, possesses either cytotoxic or cytotoxic activity.²⁰⁴ McKenna found that adverse drug reactions from chemotherapy increased sevenfold for patients over 69 years of age when compared with younger patients.²⁰⁵

Older patients are less likely to receive chemotherapy, and if treated, it is more likely to be outside a clinical trial, although this continues to improve with time. This is due partly to age restrictions on trial entry and partly to clinicians, without clinical evidence, feeling the need to reduce drug dosages in such patients. All drug therapy in elderly people is affected by altered pharmacokinetics and pharmacodynamics, and some chemotherapeutic agents pose special problems.^{39,206,207} Reduction of chemotherapeutic drug dosages may reduce toxicity at the expense of response rates, or lower response rates without any effect on toxicity, or result in better tolerance, but provide no survival advantage. Many researchers now consider that reducing doses on the basis of age alone is not justified, but data are lacking.

Other researchers have found that elderly subjects, when receiving drug dosages similar to their younger counterparts, have similar toxicity rates, although some trials do not clearly define how the patients over age 70 years were selected.²⁰⁸

A prospective pilot study by Chen et al found that although older patients undergoing chemotherapy did experience some toxicity, they could generally tolerate it with limited impact on their independence, other comorbidities, and quality of life levels.²⁰⁹ This, however, is in contrast to the views of Repetto,²¹⁰ who considered that age was such a clear risk factor for chemotherapy-induced neutropenia and its complications, particularly in the treatment of lymphoma or solid tumors that without the use of colony-stimulating factors better outcomes would not be achieved.²¹⁰ Controversy still exists as to the prevalence of hematologic toxicity in older cancer patients, with some authors finding that increasing age alone does not increase the risk of hematologic toxicity during the treatment of some common malignancies, with chemotherapeutic agents known to cause neutropenia.²¹¹ However, their paper evaluated all elderly patients of whom only about 50% of the individuals aged over 70 years received relatively full-dose chemotherapy.

To avoid unnecessary toxicity, a decision regarding dose reduction should be made on the onset of treatment, because if dose reductions vary from cycle to cycle of therapy, although tailored for individual patients, little evidence is accrued with regard to toxicity and efficacy. Although it is

difficult to establish general rules regarding the administration of chemotherapy,²¹² physicians must be aware of the diversity of levels of health among older people and tailor chemotherapy according to individual needs.²⁰⁶

Balducci and Beghe set out guidelines on the administration of chemotherapeutic drugs for older people,²⁰⁷ which include the following:

- Age 75 years defines older age for chemotherapeutic agents.
- Chemotherapeutic agents that are excreted renally should be dose-adjusted according to the patient's glomerular filtration rate.
- Hematopoietic growth factors should be used in people receiving moderately toxic chemotherapy in order to reduce the duration and severity of neutropenia.
- High-dose chemotherapeutic regimens should be avoided because the functional reserve of many older people (≥ 75 years) is decreased, and this population is more susceptible to complications of chemotherapy.
- Palliation for frail patients may include some mild form of chemotherapy.

Although Balducci and other colleagues have been keen to point out that only a minority of elderly patients should be excluded from treatment because of reduced tolerance, there is little concrete advice on who to treat and at what doses, and in those who developed toxicity, what method of assessment should be undertaken before deciding on their next dosage of chemotherapeutic agent.^{213,214} What is quite clear is that additional studies need to be undertaken to address both pharmacokinetic and pharmacodynamic changes that are present in older patients with cancer, and the need for these studies to be undertaken in not only in a systematic way but across multiple centers, to ensure that adequate numbers guide future therapy, is indisputable.²¹⁵

There is an age-dependent decrease in bone marrow stem cells, which results in increased liability to neutropenic episodes. Hematopoietic factors reduce the duration of severe neutropenia and accelerate neutrophil recovery following chemotherapy. There is no evidence that older people respond differently from younger patients to such agents.²⁰⁷

HORMONAL THERAPIES

Hormonal therapies may provide a benefit to elderly patients with advanced cancer of the breast, prostate, and endometrium. In the management of metastatic breast cancer, the beneficial effects of estrogen therapy increase steadily with age in all postmenopausal women, probably because of the increased incidence of receptor-receptor positive tumors in older women that result in an increased response rate to such therapy.

Tamoxifen (an anti-estrogen drug) prolongs survival of patients with breast cancer and also reduces recurrence rates. It is particularly useful if the tumor is estrogen-receptor positive as seen in many postmenopausal women. Tamoxifen, however, should not be used as an alternative to surgery in all but the frailest elderly patients who would not survive such treatment.²¹⁶⁻²¹⁸ Some researchers have found that tamoxifen alone appears to delay definitive treatment, and this should not be encouraged.²¹⁹⁻²²³ Although there is evidence that preoperative tamoxifen may be an appropriate

approach before breast-conserving surgery,^{173,224} its main role is in the prevention of recurrence of breast cancer in postmenopausal women. It should be administered daily for a maximum of 5 years, as there is yet no evidence for a longer duration of therapy.²²⁵

Martelli and colleagues found that elderly patients with early breast cancer and no palpable axillary lymph nodes could be safely treated with conservative surgery and adjuvant tamoxifen without the need for either axillary dissection or postoperative radiotherapy. They found during prolonged follow-up (median 15 years), 83% of the deaths were unrelated to breast cancer. This provides data that may enable some older women to choose more limited surgery and adjuvant tamoxifen over extensive surgery and postoperative radiotherapy.²²⁶ In 2008, the results of two large trials that had investigated extending tamoxifen treatment beyond 5 years were both reported. It is now suggested that following 5 years of adjuvant tamoxifen, an aromatase inhibitor is used for a further 4 years in postmenopausal women.^{227–229}

RADIOTHERAPY

If a tumor is radiosensitive, radiotherapy may be appropriate and have positive results for older patients in good health.^{199,205,230}

Organ-specific tolerance to radiation is related to aging. Lymphocytes from both elderly experimental animals and humans are more susceptible to damage induced by ionizing radiation. When radiotherapy in elderly patients is palliative in intent, it is important that minimal toxicity is experienced. However, radiotherapy can be highly effective, with many older patients completing the treatment with no serious complications. Radiotherapy may be used at times with curative intent, particularly in early stage non-small-cell lung cancer which is inoperable. In such cases, a large fraction size can be given safely, even in older individuals.²³¹ Zachariah et al found that 94% of patients aged 80 years or older diagnosed with cancer of the head and neck, lung, pelvis, or breast tolerated and completed the planned course of radiotherapy, be it either curative or palliative, without serious complications.²³² Palliative radiotherapy is particularly good in patients with lung cancer, whose symptoms include hemoptysis, although it is less effective for the more common symptoms of dyspnea and cough. In such groups, side effects are often few and usually mild, with the majority of older patients tolerating delivery of their radiotherapy over 1 week.²³³ Unless the patient is severely debilitated, there is no reason to modify a potentially curative approach.²³⁴ When radiotherapy is being used for the treatment of cancer pain, there is no evidence that age influences the efficacy of such treatment, and factors such as the pain score before the onset of radiotherapy, or the presence of radiating pain, are much better predictors of who will benefit from the treatment.²³⁵ Follow-up of such patients is often difficult, and the use of an Edmonton Symptom Assessment System (ESAS) by telephone follow-up may be more appropriate for older individuals.²³⁶

With regard to breast cancer, age unfortunately remains an independent factor that determines those patients who will receive postoperative radiotherapy, even after adjusting for other variables, including stage.²³⁷ In breast cancer, patients who received adjuvant radiotherapy are generally younger, have fewer comorbidities, and are more likely to be white,

married, and from an urban area. However, they are also more likely to have a surgeon who is female and who has a higher medical degree.²³⁸ In the future, other factors may influence which older women undergo radiotherapy, and age may become less of an issue. Even in the twenty-first century, older women continue to be less well represented when considering postoperative radiotherapy following breast cancer.^{39,239}

Myelosuppression may be problematic as elderly patients have less functional bone marrow and a slowed recovery of normal tissue. Fatigue may result in compliance problems, and radiation may result in dry skin that is more susceptible to infection.²⁴⁰ The normal aging of the gastrointestinal tract may result in increased susceptibility to anorexia and stomatitis following radiotherapy.²⁴¹

The more commonly seen radiation side effects that occur in elderly subjects are predicated on preexisting conditions; thus, radiation to emphysematous lungs will increase dyspnea, and irradiation of the mediastinum will impair declining left ventricular function. Compliance with radiotherapy in elderly subjects is additionally hampered by multiple visits and traveling. The use of split fractions does, however, reduce toxicity and is essential in the treatment of many tumors in older patients.

Patients with Non Small Cell Lung Cancer (NSCLC) who are unfit or refuse surgery may receive radiotherapy as an alternative treatment. Patients who accept radiotherapy, tolerate it well and consider it an acceptable treatment.²³³

Radiotherapy is a well-established and potentially curative treatment for small volume prostate tumors. It is often the preferred treatment because it carries fewer complications than surgery, and in some series 15-year disease-free survival rates of up to 85% have been achieved.^{242,243} The median age of patients with prostate cancer treated with radiotherapy is increasing,²⁴⁴ and more sophisticated single-session radiotherapy is now being used in younger men to provide curative treatment. It must be hoped that such methodologies can in the future be implemented in older men, as data suggest that morbidity may be considerably reduced compared to surgery.²⁴⁵

NURSING CARE

Unfortunately, elderly patients with cancer often have comorbidity, and this together with their socioeconomic status will influence the treatment that they receive.²⁴⁶ Patients with cancer will have a variety of symptoms, and many report fatigue, which may be particularly difficult to treat in elderly patients with comorbidity.²⁴⁷ Quality of life has become a more important outcome measure for cancer patients. This coupled with disease-free and overall survival time must be carefully considered in older individuals and should be an outcome measure that nurses caring for such patients should note.²⁴⁸

Ageism is an important adverse influence on the prevention and diagnosis of cancer, but also in the nursing care of elderly patients with cancer, and nurses are just as likely as others to be biased by ageism.²⁴⁹ This may be due to the inadequate preparation of nurses²⁵⁰ or to a perceived lack of attractiveness of a gerontologic career.²⁵¹ The nurse may view cancer prevention to be unnecessary, may promote dependency and learned helplessness, and may minimize the need for referral to clinicians or community resources.²⁵⁰ Nurses caring for elderly patients on general medical wards will see the three symptoms—pain, fatigue, and insomnia—as

being particularly prevalent in everyday geriatric medicine. These are the most prevalent, distressing, and often under-managed symptoms that cancer patients experience.²⁵² When they occur together, they are associated with adverse outcomes and are often first detected by nurses.²⁵²

The experience of cancer for both the patient and family is stressful, and although many treatments for cancer can be given on an outpatient basis, many require prolonged hospitalization. Upon discharge to the community, much of the physical and psychological care of the patient is placed on the family. This puts an enormous stress on elderly patients and their caregivers. Not surprisingly, there is a high correlation between severity of symptoms and impact on activities of daily living.²⁵³ Although younger cancer patients are more likely than older patients to need help with relieving distressing symptoms, elderly patients do report distressing symptoms and therefore should not be excluded from specialist palliative care services on the basis of their age. Somewhat surprisingly, Addington-Hall and colleagues found that cancer patients did not show increased independence with age, thus stressing the importance of access to both social services and community health services for cancer patients of all ages.²⁵⁴ Many patients with cancer have depressive symptoms,²⁵⁵ and there is a positive correlation between patients' self-care needs and mood.²⁵⁶ Age is an important determinant in decision making when patients present with advanced stage cancer, although, surprisingly, whereas older patients have more comorbidities, they often have lower levels of depression, anxiety, and symptom distress. Their views about treatment goals focus on pain relief and comfort, but they receive fewer prescriptions for opioids.²⁵⁷ This finding was confirmed by Kurtz et al,²⁵⁸ who assessed the mental health of patients and family members and found that of the 208 patients in the study, 83 of whom were aged 65 years or older, the most common five symptoms were fatigue, pain, nausea, poor appetite, and constipation. In this study there was no relationship between age and level of symptoms, although older people tend to underreport and this may counteract a genuine age-related increase in symptoms.

Caregivers are more likely to be wives than husbands and to care single-handedly. Wives provide twice the hours of care that husbands provide, although this is compensated by female patients having more outside care than males.²⁵⁹ Unfortunately, when illness or treatment results in restricted activity, when finance is limited, or when caregivers are not spouses, patients with cancer are more likely to report unmet needs.²⁶⁰ Using data from noninstitutionalized elderly people without cancer, there is further evidence of married, disabled women receiving fewer hours per week of informal home care than do married, disabled men, again stressing the need to target resources, particularly to married, disabled women who without the input of their children may be deficient in necessary care.²⁶¹ When the patient was younger, the caregivers tended to be more depressed, and caring had a greater impact on the caregiver's schedule; friends did provide more support to the caregiver. In 82% of cases, the caregivers were spouses of the patients, and it is likely, therefore, that elderly spouses will be solitary caregivers and have little support from other friends and relatives.²⁶² Elderly caregivers require counseling, but this may present logistic difficulties. The use of telephone counseling is of potential value and removes the need for transport and alternative care arrangements.²⁶²

REHABILITATION

Where data are available on elderly patients following treatment for cancer, functional status assessment is usually via the Karnofsky performance status. This, however, is not specific to older subjects and ignores many of the more important activities of daily living that are included in the well-validated rating schemes that geriatric frequently use. Without accurate clinical assessment of older people with cancer, rehabilitation cannot be targeted. The role of comorbidity scores is limited, and therefore there is a need for an overarching comprehensive assessment.²⁶³

SURVIVAL

Relative survival is lower among older people with cancer than among their younger counterparts. There are many possible explanations for these differences, and these include the tendency for cancer to be diagnosed at a later stage in older subjects and differences in the treatments received by elderly patients. Other age-related factors, such as comorbidity, obviously alter outcome.^{264,265}

With better diagnosis through screening methodologies, early evidence-based interventions, and good post-therapy care including rehabilitation, older patients will continue to benefit. The development of specialized shortened questionnaires for cancer patients will additionally facilitate the identification of symptoms that require palliation.²⁶⁶ All clinicians caring for older people must consider that it is often much worse for patients not to understand some of the areas that clinicians find difficult to deal with. Patients wish to know the mode of disease progression, the mode of death, and the prognosis and are more content with realistic versus unrealistic timescales. In addition, a prognosis does not in itself cause depression, and therefore collusion and physician anxiety must not detract from information-giving, particularly with older patients.²⁶⁷ Novel delivery of specialized care may be more appropriate to older patients, many of whom wish to remain at home. This not only improves quality of life, but there is evidence that it also improves survival.²⁶⁸ In addition, near-death patients are often prepared to undergo chemotherapy even for very small gains, and this may be particularly so in older cancer patients.²⁶⁹

KEY POINTS

Geriatric Oncology

- Older people commonly develop cancer, which is poorly investigated and treated.
- The incidence and prevalence of cancer is increasing in those over 70 years of age.
- There is evidence for screening for certain tumors even in old age.
- Progress has been made in various therapy modalities, although older people need careful pretreatment assessment.
- Caregivers of people with cancer are also often elderly and may need particular support to enable them to fulfill a caring role.
- Although the links between aging and cancer are well documented, it is important to promote primary prevention in this age group.
- Validation of palliative care protocols in this elderly age group will support end-of-life care.

Skin Disease and Old Age

Gopal A. Patel
Gangaram Ragi
W. Clark Lambert
Robert A. Schwartz

INTRODUCTION

Aging affects all organ systems, including the integument. Cell replacement, sensory perception, thermal regulatory function, and immune defense systems are among the many components compromised. The skin appearance changes, depending on environmental and genetic factors. The psychosocial impact, including cosmetic disfigurement and social stigma, in addition to vulnerability to skin disease, must be addressed in elderly patients. The role of the physician is to diagnose, treat, and guide patients through this visible component of aging, while preventing avoidable disease.

EPIDEMIOLOGY

The U.S. population that is older than 65 is greatly expanding. Skin complaints constitute a significant and growing portion of geriatric ambulatory patient visits. A 2005 study in the United States demonstrated that 21% of all patients seen by family practitioners had a skin problem. Seventy two percent of the time it was their primary complaint.¹ Also in 2005, the National Ambulatory Medical Care Survey showed that the number of outpatient visits was highest in the 45-to-64-year-old age group, a shift up from the 1995 survey, suggesting increasing medical use by the baby-boomer population, which is now entering the 65-and-older bracket.² Among all patient age groups, 1 in 20 visits to an outpatient office are of skin, hair, or nail concern.² Diseases such as cutaneous melanoma are on the rise, with lifetime risks shifting from 1/250 in 1980 to 1/65 in 2002 based on a U.S. population study.³ These data emphasize the importance of skin disease recognition in the elderly.⁴ Skin cancer, for example, is often preventable and with early diagnosis can be 100% curable. Also, the role of cosmetic services and the impact on psychosocial well-being that can be traced to skin disease is of added concern.

APPROACH TO THE PATIENT

A complete medical history is desirable for the skin disease patient, regardless of age. One should pay attention to medicines or chemicals used, including topical, systemic, cosmetic, or complementary and alternative ones. The duration of a complaint, previous therapy, close contacts, and patient opinions on etiology may assist or obfuscate diagnosis and treatment. Hygiene, including bathing and laundering habits, should be assessed. Geriatric patients should undergo a thorough skin evaluation under good lighting.

Older patients often have trouble with medication compliance. Dermatologic treatments are further challenging because of their frequent topical nature. Patients may need to apply creams on difficult-to-reach areas (e.g., feet, back) or may be immobilized. Shampooing, showering, or complicated treatment regimens can confuse and challenge

geriatric patients. The clinician needs to be aware of all these barriers and accommodate accordingly.

SELECTED SKIN CONDITIONS

KEY POINTS

Skin Disease and Old Age

- Skin diseases are common in the elderly, and though rarely deadly, may degrade quality of life.
- Skin cancer is increasing in incidence in light-skinned Americans and is curable if diagnosed early.
- Xerosis and pruritus are the most common complaints of the elderly and may be manifestations of many systemic diseases.
- Early treatment, within 3 days of onset, is most effective for herpes zoster patients.
- Tobacco use and unregulated sun exposure are major preventable factors in skin cancer predisposition and skin aging.

Eczematous disorders

The geriatric patient population's chief complaint is often of a pruritic (itchy) rash or lesion that turns out to be an eczematous disease. The prevalence of eczema is between 2.4% and 4.1% in the U.S. population.⁵ In the elderly, natural aging of the skin predisposes patients to eczematous diseases. In a Turkish study of more than 4000 patients, eczematous disorders constituted nearly 22% of diagnoses in the 65-to-74-year-old age group.⁶

XEROSIS (ECZEMA CRAQUELÉ, ASTEATOTIC ECZEMA)

Xerosis describes rough or dry skin, which is seen in almost all elderly persons. Conditions of low humidity, such as artificially heated rooms, especially forced hot air heating, exacerbate this condition. Xerosis is actually a misnomer, as water is not absent throughout the entire thickness of the skin. There is only diminished hydration in the superficial corneum.^{7,8} Xerosis has also been misclassified as a sebaceous gland disorder. Though sebaceous gland activity decreases with age and thus depletes the skin's moisture, it only plays a partial role in xerosis development.⁹ Other factors include an irregular epidermal surface caused by maturation abnormalities. Deficits in skin hydration and lipid content impair normal desquamation, leading to formation of the skin scales that characterize xerosis. Furthermore, old age results in altered lipid profiles and in decreased production of filaggrin, which are filament associated proteins that bind keratinocytes. Both features contribute to xerosis.⁸

Xerosis may appear scaly with accentuated skin lines, often occurring on the anterior legs, back, arms, abdomen, and waist. The scales are a result of epidermal water loss, and focal dryness may be deep enough to cause bleeding fissures.

Superimposed pruritus is possible, leading to secondary excoriations, inflammation, and lichen simplex chronicus.⁸ Allergic and irritant contact dermatitis may also complicate xerosis. Secondary infection may follow a break in the skin barrier.¹⁰ Xerosis is also a secondary feature of many of the selected conditions in this chapter.

Untreated xerosis progresses to flaking, fissuring, inflammation, dermatitis, and infection. Topical emollients make dry skin more comfortable and avoid such complications. Alpha-hydroxy acids (e.g., 12% ammonium lactate) are helpful because of their keratolytic nature, though some patients report stinging and irritation.¹¹ Formulations containing ammonium lactate or other alpha-hydroxy acids help to restore barrier function and improve xerosis.¹² Liberal use of moisturizers throughout the day is recommended. Topical steroids (classes III and VI) are recommended in moderate to severe cases, along with antipruritics for symptomatic itching. Further recommendations include decreasing hot water baths, reducing use of soap or harsh skin cleansers, avoiding rough clothes on the skin, utilizing humidifiers in dry environments, or adding emollient substances, such as oatmeal, to bathwater.

Simple xerosis is a common cause of pruritus in the elderly. Asteatotic eczema is a dermatitis superimposed on xerosis that often flares in the winter. It is dry, scaly skin, sometimes resembling, in extreme cases, cracked porcelain with bleeding from damaged dermal capillaries. The cracked porcelain, or "crazy paving," pattern is best termed eczema craquelé.¹³ Asteatotic eczema is a common condition on the shins of geriatric patients, though it is also seen on other regions of the body. Several associations of asteatotic eczema exist: one related to hard soaps, one to corticosteroid therapy, one to neurologic disorders, and an idiopathic one often located on the shins of elderly patients. Prevention is the key to controlling this entity. Contributing factors include cleansers used, frequency of showers, diet, medications, and temperature exposure. Specifically, patients should reduce hot showers and irritant detergents. Creams, humidifiers, and topical steroids can improve the effects of asteatotic dermatitis.¹³ Alcohol-based lotions feel good just after application but eventually cause increased dryness and should be avoided.

SEBORRHEIC DERMATITIS

Seborrheic dermatitis typically manifests as an erythematous and greasy-like scaling eruption, usually affecting areas with abundant sebaceous glands, including the scalp, ears, central face, central chest, and intertriginous spaces.¹⁴ When present in the scalp, it tends to cause flaking known as dandruff. It may also appear as marked erythema over the nasolabial fold during times of stress or sleep deprivation. Seborrheic dermatitis is found in greater frequency with neurologic conditions such as Parkinson's disease, a concern in the geriatric population.¹⁵ Facial nerve injury, spinal cord injury, syringomyelia, and neuroleptic treatment are also associated with seborrheic dermatitis.

The pathogenesis of seborrheic dermatitis, though controversial, has been attributed to the yeast *Malassezia* species (*Malassezia furfur*, *Malassezia ovalis*), formerly known as *Pityrosporum*.¹⁶ This yeast is a normal inhabitant in more than 90% of healthy adults, but when overgrown it can be proportionally related to the severity of seborrheic dermatitis. Treatment options against *Malassezia* species have been effective for

seborrheic dermatitis, supporting a causal relationship. Antifungals along with topical steroids are utilized, such as ketoconazole cream or shampoo and hydrocortisone valerate cream.¹⁴ Furthermore, topical ketoconazole has inherent anti-inflammatory properties. One classic study comparing these two agents determined that 2% ketoconazole cream was 80.5% effective in resolving seborrheic dermatitis, as opposed to 94.4% efficacy with 1% hydrocortisone cream.¹⁷ Though not as good as hydrocortisone, ketoconazole serves as an effective steroid sparing agent. The calcineurin inhibitors tacrolimus and pimecrolimus are macrolide immunosuppressants that are alternative agents for use on the face, to again reduce the use of steroids in this sensitive area. A 2008 randomized prospective controlled study comparing 1% pimecrolimus cream and 2% ketoconazole cream showed equal efficacy between the two, but there were greater side effects with pimecrolimus.¹⁸ Side effects included burning, itching, and redness. Both tacrolimus and pimecrolimus have a black box label by the U.S. Food and Drug Administration (FDA) warning of skin cancer or lymphoma formation in some patients using this drug, though an established link remains controversial.¹⁹ Shampoos with ketoconazole, selenium sulfide, salicylic acid, zinc pyrithione, or tar are also effective for seborrheic dermatitis in hair-bearing regions.²⁰

Pruritus

Elderly patients often experience localized or generalized pruritus, which can be severe. The cause of itching in elderly patients is often difficult to determine. Renal, hematologic, endocrine, cholestatic, allergic, infectious, and malignant causes all potentially contribute to the elderly patient's itch.^{21,22} Some of these are addressed here (Table 95-1).

Physiologically, specific C-fiber neurons that terminate at the dermoepidermal junction transmit the itch sensation to the brain. These fibers possess receptors sensitive to histamine, neuropeptide substance P, serotonin, bradykinin, proteases, and endothelin. Rubbing or scratching further stimulates these receptors.²³ As the itch and scratch cycle progresses, the skin is driven to a point of barrier function compromise, which is worrisome in elderly patients with limited means of self-care.

Table 95-1. Systemic Diseases Causing Pruritus

Uremia
Cholestasis
Pregnancy
Cancers (including lymphoma, leukemia, and multiple myeloma)
Polycythemia vera
Thyroid disease
Iron deficiency anemia
Diabetes mellitus
HIV infection
Multiple sclerosis
Drug hypersensitivity
Psychogenic causes
Senile pruritus
Sjögren's syndrome
Carcinoid syndrome
Dumping syndrome

Pruritus is one of the most distressing concerns of a patient suffering from cholestasis. The exact cause of pruritus in this disease is unknown, though an altered role of opioid receptor function has been suggested.²⁴ Treatment of the underlying disease process often resolves itching. However, some diseases, such as primary biliary cirrhosis (PBC), cannot easily be cured. Ursodeoxycholic acid (UDCA) treatment for PBC often does not resolve the patient's pruritus.²⁵ Cholestyramine, rifampin, naloxone, and phenobarbital are other agents utilized for pruritus, all of which have substantial side effects in the elderly.²⁶

Generalized pruritus is recognized as a key marker of underlying malignancy, particularly lymphomas and leukemias.²⁷ Generalized pruritus is noted in up to 30% of patients with Hodgkin's disease and may be the only presenting symptom.^{28,29} Pruritus is also a noted feature of multiple myeloma, polycythemia rubra vera, Waldenström's macroglobulinemia, and malignant carcinoid.³⁰

Pruritus is best resolved by identifying and treating the underlying systemic etiology. Unfortunately, nonspecific therapies must often be employed for elderly patients with atypical disease presentation. Emollients are valuable interventions regardless of suspected etiology, as some level of pruritus exacerbating xerosis is present in most elderly patients. Topical use of alcohol, hot water, or harsh soaps and scrubbing must be discouraged. Proper humidity, cool compresses, nail trimming, and behavior therapy may all improve the itch and scratch cycle.²³ Topical anesthetics such as benzocaine and dibucaine have been utilized for relief. A trial of oilated soap and antihistamines may also be helpful before an invasive workup, including hematologic studies, imaging for malignancy, skin biopsy, skin scrapings, skin culture, and HIV tests.³⁰ Antihistamines should be used with caution as they are not universally effective and may cause sedation in the vulnerable and often highly medicated elderly patient.

Vascular-related disease

STASIS DERMATITIS

Stasis dermatitis is a common condition affecting 15 to 20 million patients over age 50 in the United States.³¹ It often presents as a circumscribing dermatitis around the calf and ankle in patients with chronic venous insufficiency and venous hypertension. However, any body area constantly under pressure against a hard surface may be impacted. Pitting edema may be present in addition to loss of hair, waxy appearance and yellow-brown pigmentation.³² If untreated, stasis dermatitis may progress to a chronic nonhealing wound with erythema and oozing. Stasis dermatitis results from poor function of the deep venous system in the legs, which leads to backflow and hypertension in the superficial venous system.³³ Often both lower legs show stasis dermatitis. An associated self-perpetuating cutaneous inflammatory response follows.³³ Workup includes venous Doppler studies to identify flow in the involved venous plexus.

Several treatment approaches are useful in resolving stasis dermatitis. Compression of the legs to control superficial venous hypertension is critical. This can be achieved by the use of Unna boots, compression stockings, or elastic wraps. In one study of more than 3000 patients, those with stasis dermatitis had a compliance of 46% for the use of compression stockings.³⁴ Leg elevation 6 inches above the level

of the heart during sleep also improves blood flow. Topical treatments include corticosteroids and the calcineurin inhibitors, pimecrolimus and tacrolimus. Corticosteroids have an associated risk of tachyphylaxis and must be used carefully because of the high risk of infection in these patients.^{35,36} Topical antibiotics such as bacitracin, neomycin, or polymyxin B may be added if there is evidence of skin barrier compromise and infection.

For more information on stasis ulcers please refer to Chapter 38.

CHERRY ANGIOMAS (CHERRY HEMANGIOMAS, CAMPBELL DE MORGAN SPOTS)

Cherry angiomas are the most common vascular proliferations of the skin and are nearly ubiquitous after age 30. They appear as firm, smooth, and red colored papules ranging in size from 0.5 mm to 5 mm. They may also appear as a myriad of tiny spots resembling petechiae. Though patients may be concerned with a new cherry angioma, the condition is benign. Cosmetic concern may merit electrocautery or laser coagulation treatment.³⁷

VENOUS LAKES

Venous lakes are dark blue to violet colored papules that occur on sun-exposed areas of elderly patients. They are compressible lesions common on the face, lips, and ears. The differential diagnosis includes blue nevus and malignant melanoma. Venous lakes are benign lesions and treatment is for cosmetic purposes or bleeding. Electrodesiccation, excision, or lasers may be used to remove venous lakes.³⁸

Infectious diseases

HERPES ZOSTER (SHINGLES)

Herpes zoster (shingles) is a reactivation of the varicella-zoster virus, the causative agent of varicella. It is a significant ailment of the geriatric population, constituting 690 to 1600 cases per 100,000 person-years in the 60-and-older age group.³⁹⁻⁴¹ The varicella zoster virus remains latent in the dorsal root ganglia of the nervous system after its initial infection usually resolves in childhood.^{42,43} A weakening or impaired immune system is thought to precede reactivation, so underlying conditions such as lymphoma, leukemia, and possible HIV disease should be considered. Local steroid injection has also been associated with a herpes zoster flare.⁴⁴ Herpes zoster begins as a prodromal sharp pain localized to a dermatomal region, followed by a rash and vesicular eruption. Itching, burning, and weakness of muscles associated with the involved nerve may be noted. More than 20 vesicles outside of the primary dermatome suggest disseminated zoster, as may be seen in immunocompromised patients⁴⁵ or patients with granulocytic lesions. The long-lasting pain of zoster may be mistaken for gallbladder, kidney, or cardiac pain depending on location. Chronic pain or chronic pruritus localized to the dermatome may follow. These are known as postherpetic neuralgia (PHN) or postherpetic itch, respectively.⁴⁶

Herpes zoster is diagnosed by a Tzanck smear of a sample scraped from the base of an intact vesicle. Appearance of multinucleated giant cells may indicate a herpetic infection. Treatment of herpes zoster includes early antiviral therapy, within 72 hours of onset. Acyclovir is a safe but variably efficacious agent, though famciclovir is also used. In one double-blind,

randomized group study of 55 patients, it was found that famciclovir was well tolerated and had a more favorable adverse event profile than acyclovir.⁴⁷ Valacyclovir is an L-valanine ester form of acyclovir and is converted to acyclovir in vivo. It provides three to five times the oral bioavailability of acyclovir and has been shown in clinical trials to better reduce pain severity.⁴⁸ In 2006, the FDA approved the use of zoster vaccine live (Zostavax) for the prevention of shingles in immunocompetent patients over 60 years of age. According to the multicenter Shingles Prevention Study, vaccine administration reduces incidence, burden, and PHN complications in elderly patients.⁴⁹ Oral antibiotics covering staphylococci and streptococci are used to control secondary infection.⁴²

PHN is most evident in the elderly, and 10% to 18% of zoster patients develop this neuralgia according to a community-based study in the United States.⁵⁰ Treatment is more challenging for PHN and requires concomitant use of pain medication, such as topical capsaicin. Prompt prescription of analgesia, recommended when zoster is still active, often reduces long-term negative outcomes for PHN.⁵¹

SCABIES

Scabies is among the oldest recognized infections to occur in humans, with more than 300 million yearly cases detected worldwide.^{52,53} A U.K.-based study showed an incidence of 788 per 100,000 person-years of scabies.⁵⁴ Risk factors include nursing home residence, especially older (>30 years) and poorly staffed (>10:1 bed to health care provider) institutions.

The causative agent for scabies is the mite, *Sarcoptes scabiei*, whose life span is about 1 month. Transmission requires direct skin contact or indirect contact with bedding or clothing. Once the pregnant female mite is on a new host, she digs into the skin to lay eggs. The eggs, saliva, feces, and the mites themselves lead to a delayed type IV hypersensitivity reaction from 2 to 6 weeks after contact so that, at onset, multiple lesions are typically seen. These immune reactions lead to intense pruritus. In previously infected patients, the immune system response may present in 1 to 4 days after contact.⁵⁵

Scabies manifests as papules, pustules, burrows, nodules, and also urticarial plaques. Severe pruritus impacts most patients unless they are immunocompromised.⁵⁶ In the latter case, scabies may resemble psoriasis or a hyperkeratotic dermatosis. The infection is not life-threatening but is often debilitating and depressing. Common areas infected include the finger webs, wrists, waistline, axillary folds, genitalia, buttocks, and nipples.⁵⁷ An area of concern should be scraped and microscopically examined for mites. Early confirmation is imperative to avoid secondary infection and rapid spread in the susceptible nursing home environment.⁵⁸ Treatment includes permethrin cream or rinse, which should be applied to all areas of the body for an 8- to 14-hour period. Mild burning, stinging, and rash may develop. Lindane cream, crotamiton, and sulfur have been utilized previously but with less efficacy. Ivermectin is an alternative agent with the benefit of oral administration, but the FDA has not officially approved its use for scabetic infection.⁵⁶ It is particularly helpful in cases of scabetic resistance to permethrin, though cases of ivermectin resistance are also documented.^{59,60} Pruritus and inflammation may be handled with steroids and antihistamines.⁶¹

PEDICULOSIS

Parasitic lice are known to infest hair-bearing areas of the human body. Louse infection, or pediculosis, affects up to 12 million Americans each year. The offending human agents include *Pediculus humanus humanus*, *Pediculus humanus capitis* (larger body louse), and *Phthirus pubis* (pubic louse).⁶² Similar to scabies, transmission may be direct or indirect through brushes, clothing, or bedding. Higher levels of crowding increase transmission rates, as seen in some nursing homes. Pathogenesis involves deposition of eggs (nits) on hair shafts and subsequent hatching under conditions of 70% humidity and temperatures of 28°C or higher.⁶¹

The main symptom of lice infestation is pruritus.²¹ Bite reactions, excoriations, lymphadenopathy, and conjunctivitis are other possible manifestations. Hair combing may be associated with a "singing" sound because of the interaction of the tines with the nits. Red bumps on the scalp that progress to crusting and oozing are noted in *Pediculus humanus capitis*. Pediculosis is further complicated by the potential of co-transported infections. Diagnosis is established by visualization of the lice or nits. This often requires a good light source and use of a comb to expose the hair. The difficult-to-remove nits on the hair shafts appear as white specks on examination.⁶² Prevention is the best way to address lice infestations, such as avoiding continued contact with an infested individual. Chemical pediculicides—including permethrin, malathion, lindane, pyrethrin—are the main treatment modalities. These treatments should be repeated every 7 to 10 days and, because of increasing resistance, must often be rotated.⁶³ "Bug busting" with a wet comb and conditioner has limited efficacy. Dimethicone has recently been shown to treat pediculosis in a randomized controlled study where 69% of patients were cured, and only 2% had irritant reactions.⁶⁴ More studies are necessary for widespread recommendation of this treatment. All family members and contact persons should be included in therapy and prevention during patient treatment.

ONYCHOMYCOSIS

Fungal infections are among the most prevalent integumentary concerns in the elderly, and onychomycosis is a leading entity. Defined as a fungal infection involving the nail and nail plate, over 90% of onychomycosis is attributable to dermatophytes, known as *tinea unguium*, and 10% to non-dermatophytic molds or *Candida*. The prevalence of onychomycosis has been estimated at almost 6.5% in the overall Canadian population.⁶⁵ Studies have shown that onychomycosis increases with age, possibly because of poor circulation, diabetes, trauma, weakened immunity, poor hygiene, and inactivity.⁶⁶ Some studies have shown the prevalence of onychomycosis in patients over 60 years of age to be 20%.⁶⁷

Several classifications of onychomycosis exist, including distal-lateral subungual, superficial white, candidal, and proximal subungual. Distal-lateral subungual onychomycosis is the clinically most common type, often caused by *Trichophyton rubrum* invasion of the hyponychium, the white area at the distal edge of the nail plate. The nails become yellow and thick with parakeratosis and hyperkeratosis leading to subungual thickening and onycholysis. Superficial white onychomycosis is often associated with HIV infection and appears as a chalklike white plaque on the dorsum of the nail.⁶⁸ The proximal subungual type is also relatively

uncommon and may present in either immunocompetent or immunocompromised patients. In this case, the infection penetrates near the cuticle and migrates distally resulting in hyperkeratosis, leukonychia, and onycholysis. *Trichophyton rubrum* is again the most causative agent. Candidal onychomycosis is seen in patients with chronic mucocutaneous candidiasis.⁶⁶

A patient history, physical examination, microscopy, and culture are all critical to diagnosis. Onychomycosis is best diagnosed by clipping the toenail very proximally and scraping the newly exposed subungual debris for laboratory evaluation. Toenails are 25 times more likely to be infected than fingernails.⁶⁶ Typical presentation involves two feet and one hand (the dominant hand of a patient).

Treatment options include topical and systemic medications along with surgical approaches. A surgical trimming and debridement may be effective initially. Systemic therapy includes griseofulvin, fluconazole, itraconazole, or terbinafine.⁶⁹ Multiple double-blind controlled studies have shown terbinafine to be more effective than fluconazole or itraconazole for dermatophyte infections.^{70–75} Systemic antifungals may have significant contraindications in patients on other medications. Topical treatments have poorer penetration and thus are less effective. Newer treatments are being investigated, such as AN-2690 by Anacor Pharmaceuticals, which allows for deeper penetration of topical therapy.⁷⁶

Cutaneous cancer

KEY POINTS

Skin Cancer

- Current rates suggest that one in five people in the United States will develop skin cancer in his or her lifetime.
- Basal cell carcinoma is the most common type of skin cancer and the one least likely to metastasize.
- Melanoma comprises 4% of skin cancers, and suspicion is guided by ABCDE criteria (asymmetry, border irregularity, color variegation, depth, and evolution of lesion).
- Actinic keratosis is considered to be a precancerous form of squamous cell carcinoma, though its classification as malignant neoplasm is debated.
- All patients would use a dermatologist-recommended sunscreen appropriate for their skin type and should avoid sun exposure during the peak hours of sunlight.

Skin cancer is an increasingly important public health issue for the geriatric population. Current rates demonstrate that one in five people in the United States develop skin cancer at some point in their lifetime, with melanoma incidence increasing faster than any other cancer worldwide.⁷⁷ The economic burden of skin cancer is substantial in the United States.⁷⁷ The risk of skin cancer has been related to ultraviolet exposure, which has varying roles in basal cell carcinoma, squamous cell carcinoma, and melanoma pathogenesis. The use of sunblock, avoidance of peak hours of sunlight, and proper clothing are simple preventive measures all patients, young and old, can follow. Early detection is critical in the elderly patient, as a 100% cure rate is possible.⁷⁸

ACTINIC KERATOSIS

Actinic keratosis (AK), or solar keratosis, may be defined as a premalignant precursor of squamous cell carcinoma or an incipient cutaneous squamous cell carcinoma.⁷⁹ There are about 5.2 million physician visits annually for AKs in the United States, 60% by the Medicare population.⁸⁰ These precancers are most common in light-skinned populations with year-round sun exposure who have not used appropriate sunscreens. Areas most affected include the forehead, scalp, ears, lower lip, forearms, and dorsal aspect of the hands.⁸¹

AK development is attributable to ultraviolet (UV) radiation-induced DNA mutation in select keratinocyte genes. With time, AKs may develop into invasive squamous cell carcinomas. They appear as small, skin-colored to yellowish-brown macules or papules, often with a dry adherent scale. They may feel rough to palpation, reminiscent of sandpaper, though are asymptomatic in most patients.⁸² If an AK becomes painful, indurated, eroded, or greatly erythematous, squamous cell carcinoma transformation must be highly suspect. AKs may also proliferate and become exophytic so as to constitute a "cutaneous horn." This is particularly evident on the ear.⁸³ Treatment for few and discrete AKs is best performed with cryosurgery (liquid nitrogen), which approaches near 100% effectiveness and is convenient and economical. Topical treatment includes 5-fluorouracil, imiquimod, diclofenac, and photodynamic therapy with a light-sensitizing compound.⁸¹ Sun safety practice is helpful for prevention, such as proper coverage and limited outdoor activity between 10 AM and 4 PM.

SQUAMOUS CELL CARCINOMA

Squamous cell carcinoma (SCC) is a cancer arising from the epithelium, with an estimated 200,000 cases diagnosed each year.⁸⁴ SCC is often separated into two groups based on malignant potential. The more common type develops from sun-damaged skin and AKs and is less likely to metastasize. For people in this group, the lifetime risk of having SCC after developing a single AK is between 6% and 10%.⁸⁵ The more aggressive type arises from areas of prior radiation or thermal exposure, chronic drains, chronic ulcers (Marjolin's ulcer), and mucosal surfaces. In general, prolonged UV radiation exposure induces DNA damage and subsequent carcinogenesis in select keratinocytes leading to SCC formation.⁸¹

SCCs arising from AKs often appear with a thick adherent scale. The tumor is soft to hard, locally movable, and has an erythematous, inflamed base. SCCs are frequently found on the same areas noted for AKs. If a SCC is diagnosed on a mucous membrane or on non-sun-damaged skin, it may be aggressive and can rapidly metastasize to regional lymph nodes. An SCC described as firm, movable, and elevated with minimal scale and a sharp border is usually derived from actinically damaged skin but not typically from a precursor AK. The differential diagnosis for SCC is wide, including seborrheic keratosis, melanocytic nevus, AK, and chromomycosis. Diagnosis is established by skin biopsy. When SCC is in situ, it is commonly known as Bowen's disease.⁸¹ However, what Bowen originally described is slightly different and includes the presence of large atypical cells ("Bowen's cells") within the lesion.⁸⁶ Smaller SCCs are treated with electrodesiccation and

curettage, whereas larger tumors in sensitive locations such as the face are often best handled with Mohs micrographic surgery. Other treatment options include radiation therapy, carbon dioxide laser, and oral 5-fluorouracil for refractory lesions.⁸⁷

KERATOACANTHOMA

Keratoacanthomas (KAs) are a common and distinct neoplasm with a histologic pattern resembling SCC, thus challenging the diagnosis. They are often found in sun-exposed areas of light-skinned elderly patients, peaking at ages 50 to 70 years and increasing in incidence with advancing age.^{88,89} The face, forearms, and hands are frequently afflicted sites, though any area is possible. The etiology of KAs is unknown, though they are likely derived from hair follicles, with UV light, chemical carcinogens, immunocompromised status, and viruses contributory to incidence and progression. KAs are usually solitary and appear as firm, round, skin-colored or erythematous dome-shaped papules. They often have a central umbilication with a keratin plug. Diagnosis is best established by incorporating affected tissue with normal lateral tissue in a biopsy specimen so as to help distinguish SCC from KA. KAs grow rapidly in a period of 2 weeks but may slowly involute over a period as long as 1 year if no intervention is implemented.⁹⁰ The primary therapy for KA remains surgical excision.

BASAL CELL CARCINOMA

Basal cell carcinomas (BCCs) are the most common type of cancer in pale-skinned individuals. It is estimated that more than 1 million new diagnoses are made each year in the United States, comprising 25% of all cancers diagnosed.⁹¹ People who burn easily and severely in the sun without tanning are those at greatest risk for BCC. Fortunately, BCC only rarely metastasizes and is better described as a local infiltrator, with the potential of destroying underlying structures if unattended. However, our group and others have described a rare variant of facial BCC that is extremely aggressive and rapidly involves deep tissue, especially bone. Ultraviolet light exposure is the main etiologic agent, but x-rays, thermal injury, and scars may all contribute to BCC formation.⁹²

There are five major subtypes of BCC. Noduloulcerative BCC is the most common with a pearly dome-shaped nodule, central umbilication, and telangiectatic border. This type enlarges slowly, with a 4-mm-sized tumor taking years to develop. Pigmented BCCs may display a uniform dark pigment and can resemble melanoma. Cystic BCCs are uncommon and are described as bluish gray cystic nodules. Superficial BCCs are flat plaques with pearly translucency and thin borders. This subtype is most common on the trunk, unlike the high occurrence on the face of other subtypes. Sclerosing BCCs appear as fibrosing and infiltrating plaques. When these resemble a scar, it is often an ominous sign of deep invasiveness.⁹² Such "morpheiform" BCC must be excised with wide margins.

After biopsy-proven diagnosis, several treatment options are available. These include cryotherapy, curettage and electrodesiccation, radiotherapy, and excisional or Mohs micrographic surgery. For carefully selected thin and small BCCs, topical treatment options include imiquimod and

5-fluorouracil. A 2004 study of 5% imiquimod cream for superficial BCCs showed clearance rates near 75% based on clinical and histologic examination.⁹³

MELANOMA

Melanoma, a malignancy of melanocytes, comprises 4% of all skin cancers but is the leading cause of skin cancer deaths worldwide.⁹⁴ According to the American Cancer Society, cutaneous melanoma accounts for 60,000 cases but about 9,000 deaths annually. Melanoma incidence per year peaks at 30 to 50 years of age. The median age of diagnosis is 59 years, with 19.5% of cases diagnosed between 55 and 64 years of age; 17.8% diagnosed between 65 and 74 years of age; 16.4% diagnosed between 75 and 84 years of age; and 5.5% diagnosed at older than 85 years of age. The median age for death is 68 years, with 15% dying between 45 and 54 years of age; 18.8% dying between 55 and 64 years of age; 21.3% dying between 65 and 74 years of age; 23.6% dying between 75 and 84 years of age; and 11.0% dying when older than 85 years of age. Incidence is 18.5 to 28.5 per 100,000 for white persons and 0.9 to 1.1 per 100,000 for black persons for all types of melanoma.⁹⁵ Malignant melanoma formation is a multistep process of mutations with risk factors including blistering tendencies in the sun, high number of dysplastic moles, actively changing mole, family history of melanoma, previous history of melanoma, and older age.⁹⁶

There are several subtypes of melanoma. Superficial spreading melanoma is characterized as a flat or slightly elevated dark brown lesion with variegated colors. Nodular melanoma manifests as a rapidly growing dark brown or black papule or nodule that is at risk for ulceration and bleeding. Both are common on the trunk and legs.⁹⁶ Lentigo maligna is a slower-growing subtype on the rise in the United States, which when invasive is called lentigo maligna melanoma.⁹⁷ It is found on chronically sun-damaged areas of the head, also on the neck and arms with a peak incidence at 65 years of age. It is characterized as a brown to tan colored macule with possible areas of hypopigmentation and later raised blue-black nodules with dermal invasion. The last major subtype, acral melanoma, is the least common, comprising 2% to 8% of all melanomas in lightly pigmented people and 29% to 72% in darkly pigmented people. Although the proportion is higher in dark-skinned individuals, the incidence is similar across all skin types.⁹⁸ Acral melanomas are noted on the palms, soles, and subungual areas and thus are more difficult to identify with late diagnosis leading to poor outcome. They most often appear dark brown to black with irregular borders. The subungual type may show Hutchinson's sign, or proximal nail fold dark pigmentation.⁹⁹ Two percent to 8% of all melanomas are amelanotic, showing no pigmentation.⁹⁶

Diagnosis involves a proper history and physical examination, along with lymph node evaluation. The ABCDE criteria frequently mentioned is a useful tool during the initial examination, and all components must be used in concert to establish a level of suspicion. The mnemonic stands for asymmetry, border irregularity, color variegation, diameter and evolution or change over time. A biopsy with pathologic confirmation is essential to rule out mimicking lesions such as pyogenic granuloma and pigmented

basal cell carcinoma. After biopsy-confirmed diagnosis and evaluation for metastasis, the primary mode of treatment is surgery.⁹⁶

ANGIOSARCOMA

Angiosarcomas are rare and malignant neoplasms of endothelial origin. The age-adjusted incidence for soft tissue sarcoma was 3.1 per 100,000 men and women per year in the 2000–2004 period, with angiosarcomas constituting 4.1% of such sarcomas.^{100,101} Angiosarcomas have a peak incidence in the seventh decade, though any age group may be affected. Cutaneous angiosarcoma of the scalp and face is the most common form and appears as an enlarging bruise, dark blue to black nodule, or unhealed ulceration. After biopsy and staging, treatment remains challenging with a combination of surgery and radiation therapy most successful. Studies have demonstrated beneficial activity of paclitaxel and liposomal doxorubicin against angiosarcoma of the scalp and face.¹⁰²

KAPOSI'S SARCOMA

Kaposi's sarcoma (KS) is a tumor of endothelial origin in which the classic form is usually found in men in their 60s. Human herpesvirus-8 is linked to the pathogenesis of all types of KS, including the classic form. Classic KS is found as a rare and indolent lesion in elderly men of Jewish and Mediterranean descent. Specifically, it represents about 0.2% of cancer in older American men of Mediterranean and Central-Eastern European (Ashkenazi) Jewish lineage in the United States.¹⁰³ In Israel, rates of classic KS of 2.07 in men and 0.75 in women per 100,000 persons were calculated.¹⁰⁴ Clinically, it is often apparent on the distal extremities as a bluish-red hematoma resembling a macule. It can develop into plaques and nodules and may become hyperkeratotic and ulcerate. The disease progresses slowly, and patients may live for decades with the tumor. Therefore, death in these patients may well be from other causes of aging.¹⁰⁴ In localized disease, treatment can be handled with radiotherapy and intralesional chemotherapy. Systemic chemotherapy, including agents such as doxorubicin, vincristine, and etoposide, are helpful in metastasized or aggressive KS. Immunotherapy including imiquimod, interferon- α and sirolimus have been utilized, but specific health concerns of each elderly patient need to be carefully addressed.^{105,106} Other types of KS, including those in immunocompromised and AIDS patients, do not occur preferentially in the elderly.

Bullous pemphigoid

Bullous pemphigoid is an autoimmune blistering disease primarily of the elderly. The average age of affected patients is 65 years, and incidence reports vary by region.^{107,108} Rates of 0.7 cases per 100,000 have been reported in Germany in 1995 and up to 4.3 cases per 100,000 in the United Kingdom in 2008.^{108,109} The disease is characterized by large tense bullae on an erythematous base on flexor areas of the extremities, axillae, groin, and abdomen. Clear or sanguineous exudates exist in these bullae. The size can range from half a centimeter to 7 centimeters. Postinflammatory pigmentary changes may follow rupture of these bullae. Mucosal lesions are rare but heal quickly if present. There have been associations of bullous pemphigoid with other autoimmune

conditions such as psoriasis, diabetes mellitus, and rheumatoid arthritis.¹¹⁰

Consistent with its autoimmune etiology, IgG and C3 have been demonstrated in the epidermal basement membrane of bullous pemphigoid. IgG autoantibodies specifically bind to hemidesmosome adhesion complexes (components BP180 and BP230) of the basement membrane.¹¹¹ A subepidermal blister forms with eosinophils, and possible lymphocytes, histiocytes, and neutrophils. Diagnosis is established with clinical and histologic contribution. A fresh blister biopsy shows eosinophils in a subepidermal cleft, whereas direct immunofluorescence demonstrates IgG or C3 linearly deposited at the basement membrane zone.¹¹⁰

Topical or systemic corticosteroids are used for treatment, with systemic therapy most effective for multiple lesion disease.¹¹² Before the start of systemic corticosteroids, tetracyclines, with possible niacinamide, may be explored for mild to moderate disease.¹¹²

The use of steroids in elderly patients should be coupled with calcium and vitamin D to help prevent osteoporosis complications. Supplemental anti-inflammatory agents such as dapsone are useful for tapering steroid doses. Dapsone therapy requires close evaluation of liver and bone marrow function as well as ruling out glucose-6-phosphate dehydrogenase deficiency, and the adverse effect profile is severe. Other ancillary treatments include azathioprine, methotrexate,¹¹³ chlorambucil, cyclosporine, cyclophosphamide, plasmapheresis, and mycophenolate mofetil.^{112,114} The effectiveness of plasma exchange or azathioprine as adjuncts has not been concluded.¹¹² Methotrexate is an excellent option in patients according to a 2008 Swedish study of 138 patients comparing methotrexate, prednisone, methotrexate plus prednisone, and topical steroid groups.¹¹⁵

Bullous pemphigoid may be fatal if appropriate treatment is not administered. The main predictors of poor prognosis include old age, female gender, associated chronic morbidities, and poor hygiene.^{116,117} Mortality rates from 19% to 43% have been reported in some studies, and death may be related to chronic high-dose steroid use.^{116,118–120}

Systemic concerns of the elderly with cutaneous complications

DIABETES MELLITUS

Diabetes mellitus (DM) is an endocrine disease of epidemic proportions in the United States. The Centers for Disease Control in a 2005 study showed that individuals over 60 years had a diabetes prevalence of 20.9%.¹²¹ Diabetes manifests in many organ systems including the nervous, renal, ocular, integumentary, and cardiovascular. Elderly patients suffer greatly from complications such as functional disability, depression, cognitive impairment, injury, and urinary incontinence.

Diabetic dermopathy, also known as shin spots, is found in 9% to 55% of diabetics.^{121–125} It appears as round slightly indented patches of brown to purplish skin. Diabetic dermopathy is the most common cutaneous complication of DM and suggests advanced internal disease of the heart, liver, or kidney.¹²²

Diabetes mellitus is the cause of the greatest number of nontraumatic amputations in the United States. This is a result of nonhealing ulcers in diabetics with long-standing

neuropathy and reduced pain sensation. Up to 25% of diabetics suffer from leg ulcers in their lifetime.¹²⁶ Proper and frequent examination of the feet and immediate treatment of ulcers is a critical component of diabetic patient care.

Perforating dermatosis is a condition found in diabetics who suffer from severe renal disease or in patients with chronic renal failure alone. This condition presents as hyperkeratotic, pruritic, and umbilicated papules and nodules on the extensor surfaces of the legs, trunk, and face.¹²⁷

Acanthosis nigricans is probably the most recognized dermatologic sign of diabetes. It reflects insulin resistance and is common among the obese. This is a diffuse, darkened, and velvet-like thickening seen on the skin of the neck, axilla, groin, umbilicus, hands, submammary area, and areola. In exuberant form, this condition can also be a signal of internal malignancy; thus, thorough examination is critical.²⁷

Necrobiosis lipoidica diabetorum presents as a red papule that grows peripherally, becomes atrophic in the center, assuming an "apple-jelly"-like coloration, and eventually appears telangiectatic and porcelain like. Though rare, a striking 75% of patients with necrobiosis lipoidica have or will be diagnosed with diabetes.¹²⁸ Patients may respond to topical or intralesional corticosteroids among other medications, but strict diabetes management does not improve the papules of necrobiosis lipoidica.

THYROID DISEASE

Thyroid diseases, including hypo- and hyperthyroidism, impact up to 20% of elderly patients.¹²⁹ Cutaneous manifestations of thyroid disease also depend on over- or underproduction of thyroid hormones. There is an increased incidence of alopecia areata and vitiligo associated with autoimmune thyroid disease.

Characteristic features of hyperthyroidism include palmar erythema, warm and moist skin, and fragile scalp hair or alopecia. These signs are often useful for diagnosis. Pretibial myxedema is a specific dermopathy of hyperthyroidism in Grave's disease (an antibody-mediated autoimmune thyroid reaction). Firm, nonpitting, nodules or plaques form on both legs in an asymmetric pattern. The color may be pink, purple, or fleshlike.¹³⁰ An accumulation of mucopolysaccharides in the dermis is suspected to lead to this appearance. These signature features of hyperthyroidism should trigger appropriate diagnosis and treatment of the underlying disease process. Hypothyroidism is a condition occurring in about 10% of females and 2% of males over 60 years of age.¹³¹ It manifests with a cutaneous feature of myxedema that is more prolonged and diffuse. In advanced cases, the overall appearance of the skin becomes dry, scaly, and yellowish with sparse hair.¹³¹ With progressing myxedema, the face may also appear flat and expressionless. Palmoplantar keratoderma, or hyperkeratosis on the palms and soles, is possible in severe cases. Hair and fingernails are prone to break as well.¹²⁹ Onycholysis, or separation of the nail plate from the nail bed, is found in patients with thyrotoxicosis and hypothyroidism but decreases in incidence in patients over 60 years of age.¹³⁰

RENAL/ADRENAL DISEASE

Cushing's syndrome and Addison's disease are two conditions of the adrenal gland with cutaneous manifestations. In Cushing's disease, the main cause of Cushing's syndrome, there is hypersecretion of adrenocorticotropic hormone

(ACTH).¹³² ACTH levels may rise from neoplasms of the pituitary gland or from ectopic neoplasms such as oat cell lung cancer.¹³³ The primary clinical features include hypertension and weight gain. A "buffalo hump" or redistribution of fat to the upper back is evident, along with purple striae on the torso. Hypertrichosis, excessive bruising, poor wound healing, and hirsutism are additional complications.¹³² In Addison's disease, autoimmune destruction of the adrenals leads to adrenocortical insufficiency. The main dermatologic feature is hyperpigmentation of skin creases, new scars, the vermilion border, nipple, and areas of constant pressure.¹³³ The mechanism is attributable to the stimulation of melanocytes by ACTH or the closely related melanocyte-stimulating hormone (MSH). This darkening of the skin may be the presenting feature.¹³⁴

Chronic kidney disease (CKD) is a life-threatening condition affecting more than a third of patients 70 years of age and older according to the National Health and Nutrition Examination Survey.¹³⁵ Cutaneous examination of patients has shown that 50% to 100% have at least one dermatologic symptom.¹³⁶ The list of cutaneous sequelae is extensive, including pruritus, xerosis, ischemic ulcerations, prurigo nodularis, calcinosis cutis, calciphylaxis, Kyrle disease, bullous disease of dialysis, and nephrogenic fibrosing dermopathy. The majority of these improve with appropriate renal management.

Pruritus and xerosis have been attributed to uremia in CKD patients.¹³⁷⁻¹³⁹ Pruritus may be local or generalized, mild or severe, or episodic or constant. Evidently, it is highly patient specific with no demographic biases.¹³⁶ Both xerosis and pruritus may improve with kidney disease management, with xerosis specifically responding to emollients.¹³⁹ Calcinosis cutis is the result of insoluble calcium deposition in the skin, appearing as multiple, firm, whitish papules, plaques, or nodules. They may ulcerate extruding a chalky white substance.¹⁴⁰ Calciphylaxis refers to vascular calcification with skin necrosis. Patients have firm painful lesions with central necrosis along a vascular track. These may begin initially as violaceous mottling.¹⁴¹ Kyrle disease is the occurrence of widespread papules with central keratin and cellular debris plugs. It usually begins as a silvery scaled papule.¹⁴² Bullous disease of dialysis resembles porphyria cutanea tarda with blistering and mechanical fragility of the skin in sun-exposed areas. The incidence is 1.2% to 9% in patients with CKD on hemodialysis.¹⁴³⁻¹⁴⁶

Nephrogenic fibrosing dermopathy is a condition with fibrosis of the skin and internal organs that is distinct but reminiscent of scleroderma. Large areas of indurated skin, brawny discoloration, and tightening occur. Nephrogenic fibrosing dermopathy occurs almost exclusively in patients with end-stage renal disease who have had imaging studies with gadolinium.¹⁴⁷

NUTRITION

Proper nutrition, including daily recommended levels of essential vitamins and minerals, is critical in the elderly to prevent diseases with cutaneous manifestations such as scurvy and pellagra. Please find more information on these topics in Chapter 74.

MENOPAUSE

Menopause leads to significant changes in skin biology. On physical examination, the skin is thinner and less lubricated than premenopausal skin. The risk of infection is higher, and

atrophy, pruritus, stiffness, alopecia, and dryness result.¹⁴⁸ Topical estrogen-based creams have shown some improvement in elasticity and moisturization. Specifically, collagen content and dermal thickness are improved with estrogen use after menopause.^{149,150} The risks and benefits for each individual patient must be assessed before initiating therapy for moderate improvement.

TOBACCO USE

Tobacco use is a leading cause of preventable morbidity and mortality in the United States. In addition to risks of lung cancer, chronic obstructive pulmonary disease, and cardiac disease, the skin suffers significant damage from smoking. Early skin aging, SCC, melanoma, oral cancer, acne, and hair loss are some problems faced by long-term smokers. One

study of 63 volunteers noted that a 35 pack-years smoking history led to a significantly greater skin furrow depth of the volar forearm when compared to non-smokers ($p < 0.05$).¹⁵¹ A few specific signs of tobacco smoking include harlequin nail, which is a demarcation between the yellow and pink on the nail of a recent quitter. Smoker's face refers to a constellation of deep lines and furrows at right angles from the lips and corners of the eye, prominence of bony structures, and general gray-ing of the skin. In vitro and epidemiologic evidence strongly support premature aging of skin from tobacco smoke.¹⁵²

For a complete list of references, please visit online only at www.expertconsult.com

Loss of vision, one of the most feared forms of medical disability, falls disproportionately on the elderly. Unfortunately, the damage to the delicate tissues of the eye from the various metabolic insults that may occur throughout life is generally cumulative. Consequently, most forms of ocular pathology occur ever more frequently, and in more debilitating forms, with increasing age.

Estimates of the prevalence of blindness from all causes vary by perhaps a factor of 13 between industrialized and Third World societies.¹ Nevertheless, regardless of the degree of economic development, the prevalence rate for blindness in any society is typically 100-fold greater among individuals over 65 years of age than among children in the same society.² In developed countries, the major causes of blindness are primarily cataract, glaucoma, and retinal disease (mostly macular degeneration and diabetic retinopathy), all of which are strongly related to advancing age.³ In the Third World, the major causes of blindness are cataract, corneal scarring, glaucoma, and retinal disease.⁴

Delivery of adequate eye care to elderly individuals remains an unsolved problem, even in wealthy countries. Recent surveys in the United States have identified significant rates of untreated eye disease among the elderly. The nursing home population appears to be notably underserved.^{5,6}

Discussion of age-related ocular problems is conveniently organized by considering the visual apparatus in anatomic order from anterior to posterior.

EYELIDS

The eyelids are vital for the proper circulation of tears and maintenance of the smooth ocular surface necessary for clear image formation by the eye. With increasing age, the skin of the eyelids, as elsewhere, loses elasticity, and the lids become more loosely apposed to the globe. Atrophy of the fascial planes within the eyelids may lead to herniation of the orbital fat into the lid tissue, producing the “bags under the eyes” frequently seen in the elderly (Figure 96-1). Atrophy or disinsertion of the aponeurosis of the levator palpebrae muscle, which ordinarily supports the upper eyelid, may cause the opened lid to fail to uncover the pupil, as seen in senile ptosis, despite normal levator muscle function (Figure 96-2; see also Plate 96-1). Senile ptosis must be differentiated from ptosis due to mechanical and neuromuscular causes, such as oculomotor nerve palsies and myasthenia gravis.⁷

Laxity of the lower lid may allow the free lid margin to rotate away from the eyeball, a condition known as ectropion (Figure 96-3). If severe, the lacrimal punctum may fail to make contact with the pool of tears adjacent to the lower lid. This prevents the normal conduction of tears into the lacrimal sac, which may result in persistent tearing (epiphora) even in the absence of lacrimal duct obstruction. More dangerous is entropion, in which a loosening of the adhesions between tissue planes in the lid allows the muscle tone of the orbicularis oculi to rotate the lid margin inward (Figure 96-4).⁸ Frequently, the lashes come to rub directly against the cornea or conjunctiva, producing irritation or scarring.

The treatment of eyelid malpositions is generally surgical. For senile ptosis, resection of the levator aponeurosis is generally performed.⁹ Ectropion and entropion are generally treated by resection of redundant lid tissue.¹⁰

Of the tumors of the eyelid skin, basal cell carcinomas are the most common. These tumors are frequently a consequence of lifetime exposure to sunlight. If the lesions are detected early, a curative local resection is often possible. In advanced cases, the tumor may cause massive destruction of facial structures by local extension. Metastases are very rare.¹¹

LACRIMAL APPARATUS

The lacrimal apparatus consists of the lacrimal glands, which secrete the tears, and the lacrimal sac and ducts, which convey the tears into the nasal cavity. Secretory function of the lacrimal glands declines with age, and many elderly individuals develop “dry eye” syndrome. (This nonspecific reduction in tear production is much more common than the full-fledged Sjögren syndrome, which is an autoimmune disease process affecting both salivary and lacrimal secretion.¹²) Paradoxically, many tear-deficient patients complain of excess tearing, because the chronically irritated eyes may stimulate reflex tear production. Dry eyes are treated with artificial tear eyedrops, as often as needed. Some patients respond well to topical treatment with cyclosporin A.¹³ In patients whose eyes dry out overnight, lubricant ointment at bedtime may be helpful. In severe cases, small silicone plugs may be placed to obstruct the lacrimal puncta,¹⁴ or surgical

Figure 96-1. Prolapse of orbital fat through atrophic fascial planes in the eyelid produces “bags” under the eyes. (Courtesy of Murray Meltzer, MD.)

Figure 96-2. Senile ptosis. Note the low lid level and the loss of the normal lid folds. (Courtesy of Murray Meltzer, MD.)

Figure 96-3. Ectropion. Laxity of the lower eyelid allows the lid margin to rotate away from the eyeball. (Courtesy of Murray Meltzer, MD.)

occlusion of the lacrimal puncta may be performed, in order to conserve the available tears.

Obstruction of the lacrimal ducts also leads to epiphora. Uncomplicated mechanical stenosis may occasionally be relieved with simple probing, but severe cases (often following bacterial infection of the lacrimal sac) are treated surgically: a dacryocystorhinostomy is performed to anastomose the mucosa of the nasal cavity to the lacrimal sac through an osteotomy made in the lacrimal bone.¹⁵

CONJUNCTIVA

Subconjunctival hemorrhage, a localized accumulation of blood seen between the conjunctiva and the globe, is frequently encountered in the elderly, either following minor trauma or occurring spontaneously (Figure 96-5; see also Plate 96-2). Such hemorrhages are rarely of any consequence, but they are often alarming in appearance. They resolve spontaneously without treatment over a period of several days. Occasionally, recurrent hemorrhages may suggest an underlying disease such as hypertension or a coagulation disorder.

Chronic exposure to sunlight, particularly at tropical latitudes, may cause a degeneration of the connective tissue in the exposed sector of the conjunctiva between the eyelids, leading to thickening of the conjunctiva (pingueculum),

Figure 96-4. Entropion. Breakdown of the adhesion between the tissue planes in the eyelid allows the muscle tone of the orbicularis oculi muscle to rotate the lid margin inward. The eyelashes may chronically irritate the surface of the eyeball. (Courtesy of Murray Meltzer, MD.)

Figure 96-5. Subconjunctival hemorrhage. This small hematoma, seen through the transparent conjunctiva, is benign unless recurrent.

which may grow over the cornea from the periphery toward the pupil (pterygium). If the growth threatens to cover the visual axis, surgical excision may be indicated. Recurrence after surgery is, unfortunately, not uncommon.¹⁶

Tumors such as squamous cell carcinoma and melanoma may arise from the conjunctiva. Local excision and cryoablation may be adequate in early cases, but advanced cases may require orbital exenteration.¹⁷

CORNEA

The eye is unique in its requirement for transparent tissues, including the cornea and crystalline lens. The need for transparency places many constraints on the architecture and metabolism of these ocular structures. In particular, the eye must nourish these tissues with a cell-free fluid, as red blood cells preclude transparency. Similarly, the transparent tissues must rely primarily on anaerobic glycolytic metabolism, as the enzyme systems required for oxidative phosphorylation (aptly named cytochromes) strongly absorb visible light. Even in the absence of these absorbent components, the tissues must be constructed in a highly compact and regular manner, so that light scattering from tissue organelles does

Figure 96-6. Corneal edema. The cornea is thickened and cloudy because of failure of the corneal endothelium to adequately dehydrate the tissue. (Courtesy of Calvin Roberts, MD.)

not cause a white, opaque appearance. This requirement is met in the case of the cornea by a highly regular arrangement of collagen fibrils and an active metabolic pump in the corneal endothelial cell layer, which dehydrates the corneal stroma. (Absence of these tissue features explains why the sclera, which is otherwise histologically similar to the cornea, is opaque.¹⁸)

The corneal endothelial cells, on which the dehydration critical for corneal transparency depends, do not divide during adulthood. Indeed, the endothelial cell density declines slowly with age.¹⁹ If the number of endothelial cells falls below a critical level, the cornea imbibes fluid, swells, and becomes cloudy (Figure 96-6; see also Plate 96-3). Edema fluid percolates to the epithelial surface and may coalesce into subepithelial bullae. Mild cases may be managed with the use of hypertonic saline eyedrops and ointment to withdraw fluid from the cornea osmotically. If these measures fail, a corneal graft, which replaces the deficient endothelium, is necessary to restore vision.²⁰

Bacterial ulcers of the cornea (Figure 96-7; see also Plate 96-4) seem to occur with greater frequency in the elderly, perhaps reflecting impairments of tear secretion, epithelial integrity, and cellular and humoral immunity, and are associated in the elderly with a poorer prognosis.²¹ Intensive antibiotic therapy is generally required.²²

The ring-shaped deposition of lipid in the far periphery of the cornea, referred to as *arcus senilis*, is completely benign.

UVEAL TRACT

The uveal tract (*uvea*) comprises the iris, ciliary body, and choroid, which form a continuous, highly vascular layer inside the sclera. Inflammation of the uvea occurs frequently: as a primary disease process, in response to infections, in many patients with rheumatic disease, and as a sequela to accidental or surgical trauma. Clinically, inflammatory cells are seen in the aqueous or vitreous humor. These inflammatory reactions can cause ocular injury by many mechanisms. They may occlude the trabecular meshwork, causing glaucoma. They may accumulate on the inner surface of the cornea as keratic precipitates, where they may injure or destroy the corneal endothelial cells and cause corneal edema. Inflamed tissues often develop pathologic adhesions, which

Figure 96-7. Corneal ulcer. A localized infection causes an epithelial defect and attracts an infiltrate of white blood cells. (Courtesy of Michael Newton, MD.)

may derange normal ocular function. Adhesions between the anterior surface of the peripheral iris and the anterior chamber angle (peripheral anterior synechiae) may occlude the trabecular meshwork, leading to chronic angle-closure glaucoma. Adhesions between the posterior surface of the iris and the anterior surface of the crystalline lens can seal off access of the aqueous humor to the anterior chamber (pupillary block), forcing the iris to bow forward (iris bombé). In cases where the peripheral iris becomes apposed to the trabecular meshwork, the egress of aqueous humor from the eye is blocked, resulting in angle-closure glaucoma. In the posterior segment, inflammatory cells in the vitreous humor may obscure vision and lead to fibrovascular proliferation that may distort the retina, or even cause a retinal detachment.

Treatment in most cases of uveitis is generally empirical. Dilation of the pupil with cycloplegic eyedrops is generally advisable to prevent posterior synechiae and pupillary block and to relieve the discomfort (photophobia) caused by light-induced miosis of the inflamed iris. If the inflammation is confined to the anterior segment, topical corticosteroid eyedrops are usually sufficient. In cases involving the posterior segment, periocular corticosteroid injections or systemic administration of corticosteroids are frequently required. Typically, workup for associated systemic disease is appropriate. If a treatable condition is discovered, such as syphilis or tuberculosis, specific treatment for the underlying condition may simultaneously cure the uveitis. In refractory cases, success may often be achieved with systemic administration of immunosuppressive drugs.²³

Intraocular tumors in the elderly occur most frequently within the uveal tract. Melanomas are the most common primary tumor. Though prompt enucleation (surgical removal of the eyeball) was long the traditional management, many authorities now recommend that eyes containing small uveal melanomas be followed closely, rather than enucleated, as they have only a low propensity for metastasis.²⁴ Medium-sized tumors have been successfully treated in many cases with irradiation, either by temporary implantation of a radioactive plaque applied to the overlying sclera²⁵ or administered by external beam.²⁶ A large, prospective, clinical trial found no difference in 5-year survival between groups of patients randomized to treatment by radioactive plaque or by enucleation.²⁷ Primary enucleation is often

recommended for large tumors. Metastatic melanoma is usually detected initially in the liver. Regular physical examinations and monitoring of hepatic enzyme activity in the serum are advisable for patients at risk.

Tumors metastatic to the choroid are actually more frequent than primary intraocular tumors. Lung primaries predominate in men, breast primaries in women.²⁸ As the eye is seldom the sole site of metastasis, these patients generally require systemic chemotherapy.

GLAUCOMA

Glaucoma is a form of progressive atrophy of the optic nerve, frequently associated with increased intraocular pressure (Figures 96-8 and 96-9; see also Plates 96-5 and 95-6).

Open-Angle Glaucoma

In many cases, the primary pathology is presumed to lie in the trabecular meshwork, the ring of porous tissue located in the anterior chamber angle through which aqueous humor drains from the eye. Impaired facility of aqueous outflow through the trabecular meshwork is generally idiopathic (so-called primary open-angle glaucoma). This condition is generally reported to increase in prevalence with increasing age, at least in most Western populations.²⁹ Loss of outflow facility may also arise from various insults to the trabecular meshwork, including trauma, uveitis, hemorrhage, and dispersion of intraocular pigment.

Visual impairment from open-angle glaucoma is generally insidious and chronic, with visual field damage occurring initially in the far periphery, where it is rarely noticeable except by formal testing. Our ability to diagnose this condition in its early stages is quite imperfect. The actual risk of visual field loss in untreated individuals with modestly elevated intraocular pressure is only 1% to 2% per year;³⁰ conversely, histologic studies have shown that as many as 40% of the optic nerve fibers must be destroyed before any abnormality of the visual field is detectable by standard techniques.³¹

Initial treatment is usually medical. The goal of therapy is to lower the intraocular pressure, with topical (or rarely, systemic) medications, to a level that is tolerated by the optic nerve, as demonstrated by the arrest of progressive visual field loss. Available medications include parasympathomimetic miotics (rarely used), anticholinesterase miotics

Figure 96-8. Normal optic nerve head. Cup-to-disc ratio is about 0.3.

Figure 96-9. Glaucomatous optic nerve head cupping. Loss of neural tissue is seen as narrowing of the neural rim of the optic disc and enlargement of the central cup. (Compare with Figure 96-8.)

(rarely used), sympathomimetics, β -adrenergic blockers, carbonic anhydrase inhibitors, and prostaglandin analogs. The potential side effects of the various topical and systemic pressure-lowering drugs are occasionally serious, particularly in elderly patients (see Systemic Complications of Ophthalmic Medications, presented later). If medical treatment is unsuccessful or poorly tolerated, intraocular pressure may be further lowered by laser treatments to the trabecular meshwork or by "filtering surgery," which creates a fistula between the anterior chamber and the subconjunctival space, allowing easier egress of aqueous humor. Complications of filtering surgery may include hypotony, choroidal effusion, and cataract. Supplementary medical treatment after filtering surgery is may also be required. The optimal stage in the disease process for surgical intervention is unclear. Some authors have reported better long-term visual results with earlier surgery.³² One large study suggests that laser treatment to the trabecular meshwork may also be suitable as initial therapy.³³

Angle-Closure Glaucoma

Occasionally, alterations in intraocular anatomy may predispose the iris to cover the trabecular meshwork, suddenly preventing aqueous outflow and causing an acute elevation of the intraocular pressure. Common scenarios include adhesions between iris and lens (pupillary block), which may cause the iris to bow forward so as to occlude the trabecular meshwork, and dilation of the pupil, such as may occur spontaneously in the dark or following pharmacologic mydriasis. Gradual enlargement of the lens with increasing age or cataract formation is an important factor that predisposes the eye to this process in the elderly. Acute angle-closure glaucoma is generally a dramatic event, with symptoms including severe pain, blurring of vision, perception of colored haloes around lights, nausea, and vomiting. Diagnosis of acute angle closure is easy once attention is directed to the eye, but it may be missed if attention is diverted to the gastrointestinal symptoms. Cases have been reported from the emergency departments of general hospitals where concentration on the nausea and vomiting of a patient with acute angle closure has led to exploratory laparotomy!

The massive elevation of intraocular pressure following acute angle closure (often to triple the normal upper limit of 21 mmHg) may cause permanent optic nerve damage within a matter of weeks. Acute angle closure is initially treated by lowering the intraocular pressure with systemic and topical medications, including miotic eyedrops and systemic osmotic agents. In cases of pupillary block, a small hole (peripheral iridotomy) is made in the iris by laser or invasive surgery to bypass the pupillary block and allow passage of aqueous humor from the posterior segment into the anterior chamber. This prevents subsequent angle-closure attacks. Because the anatomic factors that predispose an eye to acute angle closure are generally found bilaterally, it is usually considered prudent to perform a peripheral iridotomy prophylactically in the fellow eye after an attack of angle closure.

Prolonged episodes of angle closure may result in permanent damage to the trabecular meshwork or even adhesions between the iris and sectors of the trabecular meshwork, leading to chronic angle-closure glaucoma. If the angle is sufficiently compromised, filtering surgery may be necessary.

Normal-Tension Glaucoma

Although elevated intraocular pressure has historically been the hallmark of the diagnosis of glaucoma, it has become clear in recent decades that many patients with otherwise typical glaucomatous optic atrophy and visual field loss seldom if ever are found to have elevated intraocular pressure. Identification and treatment of this so-called low-tension glaucoma (more accurately termed normal-tension glaucoma) remains problematic, although even in this cohort, reduction of intraocular pressure is thought to convey some benefit. This entity is probably more common than previously thought, as population-based surveys have demonstrated a substantial incidence of otherwise typical glaucomatous field loss in patients with normal intraocular pressures.³⁴

CRYSTALLINE LENS

The crystalline lens of the eye is a unique ectodermal structure that develops entirely within the primordial lens vesicle. Only the cells on the extreme periphery of the lens

divide, adding cells to the outer surface of the growing lens. Thus, the center of the adult lens represents the earliest tissue laid down during embryonic development. There is no mechanism by which these cells can turn over, unlike the situation in typical ectodermal structures, such as the skin. The metabolism of the lens is largely confined to anaerobic glycolysis, as neither hemoglobin-mediated oxygen transport nor cytochrome-mediated oxidative phosphorylation is available owing to the need for transparency. The lens is at a further metabolic disadvantage because of the need to maintain a state of great disequilibrium with its surroundings, as the lens must maintain the highest protein concentration and one of the lowest water concentrations of any tissue in the body. Thus, relatively modest metabolic insults or osmotic stresses may overwhelm the lens metabolism, resulting in protein denaturation and cataract formation.³⁵

The lens of the eye continues to grow and mature throughout life. As the lens ages, it becomes more rigid and responds less effectively to changes in ciliary muscle tone, decreasing the effectiveness of accommodation, the eye's mechanism for focusing from distant to near objects. This loss of accommodation (presbyopia) is managed with reading glasses, bifocals, or other refractive strategies.

The lens responds to virtually any mechanical or metabolic insult by loss of optical clarity, resulting in the formation of a cataract (Figure 96-10; see also Plate 96-7). Several patterns of opacities are commonly encountered:

Oxidation ("browning reactions") of lens proteins, particularly in the older, central portions of the lens, is referred to as *nuclear sclerosis*, which may result in alterations in the refractive index of the lens as well as frank opacity. The most common refractive change is in the direction of an increase in myopia or decrease in hyperopia. In some instances, this refractive shift will allow the patient to read without reading glasses (so-called second sight). This improvement in visual performance is usually only temporary and often heralds the development of a more debilitating lens opacity. Refractive changes in the lens need not be uniform. Patients will occasionally report monocular diplopia resulting from inhomogeneous refraction by distinct portions of the lens resulting in two distinct images being formed on the retina.

Figure 96-10. Cataract. Loss of transparency of the crystalline lens impairs visual acuity. (Courtesy of Calvin Roberts, MD.)

(The notion that monocular diplopia is generally indicative of hysteria is incorrect.)

Denaturation of lens proteins in a sector of adjacent cortical lens fibers results in a wedge-shaped or cuneiform cortical opacity. These are often found in the far periphery of the lens but frequently spare the optical zone near the center.

Aberrant proliferation of lens fibers on the posterior lens capsule produces a posterior subcapsular cataract. These are often induced by topical or systemic corticosteroid treatment and are frequently seen in other disease states, such as retinitis pigmentosa.

Treatment of cataract is generally surgical. With rare exceptions, the lens proteins that constitute the opacity are irreversibly denatured, precluding medical treatment.³⁶ Surgical strategies for removal of the lens material have evolved greatly. In all cases, an incision must be made in the eyeball. A cataract cannot be removed—even with a laser—without an ocular incision. The simplest operation is to remove the entire lens intact within its lens capsule, a so-called intracapsular procedure. At present, the extracapsular procedure, in which the opaque lens tissue is carefully aspirated from within the lens capsule, has become standard, as retention of the capsule to serve as a barrier between the anterior and posterior segments of the eye appears to reduce the rate of complications. Recently, greater emphasis has been placed on the development of minimally invasive surgical methods for cataract extraction. Often, the cataract can be liquefied by the mechanical action of a rapidly vibrating needle (phacoemulsification) and aspirated from the eye through an incision only 3 to 4 mm in length.³⁷ Frequently, such wounds can be constructed to be self-sealing, eliminating the need for sutures.³⁸

Indications for cataract surgery should be determined in relation to the visual needs of each individual patient. Occasionally, cataract extraction is recommended for technical reasons, such as those rare cases when the lens is itself causing injury to the eye (as in phacolytic glaucoma, when lens proteins leak from a cataractous lens and occlude the trabecular meshwork) or when a cataractous lens prevents adequate visualization or treatment of disease of the posterior segment of the eye, such as diabetic retinopathy. Otherwise, cataract surgery is appropriate whenever the anticipated improvement in visual function would be of benefit to the patient. In general, a visual result of 6/12 (20/40) or better may be anticipated in 90% to 95% of cases without other known concurrent ocular disease; thus, surgery is generally recommended only when the acuity has fallen to the level of 6/15 (20/50) or worse. In some patients, difficulties with glare, contrast sensitivity, diplopia, or specific occupational demands may justify cataract extraction even with less severe loss of visual acuity.

Optical rehabilitation of the aphakic eye requires replacement of the focusing power of the cataractous lens that was removed. Where economic conditions permit, this is usually provided by means of a plastic intraocular lens prosthesis, which is generally implanted at the time of the primary cataract operation. Recent intraocular lens designs are even able to restore a degree of accommodation, reducing the need for reading glasses or bifocals in many cases.³⁹ Alternatives include contact lenses (often worn on an extended-wear basis) and thick “aphakic” spectacles, which subject the

patient to substantial optical distortions and (if the aphakia is unilateral) may cause substantial difficulties because of unequal perceived image size in the two eyes. (Indeed, the difficulties with spectacle correction of unilateral aphakes are sufficiently severe that, if spectacle correction is the only modality of optical rehabilitation available, most surgeons recommend deferral of surgery until visual acuity in the *better* eye falls to 6/18 [20/60] or worse.) In some Third World countries, local custom may discourage the use of spectacles after cataract surgery. In these situations, the attitudes of the patient must be taken into account in the decision as to whether or not to perform a cataract extraction.

Some yellowing of the lens proteins is nearly universal with aging. Sufficient opacity to impair visual acuity results in more than 1.5 million cataract extractions each year in the United States, the vast majority in individuals over 65 years of age. In developing countries, the rate of cataract formation appears to be even higher, so that untreated cataract typically forms the largest single cause of acquired blindness.³ In India, for example, even at the present rate of millions of cataract procedures each year, present surgical efforts continue to fall behind the rate of new cataract formation in the general population.⁴⁰

Cataract formation may occasionally reflect an underlying metabolic abnormality, such as galactosemia or renal failure. Cataract onset is accelerated in diabetic patients and may be triggered by various drugs (particularly topical or systemic corticosteroids). In addition to these specific associations, several studies have shown a nonspecific excess mortality among cataract patients compared with age-matched control patients undergoing other elective surgical procedures.^{41,42}

RETINA AND VITREOUS

Diseases of the retina, particularly diabetic retinopathy and so-called age-related macular degeneration (formerly referred to as “senile macular degeneration”) constitute the most frequent cause of acquired blindness, at least in developed countries.

Diabetic Retinopathy

Diabetic retinopathy shows a steady increase in incidence and severity with increasing duration of diabetes mellitus, with significant visual complications rarely occurring before 10 to 15 years after the onset of the disease.⁴³ Thus, while juvenile-onset (type I) patients may develop severe retinopathy as early as the third decade, the retinal burden of adult-onset (type II) patients is borne largely by the elderly. The disease seems to attack primarily the retinal capillary circulation. Initially, small, innocuous microaneurysms are noted ophthalmoscopically. With time, the retinal capillaries begin to leak fluid into the surrounding tissue, causing retinal edema and precipitation of exudates into the retina, with a concomitant reduction in visual acuity (Figure 96-11; see also Plate 96-8) At this stage of the disease, loss of visual acuity may be reduced through the use of laser treatments, either directed at leaking microaneurysms or, if the leakage is diffuse, placed in a grid pattern over the leaky sectors of the retinal capillary bed.⁴⁴

In later stages, perfusion of small regions of the retinal capillary bed fails (capillary dropout), leading to localized retinal infarctions, which may be seen ophthalmoscopically

Figure 96-11. Background diabetic retinopathy. Microaneurysms (“dot hemorrhages”), intraretinal hemorrhages (“blot hemorrhages”), and “hard” exudates indicate deterioration of the retinal microcirculation.

as cotton-wool spots. The remaining capillaries are often seen to become dilated, irregular, and leaky. Ultimately, in many patients, the ischemic retina develops a neovascular proliferative response, sprouting new blood vessels that may grow along the retinal surface or along the posterior surface of the vitreous body. These aberrant blood vessels are prone to leaking and hemorrhages. Vision may also be lost through traction exerted on the retina by fibroblastic membranes that accompany the neovascular proliferation (Figure 96-12; see also Plate 96-9). In severe cases, the neovascular response may extend to the anterior segment, producing neovascularization on the surface of the iris (rubeosis iridis). If the fibrovascular membrane extends over the anterior chamber angle, it obstructs filtration of aqueous humor through the trabecular meshwork, producing a refractory neovascular glaucoma.

Proliferative retinopathy may often be arrested through the ablation of a large fraction of the peripheral retina with laser photocoagulation.⁴⁵ In severe cases, blood in the vitreous cavity and fibrovascular membranes may be removed surgically by introducing mechanized suction-cutter instruments through small scleral incisions over the ciliary body (pars plana vitrectomy).

The benefit of tight control of blood glucose in the management of diabetic retinopathy depends on the stage of the disease. Many attempts to retard the progression of established retinopathy by improving the degree of glucose control have been disappointing.⁴⁶ Indeed, in some studies, tight control has been associated with a worsening of retinopathy. Similarly, in one study, successful pancreatic transplantation, with near-perfect normalization of blood glucose levels, failed to improve diabetic retinopathy, compared to the retinal disease in fellow pancreatic transplant patients whose allografts failed, requiring resumption of daily insulin injections, with the usual deficiencies in control of blood glucose.⁴⁷ However, it has been demonstrated (in both type I and type II patients) that better glucose control in recent-onset diabetic patients helps retard the onset of diabetic retinal disease.^{48,49}

Figure 96-12. Proliferative diabetic retinopathy. A membrane of fibrovascular tissue has sprouted from the optic disc in response to prolonged retinal ischemia.

Figure 96-13. Atrophic (“dry”) age-related macular degeneration. Geographic atrophy of the retinal pigment epithelium causes loss of central vision.

Age-Related Macular Degeneration

Age-related macular degeneration is a common cause of impaired vision, although not of total blindness, in the elderly population. In the “atrophic” form, the retinal pigment epithelium and choriocapillaris underlying the macula appear to degenerate, resulting in dysfunction of the overlying photoreceptors (Figure 96-13; see also Plate 96-10). There is no known treatment. In the “exudative” form, a neovascular net emanates under the macular region of the central retina from the choroidal circulation, proliferating between the retina and the underlying retinal pigment epithelium or underneath the pigment epithelium.⁵⁰ Leakage of plasma components and frank subretinal hemorrhage or scarring cause loss of vision (Figure 96-14; see also Plate 96-11).

Treatment of exudative macular degeneration has been revolutionized with the introduction of injectable drugs directed against the tissue factor, vascular endothelial growth factor (VEGF), which is elaborated by ischemic retina, stimulating increased vascular permeability and the

sprouting and growth of new retinal blood vessels from adjacent vascular beds.⁵¹ The initial anti-VEGF agent Pegaptanib sodium (Macugen, an aptamer directed against VEGF) significantly reduced the likelihood of progression of visual loss in patients with exudative macular degeneration, though improvement of visual acuity with treatment was unlikely.⁵² The subsequent introduction of ranibizumab (Lucentis, a monoclonal antibody fragment directed against VEGF) has yielded even better results, preventing progression of visual

Figure 96-14. Exudative (“wet”) age-related macular degeneration. Leakage and scarring from a subretinal neovascular membrane destroys central retinal function.

loss in up to 90% of patients and actually inducing significant improvement of visual acuity in up to 40% of patients⁵³ (Figure 96-15; see also Plate 96-12). Bevacizumab, a similar monoclonal antibody directed against VEGF, has been used extensively to treat exudative macular degeneration on an off-label basis (often at considerable savings compared to ranibizumab) and appears to be equally safe and effective in numerous small case series and large cumulative series.⁵⁴ A formal head-to-head trial comparing these two drugs is now in progress.

These anti-VEGF treatments are quite demanding of patient and physician. The drugs are administered under operating-room conditions (iodophore skin preparation, sterile drape and lid speculum, sterile gloves) by injection into the vitreous compartment of the eye through the sclera and pars plana of the ciliary body. After injection, the eye must be checked for elevation of intraocular pressure. Injections must be repeated every 4 to 6 weeks, potentially indefinitely. Each eye must be treated separately. Complications are rare, with an infection rate below one per thousand injections in competent hands, and rare incidents of cataract and retinal detachment. Close monitoring of patients in clinical trials of ranibizumab has suggested a possible small excess of thromboembolic events, but this has not been borne out by subsequent clinical experience.

Where available, anti-VEGF treatment has largely supplanted other treatment modalities for exudative macular degeneration. The role of combination treatment with anti-VEGF agents and other modalities (such as photodynamic therapy or corticosteroid medication) continues to be

Figure 96-15. Treatment of wet age-related macular degeneration in a 90 year-old woman with intravitreal ranibizumab. Baseline images (*left*) show macular edema in fluorescein angiogram (*top* – note patch of white fluorescence at temporal edge of fovea) and in retinal cross-section as seen in OCT scan image (*bottom* – extracellular fluid appears as dark clefts within retinal layers). After three injections of ranibizumab, edema has resolved (*right, top and bottom*). Note absence of white fluorescence in angiogram, and resolution of intraretinal clefts in OCT image, with restoration of normal foveal contour). Visual acuity improved from 20/100 (6/30) to 20/40 (6/12).

investigated, but additional benefits beyond those of anti-VEGF treatment have been difficult to demonstrate.⁵⁵

Previous treatment modalities for exudative macular degeneration have included thermal laser⁵⁶ and photodynamic treatment using nonthermal laser.⁵⁷ In favorable cases, laser treatment of neovascular membranes outside of the foveal region may arrest the growth of these membranes before they undermine the central macula, thus helping to preserve central vision. Laser treatment of subfoveal membranes may ultimately limit the size of the central scotoma (blind spot) caused by macular degeneration⁵⁸ but is seldom recommended if anti-VEGF treatment is available.

Photodynamic therapy is an alternative modality of ablation treatment for subretinal neovascularization. Patients undergo intravenous infusion of a sensitizing agent that binds selectively to neovascular tissue. The involved retinal sector is then treated with a low-power (nonthermal) ultraviolet laser, which interacts with the sensitizing agent to create highly reactive singlet oxygen species in the target tissue. These molecules exert a cytotoxic effect sufficient in many cases to block perfusion of the subretinal neovascularization.⁵⁷ The treatment effect is often only transient, and retreatments are frequently required. Photodynamic therapy has the potential to ablate subretinal neovascular tissue with considerably less destruction of adjacent, healthy retinal tissue than is typically caused by traditional, thermal, laser treatments. In practice, photodynamic therapy appears to be a modest advance over previous ablation techniques, at least in selected patients,⁵⁷ but is not as effective as injection of anti-VEGF agents.⁵⁵

It should be emphasized that these various modalities of treatment for age-related macular degeneration have significant limitations. Anti-VEGF agents are expensive and require frequent injection—in principle, indefinitely. Many patients fail to recover visual acuity. Few patients with advanced visual loss are restored to normal or near-normal visual function.

In both atrophic and exudative types of macular degeneration, the pathologic process appears to be confined to the posterior pole. These diseases thus spare the peripheral retina in nearly all cases, so that most affected patients indefinitely retain sufficient vision for independent ambulation and may be reassured that they are not going to go completely blind.

The pale white dots known as *drusen*, frequently seen in the retinas of older patients, are usually benign. They correspond to small deposits of amorphous hyaline material seen histologically between the Bruch's membrane and the retinal pigment epithelium. However, these lesions appear to serve as a predisposing factor in the evolution of exudative macular degeneration.⁵⁹ Elderly patients with drusen or who have lost vision in one eye to age-related macular degeneration may be advised to check their vision every day by examination of an Amsler grid, a 10-cm square of ruled graph paper. Any abnormality or distortion of the central vision should prompt an immediate examination of the retina. This will maximize the chance that a subretinal neovascular net will be discovered before it undermines the fovea, when treatment is most effective.

Studies suggest that nutrition may play a role in the development of macular degeneration. In one large prospective randomized study, patients at risk for age-related

macular degeneration were randomized to dietary supplementation with a combination of antioxidant vitamins (C, E, β -carotene, and zinc) or to placebo. Treated patients at high risk for exudative macular degeneration (as indicated by the presence of large or confluent drusen, extensive geographic atrophy or advanced macular degeneration in the fellow eye) experienced a 27% reduction in risk compared with controls.⁶⁰ There was no benefit to patients at lesser risk. (The antioxidant plus zinc regimen was also of no value in preventing the development of cataracts.) Studies are now in progress to assess the benefit, if any, of additional nutrient supplements, including lutein, zeaxanthin, and omega-3 fatty acids.

Retinovascular Occlusive Disease

Both retinal arteries and retinal veins are subject to sudden occlusive events, particularly in the elderly. Retinal artery occlusions are usually either embolic or arteritic in nature. Embolic occlusions are due to the occlusion of a retinal artery by a small particle derived from the more proximal circulation, most commonly a cholesterol fragment from an ulcerated atherosclerotic plaque. A small refractile cholesterol crystal may often be visualized within a retinal artery (Hollenhorst plaque). Acutely, the affected sector of the retina appears pale and cloudy. Various measures to encourage migration of the occlusive plaque toward the retinal periphery have been recommended, including lowering of intraocular pressure by medical means or by withdrawal of a small amount of fluid from the anterior chamber with a fine needle and dilation of the retinal arterial tree by breathing an elevated concentration of carbon dioxide. No convincing benefit of these maneuvers has been demonstrated.⁶¹

Transient obscurations of vision, typically lasting less than 10 minutes (amaurosis fugax), are generally believed to represent embolic arterial occlusions that are quickly dislodged into the far retinal periphery.⁶² These attacks indicate an elevated risk of occlusive stroke.⁶³

Arteritic disease (e.g., temporal arteritis) may also cause occlusion of the arteries of the retina or optic nerve head. An elevated erythrocyte sedimentation rate is commonly, but not invariably, observed. The diagnosis is usually confirmed by temporal artery biopsy. Prompt treatment with systemic corticosteroids is indicated and may prevent visual loss in the fellow eye.⁶⁴ If the diagnosis of temporal arteritis is suspected, most authorities recommend immediate initiation of systemic corticosteroid treatment; it is unwise to wait until the erythrocyte sedimentation rate and the results of a temporal artery biopsy can be obtained, as the fellow eye may lose vision in the interim. If the tests are negative, the steroid treatment can usually be stopped promptly without a period of tapering doses.

Retinal vein occlusions result in a pattern of vascular tortuosity and intraretinal hemorrhage in the affected sector of the retina. Most retinal vein occlusions seem to be due to compression of a retinal vein by an adjacent retinal artery, frequently exacerbated by hypertension, arteriosclerosis, or glaucoma. Although there is no treatment for the occlusion itself, retinal vein occlusion carries a significant risk of subsequent neovascular complications, particularly glaucoma. In cases where retinal ischemia can be demonstrated (typically by fluorescein angiography or electroretinography), retinal ablation by laser photocoagulation can substantially

reduce the risk of subsequent neovascularization.⁶⁵ Attempts to reduce retinal edema with injection of anti-VEGF agents have yielded promising results.⁶⁶

OPTIC NERVE

The elderly are particularly susceptible to ischemic injury to the optic nerve. Infarctions of the entire optic nerve head cause sudden obscuration of vision in one eye and present ophthalmoscopically with optic nerve head swelling and hemorrhages. Many patients present with infarction of only a portion of the optic nerve head, resulting in sudden onset of a monocular visual field defect. As with retinal artery occlusions, it is important to distinguish between arteritic and nonarteritic occlusions,⁶⁷ as only the former respond well to systemic corticosteroids.

Ischemic optic neuropathy is also occasionally seen in the period following otherwise uncomplicated cataract extraction. Visual recovery is rare, and the benefit of corticosteroids in this setting is unproved.⁶⁸

The term *papilledema* is reserved in ophthalmic usage for optic disc swelling as a result of increased intracranial pressure. In these patients, visual acuity is rarely impaired (at least initially); the only visual field abnormality is typically an enlarged blind spot. In chronic papilledema, optic atrophy may ensue, with progressive visual impairment. Treatment is directed at the underlying intracranial cause of the increased pressure. In occasional cases of idiopathic intracranial pressure elevations (pseudotumor cerebri), medical treatment with carbonic anhydrase inhibitors or surgical decompression of the central nervous system via a shunt or fenestration of the optic nerve sheath may be of value.⁶⁹ Other causes of optic disc swelling that must be distinguished from papilledema include ischemic optic neuropathy, malignant hypertension, and severe uveitis.

NEURO-OPHTHALMOLOGY

The oculomotor nerves and the posterior visual pathways are targets in the elderly for ischemic injury and for compressive injuries caused by intracranial mass lesions (typically tumors or aneurysms) and shifts of the intracranial contents. Sudden loss of function of a *single*, isolated cranial nerve is quite common. An isolated trochlear or abducens nerve palsy in a patient otherwise susceptible to atherosclerotic disease is usually a benign event, and spontaneous recovery is frequently seen.⁷⁰ Ischemic insults to the oculomotor nerve typically spare the pupillary fibers.⁷¹ Patients with *multiple* cranial nerve deficits or in whom pupillary dilation has occurred require a thorough neurologic evaluation, preferably including computed tomography or magnetic resonance imaging, if available.

Abnormalities of the visual field should be thoroughly investigated. Scotomas that affect only one eye or that respect the horizontal meridian are generally the result of injury to the retina, optic disc, optic nerve, or to glaucoma. Injuries at or posterior to the level of the optic chiasm will impair vision in both eyes. Of particular importance are bitemporal hemianopsias, which suggest compression of the optic chiasm, typically by a pituitary tumor, and highly congruous homonymous field defects, which suggest an injury of the occipital cerebral cortex.

ORBIT

Tumors of the orbit generally present with horizontal, vertical, or anterior displacement of the globe (proptosis). In the elderly, the most frequently diagnosed entities include orbital pseudotumor (idiopathic inflammation of one or more orbital tissues, typically the extraocular muscles, lacrimal gland, or infiltration of the orbital fat), hemangiomas and lymphangiomas, lymphomas, and primary tumors of the lacrimal gland. Management frequently requires orbital exploration for histopathologic diagnosis, as well as for anatomic correction.⁷²

Thyroid ophthalmopathy (Graves disease) is a well-known orbital problem. The impairment of ocular motility, lid retraction, and exophthalmos are largely due to the infiltration of the extraocular muscles. The orbital fat is rarely, if ever, involved.⁷³ Progression of the orbital disease is poorly correlated with the actual thyroid hormone levels, and restoration of the euthyroid state, although desirable for many reasons, is not particularly effective as a tool in the management of the ocular complications. Early cases respond well to systemic corticosteroids, but the benefits are often only temporary. In long-standing cases, patients should be monitored closely for signs of optic nerve compression and should be promptly offered surgical decompression (generally achieved by fracturing the orbital bones to provide greater room for the swollen orbital contents) if the optic nerve is at risk.⁷⁴

OPHTHALMIC COMPLICATIONS OF SYSTEMIC DISEASES

The vision of elderly patients is at risk, not only from primary ocular diseases, but from the effects of systemic diseases as well. In addition to the effects of diabetes mellitus and thyroid disease mentioned earlier, a few of the more prominent disease entities with serious ophthalmic sequelae include hematologic disorders (such as leukemia and polycythemia), rheumatic diseases (including rheumatoid arthritis, ankylosing spondylitis, and systemic lupus erythematosus), Marfan syndrome, and renal failure. Treatment is usually directed at the primary disease process, but topical or systemic corticosteroids may be needed to control ocular inflammation.

In addition to the local, mechanical effects of metastasis to the eye or orbit, systemic malignancy may also exert a deleterious remote effect on retinal function, greatly impairing vision.⁷⁵ Chemotherapy directed at the primary malignancy has occasionally led to visual improvement.

OPHTHALMIC COMPLICATIONS OF SYSTEMIC MEDICATIONS

Many elderly patients receive several concurrent medications, some of which may frequently cause ocular symptoms. A few of the more common problems are described here.⁷⁶

Tricyclic antidepressants have a mild parasympatholytic action, which may cause mydriasis and paralysis of accommodation. Major tranquilizers, such as chlorpromazine, may also cause mydriasis and interfere with accommodation and may cause a pigmentary retinopathy. Significant visual impairment has generally been reported only with protracted, chronic use. Chloroquine may also cause a

"bull's-eye" maculopathy with impairment of central vision, particularly after prolonged use with a total dosage exceeding 100 g of the chloroquine base. Hydroxychloroquine appears to be less retinotoxic than chloroquine.

Systemic corticosteroids may precipitate an open-angle glaucoma (which frequently does not abate until several weeks after cessation of the drug), as well as accelerate the formation of cataracts. Digitalis derivatives may produce various visual disturbances, in addition to the classic "yellow vision" (xanthopsia). Ethambutol is also reported to produce dyschromatopsia, as well as optic atrophy and visual field defects. The antiimpotence drugs such as sildenafil may cross-react slightly with the retinal isoform of phosphodiesterase and may cause transient perception of a bluish haze or increased light sensitivity.⁷⁷

Precipitation of an acute angle-closure attack by the mydriatic action of systemic medications is extremely rare.

SYSTEMIC COMPLICATIONS OF OPHTHALMIC MEDICATIONS

Because the dosages of topical eye medications are generally much smaller than the dosages used in systemic treatment, systemic complications from use of eyedrops are rare. However, these drugs are rapidly absorbed across the conjunctiva and nasal mucous membranes and occasionally cause systemic complications. Of course, it is also sometimes necessary to treat localized eye disease with systemic medications, which may cause further systemic problems.⁷⁶

The topical anticholinergics used as mydriatic/cycloplegics may occasionally cause the full spectrum of systemic atropinic toxicity. Of the drugs in common use, cyclopentolate appears to cause these problems most frequently. Conversely, the parasympathomimetics, such as pilocarpine and carbachol, and the anticholinesterases, such as echothiophate, may cause side effects such as abdominal cramps, diarrhea, and nausea.

Topical adrenergic agents, such as Neo-Synephrine, may cause tachycardia, hypertension, and even frank arrhythmias. Conversely, topical β -blockers, such as timolol maleate, may cause the full spectrum of side effects of β -blockade, including bradycardia, asthma, and hypotension. The use of "cardioselective" β -blockers, such as betaxolol, has not completely eliminated these problems.

Topical use of chloramphenicol has resulted in a few reported cases of aplastic anemia, generally after prolonged treatment. There have also been rare reports of Stevens-Johnson syndrome following topical administration of sulfa antibiotics. Otherwise, there are few reports of serious systemic toxicity from topical antibiotics, other than local ocular hypersensitivity reactions.

Mannitol and glycerin are administered as osmotic agents to lower intraocular pressure in acute glaucoma. The fluid shifts that result may also cause congestive heart failure, renal shutdown, and altered mentation. Patients undergoing repeated treatments should be closely monitored for electrolyte imbalances and signs of renal decompensation.

Systemic carbonic anhydrase inhibitors, such as acetazolamide and methazolamide, are occasionally used to treat glaucoma. These are difficult drugs for many patients, frequently causing anorexia, depression, impotence, and

paresthesias, in addition to such rare complications as bone marrow depression, gout, and acidosis. Carbonic anhydrase inhibitors are now available in topical formulations, which have largely eliminated many of these complications. Patients whose quality of life is intolerable on these medications should be offered medical or surgical alternatives.

LOW-VISION REHABILITATION

The rehabilitation of individuals who have sustained an irremediable loss of vision is an important component of effective medical care, particularly among the elderly. In the United States, more than two-thirds of individuals with acuity less than 6/18 are over 65 years of age. Conversely, of individuals over 65 years of age, 7.8% are reported to have acuity worse than 6/18, a fraction that increases to 25% among individuals over 85 years old. Loss of vision has been ranked as the third most common chronic condition (after arthritis and heart disease) for which individuals over the age of 70 require assistance with the activities of daily living.⁷⁸

Low-vision rehabilitation attempts to allow vision-impaired individuals to make the most effective use of whatever vision they retain, so as to facilitate activities of daily living, prolong independence, and enhance self-confidence. Successful rehabilitation frequently requires the coordinated efforts of a team of care providers, including the ophthalmologist, optometrist, and occupational therapist, as well as the assistance and understanding of the patient's family and friends or caretakers. Rehabilitation is generally most successful if it begins as soon as permanent visual disability has been diagnosed. Critical to the functional outcome is the acceptance by the patient of the need to adopt compensatory visual strategies to cope with the loss of vision, rather than to continue vain attempts to reverse the visual loss.

Rehabilitation programs should center on the needs of the patient. A thorough functional history should be obtained. Emphasis should include the patient's perceptions of the impact of the visual disability on accustomed activities and on goals for the future. Every attempt should be made to identify specific tasks that the patient's visual limitations have curtailed and whose recovery would be particularly valued. Typical problems include inability to read, mend, or pay bills; loss of independent mobility; and difficulty with distance vision, such as watching television or reading signs.

The severity of the visual deficit should be determined, including measurements of visual acuity, visual fields, and contrast sensitivity. It is often helpful to be more specific in identifying the level of visual acuity than is typical in general ophthalmic practice. Placement of eye charts as close as 1 m may be used to expand the range of acuity testing. It is frequently essential to allow a substantially greater amount of time than usual for visual assessment in low-vision patients, especially the elderly.

Rehabilitation may then proceed.⁷⁹ A comprehensive program frequently entails the dispensing and instruction in the use of optical aids (such as spectacles, telescopes, and magnifiers) and nonoptical aids (such as improved lighting, large-print reading materials, high-contrast guides for reading and writing, and closed-circuit television magnifiers). Training in the use of residual vision, such as eccentric viewing for individuals who have lost central macular function, may be attempted but may require many hours of practice over many months in order to obtain optimal performance. Training in

KEY POINTS

Treatments for Major Causes of Blindness

Cataract

- Surgical extraction, ideally with intraocular lens implant

Glaucoma

- Initial: lower intraocular pressure with topical, systemic medications
- Additional options: laser treatment to trabecular meshwork; filtering surgery

Diabetic Retinopathy

- Tight control prevents or delays retinopathy in early stages
- Focal or grid laser treatment for macular edema
- Pan-retinal laser treatment for proliferative retinopathy
- Pars-plana vitrectomy for persistent vitreous hemorrhage or traction retinal detachment

Macular Degeneration

- Atrophic ("Dry")
 - No treatment available
- Exudative ("Wet")
 - Injection of anti-VEGF agents
 - Photodynamic therapy
 - (Thermal) laser ablation of neovascular membranes
- Dietary supplement with antioxidant vitamins and zinc may reduce risk of progression from "dry" to "wet" macular degeneration.

adaptations for activities of daily living and the introduction of suitable equipment, such as needle threaders or large-print playing cards, can help recapture self-confidence and facilitate independence. Professional counseling, often in a group setting, can play an important role in helping patients deal with the emotional impact of visual disabilities.

It is important that the patient adopt reasonable goals for low-vision rehabilitation. In nearly every case, it is impossible to recover the efficiency enjoyed before the loss of visual function. Each patient must individually decide whether the results achieved are worth the extra effort that will remain necessary to perform most visual tasks. The best results are achieved when specific tasks are targeted.

DEMOGRAPHICS OF AGING AND HEARING LOSS

Americans are living longer and are healthier and wealthier than ever before. Life expectancies at ages 65 and 85 have increased dramatically. Under current mortality conditions, people who survive to age 65 can expect to live an average of nearly 18.7 more years, almost 7 years longer than persons aged 65 in 1900. The life expectancy of persons who survive to age 85 today is about 7.2 years for women and 6.1 years for men. Hence, in the United States half of all people who have ever lived to age 65 are currently alive. The increase in longevity brings with it an increase in the amount of time spent in all major activities including work and retirement. A significant proportion of older adults are gainfully employed. Labor force participation rates have risen dramatically for older men and women over the past few decades. Baby boomers are expecting to work longer; in 2004, a substantially larger proportion of people in their early to mid-50s work after 65 years of age as compared to 1992. Of interest is that in 2006, 15% of people over 65 were in the labor force. Because of the increase in life expectancy, older adults are spending a good deal of life in retirement. In fact, the average man aged 20 today can expect to spend a third of his life in retirement. The ability to communicate effectively takes on even greater importance as we move through the twenty-first century because of the lifestyle trends characterizing older adults, the increase in average income projected for older adults over the next 40 years, and declining disability rates.

As people age, the likelihood of experiencing one or more chronic conditions increases. Approximately 88% of adults over age 65 suffer from at least one chronic medical condition that requires ongoing care and management. Interestingly, 75% of U.S. health care expenditures are for the treatment of chronic conditions. Currently, 65% of Medicare beneficiaries have two or more chronic conditions, 43% have three or more, and 24% have four or more types of chronic conditions.¹ Hearing impairment is a major chronic condition recently recognized as a major public health problem. Currently, approximately 30% of the population over 65 years of age is hearing-impaired, rising to 40% to 50% among persons older 75 years and to more than 80% in persons over 85 years of age. The risk of experiencing a hearing loss increases dramatically with each additional decade. Nearly half of the 76 million baby boomers in the United States experience some degree of hearing loss. Self-reported hearing problems are less prevalent among persons of Asian and African descent than among whites or Native Americans. In addition to ethnicity and race, gender and baseline hearing thresholds and frequency play a role in hearing loss progression and severity.² The high prevalence of hearing impairment among persons over 85 years has implications for nursing home staff, as the majority of residents of nursing homes are in their ninth decade of life. That is to say, hearing loss will be the rule rather than the exception among nursing home residents and homebound older adults. It is projected

that by the year 2030, at least 21 million Americans beyond age 65 will have a hearing impairment. Approximately 11% of adults suffering from age-related hearing loss experience permanent tinnitus, most commonly described as ringing in the ear. The prevalence of tinnitus rises with age, and age-related hearing loss is a major predictive factor. The sensation of dizziness is highly prevalent among people over the age of 65, accounting for 8 million primary care physician visits in the United States. Dual sensory impairments are prevalent among older adults, as well. Of persons over 70 years of age, 18% are reportedly blind in one or both eyes, 33% reportedly experience hearing problems, and approximately 10% report concurrent hearing and visual problems.² Despite the likelihood of experiencing either a sensory, physical, or mental disability, the majority (39%) of older adults assessed their health as excellent or very good in 2006.

Given the high prevalence of hearing loss among persons aged 65 years and older, it is no surprise that the majority of persons purchasing hearing instruments are in this age bracket. Hearing aid adoption rates are higher for older adults than for younger adults with comparable hearing loss.³ Adults over 55 years of age make up 81% of all hearing aid users; yet the majority of older adults with hearing loss do not use hearing aids. The latter is consistent with the tendency of older adults to rate their health as good even in the presence of disability. The stigma associated with hearing aid use coupled with persistent complaints from experienced users about continued difficulty understanding speech in noisy environments have kept penetration rates stable over time.³ Evidence of neural plasticity associated with auditory input from hearing aids and resulting improvements in sound perception should serve as inducement for physicians to understand hearing loss in older adults and the value of available medical and nonmedical interventions, depending on the type and degree of hearing impairment. Physicians play a pivotal role in the early identification of older adults with hearing and balance problems that require attention.

AGE-RELATED CHANGES WITHIN THE AUDITORY SYSTEM

The inner ear is composed of several functional components that are responsible for both hearing and balance. The sensory, neural, vascular, supporting, synaptic, or mechanical structures within the peripheral or central auditory systems are especially vulnerable to the effects of aging.⁴ The organ of Corti, which extends from the basal convolution to the cupula or apex of the cochlea, houses the sense organ of hearing. It is the structure within the auditory system most susceptible to age-related histopathologic changes. The cochlea rests atop the basilar membrane and is composed of sensory cells (outer and inner hair cells along with their stereocilia), supporting cells, Reissner's membrane, the tectorial membrane, and stria vascularis, among other structures. The fact that various frequencies are registered in different parts of the cochlea is the basis for the tonotopic organization

of the auditory system. The organ of Corti is the site of transduction of mechanical to neural energy, and age-related atrophy interferes with the transduction process integral to the reception of sound.

The most critical risk factor for the auditory sense organ is age.⁵ The term *presbycusis* refers to hearing impairment associated with auditory system changes within the peripheral and central systems that cannot be accounted for by ototraumatic, ototoxic, genetic, or pathologic conditions.⁴ The peripheral auditory system serves as the interface between the acoustic signals in the external environment and the brain. It is responsible for detecting and coding acoustic stimuli. In combination with the cognitive system, the central auditory system is responsible for perception—that is, modifying and analyzing the code it receives from the periphery. The changes the aging ear undergoes have been studied most extensively by Schuknecht and more recently by Willott, Chisolm, and Lister.^{4,6,7} In general, hair cell loss is the rule rather than the exception in older adults. Loss of both types of hair cells is most severe in the basal region of the cochlea, with apical and midcochlear involvement of the outer hair cells as well. Although both outer and inner hair cells tend to degenerate with age, the outer hair cells are more vulnerable than inner hair cells, and their degeneration accounts in large part for the “normal” decline in hearing with age.⁴ It is noteworthy that outer hair cells are most susceptible to the effects of noise and are vulnerable to ototoxic effects especially associated with ingestion of aminoglycosides.

Research clearly demonstrates a relation between age and loss of ganglion cells.⁸ As would be expected, neural histopathologic studies suggest that age-related loss in ganglion cells is greatest near the base of the cochlea. Similarly, age is associated with a decrease in the average number of fibers in the cochlear nerve, with nerve fiber loss greatest within the basal 10 mm of the cochlea.⁹ Neural degeneration can occur before or independently of sensory cell loss.¹⁰ That is, loss of nerve fibers in one turn of the cochlea or in all turns has been noted without severe hair cell loss.³ Stated differently, loss of inner or outer hair cells is not a condition for age-related pathology of ganglion cells.³ In conclusion, two major age-related structural changes have been observed histologically in the inner ear and auditory nerve. These include extensive atrophy and degeneration of the hair cells, numerous supporting cells, and the stria vascularis, as well as a reduction in the number of functional spiral ganglia and nerve fibers that constitute the auditory portion of the eighth nerve.¹⁰

Histologic studies of the central auditory nervous system suggest that portions undergo age-related changes as well.¹¹ These apparent changes, which predominate in the auditory brain stem pathways and the auditory cortex, are not universal across individuals, nor are they universal across the nuclei or tracts within the auditory brain stem. These changes within the central auditory nervous system have profound implications for speech understanding in less than optimal listening conditions and interfere with hearing aid benefit. In short, the locus of the degenerative changes determines the functional effects of the physiologic changes.

Although within the peripheral auditory system the inner ear and central auditory pathways are most vulnerable to aging effects, the outer and middle ear do undergo

changes with age. For the most part the changes do not have a dramatic effect on the transmission of sound energy, yet the changes are of relevance because of their functional implications. The glandular structure within the ear canal, most notably the sebaceous and cerumen glands, loses some of its secretory ability. There is also a decrease in the fat present in the ear canal and an increase in the thickness and length of hair follicles in the fibrocartilaginous portion of the canal. Additionally, failure of the self-cleaning mechanism that automatically expels cerumen/earwax, a naturally occurring substance that cleans, protects, and lubricates the external auditory canal, is common in older adults and accounts in part for its high prevalence. Interestingly, cerumen impaction is also more common in those with cognitive impairment and in individuals in nursing homes.¹² As a result, the skin in the external ear canal becomes dry, prone to trauma and breakdown, and cerumen tends to become more concentrated, hard, and impacted. One of the functional implications of an excessive buildup of cerumen and a common cause of hearing aid malfunction is physical obstruction of sound emanating from hearing aids. An additional consequence of gradual cerumen buildup is constriction of the ear canal leading to a blockage of the sound-conducting mechanism resulting in a conductive type hearing loss. More than 33% (estimates range from 19% to 65%) of adults over 65 years of age present with excessive or impacted cerumen, which is associated with close to 12 million people seeking medical care for cerumen removal.¹²

Moving medially beyond the ear canal is the middle ear including the tympanic membrane and tympanic cavity wherein the ossicles lie. The three middle ear ossicles (i.e., malleus, incus, stapes) are connected by joints, similar to joints in the body, and the cartilage within the incudostapedial and incudomalleolar joints undergoes degenerative changes consistent with osteoarthritis. According to a recent study, individuals with osteoarthritis and a negative family history of hearing loss, noise exposure, or chronic middle ear effusion had a higher prevalence of middle ear abnormalities and of sensorineural hearing loss (associated with degenerative changes in the inner ear) than the age-matched control group without arthritis.¹³ As arthritis is a prevalent chronic condition for which potentially ototoxic medications are prescribed, individuals with osteoarthritis should undergo routine hearing and balance screening after age 65. A question about the presence or absence of tinnitus should be included in the screening given the high association between tinnitus and ototoxic medications.

Age-related morphologic changes also take place in the vestibular system. Most notably there is a significant loss of hair cells in the sensory receptors in the semicircular canals, the saccule and the utricle. Further, there is a decrease in primary vestibular neurons, and a significant loss of neurons in the cerebellum. Finally, the vestibulo-ocular reflex time decreases with age and the vasculature of the vestibular system all undergo changes with age. These changes in combination with changes in the ocular system with age increase the susceptibility of older adults to falls and dizziness. The rate of falls increases with age and falls, and the experience of dizziness accounts for a high proportion of primary care physician visits, emergency department visits

and hospitalizations among older adults.¹⁴ Despite the high prevalence and consequences of hearing and balance problems among persons of Medicare age, primary care physicians rarely screen for these conditions. Since the United States Preventive Services Task Force has given a "B" recommendation for office-based periodic screening for hearing loss this chapter will conclude with a recommended protocol for screening for these prevalent chronic conditions.

In addition to age-related degeneration, a number of other factors can lead to hearing loss in older adults. These include excessive exposure to occupational or recreational noise; genetic factors; diabetes; acoustic neuroma; trauma; cardiovascular disease; metabolic disease such as kidney problems and Menière's syndrome; vascular disease; infections; and ingestion of ototoxic agents, most notably aminoglycosides, ethacrynic acid, and salicylates. Data suggest that type II diabetics experience significant impairments in hearing sensitivity and speech understanding relative to an age-matched and gender-matched group of adults without diabetes. Further, hearing impairment is more prevalent among adults with diabetes, and the association is independent of such risk factors for hearing loss as noise exposure, ototoxic medication use, and smoking.¹⁵ Finally, older adults with hypothyroidism experience impaired speech understanding and reductions in audibility for pure tone signals.

Adverse drug reactions (ADRs) in the form of auditory or vestibular symptoms are prevalent and are known to be more severe among older adults.¹⁶ ADRs in older adults occur for a variety of reasons including lack of compliance resulting from a compromised understanding of the prescription because of hearing or visual problems or possibly because of confusion between two medications that might sound alike (e.g., Plavix or Paxil) to a hearing-impaired person or may look alike to a visually impaired older adult. Some of the auditory or vestibular side effects of medications frequently prescribed for older adults include dizziness, ear discomfort, ear congestion, light-headedness, vertigo, and tinnitus. Similarly, performance on selected electrophysiologic tests conducted by audiologists are affected by selected medications, so audiologists do instruct patients to suspend taking selected medications before performing vestibular studies.

In light of the variety of medical conditions associated with hearing loss and prevalent among older adults, individuals presenting with any of these conditions should be screened for hearing impairment and associated tinnitus. Impacted cerumen, otitis media, glossopharyngeal tumors, and otosclerosis are not uncommon. The latter conditions are associated with conductive hearing loss, yet they can occur in the presence of cochlear involvement. Finally, affective disorders such as depression and cognitive disorders such as senile dementia of the Alzheimer's type are also associated with sensorineural hearing loss. In fact, the prevalence of hearing loss is higher among persons with dementia than among those without it. In addition, inattention or confusion related to depression or dementia may give the impression of significant hearing loss and should be considered in a systematic geriatric assessment. Complete audiometric studies can help identify the existence and etiology of hearing loss in older adults. Hearing loss should be ruled out in individuals being worked up for cognitive or affective disorder.

BEHAVIORAL IMPLICATIONS OF ANATOMIC AND PHYSIOLOGIC CHANGES

The aforementioned age-related degenerative changes are associated with decrements in hearing for pure-tone and speech stimuli, poor word recognition, and decrements in comprehension of connected speech. In addition to loss of audibility for tonal stimuli, compromised frequency resolution and temporal processing, deterioration in central auditory processing, visual deficits, and age-related changes in cognitive abilities ensue and compromise communication.

Most studies on hearing loss characterizing noninstitutionalized older adults confirm that age-related hearing loss commonly referred to as *presbycusis* has several distinct features. First, pure-tone hearing sensitivity tends to decline with increasing age, and the hearing loss tends to be greatest in the frequencies above 1000 Hz. Further, the hearing loss tends to be bilateral, symmetrical, and sensorineural in origin, associated with damage to the sensory structures within the cochlea. The decline in high-frequency sensitivity appears to be greatest in males, whereas the decline in low-frequency thresholds tends to be greatest in females of comparable age.⁵ The average hearing loss in males can be described as mild to moderately severe, bilateral, and sensorineural with a sharply sloping configuration, whereas women tend to present with a mild to moderate gradually sloping bilaterally symmetrical sensorineural hearing loss. The odds of hearing loss are higher in men versus women, and the probability of hearing loss is lower in black than in white individuals.¹⁷ Additionally, age, gender, and frequency effects emerge in most cross-sectional and longitudinal studies of hearing loss, such that air conduction thresholds became poorer as age or frequency increase.^{4,17,18,19} It is important to note that a large proportion of subjects in many of the cross-sectional and longitudinal studies had history of noise exposure and ototoxicity, so it is often difficult to tease out the hearing loss associated exclusively with aging. Interestingly, the rate of change in hearing varies with frequency and initial hearing threshold levels.¹⁸ Further, hearing loss seems to be setting in at younger ages or prevalence of hearing loss is increasing among individuals younger than 65 years of age.¹⁷ There is a subset of older adults including octogenarian men who do not present with clinically significant hearing loss.

Among residents of nursing facilities, the sensorineural hearing loss tends to be more significant, moderately severe sloping to severe, and more prevalent, affecting approximately 70% to 80% of residents. The fact that nursing home residents are older accounts for the high prevalence of more severe hearing loss among residents. Similarly, by the year 2011 when the first group of baby boomers will turn 65, there will be an increase in older adults with significant hearing loss who are homebound and are receiving palliative care who will have an increased need to communicate with health care professionals, caregivers, and family members.

The pure-tone hearing loss, site of involvement within the cochlea, eighth nerve, auditory brain stem pathways, auditory cortex, and cognitive factors including memory loss determine in large part the nature of the speech understanding problems experienced by older adults. The classic complaint of older adults with *presbycusis*, namely "I can hear people talking but cannot understand what they are saying, especially in noisy situations," aptly describes the problems

that derive from the reduction in transmission, reception, and perception of the speech signal attributable to sensorineural hearing loss.

The speech recognition difficulties can in part be predicted from an understanding of the interaction between speech acoustics and the compromised audibility of selected frequencies associated with presbycusis. Ordinary conversation takes place over a frequency band that ranges from 250 to 6000 Hz and within a decibel range of about 35 dB. Consonant sounds and diphthongs such as s, sh, th, z, k, t, p, and g are relatively high in frequency or pitch and low in intensity (dB) or loudness. Conversely, vowel sounds such as a, i, o, and u are concentrated in the lower frequencies and are somewhat higher in intensity. Environmental noise is high in intensity and low in frequency as well. Audibility for consonant sounds is critical to the understanding of speech. Hearing loss afflicting most older adults with age-related hearing loss renders consonant sounds (e.g., s, th, t, z) with energy in the high frequencies inaudible, yet low-frequency vowel sounds and environmental noise can be heard normally. As a result of the configuration of hearing loss, older adults claim that they can hear people talking (vowels audible) but they cannot make out the words (consonants inaudible) especially in noise (audible).

A number of variables beyond the audiogram have a dramatic effect on speech understanding in older adults. Speech understanding difficulties are exacerbated in challenging acoustic environments such as a noisy room, as background noise tends to be audible given good low-frequency hearing, yet consonant sounds important to understanding are inaudible. Speech understanding in reverberant environments (e.g., large rooms with high ceilings and walls with windows or mirrors) is also compromised for older adults. Distance between the speaker and listener can erode speech understanding. Characteristics of the speaker's voice, complexity of the message, listener's knowledge of the language, use of gestures, and availability of contextual information influence speech understanding as well. Older adults have difficulty understanding fast speech and accented speech used by non-native speakers of English and understanding speakers with dialects.²⁰ Speech understanding is compromised when presented without the benefit of contextual information, when multiple speakers are talking, and when the speaker is not nearby. Age-related changes in cognitive processing, declines in rapid information processing, decrements in auditory temporal processing because of central auditory effects of peripheral pathology vary across older adults, but those individuals experiencing such changes have dramatic speech understanding difficulties.²⁰ Table 97-1 includes a list of tips for helping to ensure that your patients understand most of what is being communicated to them.

PSYCHOSOCIAL CONSEQUENCES OF DECREMENTS IN PURE-TONE SENSITIVITY AND SPEECH UNDERSTANDING

The behavioral implications of the hearing and speech understanding difficulties characterizing older adults are considerable. Untreated hearing loss impacts daily communication function; restricts one or more dimensions of quality of life including physical functional status and cognitive

Table 97-1. Tips for Effective Communication With Patients with Hearing Loss

- Make sure your face and mouth are visible when speaking.
- If hearing difficulties are observed and no hearing aid or other hearing assist device is functioning, all communication with your patient should be conducted with the use of a commercially available personal sound amplifier.
- Speak when you are at most 3 to 6 feet from your patient.
- Repeat or rephrase what you have said if your patient doesn't understand you.
- Make sure your patient is paying attention to you when you speak.
- Raise the level of your voice to be understood, but never shout.
- Use gestures to enhance your spoken message.
- Be patient when repeating instructions to your patient.
- Make sure your lips and face are visible to your patient.
- Do not have anything in your mouth while conversing with your patient.
- Make sure your face is on the same level as your patient's when you are speaking.
- Make sure there is no glare on your face when speaking to your patient.
- Speak in an area with little noise.
- Turn off radio, close the door, and remove any other sound sources when speaking.
- Inform your patient when you change topics.
- Slightly decrease the rate of your speech.
- Write information down that is important, as multiple modalities are helpful.
- Make sure to provide a context for what you are trying to communicate.
- Make sure the receptionists and billing people in your offices look at your patient and not at the computer when they are checking them in or processing papers and make sure they speak slowly on the telephone or use an amplified telephone when contacting patients with hearing loss to ensure that the patients understand the message.

and emotional function; and interferes with one's capacity to meet personal and occupational demands.^{21–25} Dalton and her colleagues reported that older adults with moderate to severe hearing loss were more likely than individuals without hearing loss to have impaired instrumental activities of daily living (IADLs) and activities of daily living (ADLs).²⁴ They also reported that severe hearing loss had a significant association with decreased function on the mental and physical component scores of the SF-36.

Moreover, the myth that hearing loss is harmless has been debunked, and it is becoming increasingly clear that, if untreated, hearing loss can be costly to the individual and family members. Untreated hearing loss is costly from an economic vantage point; it is associated with lost wages and lower income in retirement.²⁵ Kochkin's data revealed a link between household income and hearing loss severity, with individuals with mild hearing loss reporting a household income of \$36,400 and persons with severe loss reporting an income of \$33,600.

The adverse effects of untreated hearing impairment presents a global problem. A study conducted in a geriatric medicine clinic in Singapore attempted to quantify the psychosocial consequences of self-perceived handicap in a sample of 63 older adults ranging in age from 62 to 90.²⁶ They reported that of subjects with self-reported hearing difficulty and a fail on the pure-tone screen, 70% indicated that they would be happier if their hearing were normal, 40% indicated that difficulty hearing made them feel frustrated,

and 43% admitted to feeling sad because of their hearing handicap.²⁶ Interestingly, the federal government in Australia is designing a comprehensive approach to managing age-related hearing loss because hearing impairment is the second highest cause of disability for every Australian man.²⁷

In general, unaddressed hearing loss undermines familial relationships and impacts nearly every aspect of daily life, ultimately eroding the patient's quality of life. Specifically, hearing loss does the following:

- Negatively impacts communicative behavior
- Compromises efficiency at work
- Alters psychosocial behavior
- Strains family relations
- Limits the enjoyment of daily activities and leads to activity limitations and participation restrictions
- Jeopardizes physical well-being
- Interferes with the ability to live independently and safely
- Interferes with long-distance contacts on the telephone, potentially jeopardizing safety and security
- Interferes with medical diagnosis, treatment, management, and interventions in emergency rooms
- Compromises compliance with pharmacologic regimens
- Interferes with therapeutic interventions, compromising quality of care

HEARING TECHNOLOGIES

Once hearing loss is documented, the etiology determined, medical treatment ruled in or out, and the activity limitations and participation restrictions quantified, an older adult should undergo some form of audiologic rehabilitation. Audiologic rehabilitation (AR) is a patient management process designed to reduce activity limitations, decrease participation restrictions, improve communication efficiency, and improve quality of life. The goal is to help the individual overcome challenges posed by hearing impairment and sensory management in the form of hearing aids, hearing assistive technologies, or hearing implants. Approximately three quarters (74%) of the people fitted with hearing aids in 2006 were at retirement age or older.³ Hearing aid adoption rates for people ages 85+ and 75 to 84 were 61% and 44%, respectively. Interestingly, hearing aid adoption rates decline precipitously among individuals in the younger age groups. It is notable that the average hearing aid purchaser is 70 years old, yet it is important to emphasize that most older adults with hearing loss *do not* use hearing aids.³ The significant communicative and psychosocial effects of hearing loss, coupled with the fact that a high percentage of older adults suffer from hearing loss that affects ordinary daily life, and the efficacy of hearing aids in reducing the functional consequences of hearing impairment would indicate that older adults should be encouraged to purchase hearing aids before hearing loss becomes an intolerable burden and less responsive to intervention.

A number of variables are at play, which determine whether an older adult will consider hearing aid use, including the self-perception of the severity of hearing impairment and the perception that one can get along without hearing aids. The high cost of hearing aids, especially digital devices, is a deterrent to older adults on fixed incomes, as are reports

from friends that hearing aids are of no value. Unfortunately, third-party reimbursement for hearing aids is limited, and economics dictates that nonmedical intervention for hearing loss may not be a priority.

Although a host of factors influence nonadoption rates, many variables are predictive of hearing aid candidacy, hearing aid satisfaction, and hearing aid success. These include but are not limited to the following: auditory, physical, sociologic, psychological, cognitive, and environmental factors. With regard to auditory variables, sensorineural hearing loss of nearly any degree can be remediated via a hearing aid, assuming the client is interested in pursuing amplification. Clinical experience suggests that motivation is one of the most important, yet least well understood, psychological factors that affects rehabilitation potential in general and hearing aid candidacy in particular.²² It explains why behavior is initiated, why it persists, and why it is attenuated. Motivation to pursue intervention is optimal when an individual (1) knows what he or she wants, (2) expects it can be attained, (3) believes that the rewards are meaningful, and (4) considers that intervention takes place at a reasonable cost.²⁸ It is incumbent on the audiologist to understand the patient's motivations for pursuing a hearing aid so as to ensure that their needs and expectations are fulfilled. The audiologist can optimize the patient's motivation to purchase amplification by emphasizing the positive consequences associated with a hearing aid purchase and instilling realistic expectations regarding the advantages and disadvantages associated with hearing aid use.²⁸

The new generation of hearing aids has impacted use and acceptance patterns, and an understanding of the technology can assure that physicians will partner with audiologists to encourage those with impaired hearing to seek assistance to overcome communication deficits. Present-day hearing aids improve audibility, tend to be more comfortable in the ear, can be manipulated to provide appropriate gain at selective frequencies, differentially compress high-intensity sounds, filter out background noise, and many have directional microphone technology, which picks up speech coming in front of the speaker and eliminates unwanted noise from behind the speaker. Hence, they are designed to meet the needs of individuals with varying auditory and nonauditory needs.

Hearing aids are basically miniature public address systems with several key components. They can be broken down into several categories ranging from traditional devices that are considered analog signal processing devices to digital signal processing systems, which can be described as low end, middle level, and high end. [Table 97-2](#) contrasts the style unit, the signal processing technology, and the level of sophistication of available hearing aids.

The majority of hearing aids sold in 2008 were digital; approximately 8–10 different companies manufacture the large variety of hearing aids available to consumers. Hearing aid styles range from traditional behind the ear (BTE) to open fit mini BTE units, to custom in-the-ear (ITE), to in the canal (ITC), and completely in the canal (CIC). Mini-BTEs are a new category of hearing aid that utilizes transparent tubing and a variety of open earmold options. They are small BTE units with receivers in different locations and an earmold, which varies in terms of the amount of the ear canal that remains open. Many BTE units are ergonomically shaped,

Table 97-2. Hearing Aid Classification System

Style of Unit	Signal Processing Technology	Level of Sophistication
Traditional behind the ear (BTE)	Analog,* digital signal processing [†]	Low end
Mini-BTE (mBTE)	Analog, digital signal processing	Low end, middle level, high end
In the ear (ITE)	Analog, digital signal processing	Low end, middle level, high-end
In the canal (ITC)	Analog, digital signal processing	Low end, middle level, high end
Completely in the canal (CIC)	Analog, digital signal processing	Low end, middle level, high end

*Most basic and least expensive circuitry.

[†]Greater sound precision, less internal.

most are currently available in a variety of colors, many are water-resistant, and more and more do not include volume controls. Newer and smaller BTE units are attached to thin clear tubing or thin preformed tubing and are referred to as open fittings (i.e., open fitting, BTE). Similarly in-the-ear hearing aids are referred to as open canal devices. Open fittings simply refer to the fact that the ear canal remains relatively "open" or "unoccluded." When there is no occlusion, people with good low-frequency hearing and significant high-frequency hearing loss can be comfortably fitted with hearing aids that take advantage of their good low-frequency residual hearing and that are no longer susceptible to feedback (sound leakage), which traditionally was a problem. The basic components of all hearing aids include the amplifier, microphone, receiver, earmold, and battery. An important function of the amplifier, in combination with the receiver and earmold/molded piece, which delivers sound to the ear, is to control the maximum amount of amplification the user receives. This function is critical, as the appropriate amount of gain/amplification minimizes the possibility of hearing aid rejection because sound is amplified to an uncomfortably loud level. Open canal fittings in combination with digital signal processing have revolutionized the hearing aid industry by allowing special features to be included in hearing aids that lead to dramatic performance improvements. Present-day hearing aids include features that have increased their comfort, cosmetic appeal, ease of use with the telephone, and noise suppression capabilities.

Common product features include noise suppression circuitry, feedback reduction, automatic telecoils, directional microphones, low-battery indicators, power on delay, wind noise protection, Bluetooth technology, and data logging. The size, style, and amplifier type determine which battery powers the hearing aid. All hearing aids use 1.4-volt batteries, and at the time the hearing aid is dispensed, the audiologist will advise consumers on the correct battery type for the particular unit. Battery types range from the smallest (number 10 battery) to midsized batteries (312, 13), to the largest size battery (number 675). Approximately 40% of BTE hearing aids dispensed during the first part of 2008 used the smallest battery sizes (10 or 312) and were open canal fittings, which when appropriate to the hearing loss allow for considerable user comfort. The American Association of Retired Persons is one of the least expensive sources for purchasing batteries, but they are available at most drugstores, through Costco, battery clubs sponsored by dispensers, and at military bases for veterans. The size battery that a hearing aid accommodates depends in large part on the style and size of the hearing aid. Some hearing aids come with rechargeable batteries, which have advantages and disadvantages.

Various hearing aid styles are available to the hearing-impaired older adult once it is mutually decided that hearing

aids are the appropriate intervention. According to a recent survey of hearing instrument dispensers, more than 95 percent of all hearing aids sold in 2008 used digital signal processing. Sixty-three percent of all hearing aids sold in the first half of 2009 were BTE devices, of which 42% used the smaller size ten batteries. [Figures 97-1 and 97-2](#) display a BTE and mini-BTE. Approximately 49% of all hearing aids sold in the United States in 2007 were ITE units; of these, 9.8% were CIC units, 12.4% were ITC units, and the remainder full-shell/half-shell ITE units.²⁹

Custom ITE hearing aids range in size and are identified according to their physical location and their dimensions within the concha of the outer ear or pinna. Custom in-the-ear hearing aids (ITEs, ITCs, and CICs) take full advantage of the size and shape of an individual user's ear (that is, it completely occupies the concha portion of the pinna). Typically the hearing aid for the right ear is red and the one for the left ear is blue, but other color options are available. ITC hearing aids are smaller than ITE units, having most of their components within the cartilaginous portion of the ear canal. For the most part, ITCs use small 312 batteries or even smaller size cells (i.e., 10), making the battery difficult to insert and remove for older adults with manual dexterity problems and reduced tactile sensitivity.

The electronic components of CIC hearing aids are deep within the external auditory canal, terminating close to the tympanic membrane. [Figure 97-3](#) displays CIC hearing aids with the tiny components relative to a coin. The only piece visible is the thin piece of plastic extending outward from the faceplate of the hearing aid, which is used to remove the unit. The microphone of CIC hearing aids is located deep in the ear canal providing for a natural high-frequency boost, less wind noise, and theoretically better speech understanding because of the acoustic advantage provided by the outer ear. CICs use very small batteries, and some companies make devices to assist in battery insertion and removal.

Most of the hearing aid styles discussed thus far incorporate advanced features. The majority of units sold in 2009 included feedback reduction technology, noise reduction technology, directional microphone technology, and data logging technology. The bulk of behind-the-ear hearing aids sold in 2009 were of the receiver in the canal or receiver in the ear variety furthering the fitting candidacy for the hearing impaired. Availability of these "high-tech features" is no longer limited to low-end hearing aids, providing hearing aid dispensers with the ability to custom-tailor the response of the hearing instrument to the consumer's lifestyle, listening needs, and financial situation. Similarly, the dispenser can adjust the low frequencies independent of the high frequencies depending on the hearing configuration and the nature of the input sound, providing for improved

Figure 97-1. Traditional behind-the-ear hearing aid.

Figure 97-2. Mini-behind-the-ear hearing aid.

speech understanding in favorable and unfavorable listening environments. The availability of Bluetooth and automatic telephone settings, hearing aids without volume controls, and rechargeable batteries further increases the flexibility of hearing aids and appeals to people with varying technologic skills. Finally, the majority of hearing aid fittings are binaural given the listening and speech understanding advantages of two ears, especially in noisy situations. It is worth noting that because of cognitive or central auditory processing problems, some older adults are not candidates for binaural fittings, and the audiologist should explore the appropriateness of a binaural fitting before proceeding.

The average price of hearing aids in 2007 varied according to the style, the circuitry, the level of sophistication, programming flexibility, and the number of special features. The cost differs dramatically by qualifications of the dispenser and with geography as well. The average overall

Figure 97-3. Completely in-the-canal hearing aids.

price in 2007 for an analog hearing aid was \$857 as compared to \$948 in 2006.³⁰ The average price for a low-end digital signal processing unit was \$1269, the average price of a midlevel digital signal processing unit was \$1943, and that of a high-end digital signal processing unit was \$2714. The average price of a high-end DSP CIC unit was \$2860, as compared to \$2609 for a high-end DSP BTE unit and \$1209 for a low-end DSP ITC unit.³⁰ The price typically includes a minimum 1-year warranty with an option to extend the warranty; but this too varies by manufacturer. Service connected veterans are eligible for hearing aids through the Department of Veterans Affairs and the service and technology is consistently superb. The considerable financial investment associated with the purchase of hearing aids underlines the importance of referring the consumer to a qualified professional who spends time dispensing the product, orients the individual and family members to the hearing aid in an effort to optimize the fit, and has hours daily, as problems do arise on a relatively frequent basis. Finally, with the exception of cochlear implant surgery for severely and profoundly impaired individuals, support for hearing care is modest or unavailable in most health plans. However, recently selected managed care plans and more and more corporate plans for retirees have introduced some, albeit minimal, coverage toward the purchase of a hearing instrument.

The value of hearing aids lies in their ability to restore the reduced audibility and frequency resolution accompanying hearing loss and to increase loudness of the speech signal relative to background noise so that speech understanding is more comfortable and intelligibility improved in suboptimal situations. Older adults are enjoying improved speech understanding in noisy situations, and consumer satisfaction with hearing aids that include advanced features is growing. A task force convened by the American Academy of Audiology completed a systematic review of studies on the relationship between hearing aids and health-related quality of life in adults with hearing loss.²³ The task force was charged with reviewing and summarizing the evidence regarding the nonacoustic benefits of hearing aids in light of the rise in prevalence of adult onset hearing loss, the increase in sophistication of hearing aids, and the low proportion of adults using hearing aids. The task force concluded that hearing aids are in fact beneficial in several health and social domains over the short and long term, which should serve as an inducement for health professionals to refer the hearing impaired for an evaluation to consider candidacy for intervention. It is important to emphasize that their positive impact on quality of life and on brain plasticity is maximized when hearing aids

are delivered close to the onset of the hearing loss, when two hearing aids are worn in the case of bilateral hearing loss, when hearing aids are worn on a regular basis, and, most important, when hearing-aids are delivered in the context of a holistic rehabilitation program. Brain plasticity occurs when functional representation of the brain is altered when the hearing-impaired are taught to effectively relearn and use the new speech input provided by hearing aids through some form of listening training designed to enhance auditory system.³¹ It is also important to note that lack of amplification is associated with sensory deprivation, wherein speech understanding ability declines over time in unaided ears of adults with sensorineural hearing loss, whereas hearing for pure-tones and speech understanding ability either improves or remains stable over time with hearing aid use.³²

The improved communication and reduction in social and emotional dysfunction perceived by older adults is sustainable over a period of 1 year of hearing aid use. Compared with the waiting list group, those older adults with mild to moderately severe sensorineural hearing loss who received hearing aids demonstrated an 85% improvement in social and emotional function, a 68% improvement in communication function, and a 26% improvement in depressive symptoms as assessed by the Geriatric Depression Scale. Improvements in psychosocial well-being and communication function associated with short-term hearing aid use are comparable for older and younger adults.³³ This finding is an important step toward dispelling the myth that older adults cannot derive significant benefits from hearing aids. Data from a 1999 study completed by the National Council on Aging (NCOA) revealed that hearing aid users are less depressed and more socially engaged than are older adults with comparable hearing loss who do not use hearing aids. Further, the NCOA study revealed that non-hearing aid users report more negative social effects of hearing loss than users, and non-hearing aid users reported higher levels of anger and frustration than hearing aid users.³⁴

Hearing aids + audiologic rehabilitation = improved function

The benefits derived from hearing aids are enhanced when delivered in the context of a holistic audiologic rehabilitation (AR) program.³⁵ AR is an integral part of the solution to hearing loss and its negative consequence.^{22,35,36} It is a highly variable process with several components, and current thinking suggests that AR and hearing aid fitting have a complementary relationship.^{22,37} AR consists of (1) sensory management to optimize auditory function using hearing aids, assistive listening devices, or implantable devices; (2) instruction in the use of technology and control of the listening environment; (3) perceptual training to improve speech perception and communication; and (4) counseling to enhance participation and address emotional and practical limitations.^{35,38}

Available cost utility analyses confirm that the most favorable outcomes are achieved when hearing aids are dispensed in the context of a comprehensive rehabilitation program.³² Further, of the various approaches to AR, group programs that focus on counseling, communication strategies training, and computer-assisted techniques to enhance perceptual learning are of proven cost utility and effectiveness.^{34,37} The systematic review recently completed by Hawkins concluded that there is reasonably good evidence that

Table 97-3. The Value of Audiologic Rehabilitation + Hearing Aid Use

Features of Integrated Audiologic Rehabilitation Programs

- Provide an understanding of hearing aids, their care, maintenance, and use of the data logging feature.
- Promote realistic expectations regarding the value and capabilities of hearing aids.
- Maximize sensory input by providing the best possible visual and auditory signal.
- Help the patient understand the psychological and social problems resulting from hearing impairment.
- Maximize sensory integration by making the best use of the amplified auditory signal and the visible signal.
- Promote the use of cognitive processes necessary to derive meaning from incomplete sensory messages.
- Promote an understanding of how to create a positive communication environment.
- Develop within the individual assertive and interactive ways of communicating and repairing breakdowns.
- Empower the hearing impaired and help them to become proactive.
- Engage members of the individual's support system so that they partner with the hearing-impaired person.
- Help ensure understanding of compensatory communication strategies.
- Facilitate neural plasticity.
- Promote personal adjustment to hearing loss.

hearing-related quality of life improves when adults participate in counseling-based group AR programs.³⁷ Table 97-3 summarizes the value of delivering hearing aids along with adjunctive counseling-oriented AR.

Device-related and personal adjustment counseling, perceptual and listening retraining, and familiarity with effective communication strategies will help debunk many of the myths surrounding hearing aid use and will provide realistic expectations critical to success. To ensure maximal benefit from hearing aids, older adults must have realistic expectations, patience, and the understanding that hearing aids are not very smart in that they do not automatically do a good job of helping the user to discriminate between the sounds the person wants to hear (i.e., speech) and those sounds the person wants to ignore (i.e., background noise).³² New hearing aid users should not expect to suddenly hear normally. Users must understand that it takes time to realize the potential benefit from hearing aids, and thus they should not become discouraged early. Their ears and brains must become reeducated to hear selected patterns of sounds that have been made louder by the hearing aid. In a sense, new hearing aid users are suddenly being exposed to or bombarded with a world of sounds they have forgotten existed, such as the blare of street noises in the city, and they must become reoriented to or acquainted with the location and source of these "new" sounds. Table 97-4 summarizes what the elderly can realistically expect from hearing aids.

To better adapt to the hearing aid, new hearing aid users should wear the hearing aids for as many hours during the day as they feel comfortable with the units in their ears. Ideally they should wear their hearing aids in restricted situations at first, such as while at home with family members, while watching the television, or while eating dinner. Once the individual feels comfortable with amplified sound at home, he or she should venture into new hearing situations, at all times experimenting with the volume control to

Table 97-4. Realistic Expectations Regarding Capabilities of Hearing Instruments

Hearing aids will do the following:

- Enable the hearing impaired to hear many sounds they were unable to hear previously
- Enhance high-frequency sounds with reduced feedback
- Enable the hearing impaired to understand speech more clearly in noise, but not in all environments
- Improve sound quality
- Improve the ability of the hearing impaired to hear environmental sounds
- Require some time for adjustment
- Improve job performance
- Ease communication difficulties
- Stabilize speech understanding in the ear fitted with hearing aids
- Provide high value relative to cost

maintain speech input at a comfortable level and noise at a minimum. Although full-time use should be the goal, there are some exceptions. Persons with mild hearing loss may find their hearing aids useful in business meetings but burdensome in noisy situations such as restaurants or parties.

If patients complain that some intense sounds produce an uncomfortably loud hearing sensation, they should alert the dispensing audiologist at the follow-up visit, because a simple adjustment can usually be made. Many hearing aid users report that although at first they prefer "natural sounding" louder sounds as their ears and mind adjust, they tend to prefer a boost in the high-frequency response of the hearing aid that makes the consonants of speech crisper and easier to understand. It is of utmost importance that new hearing aid users schedule and keep all follow-up appointments (a minimum of 2 to 4 weeks following receipt of the hearing aid) so that the audiologist can make the necessary adjustments to ensure that sounds are comfortable, audible, tolerable, and understandable. At these visits, the audiologist and new hearing aid user work together to modify the response of the hearing aid for optimal speech understanding and user comfort. Finally, new hearing aid users should accept their hearing loss and not continue to consider it a disgrace or a stigma. They should not cover their hearing aids as a way of hiding the hearing loss, as hearing aids signal others that a hearing loss exists and that they should speak clearly. If the hearing aid users accept their hearing loss and hearing aids, so will persons to whom they are speaking. In short, acceptance of hearing loss and motivation to overcome its consequences are conditions for hearing aid satisfaction and success.

Implantable devices and hearing assistive technologies

Of the components of audiologic rehabilitation, sensory management, or the provision of some form of amplification ranging from hearing aids and hearing assistive technologies (HATs) to medical technologies such as a cochlear implant or bone-anchored hearing aid, is the treatment of choice. Since the late 1980s, there have been considerable improvements in speech-processing strategies used with cochlear implants; they are now a realistic option for healthy, older adults with severe to profound hearing loss for whom hearing aids are not conferring enhanced quality of life in important social environments. There are approximately 300,000 older adults suffering from non-age-related profound hearing loss

for whom cochlear implants are a viable option.³⁹ Cochlear implantation is a cost-effective option for those older adults who qualify audiometrically and are considered good surgical candidates. The surgical procedure requires general anesthesia and can be completed within 3 hours.

Cochlear implants are small commercially available electronic devices surgically implanted into the inner ear. The array of electrodes bypasses the damaged hair cells and is inserted into the auditory nerve, directly stimulating it. It is noteworthy that age and duration of deafness have a negligible effect on postsurgical outcomes among subjects 65 years and older.³⁹ Available evidence suggests that cochlear implants improve the user's access to verbal communication and environmental sounds, and they enhance telephone communication and the user's enjoyment of music.³⁹ Interestingly, residual speech recognition carried higher predictive value for success than the age at which an individual received an implant.

In contrast to a cochlear implant, a bone-anchored hearing aid (BAHA) is surgically implanted into the skull behind the ear. Some consider it a surgically implantable bone-conduction hearing aid, as it works on a principle similar to that of bone-conduction hearing aids worn by individuals with chronic middle ear disease or external and middle ear deformities, which preclude use of traditional air conduction hearing aids. The BAHA delivers sound into the skull by means of sound vibration. These vibrations transfer sound from the bad ear side to the good ear side through the skull. The BAHA can be used in persons with conductive hearing loss, particularly those with chronically discharging ears, or in persons with complete or near complete single-sided deafness (SSD) or deafness in one ear.

The BAHA has three components: a titanium implant that is surgically implanted into the skull just behind the affected ear, which over time naturally integrates into the cranium; an external abutment that serves as a link between the titanium implant and the sound processor; and a sound processor, which picks up the sound, shapes it, and changes it into a vibratory stimulus that is passed through the abutment and titanium implant to vibrate the cochlea in both ears. The sound processor is either worn on the head or is worn on the body like a body hearing aid with a cord and receiver that snap onto the abutment. Older adults with SSD who have not experienced much success with hearing aids should consider speaking with an otolaryngologist to determine candidacy. Before proceeding with the surgical procedure, individuals can try the BAHA to gain a feel for the experience of hearing via bone conduction. Reports suggest that BAHAs have successfully reduced the emotional and social handicap experienced by persons with SSD from a variety of etiologies.

Surgical implants are appropriate for a select group of older adults with hearing impairment. Hearing aids in combination with AR are the primary nonmedical intervention for hearing impairment. However, for selected individuals, hearing aids do not provide for the easy clear listening in all communication environments. Their disadvantage lies in the fact that well-fit hearing aids can provide a favorable signal-to-noise (S/N) ratio if the environment is free of distractions and if the speaker is close to the person with the hearing impairment. However, in many listening situations, the hearing aid microphone at the listener's ear is typically

some distance from the sound source, making speech difficult to understand especially in a noisy room. In essence, the farther away from the sound source one is, the softer the sound pressure and the less clear the speech signal.⁴⁰

For the most part, the listening environments we live in are demanding, and hearing aids alone are insufficient to access auditory events that are not close to the person who is hearing impaired. HATS have proven invaluable in overcoming some of the environmental barriers to successful communication. They include auditory and nonauditory devices available to help individuals in a variety of listening situations.⁴⁰ Collectively, these devices rely on auditory, visual, or tactile information to augment speech understanding or to help the user to monitor environmental sounds. HATS are recommended based on an individual's communication needs including small group face-to-face communication, electronic media, telephone use and environmental alerting needs, large group communication, and noisy environments. HATS are designed to be used as a complement to or in lieu of hearing aids or cochlear implants. Their value, in part, lies in their simplicity and low cost. They enhance or help to maintain the functional communication capacities of the hearing impaired.

Divided into four distinct categories, these devices use alternate modes of sound transmission and different types of signal delivery modalities. The four categories include (1) sound-enhancement technologies, (2) television/media devices (television reception), (3) telecommunications technologies (telephone reception), and (4) signal-alerting technologies (reception of environmental warning sounds). Sound enhancement technologies enable a person with hearing impairment to understand speech clearly when the speaker is at a considerable distance away. This is accomplished by transmitting the signal directly to the listener's ear, thereby overcoming the barriers posed by distance and environmental noise. In short, the intensity of the signal relative to the noise (signal-to-noise ratio) becomes more favorable. Sound enhancement technologies include a microphone placed close to the sound source (within 6 inches), which picks up the signal, and via one of several modes of transmission, sends the signal to the listener's ear(s). Signals can be transmitted to the listener via a hard-wired connection between the microphone/amplifier/receiver and the headphones, via wireless radio transmission of signals (i.e., frequency modulated [FM] unit), via an induction loop system, or via infrared light.

Figure 97-4 shows an inexpensive, hard-wired system, available online and at audio stores, that health professionals can use when communicating one-on-one with patients who have difficulty understanding in the clinical setting. These personal amplifiers are ideal for use during an intake, when communicating at bedside with persons with hearing impairment, and when providing important recommendations to patients for whom compliance is key.

Personal FM systems are wireless communication systems that pick up the signal directly from the source and transmit it via radio waves to the hearing-impaired receiver. FM systems can be used with or without a hearing aid. They are more costly than hardwired systems, yet can facilitate listening in noisy environments, in large rooms with poor acoustics, or when the speaker is at a distance such as in a boardroom or at a conference. With this arrangement, the

Figure 97-4. Personal amplifier.

FM microphone transmitter is worn close to the source of speech (speaker), and the signal is delivered via FM signals to the listener's ears free of environmental noise. FM systems can be used outdoors and when the speaker and listener are in different rooms. FM systems benefit individuals with moderately severe to severe sensorineural hearing loss whose personal or professional lives demand adequate speech understanding to function effectively. When using FM systems in a large auditorium, the speaker talks into a microphone, and the signal is transmitted wirelessly to those in the audience wearing a stand-alone FM receiver, a BTE-FM system, a hearing aid with a telecoil system, or a cochlear implant equipped with a telecoil. If the hearing aid does not include a telecoil, the individual can link the hearing aid to an FM system using a small adapter known as a boot. Many companies manufacture behind-the-ear hearing aids that include an integrated BTE-FM system, whereas others manufacture hearing aids that can be coupled to an FM system. Present-day hearing aids that are equipped to receive FM signals also incorporate multimicrophone technology. Older hearing-impaired adults with moderately severe to severe sensorineural hearing loss or auditory processing problems should consider a BTE that incorporates an FM receiver as an option. When coupling an FM system to a hearing aid, older adults do experience improvements in communication performance in a variety of situations.⁴⁰ Further, BTE-FM systems are beneficial in restaurants, at lectures, in cars, and at noisy receptions.

In contrast to FM systems, which use radio waves to carry sound, infrared systems use invisible light, the wavelength of which is outside the range of human visibility, to transmit signals indoors in a single room.⁴¹ Infrared systems can be used with different forms of media including television, stereo systems, and in large rooms where people congregate such as theaters or houses of worship. Infrared systems provide the best quality sound for radio and television and are widely used in theaters and in concert and lecture halls. Essentially the remote microphone of the system is placed within 6 inches of the media speaker to provide a favorable S/N ratio.

Telecommunication technology facilitates communication over the telephone. A variety of options are available

ranging from portable amplifiers, speakerphones, amplified telephones, text messaging, and telecommunication relay services, such as text to voice, Internet protocol (IP) relay services, video relay services (VRSs), or text telephone services known as telecommunication systems for the deaf (TDDs).⁴¹ TDDs are invaluable to persons with severe to profound hearing loss for whom it is impossible to discriminate speech that is transmitted by telephone. TDDs are approximately the size of a typewriter. Individuals communicating over the telephone merely type in their message, or use a relay operator who types in a message, which is displayed across the listener's TDD. The telephone company provides relay service free of charge for a person wishing to speak with a TDD user. E-mail is also an excellent form of telecommunication technology for a person with hearing impairment who is unable to communicate comfortably over the telephone. Bluetooth technology, open canal hearing aids, and hearing aid compatible cellular phones allow hearing aid users to comfortably speak on the phone while wearing hearing aids. Finally, signal-alerting technology includes any system that warns, signals, or alerts a person with a hearing loss. These systems use loud sounds, visual signals, or tactile signals to alert the hearing impaired to sounds in the environment. For example, a vibrator placed under the pillow can awaken the person with hearing loss in the morning, a strobe light attached to a smoke alarm can alert the hearing-impaired person to a fire, and vibrating pagers or wristwatches can alert the hearing impaired as well.⁴¹ Signal-alerting devices are commercially available and are invaluable for hearing-impaired persons who are homebound, for persons with cognitive impairments, and for residents of nursing facilities who cannot hear external events because of hearing loss.

Audiologists are well equipped to guide persons and institutions about the system(s) that will best meet their needs and to arrange for them to purchase the necessary assistive listening devices. Hearing-impaired individuals have to be proactive about assistive technologies, as audiologists sometimes underestimate their value. A number of Web sites describe the alerting technologies available to the consumer.

SCREENING PROTOCOLS

Mounting evidence exists suggesting that at least 25% of persons between 65 and 75 years of age have undiagnosed hearing loss that may be detectable via routine, inexpensive hearing screening activities.⁴² Further, fall-related injuries are among the most common, morbid, and expensive health conditions involving older adults. Falls account for 10% of emergency department visits and 6% of hospitalizations among persons over the age of 65 years and are major determinants of functional decline. Despite the high prevalence of hearing and balance problems among persons of Medicare age, the majority of physicians do not screen older adults because of reimbursement obstacles and a limited understanding of approaches to cost-effectively screen this population.⁴⁵

In light of the functional consequences of unidentified hearing loss and balance problems, the variety of technologies available to overcome communication difficulties, and the proven value of physician referral screening programs, it is imperative that physicians periodically screen older

adults for hearing loss and balance problems. Recognizing the detrimental effects of unidentified sensory loss, the U.S. Preventive Services Task Force recommends that persons over 65 years of age undergo periodic hearing evaluations and counseling regarding the availability of hearing aids.^{44,45} Further, the national Medicare system will reimburse primary care physicians (PCPs) a fixed amount of money for completing the entire Welcome to Medicare examination, which includes hearing and balance screening using inexpensive, brief, reliable, and valid questionnaires.^{44,45} In fact, it is now acknowledged that the health-related quality of life of older adults is improved when PCPs screen for hearing and balance problems.⁴³

Self-report measures of high sensitivity and specificity, which are easy and inexpensive to use, have been recommended for use by PCPs to identify older adults at risk for hearing and balance problems. Audiologists and physicians alike have advocated the screening version of the Hearing Handicap Inventory for the Elderly (HHIE-S), which has the advantage of identifying patients who perceive hearing loss to be a problem and who are motivated to use hearing aids.⁴⁵⁻⁴⁷ The Dizziness Handicap Inventory (DHI) is widely used for screening for dizziness, a condition for which there is considerable under-referral despite the morbidity and mortality associated with falls in older adults.⁴⁹

A simple, reliable, and valid hearing screening protocol with good diagnostic accuracy has been advocated and validated by a number of investigators.⁴⁵⁻⁴⁹ The procedure entails a pure-tone screen and administration of the 10-item screening version of the Hearing Handicap Inventory for the Elderly (HHIE-S). The purpose of the screen is to identify older persons with handicapping hearing impairment who require audiologic testing and intervention. The pure-tone screen involves use of the audioscope, a hand-held otoscope combined with a screening audiometer that delivers pure tones at 40 dBHL at four frequencies: 500, 1000, 2000, and 4000 Hz. The audioscope is shown in [Figure 97-5](#). A patient fails the screen if he or she does not hear the tones at 1000 or 2000 Hz in one or both ears. The patient is instructed to raise his or her finger or hand when the tone is heard. The patient's response should be time-locked to the presentation of the stimulus signaled by a red indicator light on the audioscope. If otoscopic examination indicates the presence of cerumen impaction, this necessitates a failure and a referral. Further, patients complaining of tinnitus should be referred, as tinnitus could be a symptom of a significant medical condition for which efficacious treatments are now available.

Before or following the pure-tone screen, the patient should complete the HHIE-S using a face-to-face, paper-and-pencil, or computer-assisted presentation. A score of 10 or greater signifies the necessity of a referral. More specifically, scores of 0 to 8 signify no handicap, scores of 10 to 22 signify a mild to moderate handicap, and scores of 24 to 40 suggest significant self-perceived handicap. Scores on the HHIE-S are directly correlated to hearing aid uptake and have been shown to improve after the initiation of hearing aid use. Primary care physicians with firsthand experience with this screening protocol consider it to be simple, cost-effective, quick, and easy to administer.⁴⁶ [Table 97-5](#) lists the items that make up the 10-item screening version (HHIE-S).⁴⁷ Scores on the questionnaire are highly predictive of hearing aid use such that individuals obtaining a score

Table 97-5. Screening Version of the Hearing Handicap Inventory for the Elderly (HHIE-S)

Instructions: Answer yes (4 points), sometimes (2 points), or no (0 points) for each question. If you are a hearing aid user, answer questions according to how you hear with the hearing aid. If the question does not apply, merely enter no as your response.

- E-1. Does a hearing problem cause you to feel embarrassed when meeting new people?
- E-2. Does a hearing problem cause you to feel frustrated when talking to members of your family?
- S-1. Do you have difficulty hearing when someone speaks in a whisper?
- E-3. Do you feel handicapped by a hearing problem?
- S-2. Does a hearing problem cause you difficulty when visiting friends, relatives, or neighbors?
- S-3. Does a hearing problem cause you to attend religious services less often than you would like?
- E-4. Does a hearing problem cause you to have arguments with family members?
- S-4. Does a hearing problem cause you difficulty when listening to TV or radio?
- E-5. Do you feel that any difficulty with your hearing limits or hampers your personal or social life?
- S-5. Does a hearing problem cause you difficulty when in a restaurant with relatives or friends?

Abbreviations: "S" items probe social/situational consequences of hearing loss; "E" items probe emotional consequences of hearing loss.

of 18 or greater on the HHIE-S are considered likely to purchase and benefit from hearing aid use, irrespective of hearing loss severity. Further, veterans with a high score on the HHIE-S who report perceiving a hearing handicap (question E-3) have a high likelihood of being fitted with hearing aids. Weinstein devotes an entire chapter of her

textbook to strategies for identifying older adults with hearing loss including the use of multimedia and Web-based techniques.²⁸ Web sites containing the HHIE-S can easily be accessed, and several of these have links to audiology services nationwide.

WHEN AND TO WHOM TO REFER

Audiologists and otolaryngologists are hearing health care specialists who provide assistance to persons with hearing problems. The otolaryngologist is a medical doctor who diagnoses and treats medical diseases of the ear that may be causing a hearing problem. If medical treatment in the form of antibiotic therapy or surgical intervention is not indicated, persons with hearing loss should be seen by an audiologist. An audiologist is a professional with a doctoral degree who works with people who exhibit hearing, balance, and ear-related problems. Audiologists provide evaluative, rehabilitative, and preventive services. They work in a wide variety of settings, including private practice, hospitals, otolaryngology offices, government health facilities, and rehabilitation centers. Although audiologists can represent the point of entry into the hearing health care system, older

KEY POINTS

Disorders of Hearing

- Hearing loss prevalence increases with age such that over 50% of persons over 80 years of age have a hearing impairment.
- The majority of residents of nursing facilities have a hearing impairment.
- The hearing impairment and speech understanding difficulties that are a hallmark of presbycusis are associated with significant functional effects, including depression and isolation.
- Presbycusis arises because of atrophic age-related changes in the cochlea, auditory nerve fibers, auditory brain stem pathways, and the temporal lobe of the brain.
- Cerumen impaction is prevalent in older adults and can interfere with the proper functioning of hearing aids.
- The sensorineural hearing loss affecting a high proportion of older adults is typically not amenable to medical intervention.
- The most effective treatment for sensorineural hearing loss is hearing aids.
- Hearing aids are efficacious in ameliorating the functional, social, and emotional effects of hearing loss in older adults.
- The most favorable outcomes with hearing aids take place when a hearing aid is delivered in the context of a counseling-oriented rehabilitation program
- Counseling should assist the hearing impaired to do the following:
 - Understand hearing loss
 - Accept the handicapping effects of hearing loss
 - Overcome obstacles posed by hearing loss
 - Manipulate hearing aids and hearing assistive technologies independently
 - Understand principles of care and maintenance of hearing aids
 - Incorporate communication strategies into daily life

Sources of information about hearing loss and hearing aids are the American Academy of Audiology, the American Speech-Language-Hearing Association, and the Better Hearing Institute (BHI).

adults referred to audiologists by a physician are most likely to purchase audiologic services in the form of hearing tests, hearing aids, and AR. In the current health care delivery system, PCPs tend to be too busy to screen patients for hearing and balance problems. It behooves audiologists to partner with PCPs to develop an efficient, easily administered protocol to identify older adults with hearing/balance problems requiring evaluation and treatment.⁴³

CONCLUDING REMARKS

Approximately 30% to 50% of older adults suffer from a handicapping hearing impairment that can interfere with the quality of their lives. Adults over 55 years of age make up 81% of all hearing aid users, yet the majority of older adults with hearing loss do not use hearing aids. The stigma associated with hearing aid use coupled with persistent complaints from experienced users about difficulty understanding in public places, especially noisy environments, has kept penetration rates stable but low over time.

Technologically sophisticated hearing aids in combination with some form of audiologic rehabilitation are more effective than ever before and are a boon to older adults who are living longer and retiring early yet continue to be confronted by difficulty understanding the speech of others,

especially in noisy environments. Sound evidence is available demonstrating the improved audibility and enhanced speech understanding in noisy and reverberant environments afforded by today's digital hearing instruments, which reduce feedback, lessen the perception of extraneous noise, and include directional microphone technology that automatically picks up speech while suppressing unwanted noise emanating from behind the speaker. This improved communication translates into beneficial effects on the individual's health-related quality of life.

The availability of assistive listening devices that compensate for the shortcomings remaining with hearing aids is another avenue for persons with hearing impairment to pursue. The physician has reliable, valid, and inexpensive tools at his or her disposal to identify persons with hearing problems who require and can benefit from the expertise of audiologists. Working together, physicians and audiologists can reduce the burden of hearing loss and can promote the quality of life of the increasing population of older adults suffering from a handicapping hearing impairment.

Health Promotion for the Community-Living Older Adult

Maureen F. Markle-Reid
Heather H. Keller
Gina Browne

INTRODUCTION

Older adults (>65 years of age) are growing in proportion and number in both developed and less-developed nations¹ as a result of economic prosperity, health care, improved sanitation, and improved education. In Canada, as in many other developed countries, there will be an aging of the population as the “baby boom” generation reaches the age of 65. The fastest-growing segment is those who are ≥ 80 years; currently 1 in 30 Canadians is over the age of 80, and this proportion is projected to increase to 1 in 10 by 2056.²

Increasingly, Canada’s older citizens are aging in place, attributable to the aging of the population, technologic advances, budget constraints, and preferences of older adults, their families, and society, as well as changes in options for care. Over 90% of those aged 65 and over live in the community.³ Rates of institutionalization for older people have decreased, and formal community-based care has expanded, such that the proportion of older people receiving community care now substantially outweighs the proportion receiving formal services through an institution.⁴ Since the late 1980s in Canada, hospital beds have been reduced by 30% and nursing home beds by 11%, and ambulatory care has increased. The result is increasing pressure on community-based services to maintain accessible, high-quality, and comprehensive health care within the confines of economic constraints.^{4–6}

The benefits associated with aging in place are well documented. Residing at home optimizes an older person’s health,^{7,8} independence, control, and sense of well-being,⁹ as well as social connectedness, which positively influences health.^{8,10} Managers and policy makers alike face questions about the most efficient mix of service strategies for the promotion of health in this more community-based and less institution-oriented system.

As the population of older adults (≥ 65 years) has increased, and as medical advances continue to convert once acute life-threatening diseases into chronic illnesses, there has been an associated increase in the prevalence of unremitting chronic conditions and frailty.^{11–13} Over 80% of older people (≥ 65 years) have chronic medical conditions requiring daily self-care and management.¹⁴ Chronic conditions, including cardiovascular diseases, diabetes, obesity, cancer, and respiratory diseases, account for 59% of the 56.5 million deaths annually and 45.9% of the global burden of disease worldwide.¹⁵ Among those with chronic conditions, more than one half of older adults report having at least two of these diagnoses.¹⁶ These unremitting chronic illnesses also have a significant economic impact. The total cost of ill health, disability, and death resulting from chronic diseases is about \$80 billion annually for Canada.¹⁷ Use of healthcare services is positively related to comorbidity—use increases as

the number of chronic conditions goes up.¹⁶ The gradient effect in health service use is most apparent for acute hospitalizations, general practitioner visits, and nursing consultations.¹⁶ Left unchecked, these conditions have the potential to overwhelm the health care system and threaten its sustainability.¹⁶ The long-term solution must involve health promotion to delay or better manage these conditions to contain costs and reduce demand for services.¹⁸

Approximately 15% of community-living seniors fall into the category of being “frail,” defined as vulnerable to significant functional decline as a result of the accumulation of multiple, interacting illnesses, impairments, and disabilities.^{13,19,20} Of those considered frail, 17% are at high risk for such decline that would jeopardize their ability to live independently at home in the community.²¹ These people are typically 75 years of age or older and are living with multiple health conditions that are acute and chronic in nature as well as functional disabilities.²² They may also have cognitive impairments or social support networks that are overextended or at risk of breaking down.^{22,23} These characteristics put frail older adults at risk for increasing morbidity, disability, health service use, and death.²⁴

However, chronic disease and frailty should not be considered an inevitable or irreversible consequence of aging.²⁵ Although it is true that as individuals age, they are at greater risk of developing chronic health problems, these conditions are not inherent in the aging process.²⁶ Older adults are quite heterogeneous, including those aging “successfully,” “usually,” and at “accelerated” rates.^{27–29} A majority of the most costly health conditions are preventable, treatable, or manageable.¹⁸ The World Health Organization^{15,30} estimates that at least one third of the total economic and social burden of disease in developed countries is caused by a handful of largely avoidable risks: tobacco, alcohol, high blood pressure, high cholesterol, and obesity.³¹

For many of these risk factors for chronic disease, negative impacts can be reversed quickly, most benefits will accrue within a decade, and even modest changes in risk factor levels can bring about large improvements in people’s health.^{15,30} For example, with healthy eating, regular exercise, not smoking, and effective stress management, over 90% of cases of type 2 diabetes and 80% of cases of coronary heart disease could be avoided.^{15,30} One review reported that even a 5% reduction in preventable illnesses could lead to substantial savings in medical costs, as well as cost savings beyond the health care sector.¹⁸ Consequently, identifying modifiable factors that can reduce or delay health service use and increase quality of life in these populations is a priority.

A growing body of research in Canada suggests that older community-living adults can benefit significantly

from proactive health promotion and preventive care interventions.^{32–39} The ultimate goal of these programs is to proactively identify and address factors influencing health and to promote positive health behaviors and autonomy of older people living in the community, to prevent or delay institutionalization, reduce health care costs, and improve health-related quality of life and function.⁴⁰

This chapter summarizes this research and identifies how health promotion and preventive care for community-living older adults can be improved. The specific objectives of this chapter are as follows: (1) to describe three separate groups of older adults and their need for health promotion and preventive care, (2) to describe a conceptual framework for health promotion and preventive care for frail older adults, (3) to describe a framework for economic evaluation of health care programs, (4) to argue in favor of the importance of screening to identify older adults who could benefit from health promotion and preventive care efforts, (5) to describe successful health promotion and prevention efforts among community-living older adults, and (6) to demonstrate the need for further policy and research on health promotion and preventive care for community-living older adults.

THE HETEROGENEITY OF OLDER ADULTS AND THE NEED FOR HEALTH PROMOTION

Older adults are a heterogeneous group, and aging occurs at different rates in different people. Chronologic age does not tell the full story of functional ability or quality of life, and most disabilities of old age are not inevitable, universal, or irreversible.²⁵ In the context of health, people who are aging successfully are those who continue to experience good health for an extended period of time. “This is the 65-year-old who plans to take a cycling tour of France, the 75-year-old who plays tennis twice a week, or the 80-year-old who walks two miles each day.”²⁹ Older adults who are *successfully aging* have minimal health problems, may visit their primary health care provider for preventive checks such as blood pressure, and may have a few risk factors (e.g., family history of heart disease), but they are quite healthy, with no modifiable risk factors. These older adults are likely to be on no medications or only prophylactic formulations. They watch what they eat and try to exercise. They typically develop signs of chronic disease late in life, such as starting medication for hypertension in their late 70s. Because of this delay in onset of chronic disease, successfully aging older adults spend less time dealing with its effects.²⁹

Usually aging older adults have some signs that chronic disease has initiated. Typically, they take a few medications to manage conditions such as hypertension or dyslipidemia, they may be bothered by the occasional bout of arthritis pain, and their doctor sees them on a routine basis to monitor their conditions. These indicators or conditions do not drastically affect the quality of life of these older adults, as they still travel when they want and do most of the activities that they are interested in such as driving, babysitting their grandchildren, or taking cruises.²⁹ Approximately 80% of seniors are experiencing successful or usual aging,⁴¹ although this proportion falls among the oldest old.⁴²

The older adult experiencing *accelerated aging* appears frailer and more functionally dependent for his or her age.

These people, who represent 15% to 20% of seniors, are typically over 75 years of age and have co-occurring physical health problems, both acute and chronic.^{20,42} They are highly vulnerable, living in the community with supports that are prone to breakdown with any shift in their health and well-being.^{21–23} Many live in isolation, cut off from community services because of a lack of information, transportation, or the will to initiate action on their own.⁴³ Another important consideration is that many seniors live in poverty or near-poverty conditions, as a growing number live alone without the benefit of two pensions for married older adults.⁴⁴ Additionally, the prevalence of depression among those experiencing accelerated aging is estimated at 26% to 44%, at least twice that among older people in general.⁴⁵ These characteristics lead to a greater risk for loss of functional independence, institutionalization, and death.¹³ Long-term care facilities take care of approximately 5% of these seniors, and about 15% reside at home in the community.²⁰ These frail older adults pose a central challenge to current health systems, as they are frequently in contact with the health system including acute hospitalization and home care services.^{23,29} A further consideration is that frail seniors living at home are particularly difficult to reach and are at high risk for loss of functional independence and for institutionalization.¹³ These data underline the need for health promotion efforts in this group.

Before further discussing health promotion and preventive care in the frail older adult, it is important to clarify what is meant by frailty. Despite the dramatic increase in the use of the term *frailty* since the late 1980s, there is a lack of consensus in the literature regarding its meaning and use and no clear conceptual guidelines for establishing criteria to describe older adults as frail.²⁴ Is frailty a disease? Is it a part of aging? What does frailty look like? How is it defined, framed, and understood? Finally, exactly how frail is frail?^{46,47} A first step in addressing the problem of frailty is to understand better how to identify those who are frail.⁴⁸ Despite calls for more research,^{49,50} the components of frailty have not been sufficiently defined to identify populations at risk or in need of proactive interventions.²⁴

One literature review of definitions and conceptual models of frailty in relation to older adults suggests that frailty is a multiple-determined state of vulnerability in which an individual is at risk of becoming more or less frail over time.²⁴ The implication of this is that the process of frailty can be modified or reversed.²⁴ This finding highlights the need for rational, theoretical interventions directed toward health promotion and preventive care for this population. This chapter gives guidelines for a taking a new theoretical approach to the concept of frailty in older adults, which is (1) multidimensional and considers the complex interplay among behavioral, biologic, social, and environmental determinants on health rather than a single influence^{13,51,52}; (2) not age-related; (3) subjectively defined; and (4) considers both individual and environmental factors that influence health. (Table 98-1).²⁴

Despite the differences in these three groups in terms of their needs, each one could benefit from health promotion and preventive care efforts targeted to its specific needs.^{15,29} Programs and services that promote the health of older adults, focused on keeping them healthy rather than solely being reactive to symptoms, are underdeveloped in North

Table 98-1. Dimensions of Frailty

Dimension	Supporting Evidence
The concept must be multidimensional and consider the complex interplay among behavioral, biologic, social, and environmental determinants on health rather than a single influence.	This view is consistent with the observation that many social, socioeconomic, and lifestyle factors are associated with health and that determinants of health are often highly interrelated. ^{13,51,52} Theoretical models need to address the complexity of problems rather than focusing on a single problem, because older people typically have coexisting physical, emotional, and social problems that are interrelated with one another and with external factors. ^{24,170}
The concept must not be age related, suggesting a negative and stereotypical view of aging.	Theoretical models should reflect a positive view of aging that emphasizes the capacity for autonomy and independence and maximizes the person's strengths ¹⁷¹ as well as deficits. ²⁴
The concept must take into account an individual's context and incorporate subjective perceptions.	The trajectory of frailty is unique for each individual. ¹⁷² The emphasis is on the individual's perception of health rather than on the objective circumstances. Research supports the hypothesis that an individual's poor adjustment to chronic illness or affective state is not related to the specific physical disease or level of disability but rather to the negative meaning the individual attributes to it. ¹⁷³ Theoretical models need to incorporate subjective measures and allow for individual variability. ²⁴
The concept must take into account the contribution of both individual and environmental factors that influence health.	Frailty can originate from within an individual or from conditions in the environment. Theoretical models need to address the constellation of individual and environmental factors that influence health. ²⁴

America.^{28,53} Potentially, the lack of development of such programs is due to the narrow societal viewpoint that older adults cannot change behaviors such as smoking, eating, and exercising.⁵⁴ Chernoff⁵⁴ suggested that in some ways this belief is true, but there is also research that proves otherwise. Seniors are interested in changing and can change behaviors when given the support to do so. The goal of any health promotion program for older adults living in the community should be on optimizing their current health, even if minimal change in quantity of life is achieved.¹ Given the heterogeneity of older adults, it is essential to consider the differences in these three groups in terms of their health trajectories and quality of life when making decisions about the type and amount of health promotion activities required. As the population ages and the number of people aging in place increases, there is an urgent need to identify effective and efficient ways of promoting the health of community-living older adults.

CONCEPTUAL FRAMEWORK FOR HEALTH PROMOTION AND PREVENTIVE CARE FOR FRAIL OLDER ADULTS

Empirical evidence alone is insufficient to direct the design and evaluation of interventions. Theory is essential for program development, implementation, and evaluation, as it explains and can predict outcomes. Furthermore, theory enhances the generalizability of the results by providing the basis for informing the systematic development and implementation of intervention strategies that improve the health of older people as well as evaluation indicators.⁵⁵

An adapted version of the model of vulnerability⁵⁶ incorporates the key concepts of frailty discussed earlier to guide the development, implementation, and evaluation of health promotion and preventive care interventions. Vulnerability is a net result of an interaction between the person's personal resources (cognitive, emotional, intellectual, behavioral) and environmental supports (social, material, cultural), both of which, along with biologic characteristics (age, gender, genetic endowment), are determinants of health. Within an individual, personal resources and environmental supports intersect, as shown in Figure 98-1, and can be synergistic and cumulative.³⁷ The base of the triangle represents the degree of vulnerability,⁵⁶ and thus also the individual's health

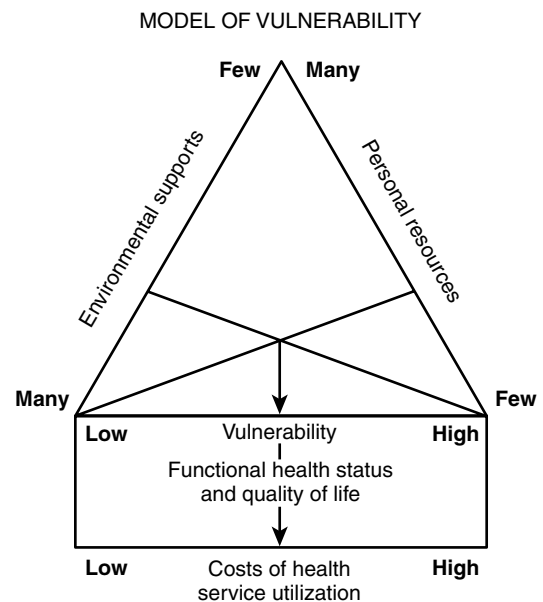

Figure 98-1. Model of vulnerability. (Adapted from Rogers AC. *Vulnerability, health and health care*. *J Adv Nurs* 1997;26(1):65–72.)

status and quality of life. Based on published evidence,³² expenditure of use of health services increases proportionately with the level of vulnerability.

Even if personal resources hold constant, changes in an individual's environmental supports can greatly alter one's degree of vulnerability and thus his or her use of health and social services.³⁷ What is needed is "a 'fit' between the needs and resources of the person and the demands and resources of the environment (p. 68)."⁵⁶ This vulnerability model provides a schema of the basic components of a multidimensional health promotion and preventive care intervention for reducing functional decline, enhancing health, and promoting appropriate use of healthcare services. Proactive health promotion and preventive care interventions either targeted at the individual or the environment can identify and strengthen available resources, thereby reducing vulnerability and the on-demand use of expensive health services while enhancing quality of life. Hence, strategies for optimizing health in the model of vulnerability are multilevel.⁵⁶

Table 98-2. Dimensions of Risk in Rogers' Model of Vulnerability

Risk Factors	Supporting Evidence
Personal Resources	
Inborn	Aday, 1993 ¹⁷⁴ ; Rogers, 1997 ⁵⁶
Age, gender, race, temperament, genetic predisposition to disease, susceptibility to illness, sensitivity to drugs and chemical imbalances	
Acquired	
Recently moved	Hebert, 1997 ²²
Recently discharged from hospital	Hollander & Chappell, 2002 ¹⁷⁵

Nutritional risk	Keller et al, 2004 ¹⁴⁶
Low level of physical activity	Tinetti et al, 1999 ¹⁵³
Excessive consumption of alcohol and smoking	Stuck et al, 1999 ¹⁰³
Environmental Supports	
Societal attitudes and stereotypes of aging	Rogers, 1997 ⁵⁶
Living alone, social isolation	Stuck et al, 1999 ¹⁰³
Low income	Li et al, 2005 ¹⁷⁹
Low levels of education	Aday, 1993 ¹⁷⁴ ; Pressley, 1999 ¹⁸⁰

Personal resources can be defined as either inborn or acquired characteristics, that interact with the environment to influence health.⁵⁶ Inborn characteristics that influence health include nonmodifiable factors such as the person's age, gender, race, temperament, genetic predisposition to disease, susceptibility to illness, sensitivity to drugs, and chemical imbalances. Acquired characteristics are modifiable factors known to increase risk for functional decline in older adults. *Environmental supports* can be defined as factors that interact with personal resources to influence health⁵⁶ (Table 98-2).

FRAMEWORK FOR ECONOMIC EVALUATION

Although the literature contains many evaluations of programs seeking to achieve improved outcomes for vulnerable populations, such as frail older community-dwelling adults, few of these outcome studies include measures of cost.³³ Economic analysis has now established itself as having an important role in the planning, management, and evaluation of healthcare. It consists of comparing both the effects and expense of alternative interventions for a single problem with the goal of maximizing improvements in health-related well-being using a fixed pool of available resources.⁵⁷ As depicted in Figure 98-2, the economic evaluation of healthcare programs⁵⁸ yields nine possible outcomes (the more favorable ones are highlighted by shading). In outcome 1, increased effects or health benefits are achieved with increased expenditure for additional resources consumed. This is called *cost-effective*, whereby more effect is achieved for more cost. Outcome 4 is also favorable, because increased effects are achieved with one approach over another at equivalent expenditures. Outcome 7 represents the win/win situation or unambiguous improvements in economic efficiency, whereby more effect is produced at lower expenditures. Outcome 8 represents the situation in which alternative health programs produce the

same effect, but some approaches are associated with lower expenditure from a societal perspective. Options 7 and 8 are superior to the often implemented option 9, in which funding is cut, along with the potential for reduced effects, which releases resources for other purposes.⁵⁸

This approach can be used to classify the main effects and expense of comparative community health interventions. In addition, this approach can be used to classify who (with what characteristics) benefits most and at what expense when various interventions are available. This is especially of concern in systems of national health insurance, in which people will use may use services (inappropriately).⁵⁹

SCREENING AND ASSESSMENT: IDENTIFYING OLDER ADULTS WHO COULD BENEFIT FROM HEALTH PROMOTION AND PREVENTIVE CARE EFFORTS

There is a growing body of international evidence that suggests that early detection of older people at risk for functional decline or loss of autonomy is beneficial. Screening or other methods of early detection would identify older adults with risk factors that could lead to significant health problems and the use of costly health care resources. Several studies of screening and case finding among older adults have been conducted in an attempt to proactively identify and address problems to reduce the use of costly resources; these studies are reviewed later on.

Many older adults living the community have unrecognized risk factors. Health concerns or risk occur in almost all (92% to 99%) older adults in practice populations, with up to 83% having at least one unreported or unrecognized risk.⁶⁰⁻⁶² Many of these risk factors are social problems⁶² that can affect a senior's support network and well-being and have the potential to increase health care expenditures if left undetected and, therefore, untreated. Unsolicited home

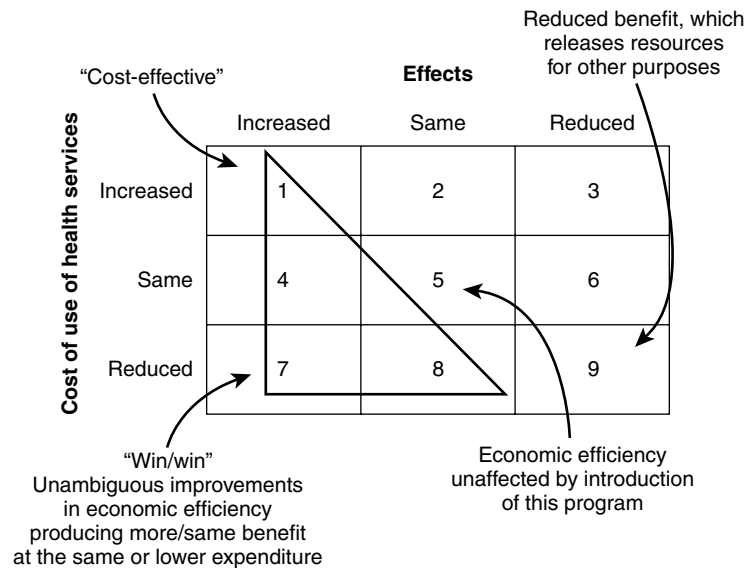

Figure 98-2. Framework for evaluating possible outcomes of economic evaluation of health care programs. (From Birch S, Gafni A. *Cost-effectiveness and cost utility analyses: methods for the non-economic evaluation of health care programs and how we can do better*. In: Geisler E, Heller O, editors. *Managing Technology in Healthcare*. Norwell, MA: Kluwer Academic Publishers; 1996.)

visits by a health visitor can be a means of recognizing these unmet needs. Harrison et al identified through this service that 35% of 110 patients over 70 years of age had previously unidentified risks that could benefit from preventive programs.⁶³ Similar results were reported by Brown et al, in an audit of 40 general practices in the United Kingdom of patients over 75 years of age.⁶⁴ In this study, 12% of the eligible practice population was seen over the study period; 44% were found to have at least one health problem that was previously undetected. Similarly, Ramsdell et al found that home-based assessment of older adults resulted in the detection of up to four new problems as compared to an office-based assessment.⁶⁵ Stuck et al identified several key advantages of in-home visits versus office-based visits.⁶⁶ A home-based assessment allows for an evaluation of the physical environment to identify risk factors and equipment needs, review of medications, observe contacts with family members, and provide better accessibility for clients with mobility problems. Further, an office-based visit often has a focus for the appointment and limited time affects solicitation of further risks.

Browne et al,³² in a review of 12 randomized controlled trials evaluating a community-based approach to care in a Canadian setting, found that for clients with multiple problems (such as the frail older adult), it is more expensive in the same year to *not* provide these clients with proactive and comprehensive preventive care and health promotion. Similarly, Caulfield et al (p. 87),⁶⁰ in a review of the literature on geriatric screening programs, concluded that “home based, comprehensive screening of the older adult for undetected physical, mental and socio-economic problems by nursing or other trained personnel may be able to prolong survival, improve quality of life, and perhaps even postpone dependency or institutionalization.” Screening eliminates a barrier between the need for help and gaining access to that help.

Discussed next are three areas—falls, nutrition, and depression—in which screening and assessment are advocated for older adults living in the community, as these conditions are

readily preventable through health promotion efforts. The term *screening* refers to the process of detecting or identifying a health condition or risk factor among a specific population. The term *assessment* refers to the process that follows a positive screen and involves evaluating the problem and older adult in a more specific fashion in order to confirm the problem or establish the diagnosis and develop a treatment plan.⁶⁷

Risk of Falls

Despite knowledge that most falls are both predictable and preventable, falls and fall-related injuries continue to negatively impact older adults' quality of life and health care resources (see also Chapter 106). Fall-related injuries are among the most common, serious, and expensive health conditions affecting community-living older adults.⁶⁸ Thirty percent of community-living adults over 65 years of age fall at least once a year, and the proportion increases to 50% by the age of 80 years.⁶⁹ In people aged 65 years and older, falls are the leading cause of injury-related admissions to acute care hospitals and in-hospital deaths⁷⁰ and explain 40% of nursing home admissions.⁷¹ The costs of health care associated with fall-related injuries are staggering. The 1999/2000 costs of fall injuries to seniors in Canada were estimated to be \$2.4 billion.⁷² With an aging population and an associated increase in the number of falls and fall-related injuries, these cost estimates are projected to rise as high as \$240 billion by 2040.⁷³

The negative impact of a fall on health and related quality of life can be profound. Fall injuries often result in fear of falling,^{74,75} leading to self-imposed restriction of activity and loss of confidence,⁷⁶ low self-esteem, depression,⁷⁵ chronic pain, and functional deterioration.⁷⁷ Falls and fall-related injuries and complications are the leading cause of death among seniors.⁷⁸ Frail seniors, exhibiting accelerated aging, are at increased risk for falls, with approximately 50% falling at least once per year (three times the risk of healthy seniors).⁷⁹ They are also more likely to sustain serious injury

and take longer to recover after falling.⁷³ Falls are caused by multiple, interacting factors, some of which are modifiable. Factors such as postural hypotension, the use of multiple medications, and impairments in cognition, vision, balance, gait, and strength increase the risk of falling and fall injuries.⁶⁸ Although no single factor causes all falls, the risk of falling increases with the number of risk factors present.⁸⁰

Evidence suggests that most falls are predictable and preventable. Previous intervention studies showed that approximately 30% to 40% of falls can be avoided.^{81–83} A 10% reduction in the number of nonfatal falls would mean 7931 fewer falls and health care savings of \$138.6 million.¹⁸ Categorizing individuals into different levels of risk through screening is thus important from both clinical and economic perspectives; seniors with the highest risk of falling will benefit most from preventive efforts and from avoiding the negative consequences of falls.⁸² The best approach to preventing falls in any group of older persons requires knowledge of where that group sits on the risk spectrum, because this will determine the type and amount of services required as well as the effectiveness of the program.⁷⁷ Essentially, fall risk screening is a means of targeting limited home and community care resources.

Home and community care providers are well positioned to play a major role in preventing falls in older people through screening and intervention. An understanding of the risk factors for falls (listed earlier) will increase the clinician's ability to effectively target the use of screening. Since the late 1990s, several fall risk screening instruments focused on community-living older adults have been developed due to the rising concern for fall-related injuries.⁸⁴ Considerable evidence now documents that the most effective fall reduction programs involve routine and systematic fall risk assessments or screens, followed by targeting of interventions to an individual's risk profile.^{79,85} This research has been substantiated by meta-analyses of many randomized controlled trials^{85,86} and by consensus panels of experts who have developed evidence-based practice guidelines for the detection and management of falls risk.^{79,82,87,88} The importance of this direction cannot be overstated. Reducing just one fall risk factor can have great effect on the frequency and morbidity of falls.⁸³

Risk of nutrition problems

As also discussed in Chapter 82, nutrition problems in older adults are common, because of the diverse individual and collective determinants of food intake in this age group.²⁷ Low intakes of various food groups, energy, protein, and micronutrients continue to be reported in those over the age 65 years.^{29,89} Poor-quality food that is energy-dense and lack of exercise also are causes of obesity in this age group.⁸⁹ Obesity when coupled with poor function results in a precarious state for older adults. Those who are frail and exhibiting accelerated aging are also highly susceptible to malnutrition.^{29,89,90}

Since the late 1990s, several nutrition screening indices have focused on community-living older adults,⁹¹ because of the rising concern for the nutritional health of older adults and a desire to intervene as soon as possible.^{29,54} Nutrition screening is viewed as a means of targeting limited nutrition resources, especially dietitian services.⁹² Unfortunately, most of the research to date has focused on describing "at risk"

populations or demonstrating the linkages between nutrition risk and negative health outcomes such as falls, other morbidity, institutionalization, and mortality, without demonstrating that nutrition screening can change practice and thus prevent these outcomes. Prevalence of risk varies depending on the index used and the subgroup of older adults screened; estimates range from 25% in "usually" aging seniors to 69% in those who are frail.^{29,93–95} Risk factors associated with poor food intake or nutrition risk include poor self-rated health,^{94,96} functional limitations,^{27,96,97} low level of education, low income, lack of social support, poor dentition, smoking, vision problems,^{96,97} stress,⁹³ lack of transportation, poor social networks, and living alone.²⁹ Food intake is complex due to its multifactorial determinants, and interventions to promote food intake need to be comprehensive and multisectoral.

In the United States, the Elderly Nutrition Program under the Older Americans Act has provided nutritious meals and other nutrition services to older adults that are especially vulnerable (e.g., those living in underserved rural areas).⁸⁹ Although not mandatory, screening, assessment and interventions such as counseling and basic nutrition education can be provided within individual communities. Screening within the program is meant to target interventions,⁸⁹ but no research on the effectiveness of the screening process has been documented. Furthermore, only 20% of older adults who could benefit from this program are reached,⁹⁸ and targeting of services to those most in need is required.⁹⁹

One article described a nutrition screening program with the NRS-2002 in 26 European hospital departments in 12 countries.¹⁰⁰ The average age of patients screened ($n = 5051$) was 60 years, and 33% were considered to be "at risk." These patients were more likely to have complications, fatal outcome, and a longer length of stay than those without risk. Unfortunately, the authors did not describe or evaluate the treatment options that may or may not have been provided to these patients, so the effectiveness of the screening is unknown. There is only one known evaluation of a nutrition screening program focused on older adults in the community, limited to describing and assessing the process of screening.³⁶

The Bringing Nutrition Screening to Seniors in Canada project³⁶ involved developing, implementing, and evaluating screening programs in five diverse communities in Canada. Almost 1200 seniors were screened and, if found at risk, provided with referrals to community services. An ethical screening process that included follow-up postscreening helped to identify the impact of the program. Seniors indicated that screening helped them to recognize their problem areas and become aware of the various programs and services available in their community. Some individuals reported improving their food intake as a result of the screening, although objective data were not collected.³⁶ As with falls, now that nutrition screening tools are available, research needs to turn to determining the effectiveness of screening and early nutrition interventions in this population.

Risk of depression

Depression is among the most common, and potentially treatable, cause of death, morbidity, functional decline, and increased health care use and costs among community-living older adults.^{101–103} Despite the high prevalence of depression in this population, the diagnosis of depression is often missed

or suboptimally managed.¹⁰⁴ Depression affects between 5% and 10% of individuals in primary care but is only recognized in around one half of the cases.¹⁰⁵ In one study of older adults receiving home care services, only 12% of those with depression received adequate treatment.¹⁰⁴

Both clinician and health care system factors impede the recognition and treatment of depression. First, older people at risk for or suffering or recovering from depression have limited access to community-based services directed toward promoting mental health. In many jurisdictions, eligibility for, and allocation of, home care services are directed toward addressing physical needs—mental health problems must be the secondary diagnosis in order to be eligible.¹⁰⁶ Second, there is limited collaboration and communication among home and community care providers, primary health care providers and others providing mental health services to community-living older adults, and a lack of continuity of care provider. Third, there is a lack of expertise among home and community care service providers in identifying and managing depression.^{106,107} Older people generally have chronic medical conditions and disabilities that mask the presence of depression,¹⁰⁸ and attitudes and beliefs about mental illness discourage health care providers from asking patients about depression and patients from revealing depressive symptoms. Finally, there is a tendency to normalize symptoms of depression in this population.¹⁰⁹

Unrecognized, untreated, and undertreated mood disorders generate enormous personal, economic, and societal costs.^{104,108} Depression in older people often coexists with other chronic illnesses, and untreated depression is a significant risk factor for functional decline, diminished quality of life, death from comorbid medical conditions or suicide, dementia, social isolation, poor adherence to treatment, increased demands on unpaid caregivers and increased use of expensive health services.^{110,111} In 1998, depression cost Canadians approximately \$14.4 billion dollars per year.^{112,113} These costs are compounded by indirect costs such as costs to unpaid caregivers. Unpaid caregivers of depressed seniors are more likely themselves to experience symptoms of depression.¹¹⁴ Depression is also associated with unhealthy lifestyle factors such as smoking, alcohol use,¹¹⁵ physical inactivity, and noncompliance with medical treatment.¹¹⁶

Those who are frail, exhibiting accelerated aging, are at increased risk for depression.^{19,117} The prevalence of depression among older persons receiving home care services is estimated to be between 26% and 44%—at least twice that among older persons in general.^{104,118,119} They also suffer from a fourfold increase in more severe forms of depression than the general population.¹²⁰ Clearly, recognition is key to referral and subsequent treatment for depression in this population.¹⁰⁹

Multiple, interacting physical, psychological, and social factors increase the risk of depression in old age. These include factors such as having a comorbid health condition(s), functional limitations, taking medications (such as centrally acting antihypertensive drugs, analgesics, steroids, and antiparkinsonians), social factors (e.g., social disadvantage, low social support), or a previous history of depression.¹²¹

Routine depression screening and assessment have been shown to be effective in improving the recognition and management of depression in community-living older

adults.^{109,122–128} A variety of screening instruments have been developed for screening and assessing depression in older adults. These screening tools were developed to reflect the differences in presentation of depression in older adults and to address issues such as the presence of concurrent medical disorders (e.g., dementia).¹²⁹

Community providers can play a pivotal role in screening for depression in community-living older adults. An understanding of the factors for depression (listed earlier) will increase the clinician's ability to effectively target the use of screening or inquire about symptoms that make up the diagnostic criteria for a depressive disorder, particularly when several risk factors are present.⁶⁷ The evidence suggests that screening is most effective when targeted to higher-risk groups.⁶⁷ Current Canadian recommendations suggest that screening for depression in primary care settings should be completed only if effective follow-up and treatment can be provided.¹³⁰ Although access to specialized geriatric mental health services remains limited in some settings, primary health care practitioners are able to provide appropriate follow-up and treatment.⁶⁷

Importance and implementation of screening

Awareness of the importance of screening and assessment of risk is required at several levels: older adults, their families, their home care providers, and the community.²⁹ Although older adults appear to be interested in health promotion, they often do not think they are at risk for falls, poor nutrition, or depression. Screening may increase their attentiveness or self-awareness. More important, assessment of risk can be used to guide the allocation of limited home and community resources to those most likely to benefit from preventive efforts.

Overall, the data underscore the important role of home and community care providers in the early identification and management of risk factors for functional decline by performing a multifactorial assessment using validated screening instruments followed by targeting of interventions to an individual's risk profile.⁸⁵ In a review of the literature, Challis and Hughes¹³¹ identified the need for greater standardization and multidisciplinary assessments as one of four factors that influenced the "margin" between institutional and community-based care for community-living seniors.

Screening in the community is a complex activity and providers need support to build capacity.²⁹ Furthermore, tools used for assessment of risk may not be standardized and often lack rigorous reliability and validity testing.^{43,132} To be acceptable to practice and relevant for a diverse group of community-living older adults, risk screening instruments need to be reliable, valid, brief and easy to use and accurately discriminate between levels of risk. Different instruments may be required for different segments of the older adult population, as they are quite heterogeneous ranging from well and successfully aging to chronically ill.¹³³ They also need to be acceptable to the individual being assessed and the provider performing the assessment.⁸⁴

In addition to an appropriate screening instrument, capacity for screening in the community is based on the development of an ethical screening process.^{134,135} An ethical screening process includes referral to community resources or services and follow-up to ensure that identified needs are

met.¹³⁵ Development of an ethical screening process is complex and time, resources, and effort are needed.¹³⁵ Research and best practice guidelines should be translated into practice so that risk assessment is implemented and appropriate interventions are tailored to individual needs.

PROMOTING HEALTH IN COMMUNITY-LIVING OLDER ADULTS: LESSONS FROM FIVE INTERVENTION STUDIES

Health promotion and disease prevention efforts are categorized as primary, secondary, or tertiary. Health promotion is the process of enabling people to take control over the determinants of health and thereby improve their health.¹³⁶ Health promotion strategies are based on a participatory model of health,¹³⁷ which seeks to expand an individual's positive potential for health. This is in contrast with preventive care, which is grounded in the traditional biomedical model of health¹³⁷ and seeks to avoid risks or decrease risks to health and well-being.¹³⁸

A participatory approach to enhancing health involves activities that seek to empower individuals and promote positive attitudes, knowledge, and skills to maintain and enhance health.^{139,140} Health promotion strategies involve goals such as autonomy, empowerment, and independent decision making.³⁷ Health promotion interventions are developed, implemented, and evaluated together with individuals, families, and stakeholders from different organizations.¹⁴¹ Empowerment for health goes beyond illness and the management of a specific disease. Its success is seen in terms of enhanced health, well-being, quality of life, sense of self-esteem, and self-worth.¹⁴²

According to the World Health Organization, health promotion strategies include developing personal health skills, creating supportive environments, strengthening community action, reorienting health services, and building healthy public policy.¹⁴² Thus, health promotion strategies are multilevel, focusing not only on individuals but also on family, community, and societal health. Health promotion not only is concerned with enabling the development of life skills, self-concept, and social skills, but is also concerned with environmental intervention through a broad range of political, legislative, fiscal, and administrative means.¹³⁷

Whereas health promotion is approach motivated, preventive care is avoidance motivated.¹³⁸ Preventive care, which is divided into primary, secondary, and tertiary levels, is aimed at reducing premature morbidity and mortality.^{137,138,143} *Primary prevention* is focused on removal of risk factors for disease or functional decline from the individual or the environment. Activities of this type are implemented for successful or usual aging older adults who are asymptomatic and free of clinical evidence of the targeted disease or health condition. *Secondary prevention* activities focus on early identification and prompt treatment of risk factors before they lead to functional decline.¹³⁵ In essence, secondary prevention is the way to add "life to years."¹ Secondary prevention can avert successfully and usually aging older adults from progressing through the stages of functional decline, and they are thus more relevant. *Tertiary prevention* is typically provided to those with accelerated aging and includes activities or measures focused on those who currently exhibit some signs of functional decline. These interventions aim both to limit

the progression of disease or functional decline or loss of independence²⁶ and to maximize function.

The current knowledge base concerning the potential role for health promotion and secondary prevention in older people remains relatively small.^{26,29} Most community-based interventions for older adults occur at a tertiary prevention level, focusing on illness and the treatment of disease and largely ignoring health promotion, secondary prevention, and partnering approaches between and among all professionals and older people with chronic diseases.^{37,144} In the United States, of the more than \$1.7 trillion in health care spent nationally every year, less than 4 cents of every dollar is spent on prevention and public health.¹⁸ This approach has come in for much criticism for its narrow focus on "downstream," diverting scarce resources away from primary and secondary prevention efforts that focus on early identification and prompt treatment of risk factors before they lead to functional decline. Functional disabilities and illnesses in older people often are managed as acute medical problems, not as ongoing life challenges that require continuous attention to health promotion and preventive care.³⁹ Older people need both health promotion and preventive care, so it is essential that health professionals become engaged in all areas of activity.¹⁴⁵

This section describes five examples of health promotion and preventive care interventions designed for community-living older adults in which either falls, nutrition, or mental health (depression) were areas of focus:

- I. Evergreen Action Nutrition: an example of a secondary prevention program^{146–148}
- II. Home support exercise intervention for frail older adults using home care services¹⁴⁹
- III. Nursing health promotion for frail older adults using home care services³⁸
- IV. Falls prevention for older home care clients at risk for falling¹⁵⁰
- V. Proactive screening, case finding, and treatment of older adults in primary care¹⁵¹

Studies I and II are prospective cohort studies of older adults living in the community with comparable types and severity of illnesses and disabilities who self-select to one community-based approach over another. Studies III to V are prospective randomized controlled trials (RCTs) that control for the methodological problems of self-selection that confound studies I and II. Measures of well-being and cost of use of health services provided to older adults randomly assigned to health-oriented, proactive care were compared with those of similar clients receiving reactive, unplanned, and disease-oriented approaches to care. The major findings from each study are described, and lessons as they relate to using results to informed practice, policy, and future research are described.

Study I. Evergreen Action Nutrition: an example of a secondary prevention program

Despite the importance of preventive nutrition interventions for older adults, secondary prevention programs are relatively absent or not documented.²⁹ Evergreen Action Nutrition is an education program provided since 1999 in a seniors recreation center in southern Ontario. Using a

community-based approach, this program was developed, implemented, and evaluated by an advisory committee that included senior members of the center.¹⁵² Nutrition screening was used throughout the program to identify needs, raise awareness, and evaluate activities. The program was voluntary, and seniors could participate solely through reading education materials or they could be involved in hands-on activities like cooking groups. Activities included resourcing the center library with quality nutrition books; a nutrition column in the monthly newsletter; monthly nutrition and nutrition displays; cooking groups for men; support groups for persons managing weight or diabetes; food demonstrations, which included hands-on activities and food consumption; celebrity chefs; and monthly deliveries of a fresh vegetable and fruit box. Process evaluation demonstrated that the program was effective.¹⁴⁸ The program had a large reach, with approximately two thirds of members (~2000 seniors) having participated in some way during a 3-year period. Respondents to a randomly mailed survey were significantly less likely to be at nutrition risk than those surveyed at baseline (38.9% vs. 56.7%, respectively). Participants, as compared with nonparticipants on the follow-up survey, had better fruit and vegetable intakes. Food demonstrations and cooking groups were effective at overcoming barriers to trying new foods and recipes.^{146,147} Participants reported the intention to change cooking and eating behaviors based on these nutrition education formats. This program was conducted with funding from a research grant for the first 3 years of the program and has continued with minimal funding from the seniors association that runs the center and from monies collected for participation in activities. Lessons learned in this program are that diverse education activities are needed to reach a wide audience—no single intervention will appeal to all seniors. Seniors are interested and motivated to improve their nutrition knowledge and behaviors. A recreation center is an ideal setting for this activity, as it is a nonthreatening environment, and creating a program that has consistent educators and other staff is important for building trust and program continuity. Finally, a participatory approach that involved the target group was essential for developing and implementing meaningful education activities.

Study II. Home support exercise intervention for frail older adults using home care services

This prospective cohort study was designed to determine the effectiveness of a home support exercise program (HSEP) for frail older adults receiving home care services.¹⁴⁹ Home exercise is an effective means to prevent falls, to maintain functional independence, and to promote rehabilitation following injury or illness.¹⁵³ The study sample consisted of 98 frail older adults (≥65 years of age) using home support services in a home care program in southern Ontario, Canada. Sixty subjects were randomly selected to receive the HSEP, whereas 38 matched controls were allocated to receive standard home care without the HSEP. A total of 77 subjects completed the 4-month follow-up (40 HSEP, 37 controls). The HSEP is a 4-month in-home physical activity intervention provided by a trained home support worker. It consists of 10 simple, functional, and progressive exercises that are to be done on a daily basis. Once the exercises have been introduced, the home support worker continues to monitor the

client's progress and to offer motivational support. Results showed that at 4 months, those who received the HSEP self-reported general improvement such as feeling better, being less stiff and stronger, and being able to walk more easily. Those in the control group reported that they felt worse than they did 4 months previously. Between groups, significant differences were observed for mobility and walking scores, with an average improvement of 14% to 34% in the HSEP group, compared with only minor improvement or functional decline in the control. Significant improvements for balance confidence were also observed, whereas the control group experienced little or no change in balance confidence. The findings support the effectiveness of the HSEP, as well as the importance of proactive and regular exercise interventions and support in this population.¹⁴⁹

Study III. Nursing health promotion for frail older adults using home care services

This single-blind, randomized controlled trial, with a 6-month follow-up, conducted in a home care program in southern Ontario, Canada, was designed to determine the effects and expense of adding nursing health promotion and preventive care to usual home care services in a national system of health and social insurance.³⁸ The study sample consisted of 242 older adults (≥75 years of age) using home support services. Subjects were randomized to intervention ($n = 144$) or control groups ($n = 144$). A total of 242 (84%) subjects completed the 6-month follow-up. In addition to usual home care, the nursing group received a health assessment combined with regular home visits or telephone contacts, health education regarding management of illness, coordination of community services, and empowerment strategies to enhance independence. The primary outcome was functional health status and related quality of life. Secondary outcomes were depression, perceived social support, coping ability, and cost of use of health services from baseline to 6 months. Results showed that providing older adults with proactive nursing health promotion and preventive care compared with providing nursing services on a reactive and episodic basis results in better mental health functioning ($P = .041$) and a reduction in depression ($P = .001$) at no additional expense (e.g., both interventions cost the same). The overall conclusion of this study is that home-based nursing health promotion, proactively provided to frail older people with chronic health needs, enhances quality of life at no additional expense from a societal perspective. The results underscore the need to reinvest in nursing services for health promotion for older adults receiving home care services.³⁸

Study IV. Falls prevention for older home care clients at risk for falling

This single-blind, randomized controlled trial, with a 6-month follow-up, conducted in a home care program in southern Ontario, Canada, was designed to determine the effects and costs of a multifactorial, interdisciplinary team approach to falls prevention compared to usual home care for older home care clients at risk of falling.¹⁵⁰ The study sample consisted of 109 older adults (≥75 years of age) using home support services who are at risk for falls. Subjects were randomized to intervention ($n = 54$) or control ($n = 55$) groups. A total of 92 subjects completed the 6-month follow-up. The intervention was a 6-month

multifactorial and evidence-based prevention strategy involving an interdisciplinary team. The primary outcome was number of falls during the 6-month follow-up. Secondary outcomes were changes in fall risk factors and costs of use of health services from baseline to 6 months. Results showed that at 6 months, there was no difference in the mean number of falls between groups (-0.04 [95% CI: $-1.27, 1.18$]; $P = .702$). However, subgroup analyses showed that the intervention was effective in reducing falls in men ($P = .009$), 75 to 84 years of age ($P < .001$), with a fear of falling ($P < .001$) or a negative history of falls ($P < .041$). There was a greater reduction in number of slips and trips (-4.97 [95% CI: -10.7 to 0.84], $P = .03$) and a greater improvement in role functioning related to emotional health in the intervention group (-14.13 [95% CI: -0.28 to 28.54], $P = .054$). These improvements were achieved at no additional cost from a societal perspective (e.g., both interventions cost the same). The overall conclusion of this study is that a multifactorial, interdisciplinary team approach was more effective and no more expensive than usual home care in improving quality of life, reducing the incidence of slips and trips, and reducing falls among males (≥ 75 to 84 years) with a fear of falling or a negative history of falls.¹⁵⁰ This study is important because of the high prevalence of falls among older adults receiving home support services. The baseline fall rate of 72% in the present sample greatly exceeds the fall rates of 30% typically reported for representative samples of community-dwelling older adults.⁷⁹ Home care policy makers, agencies, and fund-raisers should work together to ensure that an interdisciplinary team approach is available to the subgroups of seniors who could benefit from it most to reduce future falls, enhance quality of life, and reduce on-demand use of health services.

Study V. Proactive screening, case finding, and treatment of older adults in primary care

This randomized controlled trial was designed to determine the effect and expense of proactive screening, case finding, and random treatment of ambulatory seniors having 1 of 28 unrecognized medical concerns, in a primary health care setting.¹⁵¹ Seniors with unrecognized health concern were randomly allocated to treatment ($n = 209$) or nontreatment ($n = 410$) groups. Treatment consisted of one to two visits to an appropriate primary care professional (physician, nurse, or social worker) depending on the specific concerns. On the whole, there was no significant improvement in the overall functional capacity of seniors treated versus those not treated for their concerns. However, screening, case finding, and health-oriented, proactive primary care resulted in improved mental health and social functions (11% to 22%, respectively) for seniors who were 75 years of age and older and living alone. Similar seniors without treatment showed a deterioration of 2% in their scores over the 2-year period ($P = .04$). Seniors who were lonely and treated used \$2610 per person per annum in services, compared with similar untreated seniors who used \$10,971 per person per annum after 2 years. The overall conclusion of this study is that screening, case finding, and health-oriented, proactive primary care are more effective and less expensive for older adults with psychosocial risks.¹⁵¹

Lessons learned

Collectively, these studies of health promotion and preventive care interventions suggest that in a system of national health insurance, such as we have in Canada, proactive,

comprehensive, and integrated interventions for older adults with varying characteristics can result in better health outcomes for the same and sometimes lower cost compared with providing services on a limited, reactive, and piecemeal basis. The use of prospective studies allows for an estimation of change in client status over time. Studies I and II, which used a prospective cohort design, illustrate the benefit of health-oriented and proactive community services and support for older adults with comparable types and severity of illnesses and disabilities who self-select to one community-based approach over another. Studies III to V employed a randomized controlled trial design to compare the effects and costs of a health promotion and preventive care intervention with reactive, unplanned, and piecemeal approaches to care. Across these studies, subjects were assessed with different outcome measures appropriate to their circumstances, yet the same approach to the quantification of the cost of use of health services was employed.¹⁵⁴ Studies III and IV of frail, older, home care populations illustrate that health promotion and preventive care interventions compared with piecemeal and on-demand care result in improved outcomes at no more expense to society (rubric 4, Figure 98-3). In study V of ambulatory populations with chronic conditions who live alone, improved outcomes can be achieved at lower cost with health promotion and prevention care (rubric 7, Figure 98-3). Expenditure data in these four studies include the cost of the health promotion and prevention care interventions. The studies illustrate potential outcomes 4 and 7 in Figure 98-3 and collectively represent different kinds of economic efficiencies that are achieved with populations with more or less access to services to begin with.

As a whole, the results of these studies provide empirical support for the positive synergistic and cumulative effects of bolstering personal resources (e.g., physical, mental health, and social functioning) and environmental supports (e.g., community supports) on health status and related quality of life⁵⁶ to considerable economic effect (no additional or lower expense). Health care providers need to be able to assess older adults' areas of strength and vulnerability. Awareness of the sources of vulnerability and barriers to health care may assist health care providers to provide more holistic, comprehensive care to their clients.⁵⁶

These five studies illustrate a number of features of successful community-based health promotion programs for community-living older adults. First, the results have shown that comprehensive and coordinated services aimed at all of the broad determinants of health are superior when compared to individual, fragmented, and disease-oriented approaches to care.³² Because health is determined by many more things than physical needs, such approaches must extend beyond the care of medical problems to address other nonmedical determinants of health (e.g., social support, mental health, housing, income).⁵ This approach represents a fundamental shift away from a *replacement function* focused solely on physical needs to an *empowerment function* to enhance seniors' independence, autonomy, and problem-solving skills.¹⁵⁵ The results of these studies suggest that, in a system of national health insurance, interventions that address single problems or single risk or protective factors are less effective in reducing health problems or enhancing competencies in people with synergistic risks than proactive, health-oriented, and comprehensive interventions.^{33,37} Effective interventions include

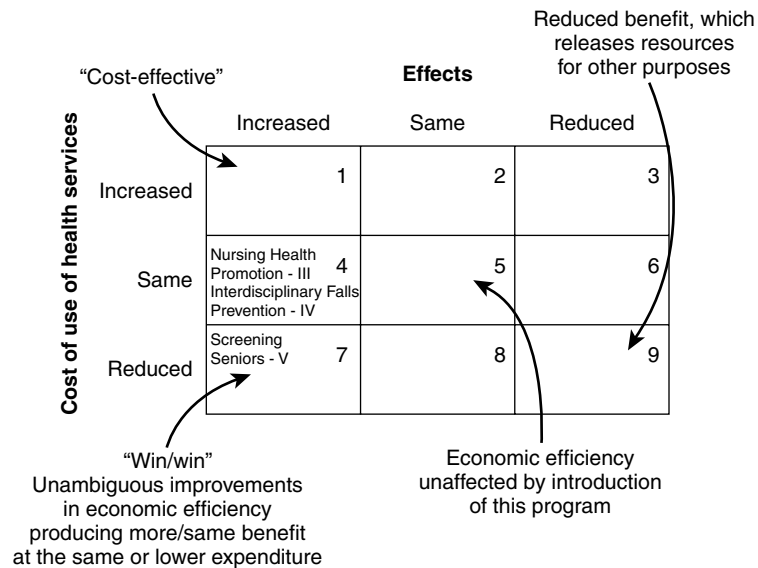

Figure 98-3. Framework for evaluating possible outcomes of economic evaluation of health care programs. (From Birch S, Gafni A. *Cost-effectiveness and cost utility analyses: methods for the non-economic evaluation of health care programs and how we can do better*. In: Geisler E, Heller O, editors. *Managing Technology in Healthcare*. Norwell, MA: Kluwer Academic Publishers; 1996.)

elements that ensure access to a comprehensive range of services provided in the right amount and delivered by the right care provider, in the right place and at the right time.¹³¹

Second, successful health promotion interventions need to be tailored to individual needs. The most expensive services are those that are not tailored to people's needs (or vulnerabilities).³³ No single intervention or mix of community services will meet the health promotion needs of all seniors. Hence, there is a need to classify who (with what characteristics) most benefits and at what expense, from various interventions, especially in systems of national health insurance where people will use, however, (in)appropriately, some service if another is made (un)available.³² Screening plays a part in targeting those who are most likely to benefit. Seniors are interested and motivated to change their behavior to enhance health. Successful behavior change is associated with the empowerment of individuals through the provision of appropriate communication, information, and support. Interventions need to respond appropriately to an individual's readiness to change through various strategies tailored to an individual's needs. Models of care should be flexible and contextualized, taking into account individual needs and comorbidities and paying particular attention to vulnerable, at-risk populations. These data can be used to target scarce resources to those most likely to benefit from preventive efforts.

Third, to be successful, health promotion needs to occur across multiple sectors. In these studies, the interventions involved a wide range of actions operating at three levels: the individual clinician (e.g., promoting changes in practice behavior), the interdisciplinary team (e.g., fostering inter-professional collaboration), and the health care system (e.g., influencing the financing, management, and delivery of services). When health problems are chronic, care must be organized and coordinated over time, among providers, and across settings.¹⁵⁵ This multisector work requires good communication and a close affiliation so that individual home and community-based services do not operate in isolation

but are part of a broader, more balanced, integrated approach to a comprehensive and coordinated system of services that address all of the factors that determine health.

Fourth, models of care need to be function based (from the client's perspective) rather than disease based. The emphasis is on the individual's perception of health, rather than on his or her objective circumstances, and in determining his or her decision to take action. The evidence is clear that increasing people's involvement in their health care management and decision making has been shown to improve health status and lower costs.¹⁵⁶

Finally, it is important to take a comprehensive approach to examine expenditures associated with different approaches to home and community-based care.³² In addition to savings within the health care sector, a program could expect to see a return on its investment in prevention in other sectors (e.g., education, social, and benefits other than reduction of disease).¹⁸ Economists argue that the effect of a publicly funded home and community-based service on society as a whole should be considered when making decisions about the use of that service.¹⁵⁷ This comprehensive societal viewpoint is often ignored in the economic analysis of health care services.³²

THE NEED FOR LEGISLATION AND POLICY

Despite the potentially important role of home and community-based services in health promotion and preventive care for older adults, several realities continue to impede this direction. Within the persistently biomedically and institutionally focused health care arena, in-home and community-based care still suffer from underfunding of services, underfunding of research to inform policy and practice, and limited consideration of the broader determinants of health in these sectors.¹⁴⁴ Since the late 1990s, health care systems have been challenged to provide more home and community care services to older, more vulnerable, and frail

individuals while limiting the growth of health care expenditures.^{158–160} Growing demand for home and community care is attributable to several factors—namely, technologic advancements, changing demographics, patient preference, and the presumed cost-effectiveness of home care.¹⁵⁸ With increasing life expectancy, substantial increases in home care expenditures are expected by 2026.¹⁶¹ Often, the need goes unmet as resources are shifted from prevention and health promotion to meet the more pressing need for postacute care substitution.¹⁶² This emphasis, coupled with the sustained biomedical orientation of services, can mean that the focus on prevention and health promotion for seniors with chronic needs is minimal at best.¹⁴⁴ The allocation of home and community services often is based on physical needs or medical services, suggesting that nonmedical services are unrelated to health outcomes, despite evidence to the contrary.⁷

A growing body of research, done mostly in a national system of health insurance, suggests that for older people with chronic health needs, these trends combine to create a fragmented system of health care delivery, characterized by providing health services on a reactive, episodic, and piecemeal basis rather than a comprehensive and proactive system of care.^{23,33} Delays or errors in detecting and responding to chronically ill older people's changing health needs can contribute to more complications, cause functional decline and negative changes in quality of life,¹⁶³ and increase the demand for expensive institution-based care such as acute hospitalization.³³ Furthermore, this experience with the acute care system often undermines chronically ill seniors' self-confidence and their interest and ability to participate in their own care. The result is a vicious circle of reliance on institutionalized care.¹⁴⁰

To address effectively the growing burden of chronic disease and frailty in older people living in the community, healthy home and community care policies are needed to provide vision, set priorities, and establish standards. Such policies and standards should support the development of basic competencies for health promotion and preventive care among providers, as well as systemic changes within home and community care organizations to allow the allocation of adequate resources for assessment of risk and delivery of health promotion and prevention strategies. There is a need to move away from a "find-it and fix-it" episodic orientation that does not match the ongoing care needs of older people with chronic condition, who need a "find-it, manage it, and prevent it" approach.³¹

Home and community-based programs need to provide a continuum of services including health promotion, prevention, and postacute care substitution services.¹⁵⁸ Enhanced funding and focused health promotion and preventive care activities should be applied to mitigate the risk factors for functional decline and loss of independence, so that living at home, even with significant challenges, can become a true reality for older populations. Without this legislation and resource provision, improvements in the health of older adults will continue to be an ad hoc affair with limited impact.²⁹

THE NEED FOR MORE RESEARCH

With the increasing demand for home and community-based services for older people, there is increasing pressure for evidence to demonstrate that community-based health

promotion and preventive care for older people is an efficient use of health care resources in developed countries.¹⁶⁴ A 2003 report by the World Health Organization for policy makers on the future direction of health-promotion evaluation emphasized the need for evidence about effective and efficient health-promotion and preventive care strategies.¹⁵ This evidence is needed to ensure that the most appropriate services are available to those who most need them, to ensure the best health outcomes.¹⁶⁰ However, the current knowledge base concerning the potential role for health promotion and secondary prevention in older people remains relatively small.^{26,29} Specifically, further investigation is needed regarding the most efficacious ways of providing health promotion and preventive care to the different groups of successfully, usually, and accelerated aging. These groups have different needs, risk factors, and comorbid conditions and experience different barriers and facilitators to health promotion,¹⁶⁵ and further research is needed to differentiate these influences.

Older adults with chronic conditions who are experiencing accelerated aging have been identified as at increased risk for functional decline, institutionalization, and death,¹³ but these individuals are often excluded in community-based trials.^{49,166} There is a need to establish a knowledge base about the needs of this vulnerable group. Understanding what factors in the individual and the environment are most predictive of morbidity and use of health services is needed to move forward with health promotion efforts in this group.

Large, randomized trials are required to test innovative approaches to health promotion and secondary prevention strategies for community-living older adults. Such studies should provide information on client-important outcomes, such as functional health status and related quality of life, mental health, and social support. These studies should also address more process-oriented outcomes associated with health promotion, such as autonomy, empowerment, and decision making.¹³⁷ Such studies should also compare outcomes achieved with different providers and different combinations of providers to inform how best to meet the needs of this client group. Future research also needs to incorporate a full economic evaluation and identify the specific subgroups of clients who will benefit most.

A major gap in the research on home-based health promotion is the lack of a theoretic framework.³⁷ As a result, it is difficult to assess the appropriateness of the intervention to the outcomes being measured or to formulate hypotheses regarding why or how a particular intervention should be expected to result in a particular outcome.^{141,167} Future research is needed that uses a theoretical framework and provides descriptive and contextual details about the health promotion strategies and measures of process to enable their replication and provide information about why an intervention was or was not found to be effective.¹⁶⁸ Further testing of the vulnerability model is needed to provide a knowledge base for designing and evaluating health promotion strategies.

Finally, research is needed on older adults' awareness and perceived need for health promotion. Despite being identified as at risk and having an awareness of the benefits associated with certain health behaviors, not all older adults decide to make positive behavioral changes.¹⁶⁵ Furthermore, some people may be less likely to change health

behaviors than others, such as the oldest cohorts and women,¹⁶⁹ and it may be necessary to target strategies to these groups. Qualitative studies would help to identify the processes involved in the decision to change behavior, including the factors that influence compliance with recommendations. This type of information can be used to identify the most effective ways of supporting health promotion behavioral change to ultimately improve older adults' quality of life. Overall, this research will assist with targeting limited home and community resources and improving the effectiveness of efforts.

ACKNOWLEDGMENTS

Dr. Maureen Markle-Reid holds a Career Scientist Award (2004–2009) from the Ontario Ministry of Health and Long-Term Care, Health Research Personnel Development Fund.

Dr. Heather Keller received a New Investigator Research Award (2000–2006) from CIHR, which allowed her to complete much of her work on the screening and community nutrition education interventions cited in this chapter.

Dr. Gina Browne is the founder and director of the System-Linked Research Unit, funded by the Ontario Ministry of Health and Long-Term Care, which supported many of the studies cited in this chapter.

Preventive and Anticipatory Care

James T. Pacala

As illnesses and adverse conditions become more prevalent with advancing age, the opportunity for prevention becomes increasingly important for elderly people. Preventive activities can be divided into five broad categories: prevention of diseases, prevention of frailty, prevention of accidents, prevention of iatrogenic problems, and prevention of psychosocial illnesses. Disease-prevention practices are designed to do the following:

- Prevent illnesses from occurring in the first place (primary prevention)
- Detect and treat disease at an early stage, thereby minimizing the morbidity and mortality caused by that disease (secondary prevention)
- Optimize treatment of existing conditions, usually chronic illnesses, to prevent adverse sequelae from these diseases (tertiary prevention)

The accumulation of chronic diseases and adverse conditions with aging often leads to severely threatened or outright loss of function, widely known as “frailty”; efforts to prevent this often common end point are particularly pertinent in the older adult population. Elderly people are particularly prone to injuries from accidents, constituting another area of opportunity for preventive efforts. It is well established that medical care itself has a propensity to cause harm, which increases with aging, indicating a need for prevention of iatrogenic problems, particularly among those who are frail. Finally, psychosocial illnesses also commonly pose a threat to functioning in older adults, and prevention of these illnesses is gaining increasing attention.

Not all elderly people stand to benefit equally from each type of preventive activity. They exhibit great variability in health and functional status, ranging from highly functioning persons who are free of disease and injury to those who are frail and totally functionally dependent. Different types of preventive activities will have different yields, depending in part on the baseline health and functioning of the person. To maximize efficiency and patient benefit, individualizing prevention by devoting time and resources toward those activities that are most likely to prevent morbidity and mortality given the status of the older adult patient seems warranted.

This chapter describes modalities for each type of preventive activity. Then, strategies for prioritizing those activities by patient status are presented.

DISEASE PREVENTION

Primary and secondary disease prevention

Primary and secondary disease prevention encompasses several activities. Screening refers to activities that detect a previously unknown condition in asymptomatic individuals. Detected risk factors are then altered, and through lowering of risk, the target disease is primarily prevented. Diseases discovered in their early stages are treated, thereby secondarily

preventing more severe manifestation of advanced disease. Immunoprophylaxis prevents significant illnesses through vaccination. Counseling promotes lowering of disease risk through behavioral change. Decreasing disease risk by administering medications is known as chemoprophylaxis.

The U.S. Preventive Services Task Force (USPSTF)¹ rigorously reviews a wide variety of primary and secondary prevention practices. Preventive services for elderly people that are recommended by the USPSTF and supplemented by immunization recommendations from the Centers for Disease Control and Prevention (CDC)² are shown in [Table 99-1](#). [Table 99-2](#) lists activities currently not recommended by either the USPSTF or the CDC but that have been endorsed by other specialty organizations. The preventive efficacy of the procedures in [Table 99-2](#) is less well established; accordingly, they might be considered more selectively in elderly people.

Tertiary disease prevention

As some elderly people age, they accumulate chronic illnesses that pose a threat to their functioning and quality of life. Although chronic illnesses by definition cannot be cured, proper management of these diseases can prevent further disease-induced functional loss. Chronic diseases that commonly lead to morbidity and mortality in the older population include the following:

- *Arthritis.* Osteoarthritis and rheumatoid arthritis affect about one half of all people aged 65 and over and lead to mobility impairment, which in turn increases the risk for numerous other conditions—and a resultant decrease in disability-free life expectancy.³ Therefore, aggressive management of arthritis through medication and exercise is indicated. (See Chapter 71 on arthritis.)
- *Diabetes.* Older adults exhibit significantly increased risk for retinopathy, nephropathy, and coronary disease when glycohemoglobin (HgbA_{1c}) fractions exceed 7.9%.⁴ Clinicians should attempt to achieve HgbA_{1c} concentrations at least below 8% in diabetic patients and less than 7% in those who are not frail. Aggressive prevention of foot ulcers should also be undertaken through patient education and foot exams at each visit. (See Chapter 96 on diabetes.)
- *Vascular disease.* Patients with prior history of coronary, cerebral, or peripheral arterial disease are at markedly increased risk for a disabling event. There is good evidence that treatment of vascular risk factors in older adults with prior myocardial infarction (MI), angina, prior stroke, or claudication significantly reduces the risk of a subsequent MI, stroke, or limb loss.^{5,6} The risk factors include hypertension, smoking, diabetes, atrial fibrillation, and dyslipidemia. (See Chapters 34, 49, and 38 on coronary, cerebral, and peripheral vascular disease.)
- *Heart failure (HF).* HF accounts for a great deal of suffering in elderly people and carries a higher mortality rate than

Table 99-1. Recommended Disease-Prevention Activities*

Type of Activity	Disease to Be Prevented/Detected	Activity	Frequency
Screening	Hypertension	Blood pressure measurement	At least yearly
	Obesity, malnutrition	Height and weight measurement	At least yearly
	Breast cancer	Mammography	Every 1–2 years [†]
	Cervical, uterine cancer	Pap smear	At least every 3 years [‡]
	Colon cancer	Fecal occult blood testing (FOBT); sigmoidoscopy; colonoscopy	FOBT: yearly; sigmoidoscopy: every 3–5 years; colonoscopy: at least once
	Coronary artery disease	Serum lipid measurement	Every 5 years; more often in persons with prior myocardial infarction, angina, stroke, or who have peripheral arterial disease or diabetes mellitus
	Hearing deficit	Hearing test	Yearly
	Alcoholism	Alcoholism screening questionnaire	At initial visit and when problem drinking is suspected
	Abdominal aortic aneurysm	Ultrasonography	Once between ages 65–75 in men who have ever smoked
	Depression	Depression screening questionnaire	Yearly in clinical practices with systems to assure accurate diagnosis, effective treatment, and follow-up
Immunoprophylaxis	Osteoporosis	Bone mineral density measurement	At least once in women aged 65 and older
	Diabetes mellitus	Fasting plasma glucose, 2-hour postload glucose, and/or hemoglobin A _{1c} .	At least every 3 years in persons with BP >135/80 mm Hg
	Influenza	Flu shot	Yearly
	Pneumococcal disease	Pneumovax vaccination	Once at age 65 [§]
	Tetanus	Tetanus booster	Every 10 years
	Herpes zoster	Herpes zoster immunization	Once in immunocompetent people without prior zoster
	Cardiopulmonary disease, several cancers	Smoking cessation	At every visit of patients who smoke
	Coronary artery disease; obesity	Behavioral dietary counseling	Yearly in those with risk factors for coronary artery disease or with BMI >30 kg/m ²
	Coronary artery disease, stroke, colon cancer	Aspirin therapy 81–325 mg p.o.	Daily in persons at increased risk for coronary artery disease

*As endorsed by the U.S. Preventive Services Task Force or the Centers for Disease Control and Prevention.

[†]Should be continued past age 70 in women who have a reasonable life expectancy.

[‡]Stop at age 65 if regularly tested throughout adult life AND there were no positive results; if never tested, can stop after two normal pap smears 1 year apart. Women without a cervix should not receive a Pap smear.

[§]Consider repeating every 7 years.

many forms of cancer. Proper and aggressive treatment of HF, especially systolic dysfunction, has been shown to reduce hospitalization rates, functional decline, and even mortality.⁷ (See Chapter 33 on HF.)

- **Osteoporosis.** With the availability of bone density measurement, osteoporosis can be detected before a disabling fracture. Treatment of osteoporosis, in patients both with and without prior fracture, has been shown to prevent new fractures. (See Chapter 70 on osteoporosis.)^{8,9}

Tertiary prevention is accomplished through chronic disease management. The Wagner model of Chronic Disease Care is widely cited as definitive of state-of-the-art care for this category of older adults. The goal of the Wagner Chronic Care model is to establish a productive interaction between an informed activated patient and a prepared proactive practice team.¹⁰ The model calls for four features that are essential in achieving this goal:

- Self-management support, featuring interventions for the patient to manage his or her own illness, with individual goal setting performed by the patient in conjunction with the health care team
- Delivery system design wherein all medical providers practice as a team with defined roles, featuring planned

patient visits, use of evidence-based care, regular follow-up, and care coordination

- Decision support, wherein evidence-based guidelines are fully incorporated into daily practice
- Clinical information systems, including the establishment of a patient registry, a database of useful and timely information on all patients that assists providers in care planning and ongoing management

A disease-specific case management program can also be a powerful intervention for tertiary prevention, frequently employing a specially trained nurse to coordinate protocol-driven care, arrange support services, and provide patient education.¹¹ See Chapter 120 for more information regarding implementation of disease management programs in health systems.

PREVENTION OF FRAILTY

Aside from preventing individual diseases, the larger question remains of whether or not their frequent end point—frailty—can be prevented. Frailty refers to a condition in which loss of physiologic reserve makes the afflicted individual particularly susceptible to disability from minor stresses. Frail individuals commonly exhibit significant functional deficits, weakness, muscle wasting, deconditioning, slowed gait, and fatigue.¹²

Table 99-2. Additional Disease-Prevention Activities That May Be Applicable in All or Selected Elderly People

Type of Activity	Disease to Be Prevented/Detected	Activity	Frequency	Comment
Screening	Dementia, delirium	Mental status testing	Yearly	May grow in importance if early treatment of dementia is shown to change outcomes
	Falls	Inquiry about falls in the past year	Yearly	Inquiry should be extended to include balance and gait problems
	Prostate cancer	Digital rectal exam or prostate-specific antigen testing	Yearly	Effective for early detection; randomized trial data is inconsistent and shows a small mortality benefit, if at all
	Skin cancer	Skin exam	Yearly	Treatment of false positives has low morbidity
	Hypothyroidism	Thyrotropin measurement	Yearly	Some experts recommend screening women
	Glaucoma	Glaucoma screening	Yearly	
Chemoprophylaxis	Malnutrition, tooth decay, oral cancers	Dental visit	Yearly	
	Osteoporosis	Calcium 1200 mg/d and vitamin D 800 IU/d intake	Daily	
Counseling	Coronary artery disease, obesity, osteoporosis	Exercise counseling	Yearly	Should include aerobic conditioning (at least 30 minutes of moderate intensity five times per week) and muscle strengthening at least twice per week

Control of a chronic condition becomes labile, resulting in frequent functional decompensation and hospitalization.

Can frailty be prevented? Data from long-term cohort studies suggest that it can, primarily through exercise and proper nutrition. Healthy adults who exercise are at lower risk of becoming frail, and functionally impaired older adults who exercise are less likely to experience further functional loss. To be most effective, an exercise program should include the following components:¹³

- **Aerobic conditioning**—at least 30 minutes of moderate-intensity activity five or more times per week. Moderate-intensity activities are those that increase heart rate and would be rated at 5 to 6 on a 10-point intensity scale by the patient. Brisk walking is an activity that many older adults can perform for aerobic conditioning.
- **Weight (resistance) training**—8 to 10 exercises of major muscle groups, 10 to 15 repetitions per exercise, at least twice a week.
- **Flexibility**—at least 10 minutes of flexibility activities (e.g., static stretching, 10 to 30 seconds per stretch, three to four repetitions of major muscle/tendon groups) at least twice a week.
- **Balance**—balance exercises are recommended in persons with mobility problems or frequent falls.

Proper nutrition is important for prevention of many conditions contributing to frailty, including certain forms of cancer, osteoporosis, obesity, and malnutrition. Studies have consistently shown less morbidity and lower mortality rate in those who eat diets featuring the following:

- **Low fat.** Less than 30% of total calories, with no more than 10% coming from saturated fats.¹⁴
- **Low sodium.** A 2.4-gram sodium diet is recommended.¹⁵
- **High calcium.** Older adults need 1200 mg of calcium per day; most American diets contain only 600 to 700 mg per day. Calcium supplementation should be provided if the diet contains less than 1200 mg per day.¹⁶

- **Adequate vitamins and minerals.** These are ensured largely through eating fruits and vegetables. Some experts recommend supplementation with vitamin D (800–1000 IU/day) for bone health, folate (at least 200 mcg/d) to keep homocysteine levels low, and possibly the use of selenium (200 mcg/d) for its antioxidant effect.^{16–18}
- **High fiber.** This is best obtained from eating fruits, vegetables, and grains.¹⁴
- **Moderate alcohol intake.** About 1 to 2 ounces of alcohol per day can actually promote health; more can be harmful.¹⁹

PREVENTION OF ACCIDENTS

Falls constitute a significant risk in older adults. Falls prevention programs (see Chapter 105 on falls) can be implemented for those who are at high risk for falls or who have already fallen.

Slowed reaction time, sensory deficits, dementia, and a host of other age-associated conditions place elderly people at higher risk of injuring themselves and others while driving. Correction of these conditions whenever possible and routine driving tests can minimize risks. All older adults should be reminded to use seat belts when traveling in an automobile. Cessation of driving poses a great threat to the autonomy of older persons, so addressing the driving ability of the geriatric patient should be undertaken with great care and sensitivity.

Household environments can also present a variety of accident hazards. For example, persons with peripheral neuropathy are at increased risk for burns from excessively hot water; setting the hot water temperature at less than 120° to 130°F can obviate this problem. Harm from fires can be reduced by the use of smoke detectors. Demented persons face many accident risks in the home, especially when operating electrical and gas appliances; the use of alarms and automatic shutoff features can be effective in these instances. A home safety checklist can be completed by patients or their caregivers to assess environmental hazards that could

lead to an injurious fall. Many physical and occupational therapy (PT/OT) departments perform home visits for accident risk assessment. For elderly people who are particularly vulnerable to injury, PT/OT consultation can be extremely helpful in reducing their accident risk.

PREVENTION OF IATROGENIC PROBLEMS

Several age-associated factors place elderly people at increased risk of iatrogenic problems. As physiologic reserve progressively decreases, the margin for clinical error gets smaller, thereby increasing the risk of an adverse effect of a medical intervention. Older adults who accumulate chronic diseases also accumulate medical providers, often resulting in a lack of care coordination. Having multiple providers frequently leads to polypharmacy. Elderly people are hospitalized more frequently than younger persons; hospitalization presents a host of iatrogenic risks, such as nosocomial infection, adverse drug events, transfusion reactions, and so on.^{20,21}

In addition to the preceding factors, the explosion of advances in medical technology has presented further opportunity for iatrogenic illness. Technologic interventions such as cardiopulmonary resuscitation (CPR), valve replacement surgery, carotid endarterectomy, combination intravenous antibiotic therapy, and use of artificial feeding tubes have dramatically increased the therapeutic options during life-threatening illnesses. Although their positive effects are often lifesaving, the potential adverse effects of these interventions are usually severe, such as brain damage from CPR, sudden death or MI from valve replacement surgery, stroke from carotid endarterectomy, fluid overload from combination intravenous antibiotics, and unwanted prolonged life from feeding tubes.

Compared with younger persons, older adults more often experience these untoward outcomes.²⁰ When elderly people confront critical illnesses, the decision of whether or not to undergo high-risk, potentially lifesaving interventions must be faced. Unfortunately, research has shown that physicians are frequently unaware of patients' preferences for aggressive care and often do not discuss these issues with patients.²² The morbidity from a medical or surgical procedure that was not wanted in the first place is thus iatrogenic.

The first step in preventing iatrogenic problems is to recognize which patients are the most vulnerable to the adverse effects of medical care. Patients most susceptible to iatrogenic problems are those who have multiple chronic illnesses, see multiple physicians, and take multiple medications.^{23,24} There is a direct correlation between the number of chronic illnesses and the chances that treatment of one illness will adversely affect the other.²⁵ Persons with multiple chronic illnesses frequently see multiple physicians. It is difficult for numerous providers to consult with each other every time they see a common patient. As a result, changes in a patient's therapeutic regimen are frequently made without the input of other providers, often increasing the risk of iatrogenic illness. Chronically ill and frail people also take numerous medications. The average elderly person takes two to three times the prescription and over-the-counter medicines taken by a younger person. Higher rates of drug use and chronic illness lead to a markedly increased risk of

drug-drug or drug-disease adverse interactions. This risk of polypharmacy is particularly increased in patients who are malnourished or who have renal failure.

Another significant risk factor for iatrogenic problems is hospitalization. Acutely ill older adults are at increased risk for treatment-related delirium, adverse drug reactions, pressure sores, and nosocomial infections.^{26,27} Patients with dementia or conditions causing immobility are at particular risk for hospital-induced iatrogenic problems, especially when undergoing surgery.^{28,29}

Once high-risk patients are identified, several interventions can be implemented to prevent the following iatrogenic complications:

- *Case management.* The primary function of a case manager is care coordination. Case managers can be employed by physician groups, parent health plans, and community or governmental organizations. Research has shown that case management is most effective at achieving beneficial outcomes in elderly people who are frail.^{30,31} Case managers facilitate communication between providers, ensure that needed services are provided, and avoid duplication of services.
- *Geriatric evaluation and management (GEM).* A GEM team can be called on to evaluate all of the patient's problems simultaneously and formulate a coordinated care plan. This intervention is resource intensive and should be applied to only patients with the most complex clinical problems.³²
- *Pharmacist consultation.* A pharmacist's input can be particularly helpful to prevent complications from polypharmacy.³³
- *Acute care for the elderly (ACE) units.* ACE units are specific wards of a hospital with dedicated staff, all designed to address the special needs of elderly inpatients. As such, these units are in tune with the iatrogenic risks of hospitalization and take specific measures to avoid these complications.³⁴
- *Advance directives.* Advance directives, including designation of proxies for medical decision making, can be helpful in avoiding administration of undesired medical treatments during periods of critical illness when patients are unable to speak for themselves. Research on the effectiveness of advance directives has been somewhat disappointing, showing that they are rarely completed by patients, occasionally not obeyed by providers, and frequently changed when patients' conditions become dire; interventions designed to increase their effectiveness have been largely unsuccessful.³⁵ However, designation by the patient of a proxy for medical decision making can often circumvent many of these limitations.

PREVENTION OF PSYCHOSOCIAL ILLNESSES

Aging is frequently accompanied by loss and isolation. Spouses and close friends become disabled or die; children often move far away from home. Retirement brings not only stoppage of work but also distancing from one's peers. Immobility and other conditions make travel much more difficult. Increasing disability and functional dependence lead to loss of autonomy. Depression, loneliness, family discord,

and other psychosocially derived illnesses and conditions can result from these challenges of aging.

Research has shown that older adults with psychosocial illness suffer higher rates of functional dependence and mortality.^{36,37} Less well established is whether or not these illnesses can be prevented. The major challenge in psychosocial illness prevention is the fact that the usual major antecedents—death or relocation of loved ones—are essentially not modifiable. Despite this challenge, the preponderance of psychosocial illness and its strong association with morbidity and mortality in older adults warrant concerted preventive efforts.

Depression is common in elderly people. Although major depression leading to suicide attempts or hospitalization appears to be less common than in younger persons, depressive symptoms (sometimes called minor or situational depression) can be quite prevalent, with a frequency greater than 10%.³⁸ Unfortunately, depression is often unrecognized in primary care practice,³⁹ prompting the question of whether screening for depression in older adults is indicated. Screening would have a higher yield in patients with depressive risk factors: female, single, positive family history, financial problems, and lack of social supports. Several simple screening instruments have been developed that do not require a physician for administration. Coupling the ease of screening with the availability of effective and safe antidepressants, many clinicians have incorporated depression screening into their practices for older patients.⁴⁰

It is well established that elders with increased social contact experience better health. Clinicians should take a social history from their patients, inquiring about situations of loneliness and isolation. In those who are isolated, efforts to increase social contact can theoretically prevent morbidity and mortality. Senior centers, social clubs, and increased family involvement are potentially effective interventions.

A sense of self-worth has also been linked to health in older adults.⁴¹ Healthy seniors often speak of the importance of feeling needed by someone else. Remaining productive at work or leisure activities is also often cited as a correlate of successful aging. Again, though supporting research has not been performed, interventions such as obtaining a pet, performing volunteer work, contributing to household chores, or any other activities that confirm a sense of social connectedness are potentially effective in preventing psychosocial (and even physical) disability.

INDIVIDUALIZING PREVENTION

Because the elderly population exhibits marked heterogeneity of health status, tailoring preventive efforts to match the condition of the patient would seem indicated. Although a continuum in reality, the health and functional status of elderly people divides the population into three basic groups: healthy elderly (60% to 75%), chronically ill (25% to 35%), and frail (2% to 10%). Healthy older adults, constituting the majority of this population, have minimal or no chronic disease and are functionally independent. Those who are chronically ill have an accumulation of incurable conditions; these persons usually have no or mild functional impairment, frequently take several prescription medications, and occasionally are hospitalized from exacerbations of chronic illness. Frail older adults, the smallest group, typically have

numerous and severe chronic illnesses, marked functional dependence, and loss of functional reserve. These persons are frequently hospitalized or institutionalized. Each of these three groups is presented with different threats to its health and functioning, calling for different preventive emphases.

Table 99-3 provides an overview of prevention in the elderly population, matching preventive priorities with patient condition. In healthy older adults who have yet to experience disease and functional decline, primary and secondary disease prevention as well as frailty prevention should be the focus of health maintenance efforts. In those who are chronically ill, it is most likely that complications from their long-standing illnesses will be the cause of future morbidity and functional decline. Thus, the highest preventive priority for these patients should center on tertiary prevention. This is not to say, however, that other preventive modalities should be completely ignored. For those patients who have become frail, there should be an increasing focus on accident prevention and iatrogenic illness prevention, as these events become much more common.

Another method of individualizing prevention is by factoring life expectancy, health status, and potential benefit of preventive activities together as the basis for decision making. The first step is to estimate an individual's life expectancy. This can be done through use of a mortality prognosticating instrument⁴² or by adjusting life expectancy up or down based on the clinician's overall judgment of the patient's health status as being above, at, or below average for age-matched peers. Then the temporal payoff of the preventive activity is estimated and compared to the life expectancy of the patient. For example, the benefit of many cancer screening tests is not realized for approximately 5 years following detection of asymptomatic malignancies.⁴³ Thus, if a patient's life expectancy is 6 years based on age alone and that patient has poor overall health status compared with age-matched peers, the clinician would be disinclined to perform cancer screening in the patient, as the likelihood of benefit for the test is low. Guidelines on individualized decision making based on age and health status have been published for preventive activities in older adults.^{44,45}

Two preventive activities are applicable to virtually all older adults regardless of condition. First, exercise can be effective for prevention of frailty, has a role in the primary prevention of diseases such as heart disease and cancer in both healthy and chronically ill older adults, and can help to preserve function and reduce accidents in patients who are frail. Second, immunization with influenza shots (yearly) and pneumococcal vaccine (once at age 65) is inexpensive, effective, and associated with minimal morbidity.

PREVENTIVE PRACTICE SYSTEMS

Provider knowledge of which preventive activities are indicated for the aging population is not sufficient for the appropriate delivery of preventive care. Implementation of an efficient disease-prevention and health-promotion system in a geriatric practice can be challenging, and delivery of routine preventive services in primary care settings is often shown to be deficient.⁴⁶ Older patients tend to have more acute care needs, manifested frequently as flare-ups of chronic conditions, the management of which occupies

Table 99-3. Prioritizing Preventive Activities by Health and Functional Status

Type of Prevention	PATIENT HEALTH STATUS			DISEASE			
	Primary	Secondary	Tertiary	Frailty	Accident	Iatrogenic Illness	Psychosocial Illness
Healthy	+++	+++	+	+++	+	0	+
Chronically Ill	+	+	+++	++	++	++	+++
Frail	0	0	++	0	+++	+++	+++

+++ = High priority; ++ = moderate priority; + = low priority; 0 = nonpriority.

a major portion of contact time with providers. Owing to the diverse nature of primary care practices, a “one size fits all” approach to implementing a disease-prevention and health-promotion program is not advisable. However, research has demonstrated that the following strategies result in greater degrees of successful preventive activities:

- *Use of nonphysician personnel.* Implementation of screening, immunoprophylactic, and counseling prevention activities are all essentially guideline driven and can be well managed by nurses or other personnel. Research has shown that nonphysicians do a better job of achieving greater compliance with cancer and other disease screening guidelines and that patients accept these activities being directed by a nonphysician.^{47,48} Nonphysicians can be used for worthwhile but time-consuming counseling and behavioral change activities, such as those involved in smoking cessation and dietary weight reduction.⁴⁹
- *Use of information systems.* Information technology has been shown to increase delivery of preventive services.⁵⁰ Computer reminders, guideline provision, and decision support, preferably at the point of care, all enhance preventive care.^{50,51}
- *Patient and provider education.* Increasing the knowledge and awareness of patients and providers about preventive activities promotes such activities in clinical practice. Evidence-based guidelines aid medical personnel in the design of preventive systems.⁵¹ Pamphlets, posters, and other education materials can increase the awareness of and demand for preventive activities among patients.⁵²
- *Community-wide promotion.* Health care organizations, in partnership with community organizations, can promote preventive activities through mass mailings, public information, and advertisements such as through billboards and over the Internet to affect a more population-wide increase in prevention interest.⁵³
- *Creation of incentives for prevention.* Reimbursement structures often favor acute care services over preventive services. Realignment of incentives to reward achievement of preventive guidelines can be a powerful intervention to increase disease-prevention activities.⁵⁴ Changing reimbursement to cover preventive services can also be a strong motivator of change.^{54,55} Designing

practice-based disease-prevention programs necessitates the direct involvement of the practitioners and staff. Working together, physicians and staff should review appropriate prevention literature, decide which disease-prevention activities will be emphasized, define barriers to practicing prevention, and design systems that will overcome those barriers.⁴⁷

SUMMARY

Preventive medicine for older adults should address primary, secondary, and tertiary disease prevention as well as efforts for preventing frailty, injurious accidents, psychosocial illness, and iatrogenic conditions. Rigorous, evidence-based guidelines exist to aid clinicians in these activities, particularly for primary and secondary disease prevention. The relative emphasis of each type of preventive activity should be individualized according to the life expectancy and comorbid status of each patient. Prevention is most effective in practices that take a systems-based approach involving extensive use of nonphysician personnel, information technology linked to evidence-based guidelines, community involvement, and creation of appropriate incentives for preventive care.

KEY POINTS

Preventive and Anticipatory Care

- Five categories of conditions can be addressed for prevention: diseases (primary, secondary, and tertiary), frailty, psychosocial illness, injuries, and iatrogenic problems.
- Disease prevention and health promotion must be individually tailored to the elderly person's health status and functional level.
- Successful disease prevention and health promotion care systems usually feature use of nonphysician personnel, information technology support, educational interventions for both providers and patients, and alignment of incentives to promote preventive activities.

MISINFORMATION, MYTHS, AND PREJUDICES

Physicians frequently overlook the sexuality of older patients during the typical medical examination and evaluation. As a result, physicians may miss the opportunity to offer their older patients reassurance about the normal changes in sexuality that may be troubling them; they may not advise these patients about the side effects of medications that can adversely affect continuing sexual activity; and they may fail to diagnose sexual dysfunction and recommend treatment possibilities.¹

Lack of public and professional medical education is partially to blame for this neglect of late-life sexuality in the medical encounter. Centuries of myths about aging, as well as prudery and ignorance, have helped close the minds of laypersons and professionals alike to the fact that many older people wish to, and do, continue expressing their sexuality until the end of their life. Because few studies have been conducted on sexuality in general, and on late-life sexuality in particular, data about the nature and frequency of sexual activity among older persons are limited. However, self-reports from surveys of older people have demonstrated that, for many, sexual desire and satisfaction remain important aspects of their lives. The main barriers to sexual expression in late life are medical and psychological problems and social obstacles. A problematic marital relationship or lack of a partner due to the death of a spouse or companion may also interfere.¹

With the discovery of the therapeutic effect in men of sildenafil citrate in erectile dysfunction (ED) and its introduction in 1998, the attitudes of physicians and that of the public have moved to more positive approaches and acceptance of sexuality for older persons. This includes a growing awareness of the need for further understanding of female sexuality, including better diagnosis and treatment for older women that parallels current breakthroughs for older men.

NORMAL AGING AND CHANGES IN SEXUALITY

Sexuality may be defined as the quality or state that comprises sexual desire (libido), arousal, function, and activity; physical satisfaction; and emotional intimacy. Many older people maintain desire (libido) and sexual capacity and satisfaction as long as they have their health, a healthy partner, and a good relationship with that partner. They experience the same four stages of the sexual act as younger people: desire, arousal, climax, and recovery. Sexual expression remains a highly complex process in old age and may involve fantasy, the central nervous and peripheral nervous systems, the circulatory system, and all six senses. The capacity for fantasy may, however, decline for older men, according to the National Institute on Aging's Baltimore Longitudinal Study on Aging. We do not know if this is equally true for women because sexual fantasy in women was not documented in the study.

Normal change in sexual functioning is usually manifested as a gradual slowing—that is, more time is needed for arousal (erection in men; lubrication in women) and reaching a climax. Unlike women, healthy men can remain fertile until

the end of life. There is no discrete climacteric for men, but rather a gradual decline of testosterone levels after age 30 that usually do not fall below normal. Testosterone levels in 70% of healthy older men are in the same range as those of younger men. With aging, the testes may become smaller and penile flaccidity greater. More direct stimulation of the penis may be necessary to reach engorgement and erection. For some older men, orgasm may last a shorter time than it did when they were younger. The force of ejaculation and the volume of ejaculate decrease. A great concern for older men (and for younger men as well) is their ability to maintain sexual potency. Impotence and ED are often automatically and inaccurately attributed to increasing age. They can, in fact, occur at any age for a variety of reasons and, once properly diagnosed, are often treatable¹ (see discussion of ED later in the chapter).

Because of cultural emphasis on a youthful female body image, older women tend to be more concerned than men about physical appearance and their sexual desirability. However, those women who are healthy can usually continue earlier patterns of sexual functioning, which includes maintaining orgasmic capacity. For some women, sexual interest may increase after menopause because they no longer experience concern about pregnancy. Nonetheless, reduced estrogen production resulting from menopause may present both physical and emotional problems for a number of older women. Physical problems include a change in vaginal shape, vaginal dryness, and thinning of the vaginal walls, which may lead to pain and bleeding during coitus and a less well-protected bladder and urethra, with recurrent cystitis as a result. Less acidic vaginal secretions may lead to greater incidence of vaginal infections. Emotional problems accompanying menopause include increased irritability and lability, often because of sleep deprivation, which is itself a menopausal symptom. Although estrogen replacement therapy (ERT) helps relieve some symptoms, extensive studies by the National Institutes of Health's Women's Health Initiative (WHI) have implicated ERT in the development of gallbladder disease and breast and uterine cancer. These studies also suggest that ERT may increase the risk of blood clots, which can result in strokes and heart attacks. However, since the results of the WHI were based on estrogen derived from the urine of pregnant mares (Premarin) that may be difficult to metabolize, further studies using other estrogen products are needed. In the meantime, diet, exercise, and drugs that lower cholesterol and blood pressure can lower risk of heart disease, and nonhormonal drugs such as bisphosphonates may be effective in cutting the risk of fractures in women with osteoporosis. Women can often find relief for vaginal dryness and irritation during intercourse with off-prescription water-based vaginal lubricants.²⁻⁴

Women who wish to remain sexually active in later life may face barriers that have nothing to do with physical symptoms. Because women typically live nearly 7 years longer than men and tend to marry men who are 3 or more years older, they have a much greater chance of surviving their male partners. About 60% of older women are without a spouse, as opposed to 20% of men, and many others may be living with

a disabled spouse who cannot be a sexual partner. As they grow older, the ratio of women to men increases greatly, and the chances of finding another partner are greatly reduced. There are approximately 150 women to 100 men over the age of 65, and 250 women to 100 men over the age of 85.

It has been estimated that up to 10% of the general population is lesbian, gay, bisexual, or transgender (LGBT), although the exact number is unknown. As in the older heterosexual population, many LGBT individuals have long-term relationships and are emotionally stable, successful, and happy in their later years. When sexual difficulties occur for LGBT couples, they involve many of the same interpersonal, physical, social, and psychological problems faced by heterosexual couples. Physicians need to be sensitive to and accepting of alternative sexual expression.²

EXAMINATION AND EVALUATION OF THE PATIENT

The general medical evaluation of an older person should include a thorough sexual history, current sexual function, and a careful physical examination. The physician should initiate questions in these areas because older patients may not volunteer sexual information about themselves. Questions should be asked in an unthreatening and unembarrassing fashion. During the examination, the physician should pay special attention to the neurologic, circulatory, and endocrine systems. Because some medical conditions, surgical procedures, and medications can affect sexual functioning, the physician should be sure to include a discussion of sexuality when treating disease or prescribing medication to patients for whom continuing sexual activity is important.

The physician should be aware of the fact that sexually transmitted diseases (STDs) occur in old as well as young persons. People of all ages should practice "safe sex." Ten percent of all AIDS patients in the United States are over 55 years of age, and not all of them contracted HIV through blood transfusions. Hepatitis B is the only sexually transmitted virus preventable by vaccine.²

EFFECTS OF MEDICAL PROBLEMS, SURGERY, AND MEDICATIONS

Sexual interest and capacity wane in the presence of illness, and some diseases have a much more powerful effect on sexuality in the later years because of their frequency and character. Heart disease is three times more common in men than in women up to the age of 60, probably because of the protection afforded by estrogen, even postmenopausally. However, after menopause the incidence of heart disease in women begins to rise and eventually reaches that in men in their early 60s. Heart disease is a source of considerable concern to sexually active older people because sexual activity increases the heart rate. Many who have had angina or a heart attack become anxious about future sexual encounters. The fear of dying during intercourse may also compound depression that is already present in response to the heart disease itself. Physicians should point out to their concerned patients that, in fact, oxygen usage or "debt" in a sexual encounter is the rough equivalent of walking up one or two flights of stairs. Physicians should reassure their patients that anyone who can carry out usual daily activities is able to engage in sexual

activity. A study published in 1996 of more than 800 men and women found that among individuals who had suffered a heart attack, the risk of a recurrent heart attack during sex was only 2 in 1 million.⁵ An earlier large-scale study of more than 5500 coronary deaths found that less than 1% were related to sex, with a majority of these involving extramarital relations (suggesting that stressful aspects associated with such affairs—guilt, anxiety, the need to hurry—may play a role).⁶ Thus, sexual activity poses extraordinarily little risk.

Patients are often uneasy about recommencing their sex lives following coronary bypass surgery. Some 4 weeks or more of abstinence is recommended before resuming sexual activity, to allow full healing to occur.

Other medical conditions that can impact significantly on sexuality are stroke, diabetes, osteoarthritis and rheumatoid arthritis, back pain, Parkinson's disease, chronic emphysema and bronchitis, chronic prostatitis in men, and stress incontinence in women. The effects on sexuality of these diseases and their treatment are summarized in [Table 100-1](#).

Surgery can significantly impair sexual functioning as well. Common surgical procedures and their effects on sexuality are outlined in [Table 100-2](#). Embarrassment or discomfort from surgical procedures such as mastectomies or ostomies can inhibit sexual drive and performance. Prostate surgery is discussed in the section on ED.

Medications are among the most common causes of sexual dysfunction. Commonly prescribed medications that adversely affect sexuality are listed in [Table 100-3](#). Physicians should familiarize themselves with medications that have fewer toxic effects on sexual function and prescribe them whenever possible. For example, angiotensin-converting enzyme (ACE) inhibitors taken for hypertension are less apt to cause sexual dysfunction than is methyl dopa. Of the antidepressants, Wellbutrin is one of the least problematic. In addition, it is possible to reduce the dosage of some drugs to avoid adverse sexual and other effects without reducing the benefits of the drugs to the patient.⁷ In certain cases, brief "drug holidays" may improve sexual function, but this requires discussion with a physician.

Abuse of substances such as alcohol and tobacco also impairs sexuality (see [Table 100-3](#)). Alcohol may increase desire but decrease performance. Tobacco use adversely affects male sexuality and causes wrinkles in both men and women.

ERECTILE DYSFUNCTION

Causes and diagnosis

Because even occasional ED can have significant emotional consequences for many men, which can, in turn, exacerbate physical problems, diagnosis should be made carefully. ED should be diagnosed only when failure in sexual encounters occurs in at least a quarter of all attempts.

It is estimated that 10 million to 20 million men in the United States experience some degree of ED. Although ED affects men of all ages, it tends to increase progressively with age because of the greater likelihood of accompanying medical conditions. The comprehensive Massachusetts Male Health Study found that 52% of men aged 40 to 70 experience some ED.⁸

It is estimated that 90% of ED cases are due to physical causes, including vascular disorders such as atherosclerosis

Table 100-1. Effects of Medical Conditions on Sexuality

Medical Condition	Effect on Sexuality	Treatment
Arthritis	Sexual desire is usually unaffected, but disability due to osteoarthritis and rheumatoid arthritis may interfere with performance	Trying sexual positions that do not aggravate joint pain; planning sexual activity for times of day when pain and stiffness are diminished
Chronic emphysema and bronchitis	Shortness of breath hinders physical activity, including sex	Rest; supplemental oxygen
Chronic prostatitis	Pain may diminish sexual desire	Antibiotics; warm sitz baths, prostatic massage; Kegel exercises
Chronic renal disease	Impotence, possibly with anxiety and depression	Dialysis; psychotherapy for underlying emotional problems; kidney transplantation may restore sexual capacity
Diabetes mellitus	Impotence is common	Very tight control of diabetes may restore potency
Heart and vascular disease		
Myocardial infarction	8- to 14-week recuperation period recommended before resuming sexual intercourse; depression and antidepressant drugs may reduce libido and capacity; fear of bringing on another heart attack if patient resumes sexual activity	Reassurance from the doctor about safety of sexual activity; exercise programs to improve cardiac function
Heart failure	Sexual dysfunction resulting from physical symptoms or medications; a 2- to 3-week week recovery period is advised before resuming sex in cases of pulmonary edema	Reassurance from the doctor about safety of sexual activity for patients with effectively managed heart failure; exercise programs to improve cardiac function
Coronary bypass surgery	4 weeks or more of abstinence is recommended before resuming sexual intercourse	Alternatives such as self-stimulation or masturbation can usually be started earlier in the recovery period; exercise programs to improve cardiac function
Pelvic steal syndrome	Example of vascular impotence—male loses erection as soon as he enters his partner and begins pelvic thrusting due to gravity's redirecting blood supply away from the pelvis	Changing position may help (man should lie on his back or side)
Hypertension	Incidence of impotence in untreated male hypertensive patients is about 15%; effects on women not established	Choose hypertensive drugs that do not impair sexual response
Parkinson's disease	Lack of sexual desire in both men and women; impotence in men	Levodopa can improve sex drive and performance in some men for a limited period
Peyronie's disease	Intercourse is painful for many men with the disease; penetration may be difficult or impossible when penis is angled too sharply	Psychotherapy to help patient adjust to changes in the penis; symptoms occasionally disappear spontaneously; surgery helps in some cases
Stress incontinence	Sexual dysfunction has been reported in up to 50% of women with this condition	Solving the underlying problem may help; Kegel exercises to strengthen muscles supporting bladder; estrogen taken orally or locally to firm up vaginal lining; biofeedback training
Stroke	Sexual desire may not be impaired, but sexual performance likely to be affected (e.g., male erectile dysfunction either because of physical or psychological reasons, anesthetic areas, or physical limitations due to paralysis)	Mechanical adjustments to assist positioning necessary for sexual activities; treatments for impotence

Data from Butler RN, Lewis MI. Sexuality. In: Merck Manual of Geriatrics, 3rd ed. Whitehouse Station, NJ: Merck Research Laboratories; 2000, pp. 1156–1164; and Butler RN, Lewis MI. The New Love and Sex after 60. New York: Ballantine Books; 2000.

Table 100-2. Effects of Surgery on Sexuality

Surgical Procedure	Effect on Sexuality
Hysterectomy	Need to refrain from sexual activity during healing (6 to 8 weeks after surgery); depression; possible reduction in sensation during orgasm
Mastectomy	Emotional reactions such as depression; loss of sexual desire because of emotional reactions of patient and partner
Prostatectomy	Need to refrain from sexual activity during healing (6 weeks); possible impotence because of surgery (nerve-sparing techniques help avoid this effect in some cases); possible psychogenic impotence
Orchiectomy	Impotence is common
Colostomy and ileostomy	Emotional reactions that can affect desire and potency (participation in ostomy clubs is recommended)
Rectal cancer surgery	Impotence is common

Data from Butler RN, Lewis MI. Sexuality. In: Merck Manual of Geriatrics, 3rd ed. Whitehouse Station, NJ: Merck Research Laboratories; 2000, pp. 1156–64; and Butler RN, Lewis MI. The New Love and Sex after 60. New York: Ballantine Books; 2000.

and pelvic steal syndrome (see Table 100-1); neurologic disorders such as trauma (e.g., sports injuries) and diabetic neuropathy; and endocrine disorders, such as thyroid disease, diabetes, and low testosterone levels, although low testosterone affects only about 4% of men. Testosterone is more likely to be associated with decreased libido than with ED. Radiation therapy and chemotherapy for cancer may destroy testicular function. In men with heart disease, fear that sex will cause a heart attack can cause sexual dysfunction.

ED may also be caused by structural abnormalities such as Peyronie's disease (see Table 100-1). Prostatectomies may create sexual problems. In some cases, a man who has had prostate surgery and has lost interest in sex may use the surgery as an excuse for avoiding sexual contact. ED may follow prostate surgery, but nerve-sparing surgical techniques, developed by Dr. Patrick Walsh of Johns Hopkins University, are available and can help avoid ED in many cases.⁹

As described earlier, certain drugs may also cause sexual dysfunction, including antihypertensives, antidepressants, antipsychotics, and others (see Table 100-3), as can overconsumption of alcohol.

Table 100-3. Selected Medications and Substances That May Adversely Affect Sexual Functioning

Psychotropics	β -Blockers
Tricyclic antidepressants	Propranolol
Clomipramine	Atenolol
Amitriptyline	Metoprolol
Doxepin	Bisoprolol
Imipramine	Timolol
Nortriptyline*	Betaxolol
Desipramine*	α 1-Blockers
Monoamine oxidase inhibitors	Prazosin*
Isocarboxazid	Doxazosin*
Phenelzine	α 2-Agonists
Tranylcypromine*	Clonidine
Serotonin reuptake inhibitors	Guanfacine
Fluoxetine	ACE inhibitors \ddagger
Paroxetine	Captopril*
Sertraline	Enalapril
Fluvoxamine	Calcium-channel blockers
Venlafaxine	Amlodipine
Mood stabilizers/anticonvulsants	Verapamil
Lithium [†]	Diltiazem
Valproate*	Anticancer drugs
Carbamazepine	Vinblastine
Phenytoin	5-Fluorouracil
Phenobarbital	Tamoxifen
Antipsychotics/neuroleptics	Cold/allergy medications
Phenothiazines	Chlorpheniramine
Chlorpromazine	Diphenhydramine hydrochloride
Fluphenazine*	Pseudoephedrine
Perphenazine	Antiulcer medications
Thioridazine	Cimetidine
Other	Famotidine*
Haloperidol	Nizatidine*
Thiothixene	Ranitidine*
Risperidone	Stimulants/anorectics
Antianxiety agents/tranquilizers	Phentermine
Benzodiazepines	Fenfluramine
Diuretics	Phenylpropanolamine
Thiazide-type	Diethylpropion
Chlorthalidone	Mazindol
Hydrochlorothiazide	Commonly abused substances
Indapamide*	Alcohol
Loop diuretics	Barbiturates
Furosemide*	Cannabis
Potassium-sparing	Cocaine
Spironolactone	Opioids
Antihypertensives	Methylphenidate
Reserpine	Amphetamine
Methyldopa	Nicotine
Guanethidine	Hormones
	Progesterone
	Cortisol

Data from Crenshaw TL, Goldberg JP. Sexual pharmacology: drugs that affect sexual functioning. New York: WW Norton, 1996.

*Studies indicate that these drugs may have fewer sexual side effects than others in their class.

[†]Direct sexual side effects of lithium are confirmed only when it is taken in conjunction with benzodiazepines.

\ddagger ACE inhibitors have fewer sexual side effects than other classes of antihypertensives.

Ten percent of cases of ED are due to psychological causes, including performance anxiety, stress, exhaustion, anger, bereavement, and depression. Sexual problems can be both the origin and a symptom of depression. Losing one's partner may be followed by grief, sometimes complicated by depression. It may lead to a kind of "enshrinement" of the lost partner. In such cases, "widower's guilt" may block the development of new relationships and cause ED when the man tries to engage in sexual activity with a new partner.²

Proper diagnosis of ED depends on taking a thorough history; asking questions about changes in libido, nocturnal erections, and problems with relationships; and reviewing diseases and medication and alcohol use. These steps should be followed by a physical examination and laboratory evaluation, including a testosterone level check. ED during sleep can be checked by rigiscan, a means of measuring nocturnal tumescence associated with rapid-eye movement sleep. It should be noted, however, that this is an imperfect method for diagnosing ED.

Treatment

In general, the old adage "use it or lose it" appears to be true. Erections bring oxygen-rich blood to the penis, which contributes to continuing healthful functioning. Good health habits promote sexual capability. In addition to helping people stay healthy, a balanced diet, no tobacco, moderate consumption of alcohol, and exercise programs all help prevent sexual dysfunction.

ED can often be treated successfully. For ED with a physical cause, the main treatment is of the underlying cause, such as diabetes or a reaction to medications. For psychogenic cases, psychotherapy, marital therapy, group therapy, and sex therapy—which is based on Masters and Johnson's use of "sensate focusing"—may be beneficial. These approaches are also useful when ED is physical in origin because there are often associated or concomitant emotional reactions to ED, and because such therapeutic approaches can reassure the patient and his partner.

However, it should be noted that ED may be an early sign of heart disease, hypertension, or diabetes. It is a sign, not a diagnosis. Therefore, ED should prompt careful evaluation.

PHARMACOTHERAPY

Sildenafil has become widely used. In dosages of 25, 50, or 100 mg (in most cases starting with 25 mg) and taken 1 hour prior to a sexual encounter, sildenafil will produce an erection, but only when the man is sexually stimulated. It is not an aphrodisiac but a "mechanical" means to facilitate intercourse. Nor does it substitute for intimacy; indeed, it may reveal strains in relationships. Sildenafil blocks the action of an enzyme, phosphodiesterase type 5, so that nitric oxide dilates the penile blood vessels. It also increases clitoral blood flow and some women report its usefulness; however, comprehensive studies have not verified this. Although there are currently no reliable measurements of female sexual response, efforts are under way to develop such instruments.

Sildenafil can cause hypotension when nitrates are used concurrently, so it is contraindicated in patients who take nitrates to relieve angina. A patient who has had an adverse heart event and has taken sildenafil that day should not be given a nitrate. Sildenafil can also cause headaches, upset stomach, bluish vision, and nasal congestion. Rarely, priapism (4 hours of tumescence) occurs and must be treated to avoid damage to the penis.

Sildenafil has not been compared directly to other treatments for ED.¹⁰ New oral drugs to treat ED are under study.

Other medications for ED include vasoactive compounds that are injected directly into the corpus cavernosum. Phentolamine, atropine, and prostaglandin E have been shown to be effective given individually or together. Prostaglandin E was the first prescription medication approved by the U.S. Food and Drug Administration (FDA) to treat ED. Erection should occur within 5 to 10 minutes after injection, and the erection can last

30 minutes or more. Injection with these substances should not be done more than once every 24 hours and not more than three times per week. Possible problems with this therapy include priapism (4%), which can be reversed with epinephrine or ephedrine; mild to moderate pain at the site of injection; and some scarring. Contraindications include sickle-cell anemia, multiple myeloma, leukemia, anatomic deformities, and implants (discussed later). Treatment of men with ED with transurethral prostatic (a synthetic compound identical to prostaglandin E₁) is effective in nearly 70% of cases, regardless of age. A major advantage of this treatment is that the drug is delivered transurethrally via an applicator rather than through injection.¹¹

Some studies of the substance yohimbine, which comes from the bark of an African tree, have shown that it has a positive effect on erection, probably because it acts on neurotransmitters such as acetylcholine and dopamine that are involved in the sexual response. However, undesirable side effects have been noted.

VACUUM THERAPY

This involves placing a cylinder over an unerect penis, sucking out air to produce an erection, and applying a wide rubber band at the base to maintain the erection. One third of individuals who try vacuum devices find them helpful. They should not be used by men taking anticoagulants or those who have low platelet counts.

IMPLANT

A permanent penile prosthesis may help a patient with an otherwise untreatable potency problem. Such a prosthesis is irreversible and therefore should be used only as a last resort. Penile implants can be noninflatable (positionable or semirigid rod prosthesis) and inflatable. Inflatable implants include an inflate/deflate pump with the cylinder in the penis or placed below the skin in the scrotum. There is a reservoir in the scrotum. Cylinders are placed behind the abdominal muscles. Contraindications to this treatment include psychiatric problems such as psychosis and untreated depression.⁵ Complications include infection, mechanical failure, and penile fibrosis.

SURGERY

Revascularization surgery is still largely experimental.

THE "SECOND LANGUAGE OF SEX"

Some older people are not interested in sex because they were never interested in it, or their sexual desire has decreased, or their opportunities for sexual activity are significantly diminished, or other reasons. On the other hand, many older people are interested and want to continue to be sexually active. Whatever his or her point of view, each older person's wishes should be elicited and respected before treatment decisions are completed. There is a range of interest and degree of sexual activity among older people just as there is among other age groups, and treatment options can be as effective for them as for younger people.

The "first language" of sexuality, generally associated with youth, is biologic and intense. The "second language" of sexuality, broader than the first, is learned by experience over a lifetime. Of course, some younger people are naturally adept at expressing the second language of sexuality and, conversely, some older people never quite learn it. But for many people,

the primary focus on genital contact gives way over time to a more encompassing definition of sexuality, which includes intimacy, mutuality, trust, love, romance, friendship, and caring.²

It is not known whether there is a clear association between sexual satisfaction and longevity, but there is evidence that love and sex enhance the quality of life. Some of the greatest obstacles to successful, intimate relationships in later life are the negative attitudes and practices toward older persons found among healthcare professionals and the public at large. Health professionals must recognize that their older patients have sexual interest, capacities, and pleasures and that—through education and other interventions—they have the means to repair many of the physical, emotional, and social impediments to continuing sexuality in late life.

SUMMARY

Physicians frequently fail to ask older patients about their sexual functioning during the typical medical examination and evaluation. Patients may be uncomfortable about revealing their sexual difficulties and may not be aware that sexual dysfunction in both sexes can often be treated. In addition, ED may be an early sign of diseases such as heart disease, hypertension, or diabetes.

Normal change in sexual functioning is usually manifested as a gradual slowing—that is, more time is needed for arousal (erection in men, lubrication in women) and reaching a climax. Healthy older women can usually continue earlier patterns of sexual functioning, but reduced estrogen production as a result of menopause may present physical and emotional problems. Ongoing studies at the National Institutes of Health are expected to help clarify indications, contraindications, and risks of hormone replacement therapy.

KEY POINTS

Sexuality in Old Age

- Some medical conditions, surgical procedures, and medications can affect sexual functioning. The physician should include a discussion of sexuality when treating disease in or prescribing medication to elderly patients for whom continuing sexual activity is important.
- It is estimated that 90% of cases of erectile dysfunction have a physical cause, whereas 10% are psychologically induced. Treatments for the latter include psychotherapy, marital therapy, group therapy, and sex therapy.
- Women who wish to remain sexually active in later life may face barriers that are unrelated to physical symptoms. For example, about 60% of elderly women are without a spouse, and many others live with a disabled spouse who cannot be a sexual partner.
- Medical conditions that can have a significant impact on sexuality are coronary bypass surgery, stroke, diabetes, osteoarthritis and rheumatoid arthritis, back pain, Parkinson's disease, chronic emphysema and bronchitis, chronic prostatitis in men, and stress incontinence in women.
- In men with heart disease, fear that sex will cause a heart attack can cause sexual dysfunction.
- With the discovery of the therapeutic effect in men of sildenafil citrate, the more positive attitudes of physicians and the public have moved to greater acceptance of the sexuality of older persons.

INTRODUCTION

Both increased and decreased levels of physical activity are associated with meaningful outcomes in older people. Increased levels of physical activity have been linked to decreases in mortality, the risk of chronic diseases, nursing home admissions, development of cognitive disorders, and decreased functional capacity. Increased levels of physical activity have been associated with increased mortality, cognitive decline, obesity, and sarcopenia.

Exercise encompasses a broad range of activities. However, virtually every system in the human body is affected in some way by increasing levels of physical activity. *Exercise* can be defined as increased (above resting) muscular activity and may be categorized as anaerobic (sprinting), endurance (aerobic), or resistive (weight lifting). *Resistive exercise* defined as muscle contract a few times against a heavy load or with high tension. This type of exercise is also termed progressive resistance training (PRT) because the load or intensity is progressively increased as an individual becomes stronger. PRT is distinctly different from *aerobic or endurance exercise*, in which muscles contract against little, or no, resistance. *Anaerobic exercise* makes use of the *phosphocreatine* and/or *glycogenolysis* for energy production. Although this type of exercise is generally thought of as the sprinting type of exercise, an extremely deconditioned patient, such as an individual with chronic obstructive pulmonary disease or heart failure may perform anaerobic exercise simply by getting out of bed and walking across a room.

The adaptive response to regularly performed exercise has been repeatedly demonstrated to have remarkably beneficial effects. The list of these adaptive responses is extensive. The Centers for Disease Control and Prevention and the American College of Sports Medicine have suggested that everyone should accumulate at least 30 minutes of exercise on most (preferably all) days.¹ This recommendation is based on evidence of a substantial decrease in all-cause mortality, resulting from a moderate amount of increased physical activity.^{2,3} The American Heart Association has stated that inactivity is a primary risk factor for cardiovascular disease.⁴⁻⁶ Because far more Americans are inactive than have elevated cholesterol or who smoke, it is the predominant risk factor for heart disease in the United States. This chapter focuses on the acute and chronic adaptations to exercise with particular attention to substrate use and effects on risk factors for chronic disease and aging.

AEROBIC EXERCISE

Maximal aerobic exercise capacity is termed $\dot{V}O_2\text{max}$. $\dot{V}O_2$ (volume of oxygen consumed during maximal aerobic exercise) is defined by the Fick equation ($\dot{V}O_2 = \text{cardiac output} \times \text{arteriovenous oxygen difference}$). $\dot{V}O_2\text{max}$ is expressed as either mL of O_2 consumed $\times \text{kg}^{-1} \text{ body weight} \times \text{min}^{-1}$ or L of O_2 consumed $\times \text{min}^{-1}$. Expressing it at $\text{mL} \times \text{kg}^{-1} \times \text{min}^{-1}$ is most often used to define an individual's aerobic capacity as differences in body weight are controlled for. The Fick equation demonstrates that there are two important determiners

of $\dot{V}O_2\text{max}$, central factors that control the delivery of oxygen to skeletal muscle and the capacity of skeletal muscle to extract and use oxygen for ATP during exercise. Regularly performed aerobic exercise increases $\dot{V}O_2\text{max}$ through the following mechanisms: (1) increased cardiac output resulting from a plasma volume expansion (approximately 15%) and increased stroke volume as a result of cardiac hypertrophy and (2) improved capacity to extract and use oxygen by skeletal muscle. This enhanced oxidative capacity of muscle is due to increased capillarization, mitochondrial density, and myoglobin content. Under most conditions, the delivery of oxygen limits maximal aerobic performance. Increasing blood hemoglobin concentration (from anemic to normal or from normal to super normal) has been demonstrated to increase $\dot{V}O_2\text{max}$ maximal and submaximal exercise performance.⁷⁻¹⁰ Anemia due to malnutrition has been demonstrated to limit functional status and work capacity. On the other hand, aerobic exercise performance in athletes can be substantially improved by increasing hemoglobin levels above normal through the use of recombinant human erythropoietin.¹¹ Anemia is common in late life and may not always be associated with a clear cause.¹²

Maximal aerobic capacity ($\dot{V}O_2\text{max}$) declines with advancing age.¹³ This age-associated decrease in $\dot{V}O_2\text{max}$ has been shown to be approximately 1%/yr between the ages of 20 and 70 years. This decline is likely to be due to a number of factors, including decreased levels of physical activity, changing cardiac function (including decreased maximum cardiac output), and reduced muscle mass. Fleg and Lakatta¹⁴ determined that skeletal muscle mass accounted for most of the variability in $\dot{V}O_2\text{max}$ in men and women above the age of 60 years. Using data from the Baltimore Longitudinal Study on Aging, this group¹⁵ also showed that the decline in maximal aerobic capacity with age accelerates after the age of 70 years. Because a decline in maximal heart rate is linear with advancing age, they ascribe this accelerated decline in late life to factors related to skeletal muscle, such as *capillary density and muscle oxidative capacity*. Short et al¹⁶ showed that most of the age-related decline in maximal aerobic capacity can be explained by a decrease in muscle mass and muscle mitochondrial function (oxidative capacity). A number of studies have demonstrated that the age-related decline in $\dot{V}O_2\text{max}$ is ameliorated by physical activity.¹⁷⁻²⁰ Bortz and Bortz²¹ reviewed world records of master athletes up to age 85 for endurance events and noted that the decline in performance occurred at a rate of 0.5%/yr. They concluded that this decline of 0.5%/yr may represent the effects of age (or "biologic" aging) on $\dot{V}O_2\text{max}$ and the remainder of the decline may be the result of an increasingly sedentary lifestyle. However, Rosen et al²² examined predictors of this age-associated decline in $\dot{V}O_2\text{max}$ and concluded that $\dot{V}O_2\text{max}$ declines at the same rate in athletic and sedentary men and that 35% of this decline is due to *sarcopenia*.

Aerobic exercise has long been an important recommendation for the prevention and treatment of many of the chronic diseases typically associated with old age. These include type 2 diabetes mellitus (and impaired glucose tolerance),

hypertension, heart disease, and osteoporosis. Regularly performed aerobic exercise increases insulin action. The responses of initially sedentary young (age 20 to 30) and older (age 60 to 70) men and women to 3 months of aerobic conditioning (70% of maximal heart rate, 45 min/day, 3 days/wk) were examined by Meredith et al.²³ They found that the absolute gains in aerobic capacity were similar between the two age groups. However, the mechanism for adaptation to regular submaximal exercise appears to be different between old and young people. Muscle biopsy specimens taken before and after training showed a more than twofold increase in oxidative capacity in older subjects, whereas those in the young subjects showed smaller improvements. In addition, skeletal muscle glycogen stores in the older subjects, significantly lower than those in the young men and women initially, increased greatly. The degree to which the elderly demonstrate increases in maximal cardiac output in response to endurance training is still largely unanswered. Seals et al²⁴ found no increases after 1 year of endurance training, while more recently, Spina et al²⁵ observed that older men increased maximal cardiac output, whereas healthy older women demonstrated no change in response to endurance exercise training. If these gender-related differences in cardiovascular response are real, this finding may explain the lack of response in maximal cardiac output when older men and women are included in the same study population.²⁴

Aerobic exercise and carbohydrate metabolism

The 2-hour plasma glucose level during an oral glucose tolerance test increases by an average of 5.3 mg/dL per decade, and fasting plasma glucose increases by an average of 1 mg/dL per decade.²⁶ The NHANES II study demonstrated a progressive increase of about 0.4 mM/decade of life in mean plasma glucose value 2 hours after a 75 g oral glucose tolerance test ([OGTT], which provides a specific amount of glucose drink in a solution and measures the changes in plasma glucose over a 2 to 3 hour period) (n = 1678 men and 1892 women).²⁷ Shimoka et al²⁸ examined glucose tolerance in community dwelling men and women ranging in age between 17 to 92. By assessing the level of obesity, pattern of body fat distribution, activity, and fitness levels they attempted to examine the independent effect of age on glucose tolerance. They found no significant differences between the young and middle-aged groups; however, the old groups had significantly higher glucose and insulin values (following a glucose challenge) than those in young or middle-aged groups. They concluded that "the major finding of this study is that the decline in glucose tolerance from the early-adult to the middle-age years is entirely explained by secondary influences (fatness and fitness), whereas the decline from midlife to old age still is also influenced by chronological age. This finding is unique. It is also unexplained." However, it must be pointed out that anthropometric determination of body fatness becomes increasingly less accurate with advancing age and does not reflect the intra-abdominal and intramuscular accumulation of fat that occurs with aging.²⁹ The results of this study may be due more to an underestimate of true body fat levels than age. Goodpaster et al have demonstrated that aging and obesity are associated with increased intramuscular lipid.^{30,31} This

increased intramyocellular lipid is associated with insulin resistance and muscle weakness.

The relationship among aging, body composition, activity, and glucose tolerance was also examined in 270 female and 462 male factory workers aged 22 to 73 years, none of whom were retired.³² Plasma glucose levels, both fasting and after a glucose load, increased with age, but the correlation between age and total integrated glucose response following a glucose load was weak: in women only 3% of the variance could be attributed to age. When activity levels and drug use were factored in, age accounted for only 1% of the variance in women and 6.25% in men.

The fact that aerobic exercise has significant effects on skeletal muscle may help explain its importance in the treatment of glucose intolerance and type 2 diabetes. Seals et al³³ found that a high-intensity training program resulted in greater improvements in the insulin response to an oral glucose load compared with lower-intensity aerobic exercise. However, their subjects began the study with normal glucose tolerance. Kirwan et al³⁴ found that 9 months of endurance training at 80% of the maximal heart rate (4 days/wk) resulted in reduced glucose stimulated insulin levels; however, no comparison was made to a lower-intensity exercise group. Hughes et al³⁵ demonstrated that regularly performed aerobic exercise without weight loss resulted in improved glucose tolerance, rate of insulin stimulated glucose disposal, and increased skeletal muscle GLUT4 levels in older subjects with impaired glucose tolerance. GLUT4 is the glucose transporter protein found in skeletal muscle. More recently, Coker et al³⁶ examined the effects of intensity of exercise on insulin stimulated glucose uptake in older, overweight men and women. They examined the influence of moderate-intensity (50% VO_2max) versus high-intensity (75% VO_2max) aerobic exercise. Although intensity was different, energy expenditure during the exercise sessions was carefully controlled so that both groups used the same number of kilocalories. They demonstrated that after 4 months, only the high-intensity group demonstrated a significant improvement in insulin sensitivity. These data demonstrate that *higher-intensity exercise* (without weight loss) may be necessary to significantly reduce the risk of insulin resistance and type 2 diabetes.

Endurance training and dietary modifications are generally recommended as the primary treatment in the non-insulin-dependent diabetic. Cross-sectional analysis of dietary intake supports the hypothesis that a low carbohydrate/high fat diet is associated with the onset of type 2 diabetes.³⁷ This evidence, however, is not supported by prospective studies where dietary habits have not been related to the development of type 2 diabetes.^{38,39} The effects of a high carbohydrate diet on glucose tolerance have been equivocal.^{40,41} Hughes et al⁴² compared the effects of a high carbohydrate (60% carbohydrate and 20% fat)/high fiber (25 g dietary fiber/1000 kcal) diet with and without 3 months of high-intensity (75% max heart rate reserve, 50 min/day, 4 days/wk) endurance exercise in older, glucose intolerant men and women. Subjects were fed all of their food on a metabolic ward during the 3-month study and were not allowed to lose weight. These investigators observed no improvement in glucose tolerance or insulin-stimulated glucose uptake in either the diet or the diet plus exercise group. The exercise plus high carbohydrate diet group demonstrated a significant

and substantial increase in skeletal muscle glycogen content and at the end of the training, the muscle glycogen stores would be considered to be saturated. Since the primary site of glucose disposal is skeletal muscle glycogen, the extremely high muscle glycogen content associated with exercise and a high carbohydrate diet likely limited the rate of glucose disposal. Thus when combined with exercise and a weight maintenance diet, a high carbohydrate diet had a counter-regulatory effect. It is likely that the value of a high carbohydrate–high fiber diet in its effects on reducing excess body fat, which may be an important cause of the impaired glucose tolerance. Schaefer et al⁴³ demonstrated that an older subject consuming an ad libitum high carbohydrate diet lost weight. Hays et al^{44,45} also demonstrated that an ad libitum *high carbohydrate diet resulted in weight loss in older men and women and a significant improvement in insulin sensitivity*. In this study, the weight loss was seen with no measurable decrease in energy intake during the 3-month duration of the study and compared with the control group consuming a higher fat diet.

There appears to be no attenuation of the response of elderly men and women to regularly performed aerobic exercise when compared with those seen in young subjects. Increased fitness levels are associated with reduced mortality and increased life expectancy. It has also been shown⁴⁶ to prevent the occurrence of type 2 diabetes in those that are at the greatest risk for developing this disease. Thus regularly performed aerobic exercise is an important way for older people to improve their glucose tolerance.

Aerobic exercise is generally prescribed as an important adjunct to a weight loss program. Aerobic exercise combined with weight loss has been demonstrated to increase insulin action to a greater extent than weight loss through diet restriction alone. In the study by Bogardus et al,⁴⁷ diet therapy alone improved glucose tolerance, mainly by reducing basal endogenous glucose production and improving hepatic sensitivity to insulin. Aerobic exercise training, on the other hand, increased carbohydrate storage rates, and therefore, “diet therapy plus physical training produced a more significant approach toward normal.” However, aerobic exercise (as opposed to resistance training) combined with a hypocaloric diet has been demonstrated to result in a greater reduction in resting metabolic rate than diet alone.⁴⁸ Heymsfield et al⁴⁹ found aerobic exercise combined with caloric restriction did not preserve fat-free mass (FFM) and did not further accelerate weight loss when compared with diet alone. This lack of an effect of aerobic exercise may have been because of a greater decrease in resting metabolic rate (RMR) in the exercising group. In perhaps the most comprehensive study of its kind, Goran and Poehlman⁵⁰ examined components of energy metabolism in older men and women engaged in regular endurance training. They found that endurance training did not increase total daily energy expenditure because of a compensatory decline in physical activity during the remainder of the day. In other words, when elderly subjects participated in a regular walking program, they rested more, so that activities outside of walking decreased and thus 24-hour calorie expenditure was unchanged. However, older individuals who had been participating in endurance exercise for most of their lives have been shown to have a greater resting metabolic rate (RMR) and total daily energy expenditure than in age-matched sedentary controls.⁵¹ Ballor et al⁵² compared the

effects of resistance training with those of diet restriction alone in obese women. They found that resistance exercise training results in increased strength and gains in muscle size and a preservation of FFM during weight loss. These data are similar to the results of Pavlou et al,⁵³ who used both aerobic and resistance training as an adjunct to a weight loss program in obese men and demonstrated a preservation in fat free mass.

STRENGTH TRAINING

Although endurance exercise has been the more traditional means of increasing cardiovascular fitness, the American College of Sports Medicine currently recommends strength or resistance training as an important component of an overall fitness program. This is particularly important in the elderly, in whom loss of muscle mass and weakness are prominent deficits.

Strength conditioning or progressive resistance training is generally defined as training in which the resistance against which a muscle generates force is progressively increased over time. Progressive resistance training involves few contractions against a heavy load. The metabolic and morphologic adaptations resulting from resistance and endurance exercise are quite different. Muscle strength has been shown to increase in response to training between 60% and 100% of the one-repetition maximum (1RM).⁵⁴ 1 RM is the maximum amount of weight that can be lifted with one contraction. Strength conditioning will result in an increase in muscle size and this increase in size is largely the result of increased contractile proteins. The mechanisms by which the mechanical events stimulate an increase in RNA synthesis and subsequent protein synthesis are not well understood. Lifting weight requires that a muscle shorten as it produces force. This is called a concentric contraction. Lowering the weight, on the other hand, forces the muscle to lengthen as it produces force. This is an eccentric muscle contraction. These lengthening muscle contractions have been shown to produce ultrastructural damage (microscopic tears in contractile protein muscle cells) that results in an acute phase response and an increase in muscle protein turnover.^{55–59}

Effects of resistance exercise and insulin on protein metabolism

Studies of insulin secretion after resistance but not endurance exercise provides evidence for insulin’s role in maintaining muscle mass. Arginine-stimulated insulin secretion is decreased with endurance training.^{60,61} In contrast, acute resistance exercise in rats has been shown to increase insulin secretion.⁶² As reviewed previously, regular aerobic exercise is known to increase insulin sensitivity and glucose tolerance. In addition to its effects on insulin action, aerobic exercise training results in decreased insulin secretion.⁶³ Regularly performed endurance exercise in young men is associated with an insulin pulse profile in the resting fasted state characterized by less insulin secreted per burst but a similar number of bursts over a 90-minute period. Thus training-induced elevations in target-tissue sensitivity to insulin may reduce the requirement for pulsatile insulin secretion. This coordinated response keeps glucose concentrations constant. Dela et al⁶⁰ demonstrated that aerobic exercise training decreases both arginine- and glucose-stimulated insulin secretion, indicating a profound β -cell adaptation.

A single bout of concentric exercise is a recognized enhancer of insulin action, whereas eccentric exercise transiently impairs whole body insulin action for at least 2 days after the bout.⁶⁴ Eccentric exercise also can result in a long-term delay in the rate of glycogen synthesis.⁶⁵ This decreased insulin action and delayed glycogen synthetic rate have been shown to result from decreased rate of glucose transport rather than decreased glycogen synthase activity.⁶⁶ This transient resistance to insulin and impaired resynthesis of glycogen can result in a systemic hyperinsulinemia that may result in an increase in the rate of muscle protein synthesis. One laboratory⁶⁷ has demonstrated age-related differences in the insulin response to hyperglycemia following a single bout of eccentric exercise. Two days following upper and lower body eccentric exercise, younger subjects demonstrated a pronounced pancreatic insulin response during a hyperglycemic clamp while this response was blunted in healthy elderly men.

The effects of resistance exercise on insulin availability appear to be opposite those of endurance exercise and thus stimulate net protein accretion. Insulin has been demonstrated to have profoundly anabolic effects on skeletal muscle. In the resting state, insulin has been demonstrated to decrease the rate of muscle protein degradation. Stable isotope amino acid studies in humans^{68,69} clearly demonstrate that *insulin inhibits whole body protein breakdown* in vivo and stimulates muscle protein synthetic rate.⁷⁰

Insulin has been demonstrated to increase the rate of muscle protein synthesis in insulin-deficient rats. However, in nondiabetic animals this effect was not seen. Fluckey et al have argued^{62,71} that insulin is not likely to stimulate muscle protein synthesis in quiescent muscle. In my own experience, an insulin infusion does not increase the rate of protein synthesis in nonexercised muscle. However, using a resistance exercise model, investigators have demonstrated that resistance exercise did not stimulate an increase in the rate of protein synthesis. It was only with the addition of insulin that an exercise-induced increase in the rate of soleus and gastrocnemius protein synthesis was seen. This effect of insulin stimulation of the rate of protein synthesis was preserved with advancing age.

Protein requirements and exercise

High-intensity resistance training is clearly anabolic in both younger and older individuals. Data from our laboratory demonstrate a 10% to 15% decrease in nitrogen excretion at the initiation of training that persists for 12 weeks. That is, progressive resistance training improved nitrogen balance, thus older subjects performing resistance training have a lower mean protein requirement than do sedentary subjects.⁷² This effect was seen at a protein intake of 0.8 g and 1.6 g, indicating that the effect of resistance training on protein retention may not be related to dietary protein intake. These results are somewhat at variance to our previous research,⁷³ demonstrating that regularly performed aerobic exercise causes an increase in the mean protein requirement of middle-aged and young endurance athletes. This difference likely results from increased oxidation of amino acids during aerobic exercise that may not be present during resistance training.

Strawford et al⁷⁴ also demonstrated similar effects of resistance exercise training on nitrogen balance in patients with HIV-related weight loss. The investigators examined the

effects of an anabolic steroid (oxandrolone, 20 mg/day, and a placebo) and high-intensity resistance exercise training in 24 eugonadal men with HIV-associated weight loss (mean, 9% body weight loss). Both groups showed significant nitrogen retention and increases in lean body mass, weight, and strength. The mean gains were significantly greater in the oxandrolone group than in the placebo group in nitrogen balance, accrual of FFM, and strength. Results were similar whether or not patients were taking protease inhibitors. These results confirm the positive effects of resistance exercise on nitrogen retention and protein requirements.

These studies taken as a whole demonstrate the powerful effects of resistance exercise training on protein nutrition. The anabolic effects have important implications in the treatment of many wasting diseases and conditions such as cancer, HIV infection, aging, chronic renal failure, and undernutrition seen in many very old men and women. By effectively lowering dietary protein needs, resistance exercise can limit further losses of skeletal muscle mass while simultaneously increasing muscle strength and functional capacity.

Resistance exercise and aging

Our laboratory examined the effects of high-intensity resistance training of the knee extensors and flexors (80% of 1RM, 3 days/wk) in older men (age 60 to 72 years). The average increases in knee flexor and extensor strength were 227% and 107%, respectively. Computed tomography (CT) scans and muscle biopsies were used to determine muscle size. Total muscle area by CT analysis increased by 11.4% while the muscle tissue showed an increase of 33.5% in type I fiber area and 27.5% increase in type II fiber area. In addition, lower body VO_2max increased significantly, whereas upper body VO_2max did not, indicating that increased muscle mass can increase maximal aerobic power. It appears that the age-related loss in muscle mass may be an important determinant in the reduced maximal aerobic capacity seen in elderly men and women.^{14,15} Improving muscle strength can enhance the capacity of many older men and women to perform many activities, such as climbing stairs, carrying packages, and even walking.

This same training program was applied to a group of frail, institutionalized elderly men and women (mean age 90 + 3 years, range 87 to 96).⁷⁵ After 8 weeks of training, the 10 subjects in this study increased muscle strength by almost 180% and muscle size by 11%. More recently,⁷⁶ a similar intervention in frail nursing home residents demonstrated not only increases in muscle strength and size, but increased gait speed, stair climbing power, and balance. In addition, spontaneous activity levels increased significantly, whereas the activity of a nonexercised control group was unchanged. In this study the effects of a protein-calorie supplement combined with exercise was also examined. The supplement consisted of a 240-mL liquid supplying 360 kcal in the form of carbohydrates (60%), fat (23%), and soy-based protein (17%), and was designed to augment caloric intake by about 20%, and provide one third of the recommended daily allowance for vitamins and minerals. The men and women who consumed the supplement and exercised gained weight compared with the three other groups examined (exercise/control, nonexercise supplemented, and nonexercise control). The nonexercising subjects who received the supplement reduced their habitual dietary energy intake so that total energy intake was

unchanged. In other words, the supplement did not add to total energy intake, but rather substituted one source of energy (the supplement) for another (their meals). In addition, investigators⁷⁷ demonstrated that the combined weight lifting and nutritional supplementation increased strength by $257 \pm 62\%$ ($P = .0001$) and type II fiber area by $10.1 \pm 9.0\%$ ($P = .033$), with a similar trend for type I fiber area ($+12.8 \pm 22.2\%$). Exercise was associated with a 2.5-fold increase in neonatal myosin (a form of myosin found in growing muscle) staining ($P = .0009$) and an increase of $491 \pm 137\%$ ($P < .0001$) in insulin-like growth factor-1 (IGF-1) staining. Ultrastructural damage increased by $141 \pm 59\%$ after exercise training ($P = .034$). Strength increases were largest in those with the greatest increases in myosin, IGF-1, damage, and caloric intake during the trial. Frail, very old elders respond robustly to resistance training with musculoskeletal remodeling, and significant increases in muscle area are possible with resistance training in combination with adequate energy intakes. It should be pointed out that this was a very old, very frail population with diagnoses of multiple chronic diseases. The increase in overall level of physical activity has been a common observation in our studies.⁷⁶⁻⁷⁹ Since muscle weakness is a primary deficit in many older individuals, increased strength may stimulate more aerobic activities, such as walking and cycling. Indeed, Campbell et al⁸⁰ demonstrated that resistance training resulted in an approximately 15% increase in energy requirement in older men and women through an increase in resting metabolic rate and an increase in physical activity.

Strength training may increase balance through the improvement in strength of muscle involved in walking. Indeed, ankle weakness has been demonstrated to be associated with increased risk of falling in nursing home patients.⁸¹ However, balance training, which may demonstrate very little improvement in muscle strength, size, or cardiovascular changes has also been demonstrated to decrease the risk of falls in older people.⁸² *Tai chi*, a form of dynamic balance training that requires no new technology or equipment, has been demonstrated to reduce the risk of older people falling by almost 50%.⁸³ As a component of the National Institute on Aging FICSIT (Frailty and Injuries: Cooperative Studies of Intervention Techniques) trials, individuals aged 70 and older were randomized to tai chi (TC), individualized balance training (BT), and exercise control education (ED) groups for 15 weeks.⁸⁴ In a follow-up assessment 4 months after intervention, 130 subjects responded to exit interview questions asking about perceived benefits of participation. Both TC and BT subjects reported increased confidence in balance and movement, but only TC subjects reported that their daily activities and their overall life had been affected; many of these subjects had changed their normal physical activity to incorporate ongoing TC practice. The data suggest that when mental and physical control is perceived to be enhanced, with a generalized sense of improvement in overall well-being, older persons' motivation to continue exercising also increases. Province et al⁸⁵ examined the overall effect of many different exercise interventions in the FICSIT trials on reducing falls. Although each of these separate interventions were not powered to make conclusions about their effects on the incidence of falls in an elderly population, they did conclude that all training domains, taken together under the heading of "general exercise," showed

an effect on falls. This probably demonstrates the "rising tide raises all boats" principle, in which training that targets one domain may improve performance somewhat in other domains as a consequence. If this is so, then the differences in fall risk correlated with the nature of the training may not be as critical compared with the differences in not training at all.

The use of a community-based exercise program for frail older people was examined⁸⁶ in a group of predominantly sedentary women over age 70 with multiple chronic conditions. The program was conducted with peer leaders to facilitate its continuation after the research demonstration phase. In addition to positive health outcomes related to functional mobility, blood pressure maintenance, and overall well-being, this intervention was successful in sustaining active participation in regular physical activity through the use of peer leaders selected by the program participants.

Although endurance training has been demonstrated to be an important adjunct to weight loss programs in young men and women by increasing their daily energy expenditure, its utility in treating obesity in the elderly may not be great. This is because many sedentary older men and women do not expend many calories when they perform endurance exercise because of their low fitness levels. Thirty to 40 minutes of exercise may increase energy expenditure by only 100 to 200 kcal with very little residual effect on calorie expenditure. Aerobic exercise training will not preserve lean body mass to any great extent during weight loss. Goran et al⁵⁰ showed that a vigorous walking program of up to 1 hr/day had no effect on total daily energy expenditure. They found that their older subjects compensated for their increased physical activity by becoming less active throughout the rest of the day. Because resistance training can preserve or even increase muscle mass during weight loss, this type of exercise for those older men and women who must lose weight may be of genuine benefit.

OTHER EFFECTS OF EXERCISE

Bone health

Nelson et al⁸⁷ examined the interaction of dietary calcium and exercise; the study included 41 postmenopausal women consuming either high calcium (1462 mg/day) or moderate calcium (761 mg) diets. Half of these women participated in a yearlong walking program (45 min/day, 4 days/wk, 75% of heart rate reserve). Independent effects of the exercise and dietary calcium were seen. Compared with the moderate calcium group, the women consuming a high-calcium diet displayed reduced bone loss from the femoral neck, independent of whether the women exercised. The walking prevented a loss of trabecular bone mineral density seen in the nonexercising women after 1 year. Thus it appears that calcium intake and aerobic exercise are both independently beneficial to bone mineral density at different sites.

The effects of 52 weeks of high-intensity resistance exercise training were examined in a group of 39 postmenopausal women.⁷⁹ Twenty were randomly assigned to the strength training group (2 days/wk, 80% of 1RM for upper and lower body muscle groups). At the end of the year significant differences were seen in lumbar spine and femoral bone density between the strength trained and sedentary women. However, unlike other pharmacologic and nutritional strategies for preventing bone loss and osteoporosis, resistance

exercise affects more than just bone density. The women who strength trained improved their muscle mass, strength, balance, and overall levels of physical activity. Thus resistance training can be an important way to decrease the risk for an osteoporotic bone fracture in postmenopausal women.

Muscle power may be a more important determinant for functional capacity in older people than is strength. Bassey et al⁸⁸ demonstrated that power (force production \times time) is more closely related to functional capacity than strength in frail nursing home residents. It is possible to design resistance exercise programs to increase both strength and power.⁸⁹ Increased muscle power should, perhaps, be the most important goal for a strength training regimen in older people.⁹⁰

Memory disorders and exercise

Leisure activities (e.g., reading, playing board games, playing musical instruments, dancing) have been associated with a decreased risk of developing dementia in men and women over the age of 75.⁹¹ A growing body of literature^{92,93} suggests that regularly performed aerobic exercise will reduce the risk of dementia and Alzheimer's disease (AD). Resistance exercise has also been demonstrated to have a significant effect on memory in older people.⁹⁴ In animal studies^{95–97} voluntary exercise results in direct effects on brain function through an increase in hippocampal brain-derived neurotrophic factor expression and a decrease in inflammation. A recent⁹⁸ randomized controlled trial of a 24-week physical activity intervention in 170 older subjects with memory problems but not diagnosed dementia, showed a persistent effect of the exercise memory over an 18-month period after the cessation of the exercise intervention. Walking at least three times per week has been demonstrated to reduce the risk of AD and dementia.

SUMMARY

Muscle strength training can be accomplished by virtually anyone. Many health care professionals have directed their patients away from strength training in the mistaken belief that it can cause undesirable elevations in blood pressure. With proper technique, the systolic pressure elevation during aerobic exercise is far greater than that seen during resistance training. Muscle strengthening exercises are rapidly becoming a critical component of cardiac rehabilitation programs as clinicians recognize the need for strength and endurance for many activities of daily living. There is no other group in our society that can benefit more from regularly performed exercise than the elderly. Although both aerobic exercise and strength conditioning are highly recommended, only strength training can stop or reverse sarcopenia. Increased muscle strength and mass in the elderly can be the first step toward a lifestyle of increased physical activity and a realistic strategy for maintaining functional status and independence.

In conclusion, exercise exerts a powerful acute and chronic effect on virtually every system in the human body. In assessing these effects and prescribing exercise, it is important to keep in mind the very different effects of aerobic versus resistance exercise. Both forms of exercise are recommended and should be a component of a comprehensive program of disease prevention and health promotion.

The effects of exercise in treating chronic debilitating disease are largely unexplored. For example, fatigue is the most common complaint of patients with cancer, yet the most common advice provided by oncologists is for increased rest. Just as cardiac rehabilitation has been demonstrated to provide an important mechanism for the post-myocardial infarction patient to improve fitness and reduce the risk of a second event, exercise can greatly improve fitness and reduce much of the fatigue associated with cancer and its treatment.⁹⁹ The proven effects of resistance training to enhance nitrogen retention and increase muscle size and strength can provide positive benefits for patients with wasting diseases (such as HIV infection) and cachexia. Resistance exercise may prove to have powerful effects on patients with chronic renal failure, who must consume low protein diets to slow the progression of their disease. Exercise therapy for those patients forced to undergo extended periods of inactivity during dialysis could also improve functional status and decrease the fatigue associated with disuse. The potential value of a reasonable and well-thought-out exercise program is great, and the exploration of this value should be a high priority for researchers. Indeed, a thoughtful and appropriate prescription of exercise for any geriatric patient should be the standard of care.¹⁰⁰

KEY POINTS

Exercise for Successful Aging

- Maximal aerobic capacity (VO_{2max}) declines with advancing age.
- Aerobic exercise has long been an important recommendation for the prevention and treatment of many of the chronic diseases typically associated with old age.
- Strength or resistance training is an important component of an overall fitness program. This is particularly important in the elderly where loss of muscle mass and weakness are prominent deficits.
- A thoughtful and appropriate prescription of exercise for any geriatric patient should be the standard of care.

An injury is defined as damage to tissues usually consequential to a disproportionate energy transfer.¹ The energy that produces an injury can be described as kinetic-causing fractures, contusions, and lacerations; thermal producing burns and scalds; chemical leading to poisoning; and electrical resulting in electrocution.¹ Injuries have been classified by type (a fracture, laceration, or burn), by intent (intentional or unintentional, also described as accidental or nonaccidental), and by cause (a road traffic accident, a fall, or a gunshot injury).¹

Injury is one of the most underrecognized major health problems facing the world today.¹⁻³ Unintentional injuries pose a serious challenge for the health and well-being of older individuals. Although people aged 65 years and older make up less than 20% of the Western population, fatal injuries are much more common among older people, accounting for more than a third of all trauma-related deaths.³⁻⁶ It is clear from studies that for the injuries of the same severity, older patients are more likely to be hospitalized and to have a longer hospital stays compared to younger adults.²⁻¹⁰ However, little research has been carried out in older victims of trauma.

Falls are the leading cause of injuries and death in older people, accounting for 75% of all injuries, followed by road traffic accidents, which account for 13%.⁷⁻¹⁶ In one study, almost half of all falls-related deaths occurred in older individuals despite forming only 14% of the entire falls-related trauma population.¹⁷ It is estimated that approximately 30% of community-dwelling individuals aged 65 years and older suffer at least one fall each year.^{3,7-8,18} Road traffic accidents account for the majority of multiple injuries.¹³⁻¹⁶ Fatalities caused by fire and flames constitute the second most common cause of accidental death in older people.¹⁹ Scalds are responsible for the majority of injuries resulting from burns, which are also associated with a high death rate.^{3,4} Nonaccidental injury resulting from elder abuse is not a new phenomenon but is one that is being increasingly acknowledged as a growing problem.²⁰

The consequences of injuries among older people include significant costs both in terms of human suffering and economic cost. The human costs among survivors of injuries are considerable, leading to disabilities, loss of independence, and institutionalization.³⁻⁶ In addition, there can be profound psychosocial consequences including fear of further falls, loss of confidence, low self-esteem, isolation, and depression.^{3,9,17,18} The economic costs are difficult to determine in view of the different type of injuries involved and the broad range of treatments used.³

In the United States it is estimated that older victims of trauma account for almost 38% of hospital bed days for all injury-related hospital admissions¹¹ and consume up to one third of trauma-related hospital expenditure, which was almost \$100 billion in 1999.²¹ The costs of treating hip fractures in the U.K. health service in a hospital setting is estimated to be approximately £160 million per year.³ However, this does not include the costs associated with informal care and the direct costs of providing social services, domiciliary support, and institutional care.³

PHYSIOLOGIC CHANGES IN OLDER VICTIMS OF TRAUMA

The physiologic response that follows trauma in patients of any age is poorly understood. A number of physiologic responses have been identified that can be classified as (1) neuroendocrine responses and (2) metabolic responses.²²⁻²⁴ Although the response in older individuals to injury is not dissimilar to that in younger adults and the aging is not associated with any impairment of these responses, the subject has not been adequately researched and the clinical importance of the physiologic response to injury that occurs in older patients remains unclear.

The neuroendocrine responses

The neuroendocrine response occurs immediately after an injury and leads to an increase in the activity of the sympathetic-adrenal system and the hypothalamic-pituitary-adrenal (HPA) axis.²²⁻²⁴ The serum levels of growth hormone, prolactin, vasopressin, aldosterone, and glucagons also rise.²³⁻²⁴ The degree and duration of such response is determined by the nature and severity of injury sustained by the individual patient and may be modulated by a number of factors such as volume depletion, hypotension, pain, hypoxia, and circulating cytokines.²²⁻²⁴

It has also been observed that the plasma cortisol concentration remains high in older individuals for a longer period after trauma compared to younger patients with injuries of similar severity.^{25,26} Studies have shown that patients with hip fractures have increased rates of cortisol production and urinary-free cortisol excretion when compared with healthy controls at 2 weeks after the injury.²⁷ The reason for the continued cortisol production is unclear. It is also not known whether the posttraumatic persistent hypercortisolemia is an adaptive mechanism or has any benefit to the organism.²⁶⁻²⁸

It has been postulated that the persistently raised cortisol levels may indicate a reduced capability of older people to downregulate the response after resolution of the stimulus.²⁶⁻²⁹ Similar observations have been made in old rats and is said to be due to a loss of corticosteroid receptors in the hippocampus resulting in a weakened feedback inhibition of the HPA axis as demonstrated by the dexamethasone suppression test.²⁸ The resistance to dexamethasone suppression has also been seen in patients with Alzheimer's disease and in elderly patients with depression and hip fracture, possibly because of the loss of corticosteroid receptors in the hippocampus.^{26,28,30} The clinical implications of such a sustained rise in the levels of cortisol in the context of trauma in older individuals remain unexplored.³⁰

Metabolic changes

There has been little research carried out in this area, particularly in older victims of trauma. A study conducted in the 1930s in younger patients found that the two metabolic phases that occur in patients with injury are the *ebb phase* and the *flow phase* based on the degree of metabolic rate.²⁴ The *ebb phase* is associated with a decreased metabolic rate and

an intensification of fuel generation.²⁴ The severity of injury determines the degree of rise in plasma glucose concentrations during the ebb phase both in the young as well as the old.^{23,24} However, this is not associated with a corresponding rise in plasma insulin because of its suppression by circulating catecholamines.^{23–24} Other changes that occur in both young and old people after injury include a rise in plasma glycerol, free fatty acids, and lactate concentrations.^{24,31} On the other hand, it has been shown that older people have increased rates of lipolysis and reesterification of free fatty acids within adipose tissue for some unknown reasons.^{24,31}

The increased metabolic rate that occurs in flow phase depends on the severity of injury and is associated with a concurrent rise in urinary nitrogen excretion resulting from the injury-related catabolic activities.²⁴ Studies have shown that the negative energy and nitrogen balance that occurs within a week after the trauma because of the catabolic activities in older hip fracture patients can be prevented in most patients by dietary supplementation of about 300 kcal/day energy and 20g/day protein.^{32–34} The likelihood of survival in patients with more severe catabolic activity has been found to be significantly decreased.³³

There is not only a transfer from carbohydrate to fat as the most desired fuel in the flow phase but also an age-related increase in the endogenous production of glucose after trauma.^{31–35} In older individuals, glucose intolerance and insulin resistance that are observed after trauma are said to be notably greater in degree as well duration in comparison to the young for reasons that are not clear but may be due to the high cortisol concentrations following trauma.³¹

DOES RECOVERY OCCUR IN OLDER VICTIMS OF TRAUMA?

Although little work has been done in the elderly, recovery following injury probably takes place in the same manner in older patients as it does in younger adults. But the pace at which recovery takes place may be slower and depends on a number of factors including the nature and severity of injury, comorbidity, nutritional state, and premorbid functional status.^{21–23} The key elements of recovery that have been identified include physiologic recovery and functional recovery.^{21–23}

The physiologic recovery

This starts with the abatement of the catabolic flow phase and ends with the replenishment of the energy and protein deficits.^{22,23,35} However, the subject of physiologic recovery has not been researched thoroughly, particularly in the older population. It is not clear, for example, what leads to the cessation of catabolic flow phase in order for the phase of anabolism to get established.^{23,35} A study conducted in the 1950s on younger patients following major surgery concluded that the physiologic recovery could not proceed without patients being fed.³⁶

The study also found that the pace of anabolic phase could not be hastened any further by interventions such as endocrine manipulations or tube feeding.³⁶ However, it is important that the dietary intake is increased in order for the patients to gain weight and for the recovery to continue unabated.^{35,36} Another study that investigated glucose and protein kinetics in 8 patients aged 56 to 79 years following

major surgery found that these patients could not oxidize glucose to carbon dioxide resulting in an increased production of lactate.³⁷ They also found that the glucose production was increased and the basal insulin concentrations were raised during the anabolic phase.

There appears to be a clear relationship between the nutritional status and the physiologic recovery in patients with trauma, particularly in terms of lean body mass, muscle strength and immune function.³⁸ These physiologic parameters have been reported to be adversely affected even in healthy older women if fed an energy rich but slightly protein deficient diet over 9 weeks.³⁹ Older patients with hip fracture if poorly nourished do badly, and there is evidence that the use nutritional supplements by overnight tube feeding can improve outcome.^{40,41} Although the effectiveness of the oral multinutrient feeds has been confirmed by the Cochrane Review, it recommends that the tube feeding should only be used in situations where the patient is severely ill nourished.⁴² Despite the high prevalence of malnutrition in older patients with hip fracture and other types of trauma, nutrition is not given the importance it deserves in the management of such patients in hospital settings.^{43,44}

Functional recovery

The type of injury as well as its severity has an important bearing on how much recovery takes place in older individuals after trauma.^{3,6,21–23} A study that explored the recovery of physical function after limb injuries in independent older people living at home demonstrated that not only hip fractures but also wrist fractures may reduce older people's chances of regaining independence.⁴⁵ The study also found that the prospects of any recovery 5 to 6 months after the injury are small.⁴⁵ The premorbid state is another important determinant of the extent to which functional recovery occurs in patients with trauma—only 40% of patients who were independently mobile before hip fracture have been shown to return to the same level of function.^{46,47} The functional outcome is also dependent on the level of social support a patient has.⁴⁸

Other factors that are known to be associated with an adverse outcome include delay in surgery, particularly in patients with hip fracture, and comorbid conditions such as stroke, dementia, arthritis, and malnutrition.^{48–56} The impact of psychological problems including depression on recovery from trauma is also being increasingly recognized, but the role of effective management of such problems on the hastening of the rate of recovery and in the improvement of the overall outcome remains unproven.^{51,53} Studies in patients with hip fracture have demonstrated that the extensor muscle power in the fractured leg was the most important determinant of walking speed and stair climbing time.⁵⁷ The adequacy of the control of pain was an important factor in this study, which determined how much strength these muscles regained during recovery.⁵⁷

The various measures that have been shown to improve functional recovery and outcome in patients with trauma include nutritional support, use of prophylactic antibiotics, and heparin prophylaxis.^{35,55,56} Patients should also be encouraged to mobilize early to avoid complications such as muscle wasting, increased risk of venous thrombosis, and pressure ulcers.⁵⁸ However, some orthopedic surgeons do not recommend weight bearing early on after the insertion

of a rigid fixation device to avoid the risk of failure of fixation, nonunion, osteonecrosis, or prosthetic dislocation.^{52–54} But these problems were not reported to occur and benefits of early mobilization were shown to outweigh such risks in a study that allowed complete weight bearing soon after the surgical intervention.⁵² Although different strategies have been adopted to help patients achieve functional recovery after hip fracture and other forms of trauma, one Cochrane review concluded that the most favorable approach to rehabilitate older patients with trauma has not yet been established.⁵⁹

HOW TO ASSESS INJURY AND MEASURE OUTCOME?

A great majority of assessment scales and scoring systems that are in use for the victims of trauma have been developed from research carried out in young adults and have not been validated to be utilized in older individuals.^{12,22,60,61} It is important to be aware of the limitations of the scoring systems when using in older population. Moreover, none of the commonly used scoring systems is completely suitable for every situation regardless of the age of the patient.^{11,62} There are three different types of scorings systems for measuring injury in clinical practice: (1) the anatomic scales (based on the extent of the injury), (2) the physiologic scales (based on the physiologic responses of the recipient of the injury), and (3) a combination of these two (based on both the anatomic extent as well as the physiologic responses).^{11,35,60–62}

Of the various anatomic scales—for example, the Abbreviated Injury Scale (AIS), Injury Severity Score (ISS) and the Anatomical Profile (AP)—the ISS is the one most commonly used in day-to-day practice.⁶³ It is valuable in service evaluation and in assessing outcome.⁶³ However, it has two major limitations. First, it has a limited role in acute settings as the data required may not be immediately available in the early stages of the assessment of a patient with trauma.^{62,63} Second, it may overestimate the severity of injury in older patients as, for example, the force required to produce a fracture is likely to be less due to a reduction in the bone mass, and the associated soft tissue injury is also likely to be less severe.²³

The Glasgow Coma Scale (GCS), the Revised Trauma Score (RTS), the Acute Physiology and Chronic Health Estimates (APACHE), and the Simplified Acute Physiology Score (SAPS) are some of the widely used scoring systems that are based on the changes in the physiologic parameters of a patient with trauma.^{60,61} Their main roles are in determining when to manage patients in critical care facilities and to treat them more aggressively.^{60,61} Their value in older victims of trauma, however, has been questioned in view of the impairment of the physiologic responses that occur with aging, which may result in an underestimation of the seriousness of the injury if these scales are used.^{60,61} However, studies have shown that this is not of any clinical significance as older people usually develop more severe physiologic disturbances and once this and comorbid factors are taken into account, age alone does not appear to be a predictor of poor outcome or survival.^{64–66}

The two widely used combined scoring systems, the Revised Trauma Score + Injury Severity Score (TRISS) and A Severity Characterization of Trauma (ASCOT), are said

to be better predictors of survival.³⁵ A Geriatric Trauma Survival Score, based on the ISS plus cardiac and infective complications plus ventilator dependence, was developed in the 1970s to overcome some of the limitations of the commonly used measurement scales.⁶¹ It has not been generally applied in clinical practice despite the claim that it was 92% accurate in predicting survival. Clearly, further studies are required to evaluate its role in the assessment of elderly injured patients.

INJURY PATTERNS IN OLDER PEOPLE

Although the patterns of injury in the elderly are not dissimilar to those in the young, fractures and serious injuries are more common in the older victims of trauma. The injured elderly patients also have certain differences in terms of injuries at specific sites and have special needs and considerations in view of the comorbidity and age-related decline in the functional reserve and ability to deal with stressors.⁶⁶

Head injuries

There are a number of important differences between the old and the young victims of head trauma in terms of the epidemiology, types of injury, and outcome.⁶⁷ The incidence rates are slightly higher after 60 years of age, and more elderly men than women suffer a head injury.⁶⁷ But the predominance of women in older age groups may result in an underestimation of the true size of the problem in older individuals if the crude figures are not adjusted for sex.⁶⁷ The types of injury that are uncommon in older people include epidural hematomas because of the fact that dura becomes firmly attached to the skull in aging brain.⁶⁷ However, subdural hematomas are much more common because of a number of anatomic changes, including a relentless loss of brain volume, leading to an increase in the space around the brain and stretching of the bridging veins, and increased venous fragility.⁶⁷ The bleeding into the substance of the brain is also more common in older people.

There is also a clear disparity in outcome between the young and the old. Only a handful (about 10%) of older patients who sustain severe head trauma with a GCS score of 8 or less, survive the initial injury.⁶⁸ The survivors are reported to have a prolonged hospital stays and are usually left with a marked disability.⁶⁸ Moreover, older people sustaining trivial head trauma are said to have a high risk of significant intracranial injury and a worse prognosis in comparison to young adults despite no evidence of skull fracture, neurologic deficits, or altered level of consciousness.⁶⁹ A study in patients (both young and old) with acute subdural hematoma found that no functional recovery occurred in older patients when the GCS score was less than 13.⁶⁸ The reasons for such a universally poor outcome in older patients with head injury are not clearly understood, but factors that may be responsible include comorbidity, nihilistic attitudes among health professionals when managing older head trauma patients, a higher complication rate, and a reduced capacity of the aging brain to recover from injury.^{64,68–70}

Thoracic trauma

Chest injuries carry a much higher risk of death and disability in older people compared to the young.^{71–73} Studies report two to three times greater chance of death in older individuals with injuries limited to the chest in comparison

to the young.^{72,73} Even minor injuries to the chest wall can lead to a flail chest, pulmonary contusion, pneumothorax, or haemothorax.⁷⁴ As the chest wall loses its elasticity with aging, rib fractures occur more easily with even mild blunt trauma to the chest in older individuals.⁷⁵ Rib fractures are regarded as a marker of injury severity.⁷⁵ Their presence not only leads to the doubling of mortality in comparison to the younger patients but also the likelihood of the mortality rises significantly with increasing number of rib fractures.^{74,75}

Complications occur more commonly in older patients with thoracic injury.⁷⁴ Older people can deteriorate rapidly even without fractures as the pain from chest trauma can lead to hypoventilation and failure to clear secretions, thereby causing pneumonia.^{66,74,75} Regular assessment and closer monitoring of patients with thoracic injury are required in order to identify complications at an early stage.⁷⁴ Prompt mechanical ventilation may be needed in older patients if they develop features of respiratory distress.³⁵

Abdominal trauma

Abdominal trauma frequently occurs in older people and has been observed in about 35% of patients with multiple injuries.^{11,12,15} Abdominal injuries in older individuals differ from those in the young in several ways. First, the fatalities have been reported to increase fivefold in elderly patients with visceral injuries compared with younger patients, with the death rate reaching almost 80%.^{6,11,12} Second, elderly patients with abdominal injuries require prompt attention and treatment as they are very intolerant of shock.^{12–16,64} Abdominal examination alone is deemed less reliable in older patients and computed tomography (CT) examination of the abdomen should always be considered in all such patients.⁶⁶ It is particularly useful in patients with a history of significant abdominal surgery.

Third, as older individuals tolerate unnecessary laparotomy poorly, the possibility of complications following emergency surgery is greatly increased requiring a thorough perioperative evaluation before surgical interventions are contemplated.^{35,76} However, delaying surgery has its downsides as older patients are intolerant of shock that may lead to multiple organ failure, which is invariably fatal.⁷⁶

Fractures following falls

Fractures occur more commonly in the elderly population for two main reasons: their bones are weak and they are more prone to falls.³ It has been observed that a reduction in bone mineral density by one standard deviation increases the risk of fracture two to threefold.^{77,78} Injuries that may only result in soft tissue trauma or dislocation in the young produce fractures in the elderly. Several community studies have shown that elderly women are more likely than men to sustain fall-related fractures.⁹ This is partly due to a higher prevalence of osteoporosis among older women.

Significant injuries have been reported among one tenth of fallers aged over 70 (10%).⁷⁹ It has been demonstrated that following a fall two fifths of women (40%) and a quarter of men (30%) aged 75 and over sustained fractures and that the proximal femoral fractures were responsible for the peak in trauma mortality in the old age.⁸⁰ Pelvic fractures also cause substantial mortality and morbidity, with fatalities approaching nearly 90% if the fracture is open.^{11,12,15,21}

A study of older patients has shown that the most common type of fracture after pelvic trauma was pubic rami fractures (56%), followed by acetabular fractures (19%), and ischium fractures (11%).⁸¹ The study also found that over half of patients had multiple trauma and the mortality was four times greater than in a younger population.⁸¹ The reasons why pelvic fractures carry such a high mortality and morbidity include an increased association with bleeding as well as visceral and multiple injuries.⁸²

Falls are also responsible for most of the cervical injuries and fractures in the elderly.⁸³ Studies have shown that elderly trauma patients are twice more likely to reveal cervical fractures on X-ray examination compared to the young and are at an increased risk of fractures at multiple levels.^{84,85} Upper limb fractures commonly occur in older people, with the preponderance of proximal humerus and distal radius fractures.^{9,21,86} However, the incidence of tibial fracture declines with age in men but remains unaltered in women.^{21,86} Moreover, the incidence of ankle fractures has been shown to be rising, particularly in older women.²¹

The type of the fractures observed depends on how falls occur.³⁵ Whereas falls on an outstretched arm that usually happen when a person is mobile lead to fractures of the wrist and proximal humerus, hip fractures are much more commonly associated with falls from a static position or when a person is moving slowly.^{21,35,87} Long bone fractures without a clear history of injury or falls have been reported in frail older individuals. Although precise mechanisms as to how these fractures, also referred to as "minimal trauma fractures," develop are not clear, the factor that has been shown to be responsible includes mobility problems.⁸⁸

To design strategies to prevent falls and fall-related fractures, it is important to develop a better understanding of why and how people fall and how this relates to the risk of fracture.^{89,90} Some of the key reasons why people fall include environmental factors (poor lighting, loose carpets, etc.) and patient-related factors (arthritis, stroke, dementia, postural hypotension, etc.).⁹¹ Although it is vital in falls prevention that these factors are managed effectively, it is also crucial that other factors that are responsible for a fracture are carefully taken into consideration.^{92,93} These are the determinants of the strength of bone and the active and passive protective factors that determine how much kinetic energy of the fall is transmitted to the bone.^{92–96}

A typical fall usually generates more than enough energy to break an old hip.⁹⁵ However, the risk of impact leading to fractures can be minimized by employing energy absorbing/dissipating mechanisms to reduce the force delivered to a bone: active mechanisms (e.g., muscular contractions and use of the outstretched hand) and passive energy absorption by soft tissue, clothing, floor coverings, and hip protectors.^{94–97} As it has been found that fracture load is linearly related to bone mineral density, measures to increase bone mineral density of the proximal femur will have additional beneficial effect in order to reduce the risk of fracture.⁹⁸

Multiple injuries

In general, patterns of injury are similar in young and old.⁹⁹ However, visceral injuries rarely occur in the elderly in the absence of major bony injuries.^{6,15,99} The injuries that are associated with the majority of early fatalities are skull fractures leading to brain injuries and pelvic fractures that result

from massive bleeding from lacerations to the pelvic venous plexus and visceral injury.^{6,15,35,66}

Other common injuries that occur in patients with multiple trauma include long-bone fractures, especially of the tibia.¹⁰⁰ Such injuries call for an urgent assessment and treatment in order to control blood loss, reduce the risk of fat embolism, and enable early mobilization.^{6,35,101,102} Older people are quite intolerant of delays in surgical intervention, as their condition can deteriorate rapidly even after isolated hip fractures.¹⁰³ Although a more recent study revealed that patients sustaining isolated hip fractures had similar injury severity scores, and a similar incidence of severe complications as the trauma population in general,¹⁰⁴ it is important to be aware of the negative impact of the age-associated decline in functional reserve and comorbidity on the outcome in older individuals.^{22–23,66}

CONCLUSIONS

With the demographic changes predicting an increase in the population of older people worldwide over the next few decades, trauma in the old age will remain an important public health problem. Injuries are not only common in older individuals but are also a huge burden on the finance of a country's health service and pose considerable diagnostic as well as therapeutic challenges. Considerable progress has been made to develop a better understanding of the process of care of injured people, which has helped to reduce morbidity and improve survival.⁶⁶

There is evidence that an early and appropriate use of investigations, invasive monitoring, and interventions including the support of a trauma center/team combined with an effective management of comorbid conditions and prevention of complications can influence outcome positively in older victims of trauma.^{66,105–107} Although a great deal of work has been carried out to improve our knowledge and understanding of the impact of the age-associated physiologic changes, injury severity, comorbidity, and the

patterns of injury in older trauma patients on the outcome, further research is clearly needed to identify the factors that adversely affect the functional recovery and outcome and to develop an evidence-based strategy to deal with them successfully.¹⁰⁸

KEY POINTS

Injury in Older People

- Although injuries are more common in younger adults, older people are much more likely to die from their injuries (accounting for over a third of all trauma deaths).
- Fractures and serious injuries are more common in older victims of trauma, and there are certain important differences in terms of injuries at specific sites.
- Falls remain the leading cause of injuries and death in older people, accounting for 75% of all injuries.
- Older injured individuals consume a greater proportion of the health care budget in comparison to younger adults.
- A great majority of assessment scales and scoring systems that are in use for the victims of trauma have not been validated in older individuals, and it is important to be aware of the limitations of the scoring systems when applying them to the older population.
- The pace and extent of recovery that takes place in older victims of trauma depends on the nature and severity of injury, comorbidity, nutritional state, and premorbid functional status.
- There is evidence that an early and appropriate use of investigations, invasive monitoring, and interventions including the support of a trauma center/team combined with an effective management of comorbid conditions and prevention of complications can influence outcome positively in older victims of trauma.
- Further research is needed to identify the factors that affect the functional recovery and outcome adversely and to develop an evidence-based strategy to deal with them effectively.

Rehabilitation: Therapy Techniques

Valerie M. Pomeroy
Marion F. Walker

Geriatric rehabilitation has a major impact on length of hospital stay and unnecessary admissions to institutionalized care, burden on caregivers, and numbers of crisis “social” admissions.¹ In recognition of the contribution of rehabilitation, the recent National Service Framework for Older People in the United Kingdom emphasizes the importance of promoting elderly people’s health and independence.² Therapy is an important component of this service. Specific techniques are used to prevent the onset of disability and to restore, maintain, and control the deterioration of functional ability.

Loss of functional ability can take many different forms. These include the loss of the ability to communicate, remember, walk, perform personal care tasks, and/or perform social roles that are perceived as the norm. Indeed, loss of functional ability can itself lead to secondary difficulties such as depression, muscle wasting, and withdrawal from social interaction and activity.

Rehabilitation is therefore a multifaceted service with therapy provided by a multiprofessional team. For example, speech and language therapists provide interventions targeted at communication difficulties and swallowing problems; psychologists provide interventions targeted at emotional function and cognitive function (e.g., memory and perception); and nurses provide interventions targeted at personal care, mobility, and psychosocial interactions. Effective teamwork is central to the success of rehabilitation. Multiprofessional assessment is followed by treatment and goal-setting with individual patients who are also recognized as being members of the rehabilitation team. Most treatment packages are therefore complex and require continued teamwork to ensure integrated delivery and adjustment.

The complexity of the rehabilitation package is widely recognized and it is frequently perceived as a “black box,” particularly by medical members of the team. The aim of this chapter is to describe for doctors some of the techniques that are used by therapists to help elderly people maintain or regain optimal independence. To make this task more manageable, the techniques described in this chapter are restricted to those provided by occupational therapists and physiotherapists. Of course, the therapy component of rehabilitation services for elderly people consists of much more than is outlined here, with many other professional groups making key contributions. The techniques outlined in this chapter are therefore presented as examples of therapy, illustrating how these are combined for specific patients and groups of patients. The findings of narrative and systematic reviews are used where these are available, but this chapter does not seek to provide a thorough review of the effectiveness of the interventions described.

Descriptions of therapy techniques would be meaningless without placing them in the context of professional expertise and clinical application. Therefore the next section outlines the core skills of occupational therapists and physiotherapists, the therapy research culture, and the process of

therapy. Therapy techniques are then connected with the specific conditions of stroke, fractured neck of femur following a fall, Parkinson’s disease, and frailty.

OCCUPATIONAL THERAPY AND PHYSIOTHERAPY

Occupational therapy

Occupational therapy has been defined as “the treatment of physical and psychiatric conditions through specific activities in order to help people reach their maximum level of function and independence in all aspects of daily life.”³ An earlier definition by Turner⁴ captures the more holistic approach, still favored by many occupational therapists today: “Occupational therapy is the treatment of the whole person by their active participation in purposeful living.”

The roots of occupational therapy were first established in the eighteenth century with the work of the French physician and psychiatrist Phillippe Pinel, and the Englishman William Tuke, who—in founding an asylum, “The Retreat at York”—made early attempts to rehabilitate the mentally ill.⁵ By the twentieth century a group of professionals evolved the concept of occupation as a restorative agent and of the person as an active participant in promoting personal health.

George Burton coined the term “occupational therapy” in 1914 and the first school of occupational therapy in Great Britain was founded in Bristol in 1930.⁶ The main impetus came to occupational therapy during World War II with the first curative workshop set up at Shepherd’s Bush Military Hospital by Sir Robert Jones, an eminent British surgeon of the day. He enthused about the value of occupational therapy and urged the War Office to set up other centers. Unfortunately at this time treatment activities were limited to the field of crafts because the more realistic occupations were not possible because of trade prejudice.⁶ This liaison with crafts is where the erroneous concept of the occupational therapist as “diversional therapist” originated.

Reed and Sanderson⁷ list some basic concepts that do not belong to occupational therapy:

- Occupational therapy should not be used as a means of keeping a person busy.
- Occupational therapy does not provide employment.
- Occupational therapy should not be unplanned or a haphazard program of activities.

Since the early 1900s, occupational therapists have recognized the importance of having a strong theory of occupation to support their practice. Several authors have contributed to this theoretical base in the last 30 years, generating and expanding many models and approaches to be used in treatment.⁵ The actual techniques used in day-to-day practice by occupational therapists are both numerous and diverse, and as clinicians primarily use a pragmatic eclectic approach to treat individual patients, it would be inappropriate simply to

list them in a book of this nature. However, the main techniques used with elderly people are set out in this chapter.

The skills of the occupational therapist

Joice and Coia⁸ describe the core skills of the occupational therapist as follows:

1. The use of selected activity which must be purposeful and meaningful to the individual. For example, in preparation for discharge from hospital to home, the occupational therapist would encourage the patient to practice making a hot snack. The task would be purposeful and meaningful either because the patient lives alone or the main caregiver is out at work all day.
2. Activity analysis to break activities down into physical, cognitive, interpersonal, social, behavioral, and emotional components. To use the example given above: Can the patient manage both the physical and the cognitive components of making a hot snack? Can the person stand for long periods at the sink and cook unaided, or does he or she require the use of a seat or perching stool? Can the person remember putting toast under the grill? Is the person aware of the sequencing of the tasks involved in making a hot drink? Does the person need to use any specialized equipment to achieve the task independently? If the individual's visual field has been affected by a stroke, can he or she see all the ingredients on the worktop and use them appropriately? Does the person have sufficient concentration and motivation to achieve the task?
3. Assessment and treatment of functional capabilities. The therapist must have the knowledge and ability competently to assess the functional, cognitive, and emotional capabilities of the individual and apply the appropriate treatment. A thorough knowledge of prehospital ability is essential for setting appropriate goals. "Competent assessment" in the current climate of evidence-based practice should, where possible, include the use of standardized, valid, and reliable measures. These will permit objective measurement of patients' progress.

The occupational therapist therefore strives to promote recovery through purposeful activity, and encourages the patient to retrain, to practice, and to become independent in some chosen activities of everyday life. These activities may incorporate personal care tasks such as washing, dressing, feeding, toileting, and bathing (known as activities of daily living [ADLs]) or more demanding tasks such as outdoor mobility, using public transport, household tasks, and leisure interests (known as extended activities of daily living [EADLs], or instrumental activities of daily living [IADLs]).

Occupational therapy training

In the United Kingdom, training in occupational therapy involves a 4-year course culminating in an honors degree. Topics covered during training include anatomy and physiology, behavioral science, psychology, clinical sciences medicine and psychiatry, research methods, management and social policy, profession-related practice, fieldwork

education, theoretical frameworks, therapeutic activity, and core professional skills.

Occupational therapy settings

In the United Kingdom, occupational therapists work in a variety of settings: hospitals (ward-based), day-hospitals, day-centers, outpatient departments, social service departments, and health centers. In parts of the United Kingdom, and in response to government initiatives (see Chapter 103B online), new community occupational therapy posts are developing within primary care settings, such as in general practitioner surgeries or within health care centers. These posts mainly come under the jurisdiction of the primary care groups, or more recently, primary care trusts.

The social services occupational therapist (SSOT) can provide occupational therapy also in the patient's own home. Local health authorities currently fund these posts. This specialist group of occupational therapists is concerned mainly with clients who have permanent and substantial disability, with the aim of helping these people to live independently in the community. They can provide equipment to help a client function more independently or may supply equipment simply to ease the burden on the caregiver—such as by the provision of a hoist for bathing. Another remit of the SSOT is to give advice and facilitate structural changes within the disabled person's environment. This may range from outside ramps to enable wheelchair access to major adaptations such as building a ground-floor bathroom. Social services occupational therapists also provide advice on financial benefits when appropriate.

Surveys indicate that although social services occupational therapists are highly valued specialists, staffing levels and limited resources mean that their individual case contribution is often very limited.⁹

Physiotherapy

Since its inception in 1895, the profession of physiotherapy has been concerned with movement. Physiotherapists use many techniques to prevent the onset of movement problems to facilitate recovery in the acute phase following injury, and to rehabilitate people who have a longer-term movement problem. These therapies can be broadly classified as: exercise, manipulation and mobilization of joints and soft tissues, electrotherapy, acupuncture, and hydrotherapy. Physiotherapists also advise on the suitability of various types of devices (e.g., walking aids and orthoses) to assist movement and mobility. Problems with movement occur as the result of many processes, including fractures, arthritis, whiplash injuries, back pain, stress incontinence, repetitive strain injuries, cystic fibrosis, sports injuries, stroke, and stress disorders. Physiotherapists work in many health care, social care, and community settings.

The skills of the physiotherapist

Understanding how and why people move as they do underpins the core skill of physiotherapy. Physiotherapists have extensive knowledge and experience of "normal" movement throughout the life span and how this is altered by various pathologies and lifestyle processes. An initial assessment identifies what the person can do, what he or she cannot do, where movement becomes difficult, and why. From this

a treatment plan is drawn up, in partnership with the patient if possible. Assessment and treatment are therefore based on theoretical knowledge and clinical experience of neural and musculoskeletal mechanisms involved in movement control and how these are affected by pathology, age, gender, life-style, and treatment modality.

Specialization is important to ensure that patients receive high-quality treatment. Physiotherapists specialize in a number of areas of health care, including orthopedics, intensive care, pediatrics, musculoskeletal injury, elderly care, sports injuries, psychiatry, neurology, and rheumatology. Consequently physiotherapists have additional core skills pertinent to their particular area of specialization. In addition to specialist knowledge and experience of particular conditions, specialist skills also include those relevant to the theory and practice of specific physical therapy techniques which are gained through postgraduate education and training. This chapter, which outlines only the physical therapy techniques used with elderly people, testifies to the range of skills deployed by physiotherapists.

Development of a research culture

In the United Kingdom, physiotherapy became an all-degree profession in 1992. Since then the number of physiotherapists with research skills has risen considerably. In the early 1980s only a few physiotherapists in the United Kingdom had been awarded a PhD. In 1997 there were 70 physiotherapists with doctorates and eight professors.¹⁰ At the beginning of 2001 there were 100 physiotherapists with doctorates and 23 professors (nine without doctorates).¹⁰ This is a dramatic increase, but still only a small proportion of the 35,000 physiotherapists in the United Kingdom.

Occupational therapy is also relatively new to the world of research, with many training schools introducing research modules into the curriculum only in the mid-1990s. The British College of Occupational Therapists has developed a research strategy to meet the research needs of occupational therapists.¹¹ Occupational therapists are required by the Code of Ethics and Professional Conduct to have: "A duty to ensure that wherever possible their professional practice is based upon established research findings."¹²

The increase in research-aware and research-active therapists is resulting in a more critical approach and a better evidence base for clinical practice. Despite these advances and the recommendations made in a position statement to the Department of Health in 1994,¹³ standard career paths that include research activity have not yet been established. However, with the increase in the number of research-active therapists and the publication of high-quality research in peer-reviewed journals, this situation is likely to change.

THE THERAPY PROCESS

Rehabilitation is an active participatory process, so the first contact with the patient is crucial in establishing a good rapport and therapeutic relationship. Assessment, which is essential to determine subsequent interventions and should be an ongoing activity throughout the rehabilitation process, begins at the first meeting.¹⁴ Assessment ascertains what the patient can do, what he or she cannot do, where

activities become difficult, and importantly why difficulties are experienced.

For example, the Rivermead Perceptual Assessment Battery¹⁵ can be used to assess individual components of perceptual competence. One subtest examines the ability of the individual to discern specific objects in the foreground of a complex picture (figure/ground). Any difficulty experienced with this subtest could explain why a patient cannot simply select trousers from a group of clothes lying on a bed. When a specific problem has been identified, the therapist can suggest the most appropriate therapy.

It is also important at this early stage to ascertain the prehospital history of functional ability. Was a patient who has suffered a stroke, for example, able to walk before the stroke, or is the deficit only part of a history of progressive disability? Specific information is needed about the type of activities the patient participated in before referral to therapy, such as how active the person was, what help is presently available at home, and what the person wishes to attain through the therapist's intervention. On interpreting a detailed assessment, movement, and functional diagnoses can be made and both are considered with the pathology and medical prognosis.

Goal-setting and treatment planning¹⁶ are based on levels of existing functional and cognitive ability, discussion with the patient (and if appropriate the caregiver), and clinical judgment. Goals must always be realistic and attainable. As the patient progresses, they need to be reassessed and updated where necessary.

Therapists will also describe, to the patient and caregiver, their role within the multidisciplinary team and how they would hope to be able to contribute to the restoration of functional ability and social activity.

The framework for assessment, goal-setting, and intervention can be described by the bio-psycho-social approach of health care.¹⁷ This holistic approach considers all elements of health: what is happening to parts of the body (pathology, impairment); what processes are happening at the level of the person's experience (disability); and what is happening in the person's wider social context (handicap). This framework is therefore complementary to the commonly used one proposed by the International Classification of Impairments, Disabilities and Handicaps (ICIDH),¹⁸ which was recently updated with important terminological changes (see Chapter 103B online). As each framework is closely linked with the other, it is immaterial which is used by therapists.¹⁹

Once intervention has started, continued involvement and education of the main caregiver is essential if that person is to be able to use the techniques taught to best effect. This is particularly important when the patient is discharged from the hospital, at a time when therapeutic interventions are often minimal. Patients, caregivers, therapists, social services personnel, and homecare services are essential collaborators when planning a successful discharge back into the community.

It is also prudent for the therapist to listen to the patient and caregiver, as much can be learned from their experiences and suggestions for solutions to individual problems. Therapists also help and support caregivers throughout the rehabilitation process by providing an ear and an environment where they can express their feelings of frustration, anger, depression, and possibly guilt.²⁰

SOME SPECIFIC THERAPY TECHNIQUES

The context for the description of therapy techniques is provided here by four of the most common conditions presenting to therapists: stroke; fractured neck of femur following a fall; Parkinson's disease; and frailty. However, it should be appreciated that a patient may have more than one problem. For example, an elderly person having recently sustained a cardiovascular insult may also demonstrate longer-term frailty with deconditioning and/or permanent impairment of the cardiovascular and musculoskeletal systems. In such circumstances, a therapist addressing each of a patient's difficulties may adopt a "mix and match" approach in devising a treatment program. Adaptability and flexibility are key therapy skills. This might explain why therapists report using a large number of different interventions for defined clinical presentations; for example, 31 interventions for gait apraxia²¹ and 175 interventions for poststroke shoulder pain.²² Such detailed description of techniques is important, especially if interventions are being tested in clinical trials; but as the aim of this chapter is to give an overview, techniques will be described here in rather less detail.

Although research into the effectiveness of specific therapy interventions for elderly people is limited at present, there are several therapy topics that are now the subject of Cochrane reviews. However, caution needs to be used when interpreting the results of these reviews. For example, it is difficult to collate the findings from different primary trials because of variation in aims, interventions, and outcomes,^{23,24} and the identification of small numbers of compatible trials for meta-analysis.^{25,26} Where adequate numbers of compatible trials are available, positive effects of some therapy interventions have been reported; for example, behavioral interventions and targeting environmental hazards to prevent elderly people sustaining a fall.²⁵ On the other hand, the optimum amount of therapy—its intensity, duration, and timing in the course of treatment²⁷—is also uncertain. The descriptions that follow are therefore a snapshot of a changing science of therapy interventions for elderly people.

Stroke

Stroke is the commonest cause of permanent disability in elderly people and is an important area in rehabilitation as evidenced by its use as a "tracer" condition in the Audit Commission's report "The Way to Go Home: Rehabilitation and Remedial Services for Older People."²⁸ Therapy forms an important part of the multidisciplinary stroke care package which has been shown to prolong life and reduce disability,²⁹ an effect that is maintained 10 years after stroke.³⁰ The U.K. National Clinical Stroke Guidelines recommend that patients in the early phase should see a therapist each working day if possible and that they should be given as much therapy as they find tolerable.³¹

Before looking at some specific therapy techniques, it is important to touch on an issue of particular relevance to physical therapy—the use of "labels" to describe groups of techniques. Physical therapy given after stroke has historically been described by named approaches, and there have been a succession of these (Partridge³² describes nine). Narrative reviews and trials, however, have not found any one "approach" to be better than any other at reducing disability.^{33–35} Currently in the United Kingdom, the majority of

physiotherapists and 50% of occupational therapists probably use the Bobath approach,^{36–38} which emphasizes the facilitation of normal muscle tone and normal, good-quality movement³⁹ in preference to the direct training of movement tasks. Outside of the United Kingdom, the Bobath approach is not as predominant and other approaches are more favored—for example, the "movement science" approach, which emphasizes the importance of training everyday activities.⁴⁰ However, describing therapy by using these labels probably does not allow any inferences to be made about which specific techniques are used.⁴¹ For example, a recent survey (already alluded to) of nurses, occupational therapists, and physiotherapists in England found that 175 different types of interventions were reported as used for poststroke shoulder pain, and suggested that there was intraprofessional variation.²² These data support the clinical impression that the same label can be applied to different collections of therapy techniques, and so this chapter will not describe specific named approaches. Instead we want to give a flavor of the type of techniques that have been described in the stroke rehabilitation literature.

Initial steps

During the early period after stroke in patients with major motor impairment, positioning—the use of specific body postures—is advised in the U.K. National Clinical Stroke Guidelines.³¹ A recent survey of physiotherapists found that the most common positions recommended during the first week after stroke were sitting in an armchair, side-lying on the hemiplegic side, and side-lying on the opposite side, with particular importance given to the position of the proximal joints of the limbs. For example, in side-lying on the hemiplegic side, the five most important components were found to be: head in neutral, scapular protraction, glenohumeral external rotation, hip extension, and knee flexion.⁴²

During this early rehabilitation period, occupational therapists undertake a comprehensive ADL assessment and screen for perceptual and cognitive difficulties (e.g., the Rey figure screening tool⁴³). Perceptual problems are common in both right and left hemiplegic stroke patients.⁴⁴ Perceptual screening involves asking the patient to copy a drawing of a complex figure made up of 18 components. This assessment is particularly important if the patient has the physical ability to complete a specified task but still remains dependent on assistance. If ADL difficulties are persistent and unexplained, the occupational therapist will then carry out a more detailed perceptual assessment, using perhaps the Rivermead Perceptual Assessment Battery.¹⁵ This may clarify the type and nature of the perceptual problem and act as a pointer to the specific strategies to be used.

It is also important, early after stroke and throughout the rehabilitation process, to provide information to patients and caregivers on the nature of stroke, the difficulties they are experiencing, and the therapy interventions they are receiving. This will ensure that patients and caregivers are totally involved and knowledgeable about the therapeutic aims and objectives of the rehabilitation sessions. Compliance with the treatment regime will therefore be greater. Stroke Family Support Workers also provide much practical, psychological, and emotional support. This support is especially valuable when discharge from hospital is imminent.

Also from the very beginning of the rehabilitation process, therapists emphasize the importance of integration of interventions, and teach other members of the team (including informal caregivers) specific techniques for individual patients. For example, the occupational therapist may teach techniques to help with dressing, toileting, and/or feeding. These specifics may be directed at improving patients' ability to dress themselves. Some examples are:

- Cross the paretic leg over the nonparetic one to be able to reach the paretic foot.
- Use a footstool to reach the feet.
- Adopt clothes that are easier to put on and take off, such as elastic-waisted jogging trousers (this can be modified as function returns).
- Use visual cues—such as red thread around armholes, or red thread next to one button and one hole for correct alignment of buttons.
- Practice backwards chaining. Start with the last step in a functional task and then, when this is achieved, work backwards to the first step, so that eventually the person is able to complete the whole task.
- Encourage and exploit progression of ability by, for example, reducing the support provided by a firm chair with arms, to sitting on a bed while getting dressed.

The physiotherapist may place a description/diagram of recommended positions above the patient's bed and/or run study days on the principles of normal movement.²²

Re-education of movement

Therapists are often concerned with the reeducation of movement, and many techniques have been used or are being developed.⁴¹

ACTIVE MOVEMENT

The patient can be asked to produce, or attempt to produce, a voluntary contraction of paretic muscle.^{45,46}

BIOFEEDBACK

Biofeedback has been used to provide patients with information about muscle activity during movement.^{47,48} The technique involves placing EMG electrodes over the belly of the target muscle and producing a visual display of the electrical activity during a movement or functional task.

CONSTRAINT-INDUCED THERAPY

This is based on experimental evidence of the benefits of "forced" use in monkeys (reviewed by Morris et al⁴⁹). Essentially the technique involves using a sling or a bulky mitten to restrict the nonparetic upper limb. During the period of restriction, the patient is provided with an intensive functional exercise program and is encouraged to use the paretic upper limb during everyday activity.^{50–56} This technique has not yet been the subject of evaluation in definitive clinical trials and is not in widespread clinical use. Research is ongoing.

ELECTROSTIMULATION

Electrodes are placed on motor points of wrist and finger extensor muscles to produce full wrist and finger extension with 10 seconds on and 10 seconds off, 1 hour a day for 15 sessions.^{57,58} Francisco et al⁵⁹ placed electrodes on extensor

carpi radialis and gradually increased the stimulus threshold with each session as voluntary recruitment increased. Functional electrical stimulation is also used particularly to improve ankle dorsiflexion during walking.⁶⁰ The technique involves stimulating the common peroneal nerve or tibialis anterior muscle, with the stimulation triggered during the swing phase of gait by a force-sensitive switch placed in the patient's shoe.

Facilitated muscle activity and movement An example is weight-bearing through the heel of the hand with an extended elbow.^{45,46,61} A particular example relating to postural adjustment was described by Pomeroy et al.²² The therapist sits behind the patient and the therapist's hands are placed each side of the patient's thorax while the therapist mobilizes the patient's trunk to produce lateral movement of the thorax on the pelvis.

Gross movement can also be facilitated. For example, stepping is effected by the therapist facilitating a patient to displace his or her weight diagonally forwards and outwards, so that balance reactions produce a forward stepping movement with the opposite lower limb. In effect the therapist is facilitating the accentuation of normal posture changes during movement. This technique can also be used to facilitate sit-to-stand. This activity requires an accentuation of the forward and downward movement of the head and shoulders, which occurs during normal standing from a chair.

These techniques require a detailed knowledge of the mechanisms of both normal and disrupted movement (see "Fractured Neck of Femur Following a Fall" section).

AEROBIC EXERCISE

An example is cardiorespiratory and musculoskeletal fitness training, typically over a period of about 10 weeks, using a cycle ergometer.⁶² Over the first 4 weeks the initial workload of 30 to 50% of maximal effort is gradually increased to the highest level subjects could attain, and this level is then maintained for the last 6 weeks of the training period.

FUNCTIONAL ACTIVITIES

These include leg and arm training.⁶³ Training techniques for improving sitting balance include that described by Dean and Shepherd.⁶⁴ Patients are seated and undertake reaching tasks to retrieve different objects placed beyond arm's length. Distance and direction are varied, as are seat height, movement speed, object weight, and extent of thigh support on the seat. During reaching, patients are trained to give attention to placing weight through their paretic lower limb.⁶⁴

Walking is a functional activity that is reeducated using numerous therapy techniques depending on the approach being used. A recent development has been to train walking as a whole activity using partial (<40%) body weight support while walking on a treadmill.^{65–69} Essentially patients receive partial body weight support from a "parachute harness," which allows them to walk at a low velocity on a treadmill with or without manual guidance from a therapist to ensure that the gait pattern is as normal as possible.

MASSAGE AND SELF-STROKING

An example of this is tapping and rubbing the skin overlying the paretic muscle.⁴⁶

ORTHOTIC ASSISTANCE

Orthoses might be provided to improve control of the ankle during walking. A variety of orthoses is available. Some, such as the air-stirrup brace, limit ankle eversion and inversion⁷⁰; others “control” ankle dorsiflexion and plantarflexion.^{70–73}

POSITIONAL FEEDBACK

Specific interventions include feeding information back to patients about weight distribution recorded by devices to measure force,^{74–76} and about posture or joint angle recorded by devices to measure deviation from a set position.^{77–80}

RESISTIVE EXERCISES

Resistive exercise training can be given for grasp, hand extension, and ballistic extension including flicking a table-tennis ball at a paper cup target.⁸¹ Other techniques include training grip strength by squeezing two bars separated by springs, and performing wrist extension with weights attached to the dorsum of the hand.⁸² Yet other interventions have involved the use of a dynamometer to produce the resistance.⁸³

ROBOT-AIDED THERAPY

This is a novel therapy which is currently being developed and tested. The technique uses a robotic arm, which is programmed to guide the patient’s hand to a target if the patient cannot produce the required movement unaided.⁸⁴

Secondary complications

Prevention and management of secondary complications, such as pain and contractures, is important. Specific interventions include pain assessment and management, and passive movements and stretching.⁴⁵ Other specific techniques include providing information about the structure and function of the shoulder, giving frequent feedback to the patient about the position of the arm, and reminding the patient to support the arm all the time.²²

Training of ADLs

Training of ADLs is another area for specific therapy interventions. For example, in teaching dressing techniques, the therapist can place the armhole of a garment between the patient’s legs. The patient puts the paretic upper limb into the armhole with the paretic elbow resting on the paretic knee. The therapist then takes the sleeve over the patient’s elbow and shoulder before the person puts his or her nonparetic upper limb into the garment.²²

Attention is given to the supply of assistive equipment. Examples are a stocking aid, and special cutlery and kitchen equipment (such as belly clamp, one-handed tin-opener, Dycem matting, etc.).⁸⁵

Prior to discharge

As hospital discharge approaches, therapists give particular attention to preparing patients for living with a disability outside the protected hospital environment. A pre-discharge home visit is essential to assess safety (see later in the “Fractured Neck of Femur Following a Fall” section) and to provide the opportunity for patients to test how they will manage essential personal care and move around their home after stroke. Important activities are practiced, such as getting out

of bed, bathing, getting dressed, moving between rooms, and getting in and out of the house.

A home visit is an encounter with the real world and it is often the first time that patients and caregivers fully appreciate the impact of the stroke on their everyday life. The realization that “at a stroke” they have become disabled and that everything is not going to be fine when they go home can be devastating. Aspects of the home environment that were not even noticed before the stroke—such as a step down into the kitchen—are now seen to threaten a severe restriction on independence. For this reason the home visit and the days following it can be emotionally charged. Counseling is often required. Following these visits it may be necessary to refer the client on to a social services occupational therapist, particularly if larger pieces of equipment such as bath aids and ramps or structural changes to accommodation are required.

After discharge

After hospital discharge, therapy may continue and improvements continue to be made.^{86–89} Specific interventions include problem-solving, repetitive practice of ADL activities, advice about self-management and re-education of abnormal components of gait by providing practice, and provision of appropriate walking aids.⁸⁶ Reintegration of social activity is promoted, and information is given on such facilities as Dial-a-Ride, shopmobility, and suitable swimming classes, where they are available. Leisure activities are promoted, and where previous leisure interests are no longer possible, alternative activities are explored. Where possible, every effort is made to regain the independence in every aspect of the patient’s prestroke life. Unfortunately, rehabilitation in nursing or residential homes to date has been sparse, haphazard, and poorly defined⁹⁰; this area is currently being researched.

Fractured neck of femur following a fall

During the acute postoperative period, therapists are most concerned with enabling patients to regain mobility and independence in personal self-care tasks. Of course all therapy interventions are influenced by the particular surgical procedure undertaken, so information given here can only be general in nature. Very early mobilization techniques frequently require patients to be assisted by one or two members of the therapy team so that they can practice fundamental skills such as moving around in bed and standing. Assistive devices such as tilt tables, wheelchairs,⁹¹ raised toilet seats, and dressing aids (e.g., long-handled shoe-horn and stocking aids) might also be used. At this stage in rehabilitation it is also important to establish the patients’ preinjury level of independence so that appropriate goals, both formal and informal, can be set with patients and caregivers. As patients become more independent in everyday tasks, more emphasis is given to the prevention of further falls.

Mobility training is often based on an understanding of “normal” biomechanical models of performing particular tasks. Deficient or missing biomechanical components are identified and individualized exercises are given to each patient to remedy the deficient component. Exercises to increase flexibility, strength, and movement control are given in the context of the task being trained. If patients are unable to complete the whole task, then components of the

task are practiced in isolation before being incorporated into the desired activity.⁹²

For example, sit to stand has two major phases of initial forward trunk lean (first 35% of rising) and upward movement.⁹³ This division of the task can be further divided into four phases⁹⁴:

1. Flexion momentum is initiation of movement to just before buttocks "lift off." The trunk and pelvis rotate anteriorly while femurs, shanks, and feet remain stationary.
2. Momentum transfer is "lift off" to maximum ankle dorsiflexion. The center of mass moves anteriorly and upward.
3. Extension begins just after maximum ankle dorsiflexion and ends when the hips cease to extend.
4. Stabilization begins when the hips cease to extend and finishes when all motion associated with rising is complete—although the end point is not easy to define.

Some patients have difficulty with the momentum transfer phase because of lack of explosive power in the knee extensors. In this case, strength training of knee extensors combined with practicing "sit to stand" from an initial hip flexion angle of 120 degrees, and gradually reducing this to 90 degrees, is frequently used. Other aspects of functional mobility, such as transfers, gait and stair-climbing, are addressed through movement analysis.

In combination with specific techniques, opportunities are taken throughout the day to ensure that a conducive rehabilitation environment surrounds the patient. For example, the use of a perching stool (a high stool with slight downward slope to the seat) while shaving has the advantage over a standard chair of encouraging weight-bearing through the lower limbs.

A predischarge home visit identifies the potential risks that may cause the patient to fall. Such environmental hazards might include inappropriate heights of beds and chairs, loose or ill-fitting footwear, loose rugs, and slippery floor surfaces.⁹⁵ Of course it is not always possible to eliminate such hazards, so therapists need to respect the autonomy of patients and caregivers in making their own decisions—and remove, replace or modify any environmental hazards only with the person's consent.⁹⁶ At the very least, the therapist's role is to raise awareness of potential hazards and to teach patients and their caregivers the appropriate strategies to avoid them.

Other therapies designed to prevent further falls include^{96–98}:

- Balance retraining (e.g., standing balance exercises in front of a mirror progressing through different feet positions, correction of a tendency to fall backwards (by applying pressure to the front of the body), and ADL practice)
- Strengthening lower limb muscles
- Increasing flexibility of the trunk and lower limbs
- Providing mobility aids and appliances
- Raising awareness of unhelpful strategies adopted to avoid a fall (e.g., fixation on the target and therefore being unaware of environmental changes on the way, and tensing muscles to avoid falling (the "walking on ice" strategy), which does not allow for subtle postural adjustments).

Further falls do happen, nevertheless, so it is useful to teach methods of rising from the floor. The conventional method is to help the person on to the floor and then teach him or her how to get on to the knees, so that the person is in a position to rise by pulling on available furniture. An alternative method is to use backward chaining of the task (i.e., first teach the ability to achieve the last component of the task successfully, and then to work successively backwards through the preceding components so that eventually the person is able to stand up independently when placed on the floor.^{99,100} It is also possible to teach methods of summoning help, moving about, and keeping warm while on the floor.

Fear of falling is a problem for elderly people—they perceive themselves to be at risk of falling, and then they anticipate adverse consequences of doing so.¹⁰¹ Fear of falling may negate any gains made through rehabilitation¹⁰² and therefore is a major focus of therapy intervention. This may be resolved by graded exposure to a hierarchy of anxiety-provoking situations agreed by the patient and therapist—starting with the situation least feared until fear is reduced and confidence increased, then moving on to the next situation in the hierarchy. Relaxation techniques may be used as an adjunct to therapy.⁹⁸

Parkinson's disease

As Parkinson's disease is a progressive condition, it is clear that therapy techniques will alter as a patient's disability changes. For example, patients with mild disability might receive a preventative exercise program and counseling, while those with severe disability might receive respiratory exercises and assistive devices.¹⁰³ A range of specific techniques suitable for people with Parkinson's disease is described in this section, but it is important to appreciate that these will be modified for individual patients depending on factors such as cognitive impairment, medication, and secondary changes in musculoskeletal and cardiovascular systems.¹⁰⁴

Early in the disease, interventions might be aimed at maximizing trunk and pelvic range of movement and strength. Interventions are focused on stretching and strengthening the trunk and pelvic muscles,^{102,103,106} rhythmic walking, turning, and maintaining the length of flexor muscle groups. Particular techniques may include the therapist resisting the patient walking forward by placing hands on the patient's pelvis at the anterior superior iliac spines.¹⁰⁵ Group exercise to music is frequently encouraged with warm-up, aerobic conditioning, and cool-down sections to each session. One paper describing such exercise groups reported that participants exercised initially at 65% of their maximum heart rate and this was increased by 5% every 4 weeks over a 12-week exercise period. Participants were actively discouraged from exceeding 85% of their maximum heart rate.¹⁰⁷

Functional mobility

As disability becomes more pronounced, other therapy techniques are incorporated into treatment. Techniques to improve functional mobility "are based on the assumption that normal movement can be obtained by teaching strategies to avoid the basal ganglia pathology."¹⁰³

External cues can be visual, auditory, or sensory.¹⁰⁸ An example of the use of visual cues to aid mobility exercises would be placement of colored objects in boxes positioned at different levels on the side opposite to the active upper

limb, to encourage trunk rotation.¹⁰⁹ Auditory cues include a metronome and music with a steady beat to increase temporal spatial parameters of gait, such as stride length and velocity.¹⁰⁸ Sensory cues might include repetitive movement alternatively to left and right, to initiate walking in those with gait initiation difficulty.¹¹⁰

Internally generated cues have also been given, such as training patients to concentrate on heel strike so that the foot is lifted from the ground and bigger steps are taken,^{111,112} and counting while walking.¹¹² Interventions can increase awareness of abnormal posture and how to correct it by using a mirror and feedback from the therapist during gait training.¹⁰³

Attentional strategies can be taught. For example, when turning consciously think of a clock and place feet at specific points on the clock face to ensure larger steps and turning circle. Other attentional strategies include asking the patient to focus on the point in the movement where difficulty begins and then beginning retraining activity. Specific retraining strategies are teaching people to walk with larger steps, encouraging them to lean forward when standing up, and promoting participation in everyday physical activity.

Cognitive strategies include mental rehearsal and visualization, and patients can be advised to concentrate on one task at a time so that available cognitive resources are used to “control” the required task, rather than relying on subcortical movement control mechanisms. Mental rehearsal involves patients thinking through the steps of a task before performing it. This may also include prior visualization, so that patients imagine themselves performing the activity before they physically attempt it.

One can change the form of the task. For example, patients can be taught to turn in a larger circle to avoid smaller and smaller steps and falls, and break down complex sequences of movement tasks into simpler components.

A recent therapy approach is based on the principle of improving functional mobility directly by repetitive practice. One example is treadmill training with partial body weight support¹¹³ (as outlined above in the section on techniques used with people who have had a stroke). Another is practicing the components of walking on one spot.¹⁰³ It has been proposed that the current approach to therapy might change if further evidence emerges to support the finding that older people with Parkinson’s disease (Hoehn and Yahr stages II and III) can improve the performance of movement following repetitive practice.¹¹⁴

In addition to the techniques used to improve the movement required for functional mobility, therapists also apply techniques to improve facial mobility. Techniques include brushing muscles, applying ice to muscles, and asking patients to blow through a straw.¹¹⁵

Therapists also use specific techniques aimed at limiting the effects of immobility, social isolation, and psychological withdrawal—so-called “secondary disability.”²⁰ Depression is frequently encountered especially as mobility and communication skills decline. Group therapy provides a safe supportive environment in which to practice several types of skills.²⁰ For example, an integrated physical and occupational therapy rehabilitation program has been described that consists of 69 repetitive exercises to improve range of motion, endurance, balance and gait, and fine motor dexterity. These exercises were provided for 1 hour, three times a

week, for 4 consecutive weeks.¹¹⁶ Such a group activity has clear opportunities for communication practice and enables therapists to identify difficulties that might be alleviated by the provision of a word chart or communication device. A speech and language therapist should ideally be involved in such group activities.

Of course there are times when compensatory strategies are appropriate. Compensatory strategies to enable “sit to stand” include: training the patient to stand up by placing hands on the armrests of the chair and by edging to the front of the seat before beginning to rise; and raising the seat height of the chair. Changes to the environment might also be needed¹⁰⁴ similar to those outlined already. Assistive devices can be supplied, such as elastic shoelaces and the replacement of small fasteners with Velcro.

Environmental changes

Eating is often a particular problem and therapists advise the use of plate warmers to keep food hot. Other useful devices include enlarged handles on utensils (weighted to dampen tremor), and use of a Dycem mat under the plate to improve stability. Sometimes raising the table to a height at which the patient can use one elbow as a pivot can enhance control during eating.

Other simple changes can be made to the environment to ensure that the patient is able to continue with desired activities. For example, place all of the most frequently used kitchen ingredients on one shelf to avoid unnecessary stretching and bending, and/or use a kitchen trolley, which improves the walking pattern, increases stability, and reduces energy expenditure. There are a number of devices available to help, such as an electric tin-opener and teapot tipper.

Educating the caregivers

As in many other areas of geriatric rehabilitation, an important focus of therapy is educating the caregiver. Caregivers need to be advised that, although it may appear easier to carry out the task for the person, it is in fact kinder and indeed more therapeutic to let him or her struggle (within reason) with the task. This helps avoid inactivity and reduced self-esteem. Therapists work with caregivers and patients to set a hierarchy of tasks that should be done for the patient and those that the patients should do themselves. As the disease progresses, caregivers require training on positioning, moving, and handling. Specialist equipment might be needed such as a hospital bed, hoist, and/or wheelchair. Therapists work closely with patients and caregivers to ensure a best match of therapeutic interventions to abilities, needs, and the environment.

Frailty

In this chapter we shall use the definition of frailty proposed by Campbell and Buchner: “a condition or syndrome which results from a multi-system reduction in reserve capacity to the extent that a number of physiological systems are close to, or past, the threshold of symptomatic clinical failure.”¹¹⁷ The components of frailty appropriate for restorative therapy techniques are musculoskeletal function and aerobic capacity, which might interact with an adverse environment to result in difficulty with mobility, personal care, and social interaction.¹¹⁸ Therapists are also involved in the prevention of decline in the mobility and daily activities of elderly

people, and consider it important to maintain function at the highest level possible, especially during periods of acute inpatient hospital care.¹¹⁹ The detrimental effects of immobility are well recognized and even a relatively brief period of nonuse of a limb or a limb segment can lead to muscle atrophy and shortening.¹²⁰

People who are frail are clearly at risk from falls, immobility, and social isolation. The specific therapy techniques to address these problems have been outlined in previous sections. This present section will therefore concentrate on techniques to improve the mobility and daily activity of frail elderly people. Many of these techniques are contained within exercise programs to improve mobility of joints and body segments, stability in weight-bearing postures, and control of functional movement.^{118,121–129}

Exercise programs

Knee contracture might be helped by therapist-provided low-load prolonged stretch to increase knee extension while the patient lies supine, and then maintaining the extended position using foam roll or wedges under the knee before strapping the knee into the position on the supporting surface.¹²⁹

Exercises can be designed to move each joint passively through its full range of movement.¹²² Progression is effected through a program of active exercises by patients to produce voluntary movement through a full range of joint movement,^{122,124,125} and when appropriate resistance to movement is provided.^{122,125} Resistance can come from the patient's own body weight,¹²⁷ arm pulleys,¹³⁰ external weights,^{128,130} and Thera-band (a color-coded series of different resistive strength latex rubber, which can be cut to the required length for individual patients).^{122,125,127,130} Resistive exercises are often provided for muscle groups, such as knee extensors, hip flexors, and deltoid and biceps brachii concentrically and eccentrically.^{130,131} Some therapists also promote the use of resistance to movement, which is required for functional ability.^{127,128} An isokinetic exercise system might be used to provide progressive resistance to the lower limb movement required during walking,¹²⁶ as might an exercise bike.¹³⁰

An appropriate sized gymnastic ball^{132–134} can be used by frail elderly people in sitting or standing, and the automatic responses stimulated by the ball's inherent stability can be used to improve dynamic balance. The attending therapist provides stability or instability as appropriate. To increase stability of the ball to enable elderly people to gain confidence in its use, it can be placed inside a cuff positioned on the floor to encircle the ball.¹³³

There may be a need for functional training of tasks, such as transfers, walking, wheelchair propulsion, and personal care.¹²² The biomechanical approach to analysis and remediation is usually followed as set out in the previous section on "Fractured Neck of Femur Following a Fall." The current trend seems to be toward use of assistive devices such as treadmill retraining of gait with partial body weight support.¹³⁵

The techniques mentioned above are not applied in isolation and delivery is often in the form of group exercise to music. Schedules for these groups vary but include a selection of warm-up exercises, conditioning exercises (aerobic, balance, hand-eye coordination, hand-foot coordination, strengthening), a stretching period, functional

exercises (walking, seated exercise to stretch trunk, chair rising, stair ascent and descent), and a relaxation/cool-down period.^{136–138} Although exercise programs are frequently recommended, it is important to appreciate that frail elderly people may lack confidence in their ability to undertake exercise. Therapists therefore have to balance this lack of confidence with providing an exercise program that is sufficiently challenging to produce functional improvements quickly to motivate continuation.¹³⁹

Exercise programs frequently provide a forum for the provision of information on exercise, safety in the home (set out in the earlier "Fractured Neck of Femur Following a Fall" section), and foot care. Footwear has been shown to affect performance of functional activities^{140,141} and is addressed specifically in treatment programs.^{124,142} Finlay¹⁴² gives examples of dangerous footwear, including a shoe with excessive wear on the medial border thus "forcing" the foot into an everted position. Therapists provide information to patients and caregivers about the preferred shoe, avoiding in particular excessive heel height and using nonslip soles. It is sometimes necessary to refer to an orthotist for special footwear and/or to a podiatrist for special foot care; this is particularly important in diabetic patients. In addition the exercise classes, allow the therapist to assess the need for, and current condition of, assistive devices such as walking aids, wheelchairs, dressing aids, and hoists.¹⁴³ It is not uncommon for therapists to find patients using unsafe equipment or equipment in need of repair. Other areas of daily life may also benefit from a technology assessment and subsequent provision of appropriate assistive devices.

Cognitive impairment does not preclude the provision of therapy. However, the therapist must be adaptable and flexible.^{144,145} Exercise programs involving treadmills, bicycles, and weight-lifting have all been used with frail elderly people with cognitive impairment.¹⁴⁶

The environment

Good seating is important for elderly people. It helps to maintain mobility if it is easy to get in and out of the chair. It facilitates communication and social interaction if the chair is orientated in a room appropriately. A good chair can prevent or reduce postural pain and promote comfort and security—and thus reduce agitation. The chair can enable adequate nutrition and hydration, and maximize respiratory function through adequate postural support. Therapists consider the following important features of chairs.¹⁴⁷

- The seat depth should be adequate to support the thighs while leaving about 5 cm behind the knees to avoid compression of the popliteal fossae, which would impair circulation and the nervous system.
- The seat should be wide enough to prevent compression of tissues but allow the sitter to use the armrests for support.
- The seat height should be at least equal to the floor-to-knee height of the user, to make it easier to stand up and sit down.
- The back rest should support the whole of the back, preferably with contoured spinal curve support.
- The seat-to-back angle should be 95 degrees ideally.
- The armrests should be level with the patient's elbow and as long as the seat depth.

Therapists can provide individualized cushioning to adapt chairs,^{147,148} including pressure-relief cushions. It is very important for each patient to have more than one chair in which to sit because it is not normal to sit in one position or in one chair for long periods.

Also important for frail elderly people is the promotion of personal energy conservation. Organization of the environment can make best use of a person's abilities. For example, gather all garments before attempting to dress, dress all the lower half at once, reduce the difficulty of fastenings by applying Velcro, and reduce the burden of full weight-bearing by using a perching stool during kitchen activities.

FUTURE DIRECTIONS

The rapid expansion of rehabilitation doctorates, academic posts, and research output^{10,149} is indicative of the increasing commitment of the therapy professions to base their practice on evidence. Therapists are now more critical of the methodology and rationale that governs their practice. As the research culture grows, therapists will test conventional techniques for their purported effects and implement those found to be most effective. Future innovations in therapy should therefore be based on research evidence in addition to clinical impressions.¹⁵⁰

A recent U.K. Medical Research Council document¹⁵¹ provides an excellent basis for a research strategy in geriatric rehabilitation, highlighting the need for systematic investigation of techniques, and combinations of techniques, in both exploratory and definitive clinical trials. However, in the present climate of a rapidly developing rehabilitation research base, it remains essential to remember that clinical evidence outside of formal research studies can also be an important source of information. Moreover, not all experimental evidence reaches peer-reviewed journals. Trials with positive results are still deemed to be more attractive by publishers and the inconclusive or negative trials are less

likely to be published. Therefore the evidence base might actually be evidenced-biased.¹⁵²

Expert opinion in the absence of scientific evidence has an important part to play in the rehabilitation process. Indeed, it is imperative that we do not throw away years of clinical judgment, especially in an area of rehabilitation as complex as elderly care. Specialist multidisciplinary groups such as SRR (Society for Research in Rehabilitation) and profession-specific bodies including OCTEP (Occupational Therapy for Elderly People) and AGILE (chartered physiotherapists working with older people) are essential networks from which future developments in elderly rehabilitation will flourish.

KEY POINTS

Rehabilitation Techniques

- Rehabilitation consists of a complex package of techniques delivered by a multiprofessional team and involving the active participation of patients and caregivers. It makes an important contribution to maintaining independence and quality of life of elderly people.
- To reduce the complexity of description, this chapter uses some of the techniques used by occupational therapists and physiotherapists as exemplars to illustrate the range of possibilities within the package.
- Although techniques are described here within sections of stroke, fractured neck of femur following a fall, Parkinson's disease, and frailty, these techniques are often used in different combinations to meet the complex needs of elderly people.
- The research culture in the therapy professions is growing fast as more therapists obtain doctorates and pursue research into the most effective techniques to maintain the independence of elderly people.

Rehabilitation: General Principles

John Young

Rehabilitation, always at the heart of geriatric medicine, has a rich heritage that dates back in the United Kingdom to early pioneers such as Sheldon, Warren, and Adams. Their contributions were based on systematic observations, on common sense, and on simple principles, which we would still recognize today as central to the process of rehabilitation. In our modern health services, practitioners are nervous when challenged to justify the effectiveness of rehabilitation. Early evidence of the potential of rehabilitation in the United Kingdom was provided by Warren with the unblocking of chronic sick beds to such an extent that whole wards could be permanently closed. In one of her several inspiring papers, Warren described the factors that had led to her success.¹ They included taking a positive approach, the importance of individual patient assessment and patient involvement, team-working, and the concept of promoting independence by optimizing the patient's environment and by special and general therapeutic techniques. Contemporary evidence of the continued success of these core processes of rehabilitation comes from a recent meta-analysis,² demonstrating the superior effectiveness of "comprehensive geriatric assessment"—clearly a reassuring finding in the current climate of evidence-based practice. A more consistent application of the "Marjorie Warren" process across our contemporary medical and surgical wards, and in the community, would make a major contribution to the health of older patients. Indeed, it seems frustrating and perplexing that there has been a resistance to applying established rehabilitation concepts beyond elderly care departments. This has now been recognized in the United Kingdom and has stimulated the National Service Framework for Older People.³

This chapter describes the core principles of rehabilitation practice, and their underlying evidence-base. Additional detail for the specific rehabilitation techniques is also provided in this Chapter. Although the core principles of rehabilitation are generalizable to various health care settings in different countries, this chapter adopts a largely U.K. perspective. Chapter 123 provides a description of the rehabilitation services in the United States.

DEFINITIONS OF REHABILITATION

Several definitions and explanations of rehabilitation have been proposed. Although the similarities between the definitions are considerable, the perceived diversity of view has contributed to a confusion over the purpose and process of rehabilitation. This apparent ambiguity, and the intangible qualities of rehabilitation, have been in contrast to the concrete "ologies" of contemporary organ-based medicine and has contributed to the vulnerability of rehabilitation in some hospital-based services. Some general definitions of rehabilitation include:

- "Rehabilitation comprises re-ablement—the acquisition of skills needed for independent life-and-re-settlement, the restoration of the person to his (or her) own or to another environment."⁴

- "[Rehabilitation is the] restoration of the individual to his (or her) fullest physical, mental and social capability."⁵
- "[Rehabilitation is the] combined and co-ordinated use of medical, social, education, and vocation measures for training and retraining the individual to the highest level of functional ability."⁶
- "The primary objective of rehabilitation involves restoration (to the maximum degree possible) of either a function (physical or mental) or a role (within the family, social network or workforce)."⁷
- "Rehabilitation is a problem-solving and educational process aimed at reducing the disability and handicap experienced by someone as a result of disease, always within the limitations imposed both by the available resources and by the underlying disease."⁸
- "The primary objective of rehabilitation is to seek a role which is appropriate to the personality, functional ability and social position of the patient in the light of a realistic assessment of his (or her) functional prognosis; and to seek his (or her) co-operation and that of the professionals complementary to medicine in achieving this aim."⁹

Isaacs is one of the few authors to suggest what rehabilitation is not: "The aim of rehabilitation is not (although it is often assumed to be) the attainment of an objective appropriate to the needs of the service (i.e., an early discharge of the patient from hospital)."⁹

One common thread within these definitions appears to be a focus on restoration of function. However, frequently used terminology in elderly care distinguishes between active and maintenance rehabilitation. The former implies an expectation of improvement in function; and the latter, an expectation of prevention of deterioration where restoration does not readily apply.

The concept of frailty is a further complexity for an understanding of rehabilitation in respect of elderly people. Frailty is regarded as a disease- or age-related loss of physiologic reserve such that minor stress events result in disproportionate functional consequences. This has led to the notion of unstable disability,¹⁰ characterized by the marked fluctuations in functional abilities that are familiar to professionals working with "old-elderly" people.

In these definitions of rehabilitation, value judgment words such as "fullest" or "optimal" are used. This begs the question of whether results are being judged from the perspective of the doctor, the nurse, the therapist, or perhaps the patient or caregiver. In stroke, for example, a "good recovery" as far as the therapy team is concerned relates to the maximum impairment at stroke onset as the baseline against which recovery is judged. For the patient, however, the baseline is the prestroke lifestyle.¹¹ A patient with a fractured neck of femur may not share the notion of a "successful" home discharge when returning to the prospect of a living room commode. Such ambiguities of perspective,

commonly unvoiced, can smolder and lie at the heart of disability adjustment difficulties.

As with many complex issues, it is often rewarding to return to the beginning. Rehabilitation in the United Kingdom, at least for older people, emerged as a remedy for aged incurables: the bedridden chronic sick who languished in the Poor Law workhouses. The process was a holistic one in which the central theme was careful individual assessment "both for the establishment of a correct diagnosis and for full treatment" which was to be "undertaken by a (rehabilitation) team."¹¹ The novelty lay in its emphasis on function—not of a body part (for example, surgical revascularization to preserve a limb), but at the level of the whole person set in the context of his or her personal circumstances: family, social, and home environment.

A further important distinction between rehabilitation and other health interventions is that patients are not the passive recipients of a treatment. Rather, rehabilitation is a highly energetic process in which the patient struggles against his or her disability with guidance from a rehabilitation team. The process is characterized by active, positive, and planned actions taken with the patient working at the extremes of physical and functional capabilities.

OLDER AGE AND REHABILITATION NEED

Between 7% and 10% of the world population are significantly affected by disablement, defined as the limiting consequences of chronic health conditions.¹² Disablement affects persons of all ages but there is a strong association between older age and disablement so that most disability occurs in later life. The Office of Population Censuses and Surveys (OPCS) in the United Kingdom reported a near doubling of disability prevalence rates with each 10-year increment in age, from 7% of those aged 40 to 49, to 68% for those aged 80 and above.¹³ This most recent OPCS report caused a considerable upward revision in the estimated numbers of disabled people living in the United Kingdom. The figure now stands at more than 6 million and represents a substantial increase from the previous estimate of just more than 3 million. The recent survey used a more realistic and broader operational definition of disability, which took better account of restriction of function, and was therefore more reliable in the assessment of disability consequences for conditions such as arthritis and cardiorespiratory disease, which commonly affect locomotor function. For people in private households, arthritis is the commonest cause of disability, accounting for 48% of disability. It is second only to cognitive impairment in the disabling disorders seen in institutional care residents.

As far as older people in the United Kingdom are concerned, an estimated 4.3 million people over 60 years are disabled; this represents 70% of all disabled people and 46% of all older people. Most (more than 90%) older disabled people live in their own homes, and most (more than 80%) have only "mild" disability, but many have several types of disability. Indeed, these self-reported disability categories are more diverse than often appreciated (Table 103B-1) and have resource implications across nearly all health and social service departments. In the United Kingdom, people aged over 65 years constitute 14% of the population but consume nearly half of health¹⁴ and social service¹⁵ expenditure, and this is expected to rise by 3% a year.¹⁶

General disability surveys, and disease-specific epidemiologic surveys, provide quantitative information that is important for indicating the scale of disablement, and are valuable for service planning purposes. However, they provide little insight into the experience of disablement for the sufferer. This more human dimension to disablement requires qualitative research methods. Mildred Blaxter's work remains exemplary because of its rigor and clarity, and because it was a longitudinal observation of patients at several points through what Blaxter termed their "career in disability."¹⁷ The study followed 194 people after discharge from the hospital with new-onset disability. What emerged was a fairly universal feeling of intense frustration and unnecessary hardship experienced by these people. Blaxter demonstrated how the disabled person could be surrounded by a bewildering array of potentially helpful professions and agencies who lacked visibility, coordination, or an identifiable structure. This resulted in confusion for patients and caregivers and a consequent failure to access services. Blaxter demonstrated how interventions (for example, equipment provision) often occurred more by chance or as a result of the ruthless determination by a patient or caregiver than by the consequence of service engagement. In the succeeding quarter century, despite frequent changes and reorganizations, the experience of being old and disabled all too often remains one of frustration. A recent King's Fund review described the pressing requirements for an effective rehabilitation system most of which would be judged as disappointingly basic.¹⁸ The consequence of disability continues to be that of multiple waiting lists with poorly coordinated services.¹⁹ A person may wait separately and sequentially for a wheelchair assessment, and for wheelchair delivery, and then experience more waiting for an access ramp.²⁰ There is no reason to expect that matters are better organized in many other countries.

PREVENTION OF DISABLEMENT

"Prevention is better than cure" is a familiar adage. But can disability be prevented in older people? This is an attractive notion to currently independent middle-aged and older people and to service funders (largely taxpayers) struggling to meet the steadily rising health and social care expenditure for age-related disability. Almost certainly much more could be done to minimize the disabling consequences of disease in elderly people: firstly, by better disease prevention, much of which could be quite simple (e.g., improved hypertension

management to reduce stroke incidence);²¹ and secondly, by more widespread implementation of rehabilitation procedures and systems of proven effectiveness.²² Beyond the wider implementation of best clinical practices lies the issue of primary disability prevention.

The first step in tackling primary disability prevention/limitation is a more profound understanding of proximal factors, particularly teasing out directional relationships (e.g., does depression predispose the physical disability, or does physical disability generate sufficient misery to trigger depression?). Cross-sectional studies are cheap (and therefore plentiful) but are limited by cohort effects and by ambiguous directional inferences. Longitudinal studies are complex and expensive (and therefore scarce) but allow baseline factors to be examined against future events, thereby more precisely locating cause and effect.

A recent systematic review brought together several longitudinal observational studies in which functional decline was the main outcome measure.²³ The synthesis was carried out carefully, with transparent solutions to the testing problems of quality assessment and results formulation across diverse studies. The findings are interesting. First, a big surprise was the number of studies identified (78). The big disappointment was the meager contribution from Europe (United Kingdom, 2 studies; other European countries, 10 studies). The lion's share came from the United States (62, and hugely larger sample sizes). The review findings are largely comfortable in that they support rather than contest established thinking. The baseline risk factors associated with subsequent functional status decline in older people were: cognitive impairment; depression; disease burden (comorbidity); increased and decreased body mass index; lower-extremity functional limitation; low frequency of social contacts; low level of physical activity; no alcohol use compared with moderate use; poor self-perceived health; smoking; and vision impairment. Such observational relationships do not necessarily imply that risk factor modification will translate into desired disability reduction; only randomized controlled intervention trials can reliably establish this. Falls prevention/exercise programs have progressed to this level of evidence, even for frail older people,²⁴ and the solid paradigm relating exercise to disability prevention/limitation should encourage action from practitioners and service providers.

On a wider, population scale, is there evidence of a reducing burden of disability? One aspect is the thesis of compression of morbidity: people living longer but with a shorter phase of late-life physical and/or mental decline.²⁵ Some evidence is now available to support this thesis, with reports that older people have improved health reflecting a legacy of better childhood nutrition, less exposure to infection, and more education.²⁶ However, the evidence is far from substantial, and the relative contributions of genetic factors, environmental lifestyle, and socioeconomic factors remain to be unraveled.

POLICY FRAMEWORK FOR REHABILITATION SERVICES FOR ELDERLY PEOPLE IN THE UNITED KINGDOM

Health care policy is the mechanism by which local and national authorities can encourage a desired outcome from a service or services. It has been a crude and clumsy tool for

rehabilitation. Rehabilitation relies heavily on culture ("the way we do things around here") and interprofessional and interagency relationships as key organizational attributes; none of which is easily orchestrated. Moreover, squabbles have broken out concerning cost-shifting (for example, faster hospital discharges have represented a cost burden to social services). And distracting, mundane arguments have occurred (for example, the differentiation of a "health" from a "social" bath). A special difficulty has been the entanglement of rehabilitation with long-term care.

The bedrock of evidence-based medicine as a foundation of clinical practice has led to demands for a similar standard of evidence-based health care policy.²⁷ Unfortunately, much policy remains opinion-driven, largely because of the short time scale of the political cycle that imposes a demand for visible changes. There is therefore a temptation for large-scale reforms rather than incremental learning from restricted pilot schemes. Moreover, there is a further temptation to avoid commissioning research for the fear that the findings might prove an embarrassment.²⁸ Much of recent health care strategy for rehabilitation of older people is opinion-driven.

The NHS and Community Care Act

The 1980s witnessed a rapid expansion in private institutional care, fueled by the easy availability of social security payments, which were related to expressed rather than to assessed need.²⁹ This represented an easy option for hard-pressed hospitals that readily grasped an exit solution for "bed blockers" and with it an associated loss of impetus to maintain, let alone improve, the rehabilitation component of acute care. Expenditure increased dramatically and prompted the NHS and Community Care Act (1990), which was implemented in 1993. The Act required systematic needs assessment and case management, and made long-term care funding cost-limited. Local authority social services departments became the lead agency, resulting in fundamental changes to the traditional social worker role: it changed from that of adviser and counselor to one of a resource manager. However, the die was cast and insidious rehabilitation decline continued within acute hospitals.

The strategic shift of continuing care for elderly people from (free) NHS to (means-tested) social services was not to change. Rather too late it was recognized that this strategic shift had been too extreme and a readjustment was attempted in the form of a "guidance" document from the Department of Health to health authorities.³⁰ Somewhat ambitiously, the "guidance" set out a clarification of continuing care in the much wider context of a respecification of all the services expected from the NHS for older people. The range of services was to embrace rehabilitation, continuing, palliative and respite care, community services and even special transport. However, no new money accompanied the initiative and implementation required disinvestment from elsewhere.³¹ In terms of political priorities in the NHS, little could compete with the obsession with the surgical waiting list, and, as a result, little changed.

"The coming of age: improving care services for older people"

In this influential report, the Audit Commission took stock and emphasized the accumulated damage to rehabilitation services.³² It was estimated that, in the 5 years 1989/90 to

1994/95, the average length of stay in elderly care in the hospital fell by 45%—from 36 to 20 days. Opportunities for recovery and rehabilitation therefore had probably diminished and there was a recognition that hospital provision of rehabilitation for older people was foundering.²² Moreover, there had been no compensatory increase in community-based rehabilitation. Rather, the notion of a “vicious cycle of care” was promoted in which lack of community rehabilitation services stimulated increasing demand for hospital admission. There was an associated earlier discharge of incompletely recovered people; and this drove higher requirements for expensive residential and nursing home care. It was clear that the “magic remedy”—rehabilitation—had withered in the hospital sector and had atrophied in the community.

“Not because they are old”

This was a critical report from the Health Advisory Service concerning the care of elderly people in 16 randomly selected acute hospitals across the United Kingdom (sample size: 71 patients; 59 relatives; 305 staff).³³ Although the methods used were far from robust, the report was influential because it drew upon the prevailing concerns about hospital services and was a further stimulus to the urgent formulation of the National Service Framework for Older People. The survey identified that basic deficiencies in care were jeopardizing effective recovery and rehabilitation of elderly people. The physical environment of the wards was often poor, access to basic rehabilitation equipment such as chairs was chaotic, privacy and dignity for the patients was not sufficiently respected, and staff training was a low priority.

National Beds Enquiry

A succession of politically embarrassing winter NHS bed crises prompted the Department of Health to commission the National Beds Enquiry.³⁴ This laid out facts that were already well known.³⁵ Pressures caused by year-on-year rising emergency admissions³⁶ and cost-driven bed closures had necessitated steadily reducing lengths of stay³²; and rehabilitation, as a less visible component of care, had tended to become squeezed out.²²

The National Beds Enquiry offered three possible scenarios to improve future service provision. The first option was essentially a status quo with a slight rise in bed capacity in the acute sector and moderate expansion of the primary and community care services. The second option was a larger expansion of the hospital sector with rehabilitation being predominantly provided in hospital settings. The third option, “care closer to home,” was an active expansion and development of community health and social services into a new critical mass sufficient to address avoidable hospital admissions.

Although this was a consultative report, the Health Secretary signaled his preference strongly in favor of the third scenario and it has become accepted as the current health care policy for rehabilitation.³⁷

A primary care-led NHS

The current strategic policy framework for older people, including rehabilitation, is located within a primary care-led NHS reflected in the new structure of the Primary Care Group/Trust (PCG/T).³⁸ The PCG/T is expected

Table 103B-2. Examples of Intermediate Care Services

to have a strategic role in the planning, purchasing, and commissioning of a broad range of services. General practitioners, therefore, will be increasingly held responsible for local health services. Each PCG/T is intended to serve up to 100,000 patients, many of whom will be elderly and disabled and using resources disproportionately. A potential weakness is that most general practitioners have never worked in an elderly care department,³⁹ and so their perceptions of service need may be influenced by the considerable demands made upon primary care from the private nursing and residential care home sector.⁴⁰ Moreover, and encouraged by the limited public appeal of low technology health interventions,⁴¹ rehabilitation may again become a tempting target for financial cuts.

On the other hand, there are genuine opportunities for rehabilitation contained within the PCG/T and a primary care-led NHS. One obvious possibility is the development of locality-based rehabilitation teams working within the PCG. Such an approach would maximize the opportunities for rehabilitation at various points in the overall system of health and social care, and at various times in the “career” of older people with disability. Such an initiative would need careful coordination and implementation strategy by health authorities as part of their Health Improvement Programmes (HIMPs).

Intermediate care services

Clarity for a fresh strategic approach to rehabilitation for older people has consequently gradually emerged. It has been summarized using the umbrella term “intermediate care.” The concept of intermediate care is therefore the final product of a policy cycle encompassing the last 1 to 2 decades.

Definitions of intermediate care have moved from the conceptual⁴² to the prescriptive⁴³ (see box on Conceptual Definition of Intermediate Care), the shift reflecting genuine experience and learning.⁴⁴ Examples of intermediate care (Table 103B-2) are, at first glance, comfortably familiar. For example, both the geriatric day hospital and the community hospital have long pedigrees. Rehabilitation in social settings such as residential care homes, however, is less familiar and is a recent development. This form of intermediate care was introduced partly as a response to the irritation felt by some social service departments forced into the position of taking older people discharged prematurely from acute wards. It was considered necessary to fill the rehabilitation gap created by inadequate health service provisions. However, these social service solutions to unmet rehabilitation need have now been put on a more collaborative and

Conceptual Definition of Intermediate Care

That range of services designed to facilitate transition from the hospital, and from medical independence to functional independence, where the objects of care are not primarily medical, the patient's discharge destination is anticipated, and a clinical outcome of recovery (or restoration of health) is desired.⁴²

Prescriptive Definition of Intermediate Care

Intermediate care should be regarded as describing services that meet all the following criteria:

- Targeted at people who would otherwise face unnecessarily prolonged hospital stays or inappropriate admission to acute inpatient care, long-term residential care, or continuing NHS inpatient care
- Provided on the basis of a comprehensive assessment, resulting in a structured individual care plan that involves active therapy, treatment and opportunity for recovery
- Having a planned outcome of maximizing independence and typically enabling patients/users to resume living at home
- Time-limited, normally no longer than 6 weeks, and frequently as little as 1–2 weeks or less
- Involving cross-professional working, with a single assessment framework, single professional records and shared protocols. (Based on Health Service Circular, 2001)⁴³

consultative footing within the framework of Joint Investment Plans (JIPs).³⁸ Indeed, JIPs provide insight into the real novelty of intermediate care services. They are not about the relaunching of old style services. There is an expectation that intermediate care services will become a platform to incorporate new patterns of working and new professional relationships both between disciplines and between agencies. It is an attempt to impose a strategic structure in the hitherto chaotic area of community care characterized by competing demands, conflicting pressures, and resource rationing. Unlike earlier community care initiatives, this one comes with a promised injection of resources, and on a large scale: \$1.3 billion (£900 million) by 2003/04.³⁷ At present, however, the United Kingdom-wide implementation of intermediate care is a political initiative. The involvement of geriatricians is ambiguous and the PCG/T, as the lead agency to develop intermediate care services, is still relatively immature.

The concept of intermediate care has not been universally well received by U.K. elderly care specialists.⁴⁵ However, the British Geriatrics Society has recommended that geriatricians should become involved with the planning and delivery of these services.⁴⁶ This implies a greater commitment from geriatricians to community working in the future.⁴⁷ In some areas, the medical input to intermediate care services will be discharged by a community geriatrician,⁴⁸ but at present there is no training program for such a post. There is a wider issue of training as one practical implication of this service reconfiguration will be appropriate preparation of future consultant geriatricians to contribute to intermediate care services.⁴⁹

The program of intermediate care service implementation now has a massive momentum.^{32,38} It is consistent with a primary care-led NHS and the imperative of joint working between health and social services. It has a self-evident role in postacute care for elderly people to complement the scaled-down district general hospital by reinstalling a time-space for rehabilitation and functional recovery. The main concern has been the additional proposed function of intermediate care for admission avoidance: to bypass, or delay access to, specialist district general hospital assessment and investigation facilities. Acute ill-health in elderly people typically presents in an ill-defined way. For example, an older person "found lying on the floor" might have simply rolled out of bed but, alternatively, may have a fractured neck of femur, pneumonia, or heart failure. Admission avoidance could easily become an institutional barrier in the expeditious assessment of sick older people. This worrying aspect of intermediate care has been reflected in its being referred to as "indeterminate care."⁴⁶

UNDERSTANDING DISABILITY

The disablement process

The medical model concerns itself with diseases and their effects on the body. An abnormality of insulin production, release, or receptor binding causes varying degrees of hyperglycemia: the disease of diabetes. During the early stages, this may have no impact on well-being (no symptoms), and indeed the disease may be diagnosed only unexpectedly after a routine screening blood test. Diabetes is, however, an example of a progressive disease and eventually the chronic hyperglycemia will produce symptoms—sometimes, for example, nerve damage resulting in a peripheral neuropathy. At this stage, the person (in medical terminology now a patient) will find some previously routine everyday activities, such as walking to the shops, more difficult. The disease has now impacted on the person's daily life—a process of disablement has occurred, or the person has become disabled.

On this simple level disability is straightforward. However, a precise definition is elusive. Consider the different impact of the disease when the patient lives near to shops, or a similar diabetic patient already restricted by severe knee arthritis. In both cases the new disease of diabetes may have no noticeable additional impact. The disablement process needs therefore to describe how chronic and acute conditions affect specific physical and mental functions, and daily living activities, but also to account for the personal and environmental factors that have the potential to mediate the disablement process.⁵⁰ Thus, the wider context of disability requires us to understand the process as a gap between personal capability and environmental demand. It would appear, therefore, that disability is a relative phenomenon and difficult to capture unequivocally in a simple description.

Consider another patient, a bilateral amputee living in a nursing home. He enjoys socializing, trips out, singing, and placing racing bets by telephone. He is clearly content and has a fulfilled life. Is there a process of disablement here? A further difficulty lies in the origins of the disease process. Disability tends to conjure up an image of physical insult. So how should we regard the restricted life of a person with agoraphobia? And how should we accommodate the degree or quantity of disability? Presumably there is a continuum

from “mild” to “severe.” This implies that some form of objective measure should apply, but should this be based upon an external judgment, or upon the patient’s perception? Obvious inconsistencies arise, when, for example, a patient who is “slightly” disabled from an external “objective” assessment perceives a “severe” disability. Moreover, disability definition may take several forms: legal/administrative; medical; cultural; self-definition. Administrative disability is particularly confusing. A person may be administratively disabled and qualify for a special parking permit, but administratively not disabled and ineligible for the attendance allowance benefit, and disabled by virtue of age (over 75) and eligible for a free television license. The fog surrounding an adequate and agreed definition for disability has been summarized aptly by Townsend:

“Although society may have been sufficiently influenced in the past to seek to adopt scientific measures of disability, so as to admit people to institutions, or regard them as eligible for social security or occupational and social services, these measures may be applied in a distorted way, or may not be applied at all, or may be replaced by more subjective criteria by hard pressed administrators, doctors and others. At the least, there may be important variations between ‘social’ and ‘objective’ assessments of severity of handicap.”⁵¹

The WHO classification

The complexities of disability demand some form of classification map capable of providing a systematic method to describe the disablement process at the level of an individual. This has been the purpose of the International Classification of Impairments, Diseases and Handicap (ICIDH), first published by the World Health Organization in 1980. It is generally regarded as a useful classification framework within which to consider the rehabilitation process. The framework relates illness to four levels: pathology, impairment, disability, and handicap:

- Pathology: the process of damage in an organ or organ system that results in disease
- Impairment: any loss or abnormality of psychological, physiologic, or anatomic structure or function
- Disability: any restriction or lack of ability (resulting from an impairment) to perform an activity in a manner or within a range considered normal
- Handicap: a disadvantage for a certain individual, resulting from an impairment or disability, that limits or prevents his or her fulfillment of a role that would be normal for that individual

The value of this classification in relation to older people is that it prompts the need to uncover a cause (pathology and impairment) for the disability when the person has, for example, a mobility problem; while also prompting examination of the consequences of the disease in functional terms (disability) and in relation to the lifestyle and environment of the individual patient (handicap). Thus a balanced approach is achieved between disease modification (usually drugs or surgery) and maximizing independence (physical treatments, aids, and adaptations). A common misunderstanding is to assume a progressive and proportional relationship between the four levels. The relationships are often discontinuous. For example, cerebral infarcts (pathology) are commonly found on head CT

scans without associated impairments; severe knee osteoarthritis (pathology) may restrict a person to a wheelchair (mobility disability), and necessitate institutional care, but the individual may adjust, develop a new and contented lifestyle, and have a strong sense of purpose and well-being (minimal handicap). The variable relationship between the levels emphasizes the need for individual patient assessments that respectfully the perspective of the patient and close supporters.

Illness or role rehabilitation

To some, the ICIDH classification has represented an over-medicalized model of disability in which disablement is seen as located primarily within the individual.⁵² In the social model of disability, disablement is perceived less as an attribute of a person and more as a set of circumstances, many of which arise from the external environment.⁵³ Handicap is caused by having steps into buildings and not just by difficulty in walking. Within this paradigm, “the disabled elderly” can be considered as a disadvantaged minority group, an argument that forms a component of a larger thesis concerning the social construction of old age.⁵⁴ A continuation of this perspective is to discuss disablement in the language of social discrimination and oppression.⁵⁵ Here, problems are located at the level of an individual but caused through a prevailing unhelpful attitude towards disablement by society as a whole. This underpins arguments for a more inclusive research agenda, which acknowledges more fully that disablement is a personal experience created as much by wider society as by the individual.⁵⁵ The debate over the relative merits of the different models of disability continues,^{52,53,55,56} and it is the intention that both models will be encapsulated in the forthcoming revised version of the ICIDH (see later discussion).

The two competing rehabilitation paradigms—medical and social—translate to an illness (sickness) model and role (person) model. Illness rehabilitation is most apparent when it is tacked on to various medical specialties. Examples are cardiac or pulmonary rehabilitation programs. Although these programs have extended the spectrum of care available to patients, they have not usually been integral to the medical specialty concerned but generally require a purposeful secondary referral. However, it has become increasingly recognized that these disease-specific rehabilitation programs have tangible benefits.^{57–59} The lack of medical enthusiasm engendered by these programs can be located within our contemporary curative medical approach with its emphasis on brief interventions. Unfortunately, complexity appears integral to the effectiveness of rehabilitation programs,⁶⁰ and it is far easier to introduce a novel drug than a novel rehabilitation program.

The revised ICIDH model (ICIDH-2)

The ICIDH has been criticized for its unwieldiness, and for the consequent unreliability of the codes arising from it.^{49,61–63} The original ICIDH included 1009 impairment items, 338 disability items, and 72 handicap items. However, it was designed as a comprehensive classification scheme, not as a measurement instrument in its own right. After 2 decades of use, the ICIDH is undergoing a major revision. The revision is prompted partly by the need for a more profound recognition of the social determinants of disability, and partly to

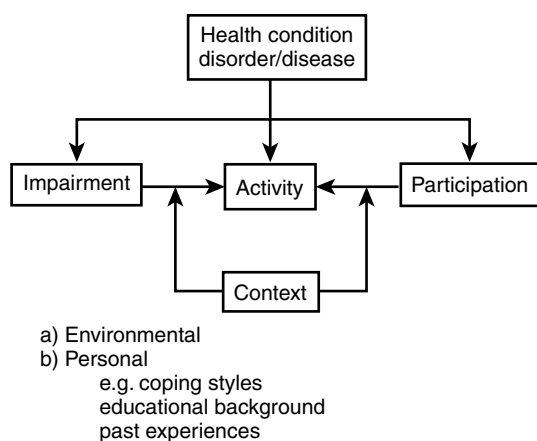

Figure 103B-1. The revised World Health Organization ICIDH model of illness.

reflect a positive description of health rather than the negative description of illness.

The new version, known as ICIDH-2, is described as a multipurpose classification designed to provide a common framework for understanding the dimensions of disablement and function at three different levels: body, person, and society. The wider application is its integration with the International Classification of Disease and it therefore uses a standardized common language permitting communication about health and health care across the world in various disciplines and sciences. Its use therefore goes beyond that of a practical clinical tool—for example, for service planning, policy development, and to progress human rights issues. As such, it attempts much and therefore can be criticized as being too all-embracing and unwieldy for the clinician. The general scheme of ICIDH-2 is given in Figure 103B-1. The definitions of the components of the framework model comprise:

- Impairment: a loss or abnormality of body structure or a physiologic or psychological function
- Activity: the nature and extent of functioning at the level of the person
- Participation: the nature and extent of a person's involvement in a life situation in relation to impairment, activities, health condition, and contextual factors

Activities may be limited in nature, duration, and quality (e.g., taking care of oneself, maintaining a job). Participation may be restricted in nature, duration, and quality (e.g., participation in community activities, obtaining a driving license).

Thus, as with ICIDH-1, there are four dimensions (with the inclusion of pathology), but with outcomes expressed as negative or positive levels of function. In effect, a continuum has been created between the expression of problems (e.g., impairment, activity limitation, or participation restrictions), summarized under the umbrella term disability; and, at the opposite end, nonproblematic (neutral) aspects of health and health-related states, summarized under the umbrella term function. However, the negative levels comprise impairments, activity limitation, and participation restriction, and in this respect ICIDH-2 appears no different from its deriving parent, other than the substitution of one

word for another: disability becomes activity while handicap becomes participation. The disablement process is again illuminated by the consequence of the dynamics between the four levels. However, the changes implicit in the proposed new model are more profound than simple substitutions of more politically correct words. The emphasis is on contextual factors, which act as mediators between the levels of the model, thereby changing the process from one of general disablement to one that becomes highly individualized. The contextual mediators are subdivided into environmental and personal factors. Important examples of personal context factors are goals (what the person aspires to) and beliefs (the person's own explanation and understanding of his or her illness).⁶⁴ These aspects are, in turn, influenced by personal educational and life experiences, by family and supporters, and by wider prevailing societal values.

How, and to what extent, the ICIDH-2 will impact on rehabilitation thinking—and indeed how clinical practice might change—is speculative. It will depend on whether the opportunities perceived are sufficiently attractive to overcome resistance to a more complex classification model. One view is that considerable change in rehabilitation practice may occur.⁶⁴ The current version, ICIDH-2 beta-1, is undergoing field testing. The situation is clearly fluid with constant incremental change, which is best followed on the WHO Web site (www.who.ch/icidadh).

ASSESSMENT AND REHABILITATION POTENTIAL

Many elderly people have several conditions of varying severity, and it can be challenging to unravel and identify the components and then to develop a personalized intervention plan. This process is called assessment and has been central to good practice since the inception of special services for older people.¹ The process aims to determine impairments, disabilities, and handicap, and then to trigger selective interventions at one or more of these levels, followed by observation and evaluation of response.

There is reliable evidence that the process is effective in improving outcomes for elderly people, but with the common sense proviso that the assessment process is closely linked to interventions.⁶⁵ The effectiveness studies have been summarized in a systematic review and meta-analysis.² The studies included (15 in North America, 8 in the United Kingdom, and 5 others) are heterogeneous but have as a common thread an evaluation of "comprehensive geriatric assessment": a core process characterized by multidisciplinary assessment and treatment. The pooled estimates of effectiveness across a range of outcome measures were encouragingly positive (Table 103B-3). The best effects were obtained for comprehensive geriatric assessment delivered by hospital-based elderly care departments, in which the assessment process and subsequent interventions were integrated and when organized postdischarge follow-up was arranged. In a review of the literature, Wade concluded that successful assessment is more likely if the assessor is experienced and if multiple aspects are covered by the assessor(s), but that, at present, there is little evidence to guide the most appropriate or efficient methods of assessment.⁶⁶

The process of assessment is self-evidently complex—generally more so than determining a drug prescription or

Table 103B-3. Outcomes of “Comprehensive Geriatric Assessment”: Hospital Geriatric Unit Versus Alternative Care

Odds Ratio (and 95% Confidence Limits) at 6 Months	
Living at home	1.8 (1.28–2.53)
Reduced mortality	0.68 (0.45–0.91)
Improved physical function	1.63 (1.00–2.65)
Improved cognitive function	2.0 (1.13–3.55)

planning an elective operation. Part of the complexity arises from the nature of the clinical problems: their diversity, varying severity, and multiplicity. Moreover, the problems interact at the level of personhood, so that disentangling physical and psychological factors is challenging. In addition, there may be a close association with social and environmental factors, and the interventions used are themselves complex. Interventions are based on human skills and therefore subject to variation, and they rely considerably on active patient participation, which is also subject to variation.

Standardized assessment measures or professional assessment?

The scientific basis of rehabilitation demands objective measurement.⁶⁶ One problem has been the multitude and diversity of standardized measurement tools available,⁶⁷ described aptly as “a tower of Babel.”⁶⁸ The most important consideration in selecting a particular measure is whether it is appropriate to the task in hand.⁶⁷ Additionally, measurement tools require research studies involving different patient groups in different settings and using advanced statistical methods to demonstrate various properties⁶⁹:

- **Validity:** Does the instrument actually measure what it purports to measure?
- **Reliability:** Does the instrument give similar scores when used on the same patient by two observers, or when repeated on stable patients?
- **Sensitivity:** Does the instrument detect clinically important changes?
- **Acceptability:** Is the instrument simple and quick to apply, easy to understand, and easy for patients to complete (so that there is a high response rate)?

These instrument measurement properties are not independent and perfect scales do not exist. Compromises have to be achieved between, for example, sensitivity and reliability—a scale sensitive to small changes has low reliability.

In the United States, a task force established a uniform data system for medical rehabilitation, which incorporated the use of the functional independence measure.⁷⁰ In the United Kingdom, the Royal College of Physicians and the British Geriatrics Society have jointly recommended six standardized assessment instruments for routine use when assessing older people (Table 103B-4).⁷¹ However, few of these instruments have been adopted in routine practice.

Indeed, in clinical rehabilitation practice, as opposed to research, debate continues over the balance between professional assessment and the use of objective standardized measures. Compared with professional assessment, standardized measures have the advantage of being less subject to bias,

Table 103B-4. Standardized Assessment Instruments Jointly Recommended By the Royal College of Physicians of London and the British Geriatrics Society for Routine Use When Assessing Elderly People

Domain of Interest	Recommended Scale
ADL disability	Barthel Index
Vision and hearing	Lambeth Disability Screening Score
Mental impairment	Hodgkinson Abbreviated Mental Test
Depression	Geriatric Depression Score
Quality of life	Philadelphia Geriatric Center Morale Scale
Social circumstances	Social Indicators Checklist

more systematic, more communicable, and able to provide a numerical result. Further, they open up the possibility for postal or telephone disability assessment, or assessment by support staff rather than senior staff. On the other hand, a disadvantage is that the result from a measurement instrument is not easily related to an intervention. This is not surprising because rehabilitation measures have not been designed to do this. For example, a Barthel score of 16, although providing a useful disability profile summary, does not equate to a patient treatment strategy. To determine a treatment strategy requires an exploratory, discursive process that seeks to identify patient-related problems and their context. This is the antithesis of the pervasive reductionalism characterizing the conventional biomedical model. Rather, it is the bio-psycho-social model propounded by Engel,⁷² summarized as: “Do my doctors/therapists know who I am, who I have been, who I still want to be? Do they understand what I am going through, my suffering, my pain, my distress? Do they understand my hopes and aspirations, my fears and shames, my vulnerability and strengths, my needs and obligations and my values? Above all do they sense my personhood and my individuality?” It is impossible to achieve this level of understanding through standardized assessment instruments.

Isaacs⁹ has argued for a discursive approach to the assessment of elderly people, with a list of open questions designed to identify problems but located in the context of the patient’s personal attributes, daily life, family, and friends. This type of semistructured format is a part of what has been described as narrative-based medicine.^{73–75} There is a concern that narrative-based medicine is becoming a lost tradition and should be revived in mainstream medical practice.⁷⁵ Its special relevance lies in the series of unfolding events told, importantly, from the viewpoint of the patient. These events provide meaning, context, and perspective for the patient’s predicaments. The attraction of the narrative approach is that it is both diagnostic and therapeutic. The telling of the story helps the patient make sense of events and, from the rehabilitation professional point of view, one outcome includes the possibility that novel and specific treatment options can be identified, or that a specific and especially valued element of information can be provided. One problem in practice is the difficulty in capturing adequately the richness of a narrative within the usual health care case records. This is one important reason why each multidisciplinary team member will wish to listen first-hand to a patient’s account. This can appear frustratingly inefficient to health care managers, but it is in the small details that the special events and circumstances surrounding, for

example, a fractured neck of femur emerge and change the commonplace (another admission with fractured neck of femur) to the particular narrative of an individual person with a fractured neck of femur.

DETECTION OF DEPRESSION AND DEMENTIA

It has been long recognized that depression and cognitive impairment can be significant barriers to successful rehabilitation.⁷⁶ There is therefore a good argument for routinely assessing patients on these domains using standardized instruments. Depression is common in elderly people,⁷⁷ but it can be difficult to detect because of overlap between the physical symptoms of organic disease, the vegetative symptoms of depression, and somatization of psychological distress.⁷⁸ The short version of the self-report Geriatric Depression Scale⁷⁹ can be used to screen for depression in medically ill older people and has a sensitivity and specificity of more than 70% when compared with formal psychiatric diagnosis.⁸⁰ However, some of the questions (e.g., "Have you dropped many of your activities or interests?") have questionable face validity in the presence of a new condition, such as a fractured neck of femur or stroke. The Hospital Anxiety Depression Score⁸¹ is another commonly used mood scale. It is easy to use and encompasses both depression and anxiety in separate subscales. However, the validity and reliability of this instrument for frail elderly people remains to be established. Several brief cognitive screening tools are available, such as the Abbreviated Mental Test⁸² and the Mini Mental State Examination Score,⁸³ and their routine use in rehabilitation involving older people has been recommended.

Significant aphasia and severe deafness may make formal assessment of mood and cognitive impairment difficult. Also, these screening tools are not diagnostic instruments: they merely indicate that cognitive impairment or depression may be present. For example, the Abbreviated Mental Test score has a false positive rate of up to 25%.⁸⁴ Careful patient observation and information from supporters remain fundamental. This approach has been reinforced by the recently described observation-based rating scale for use by nurses or care staff in daily contact with the patient.⁸⁵ It comprises six questions and has acceptable sensitivity and specificity for the identification of depression.

Rehabilitation potential

Part of the initial assessment process is to determine the rehabilitation potential of a patient. Although this is a nebulous concept, it is a common and challenging clinical task with an inherent self-fulfillment risk for the patient who is classified as possessing "limited rehabilitation potential". Caution is needed with a one-off, snapshot assessment, as there is evidence that agreement on rehabilitation potential even within a multidisciplinary team is unreliable.⁸⁶ Repeated assessments or a "trial of rehabilitation" may be the preferred clinical approaches, but are not yet adequately researched.

ASSESSMENT OF MOBILITY

Restriction of mobility is one of the most serious health-related problems. If an elderly person has insufficient mobility to be able easily to leave home, it follows that the

person must be dependent on others for basic activities such as shopping, and there is also the important loss of social opportunities. Objective assessment of gait and mobility is therefore important.⁸⁷

A gait laboratory is capable of describing and reporting many of the components of a gait cycle and is considered the gold standard in gait analysis—though it is too expensive, cumbersome, and time-consuming for use as a routine clinical tool.⁸⁸ It is therefore gratifying to note that simple clinical observation of gait can be rewarding: in a study of frail elderly people at high risk of falls, those who were observed to "stop walking when talking" were at the highest risk of falling during the next 6 months.⁸⁹ Unfortunately, though, gait assessment based on observation alone can be unreliable.^{90,91} There is no shortage of standardized approaches to assessment: a recent review identified 42 measures of balance and gait.⁹²

The timed walking test

The timed walking test is quick, needs little equipment (only a stopwatch and tape measure), and can be done easily in the clinic or at home. It has been described as "remarkably simple, reliable, valid, sensitive, communicable, useful, and relevant—almost the perfect measure."⁶⁷ It involves timing patients using a stopwatch as they walk a measured 10-meter distance, or walk 5 meters and return (more applicable for home assessment). It has been found to correlate with recovery after stroke,⁹³ and with other aspects of gait—such as a functional walking test and number of steps taken,⁹⁴ balance,⁹⁵ use of walking aids,^{96,97} falls,⁹⁸ and extent of personal mobility.⁹⁹ Gait speed measurement is suitable for routine use in geriatric day hospital practice.¹⁰⁰ A practical point is that the first walk is often significantly slower than subsequent walks and should be regarded as a warm-up/practice measurement and excluded from gait speed measurement results.¹⁰¹

Selection of a walking aid

An appropriate walking aid can lessen many gait impairments and reduce disability. The commonest aids are walking sticks¹⁰² and various types of walking frame. The introduction of the walking frame is ascribed to a 12-year-old Cincinnati boy who designed and constructed a frame for his aunt who had sustained a fractured neck of femur.¹⁰³

There are now more than 40 types of frame available in the United Kingdom,¹⁰⁴ including the Zimmer and various wheeled frames (e.g., the Delta Rollator). There are several disadvantages to the Zimmer frame because it promotes a slow and abnormal gait characterized by an intermittent stop/start or nonphysiologic stepping pattern. Wheeled walking frames, on the other hand, encourage a smooth, physiologic, striding type of gait pattern.

Comparison studies favor wheeled frames,¹⁰⁵ but the clinical issue is to select the most helpful walking aid for an individual patient. The "S test" has been designed to fulfill this practical clinical task.¹⁰⁶ It comprises a series of assessments in which the patient is asked to complete set maneuvers with different mobility aids. Patients are tested in their normal clothing and footwear in a carpeted area. Initially the therapist adjusts the aids usually to a height of the wrist crease and gives basic instruction. Subjects start the test seated in a chair and are then required to stand and walk a measured 5 m, which is timed by a stopwatch. They then

make a 180-degree turn before walking a further 5 m. Finally they make a 180-degree left turn before reversing into the chair. The test is repeated with different walking aids and the preferred aid is determined by considering five factors: safety, stability, stance, step/stride pattern, and speed. It is surprising how often this test selects a wheeled frame as the preferred walking aid.

Mobility handicap

One system that readily depicts mobility handicap is based on the concept of "life spaces."⁹⁹ Life spaces are divided into five concentric zones into which the individual can be placed: the bedroom, the rest of the dwelling, grounds surrounding the dwelling, the block, and the area across a traffic-bearing street. The system facilitates a better understanding of the relationship of the individual to his or her surroundings and stimulates an examination of barriers (i.e., why a person cannot move from one circle to the next).

In a community survey of arthritis sufferers, the availability of a car, the type of housing, and the distance to local shops emerged as the most restrictive barriers.¹⁰⁷ Ease of access to shops is important for elderly people as it fosters independence and reinforces ties with friends and neighbors. It is an activity that might well be curtailed even in the face of modest mobility restriction if the environmental factors are hostile.

It is not just external environmental factors that are important. The internal architecture and distances between rooms are other important factors that can elevate a modest disability into a severe handicap. For example, in a survey of 15 "typical homes" in East Cumbria, 80% of the houses had their main living room separated from the nearest toilet by a distance of more than 20 m.⁹¹ For some elderly people, this might represent a handicapping distance. This may be one reason why accommodation that is more sympathetic to the needs of disabled older people, such as sheltered housing schemes, is associated with a reduction in mobility handicap.¹⁰⁸

ASSESSMENT OF DISABILITY

Activities of daily living

"Activities of daily living" (ADLs) is a term commonly used by rehabilitation professionals. It reflects the disability level of disease consequence in the WHO classification model. ADLs include tasks such as washing, dressing, transferring, toileting, and mobility. These may initially appear as a disparate collection of activities that have been force-fitted together. However, ADLs can be considered as a unified construct and, importantly, performance is critical for elderly people struggling to maintain independent living.¹⁰⁹ The systematic assessment of ADLs, therefore, is an important aspect of the overall assessment of elderly people. Once again, a multitude of standardized instruments has been developed—a testament both to the perceived importance of this area in rehabilitation practice, and to the difficulty in producing the optimal instrument. Fortunately, most ADL measures are remarkably similar, at least in item content.^{8,109}

The Barthel Index

The Barthel Index has become widely adopted in routine clinical practice in British geriatric medicine and elsewhere. The popularity of the Barthel Index against the backdrop

of numerous other rival ADL standardized instruments supports its clinical utility. The Barthel Index originated as an empirically derived measure for younger disabled adults.¹¹⁰ Its widespread adoption into routine practice owes much to Wade and colleagues¹¹¹ who were the first to demonstrate its reliability and validity.¹¹²

The Barthel Index is an ordinal scale (as are most rehabilitation measures). Consequently, an improvement in score from, say, 5 to 6 does not represent the same clinical improvement as a score of 10 moving to 11. It assesses levels of independence or dependence for 10 ADL tasks with a score range of 0 (dependent) to 20 (independent):

- Dressing
- Feeding
- Grooming
- Toilet
- Bathing
- Bed/chair transfers
- Walking
- Stairs
- Bladder
- Bowels

The Barthel Index score correlates well with mortality,¹¹³ length of hospital stay,¹¹⁴ and requirement for institutional care.¹¹⁵ It is a simple measure that is easy to interpret in clinical practice, and it can both aid systematic disability assessment and also monitor rehabilitation progress if repeated at intervals.¹¹⁶ It is an independent indicator of nursing dependency levels.¹¹⁷

One disadvantage of the Barthel Index is that the steps on the scale are fairly large, so it is not very sensitive to small changes. Also, especially for disabled people living at home, there is a marked "ceiling" effect; patients can score the maximum 20 points and be "independent" according to the index, but still have daily living restrictions. This low ceiling effect limits its applicability for outpatient rehabilitation settings such as the day hospital.¹¹⁸

Extended activities of daily living

One limitation of the ADL scales is the restricted range of the content items. Living independently at home requires a more extensive repertoire of skills—including kitchen, domestic, transport use, and leisure activities. These types of activities are referred to variously as "instrumental," "extended," "social," or "advanced" activities of daily living. Although there is a conceptual understanding of instrumental activities of daily living, there is no agreement on the exact categories to be included in such measures.¹¹⁹ Examples of these measures include the Frenchay Activities Index¹²⁰ and the Nottingham Extended Activities of Daily Living Scale.¹²¹ These measures are less reliable both in total scores and individual items than ADL scores, probably because they rely on recall of activities undertaken during the preceding weeks.¹²²

Assessment of handicap

Handicap, the disadvantage to the individual as a result of ill-health, is from the patient's point of view the critical level at which to effect change. There is an increasing recognition that the ultimate goal of rehabilitation for older people should be reintegration into normal patterns of life.¹²³ This involves placing the individual in the context of his or her home, local environment, and facilities, and the person's relationships, motivation, mood, and expectations. Unsurprisingly, the uniqueness of this context makes the development of a generic standardized assessment tool difficult. The development of robust measures of handicap

has proved difficult,⁶⁷ and has only recently been described for stroke. Even here it remains a research tool for assessing the outcome of services rather than assisting rehabilitation assessment.¹²⁴

The World Health Organization's ICIDH contains six basic "survival roles" in the handicap section: orientation (including sight, hearing, and cognition); physical independence; mobility; occupation (including employment, domestic work, and recreation); social integration; and economic self-sufficiency. Its main limitation is that it is a classification system rather than an assessment tool. Alternatively, the Rankin scale is often cited as a handicap measure but is, in fact, a crude disability scale and moreover heavily biased towards mobility.¹²⁵

Social activity is an important domain of handicap and an important aspect of the reintegration process.¹²⁶ As there has been greater success in the development of measures of social activity, referred to above as "extended activities of daily living," these measures are the best current clinical compromise for a standardized approach to handicap assessment.

Location of assessment

Assessment was originally conceived as a hospital-based process, and the evidence for effectiveness is strongest for multidisciplinary teams working in the setting of hospitals. Emergency day-hospital assessment has been described as an alternative.¹²⁷

Much less information is available on successful assessment of disabled elderly people at home. Here, the primary health care team is the main health contact for disabled older people working in collaboration with social service staff. The effectiveness of assessment of primary health care teams, and community rehabilitation teams, has become a more pressing concern following the introduction in the United Kingdom of intermediate care services. The first health care contact for elderly people struggling to cope at home is frequently the community nurse. Each year about half the population aged over 85 years is seen by a community nurse.¹²⁸ Such nurses work closely with general practitioners to coordinate the care with social service staff and therapists, and to organize services such as respite care and day-center attendance. A recent comprehensive review conducted by the Audit Commission concluded that there was considerable scope to improve the service, with a specific recommendation for the introduction of improved standardized assessment methods accompanied by an associated training program.¹²⁸

The Easycare assessment

Easycare was developed on behalf of the European Regional Office of the World Health Organization for use in Europe as a first-stage assessment of elderly people in primary or community-care settings. It is designed as a system for rapid assessment of an older person's physical, mental, and social well-being, and provides a broad picture of the person's needs. It focuses on quality of life rather than disease, and recognizes the roles of family and caregivers. It comprises a structured assessment of hearing, vision, and chewing; self-care and mobility; social functioning; and mood and cognition.

Provisional evaluation of Easycare has confirmed its usefulness as a combined medical and social assessment of elderly people in domiciliary settings.¹²⁹ Completion time

is between 14 and 40 minutes.¹³⁰ However, the extent to which the Easycare system leads to improved outcomes for elderly people living at home has not yet been researched.

Home assessment

Home assessment shifts the rehabilitation orientation from disability to handicap. The U.K. College of Occupational Therapists defines a home visit as "a visit to the home of a hospital inpatient, which involves an occupational therapist in accompanying the consumer to assess his or her ability to function independently within the home environment or to assess the potential for the consumer to be as independent as possible with the support of caregivers."¹³¹ This is an overly narrow definition that ignores home assessment visits for elderly people who are not in hospital. Also, a home assessment should allow the patient and the rehabilitation team to obtain first-hand experience of the challenges faced in coping at home and thereby trigger new interventions and rehabilitation goals.

Like much in rehabilitation practice, the home assessment visit has become absorbed into mainstream practice in an uncritical way and its effectiveness is uncertain. Moreover, the function of the pre-discharge assessment visit has insidiously changed from a handicap assessment to inform the rehabilitation process, to an administrative component of the hospital discharge process. A systematic review of pre-discharge home assessment visits identified only five reports, of which two described retrospective surveys and three were descriptive surveys of current clinical practice.¹³² One randomized controlled trial involving 50 cases has since been published.¹³³ It investigated the important but relatively specific issue of falls. Pre-discharge home assessment visits and subsequent environmental modifications resulted in a significant reduction in the fall rate during the 12 months of follow-up, but the treatment effect was confined to those high-risk patients with a history of falls in the preceding year. Another systematic review (15 studies) has examined the effectiveness of preventative home assessment visits and reported inconclusive findings for relatively low-risk elderly people at home.¹³⁴

TEAMWORK IN REHABILITATION

The concept of teamwork, arguably formalized first in rehabilitation,¹ is now familiar in most areas of health care: primary health care teams, surgical teams, cancer teams, palliative care teams, etc.¹³⁵ However, working as a team in rehabilitation has two distinctive features. First, the team is built around the patient rather than a condition (such as a cancer or a surgical treatment). Second, the range of professional staff involved is exceptionally diverse in terms of professional backgrounds, and this necessitates careful coordination of each member's contribution.

Multidisciplinary team care

More has been written about successful and unsuccessful teamwork in the context of general management. A consistent finding has been that successful teams are made up of people with different styles and backgrounds who bring different angles to the issues at hand, rather than "clones" who are likely to adopt similar approaches.¹³⁶ Creativity and successful problem-solving therefore require a mix of

character styles and skills, albeit at the expense of some tension when inevitable differences arise. The multidisciplinary rehabilitation team structure for rehabilitation, therefore, may be ideally suited for the complex problem-solving required for elderly people with disabilities.

Rehabilitation staff generally endorse the team approach and it is regarded as established practice. There is evidence of its importance as up to 75% of disabilities may go unrecognized by hospital doctors,¹³⁷ and although general practitioners are probably more aware, they still fail to recognize 40% of disabilities.¹³⁸ Successful impairment and disability assessment requires separate assessments by each member of the multidisciplinary team if problems are not to be overlooked.⁸⁶ However, there is little consensus and few empirical studies provide insight into the best methods to promote effective teamwork. Measurement of important aspects of team care, such as clinical and interpersonal skills, interprofessional relationships, and group dynamics are poorly developed. It has been suggested that effective teamwork requires at least three components: agreed and explicit aims; recognition of the contribution of different team members; and structures to facilitate collaborative working.¹³⁹

Issues of role overlap are rarely addressed openly,¹⁴⁰ and professional "tribalism" can occur with recurring conflicts caused by the failure to understand and value the contribution of other team members,¹⁴¹ resulting in arguments over professional boundary issues.^{141,142} There are both interprofessional and intraprofessional tensions. For example, one view is that physiotherapy has veered too far toward a biomedical reductionist approach with an emphasis on physical symptoms and the level of impairment, and too far from a more behavior/educational holistic approach.¹⁴³ Also, status problems can develop,¹⁴⁴ frequently resulting in jealousy and lack of cooperation.¹⁴⁵ Autonomy of rehabilitation staff within a team structure is required to realize the full potential of the team, but needs careful nurturing.¹⁴⁶ An effective team should be prepared to modify its approach in the light of emerging research, but relating practice to an evolving evidence base remains poor owing to insufficient time to read and discuss research literature.¹⁴⁷

Interdisciplinary team care

Professional and clinical overlap inevitably occurs between members of a multidisciplinary rehabilitation team. Arguments have been advanced for a "generic therapist,"¹⁴⁸ but separate therapy disciplines remain the norm in the United Kingdom and elsewhere. Some progress has been made with generic therapy assistants within vocational training programs, but complex professional regulations have presented daunting practical obstacles. Team overlap and areas of duplication have led to a greater emphasis on interdisciplinary working.^{141,149} This approach has been further promoted by limited resources and national shortfalls in trained rehabilitation staff, resulting in some rehabilitation disciplines being severely rationed or unevenly available—particularly clinical psychologists and speech and language therapists.

Interdisciplinary working is a higher order of team functioning than the traditional multidisciplinary approach. It involves acknowledging the overlap between disciplines, with greater sharing of duties and responsibilities. Formal strategies to promote interdisciplinary working are largely untested but include collaborative clinical records, shared

goal-setting, and closer working practices. Interdisciplinary training programs may be one practical way of promoting this style of working. Such programs can be developed and implemented without additional resources and are associated with improvements in rehabilitation process, patient outcome, and a more positive attitude among nurses toward rehabilitation work.^{150–152}

The role of the nurse in rehabilitation

Literature reviews of stroke and elderly care nursing suggest there is a lack of clarity over the role of the nurse in multidisciplinary teams of sufficient degree to impede the effective functioning of those teams.^{140,153–155} It has been argued that nurses lack the confidence, knowledge, or skills to assume an appropriate role in rehabilitation,¹⁵⁶ and findings from action research seem to confirm this.¹⁵⁷

Previous work has drawn attention to competing models of care between the traditional caring/doing role of nurses and the encouraging/facilitating role more appropriate to rehabilitation.^{154,158,159} These competing models of nursing care are not simply of theoretical interest: they exist as observed practice.^{153,154,160} Addressing deficiencies in nurses' knowledge is believed to increase motivation to work with rehabilitation patients and improve team communication, coordination, and collaboration.^{157,159}

It is clear, therefore, that nurses working in elderly care should receive additional training to enable them to incorporate some of the treatment concepts used by therapists as an integral component of their work. Training programs are now proposed in the United Kingdom by the Royal College of Nursing to underpin the new post of the gerontological nurse specialist.¹⁶¹

Promoting teamwork

One strategy to promote coordination of rehabilitation teams is based on shared documentation. This has been considered as expected practice in the United Kingdom for new intermediate care services.⁴³ One study involving the implementation of such an approach reported that patients made faster progress, with an associated increased rate of home discharge.¹⁶² The system under study was a relatively simple one of shared documentation for assessment and progress. There were weekly summary sheets on which treatment goals and patient expected progress were recorded. A particular difficulty with the generalizability of such documentation is disentangling the effects attributable to the documentation from the process undertaken by the local team in arriving at the documentation. The exercise inevitably involves team building and shared ownership of the final product, either of which may independently improve patient outcomes.

Teamwork can also be promoted by multidisciplinary ward rounds. In a trial (n = 1102) investigating multidisciplinary ward rounds (physician, nurse, pharmacist, nutritionist, and social worker), clinical outcomes were unchanged but there were useful resource benefits, including decreased length of hospital stay and associated lower hospital costs.¹⁶³

AN INTEGRATED CARE PATHWAY (ICP)

This is a technique that uses a pro forma template to describe explicitly the content and timing of complex multidisciplinary care. It is overseen by a delegated professional, usually a nurse. Intuitively, ICPs should be of greatest value

if the starting position is one of disorganization, and of least value in well-ordered settings. Thus they have been shown to reduce hospital length of stay when introduced for fractured neck of femur,¹⁶⁴ but had no additional advantage in an established stroke unit where the care was already well organized.¹⁶⁵

THE CONTENT OF REHABILITATION

The content of rehabilitation is of great concern to patients. It is, after all, what the patient and caregiver actually experience. In this sense, assessment, teamwork, goals, and rehabilitation professionals are collectively the vehicle to deliver the treatment elements that have the potential to improve functional abilities and health status. The vehicle has a daunting task, for the repertoire of rehabilitation treatments is enormous. Selecting the right interventions, in the right order, for the right patient, in the right circumstance, requires fine judgment. Moreover, negative experiences, or critical incidents, have lingering effects and impede disability adjustment.¹⁶⁶

A recent report identified a staggering 35 systematic reviews for rehabilitation topics of relevance to older people.⁶⁰ Reviews were available for back pain, neck pain, diabetes, fractured neck of femur, occupational therapy in nursing homes, chronic pulmonary disease, cardiac rehabilitation, falls, and stroke. However, these reviews disguise an important general deficiency in our knowledge. They largely describe the effects of complex interventions—sometimes called packages of care. The content of rehabilitation packages can appear chaotic and the relative contribution of an item, or items, is speculative. The term “black box” has become a fashionable concept to indicate our imprecise understanding of these rehabilitation packages. Some light has now been let in to the black box and, as anticipated, it contains individualized, dynamic, and multicomponent interventions.^{166–168}

One approach that can be helpful in understanding and clarifying the components is to consider rehabilitation in terms of “hard” and “soft” elements (Figure 103B-2).¹⁶⁹ Traditionally, rehabilitation has been described in terms of hard components. Many of these are described in this chapter. These are the tangible entities—aids, physical treatments, environmental adaptations—that can be observed, counted, and costed. However, patient descriptions of the experience of rehabilitation emphasize the importance and value of soft rehabilitation: talking to, listening, understanding, encouraging, and counseling.^{166–168} These are less visible components, harder to quantify and record, and easily neglected in hard-pressed services. Successful rehabilitation requires an appropriate and unique balance between the hard and soft components for each patient and his or her family.

Rehabilitation goals

Rehabilitation goals are highly focused statements of intent which result from a distillation of the assessment process.¹⁶⁹ A helpful definition of a rehabilitation goal is “a future state that is desired and/or expected. The state might refer to relative changes or to an absolute achievement. It might refer to matters affecting the patient, the patient’s environment, the family or any other party.”¹⁷⁰ Goal-setting is “the process of agreeing on goals, this agreement usually being between the

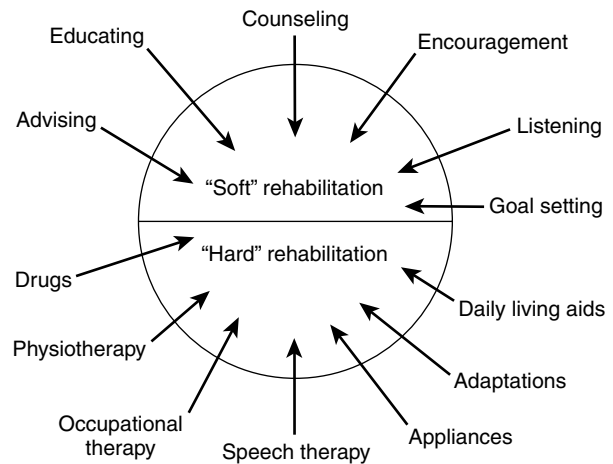

Figure 103B-2. The concept of “hard” and “soft” rehabilitation. From Young J. *Rehabilitation and older people*. *BMJ* 1996;313:677–81.

patient and all other interested parties. The process might include setting goals at various levels and in various time frames.”¹⁷⁰ A goal is not a vague statement (for example: “to improve mobility”), but is a clear, unambiguous, and measurable statement (for example: “Mrs. Brown will walk with the Zimmer frame without assistance six times each day”).

The literature on goal-setting covers conceptual approaches,¹⁷² consideration of their applicability,^{171,172} direct practical advice on the use of goals,¹⁷³ and the use of goal-setting as an outcome tool.¹⁷⁴ Good descriptions of the importance and construction of rehabilitation goals are available.¹⁷⁴ Research evidence has demonstrated that using goals improves rehabilitation outcome provided that there is significant patient involvement, that both short-term and long-term goals are developed, and that the planning of goals is supported with specific interventions.¹⁷⁰ However, the research base is derived almost exclusively from studies of stable disability, generally in the context of outpatient work. The extent to which these studies generalize to the “frail” elderly population is speculative. Moreover, there is little consensus about how goal-setting should take place. Its implementation in practice varies considerably, and there appears to be no widely accepted method to promote patient and caregiver ownership of rehabilitation goals.¹⁷⁵

Within the concept of goal-setting, there is often tension between idealized and actual practice, between negotiated/patient-centered and more externally imposed goals, and between explicit (written) and implicit goals. The goal-setting process itself may highlight differences in expectations of patients and therapists.¹⁷⁶ In essence, a delicate balance needs to be struck to present a meaningful challenge and thereby to promote recovery. Importantly, although goal-setting may be a recognized and established part of the rehabilitation process, an understanding of the term is not always shared by patients and caregivers.¹¹ The process of negotiation and renegotiation of goals with patients and caregivers can be laborious but can avoid conflicts of interest and lead to improved relationships between patients and staff.¹⁷⁷

Patient motivation

Patient motivation is a nebulous concept, referring to something that has a major impact on the outcome of rehabilitation. It is undoubtedly influenced by mood-state and by

cognitive and perceptual impairments. However, motivation and rehabilitation goals dance around one another. "The well-motivated patient" will rise to challenging goals, and challenging goals can raise the motivation of a patient to improve. Conversely, "the poorly motivated patient" can be deflated by even unchallenging goals, and unchallenging goals can leave the unmotivated patient stalled.

Although rehabilitation professionals commonly believe that motivation of patients has an important role in determining outcome, there is a lack of shared understanding about the term "motivation."¹⁷⁸ In an important qualitative study, Maclean et al¹⁷⁹ investigated the factors affecting motivation for rehabilitation in stroke patients. Information about rehabilitation, favorable comparisons with other stroke patients, and the desire to leave the hospital were positive determinants of motivation; whereas overprotection by family members and professionals, lack of information, and the provision of mixed messages about rehabilitation, and unfavorable comparisons with other patients were negative determinants of motivation. It seems, therefore, that the wider context of motivation lies in the nature of the relationship between patient and professional. Indeed, Blaxter observed that problems in adjustment and rehabilitation were very likely when the patient's own view of his or her condition differed from that of the rehabilitation team.¹⁷

Patient education programs

A natural extension of patient involvement in the planning of goals is patient participation in chronic-disease educational programs. These should not be confused with the largely passive provision of information more commonly undertaken in rehabilitation. Simple provision of information to patients and caregivers may not influence outcome.¹⁸⁰ With the emergence of chronic disease as the largest threat to health status and the largest reason for health care expenditure, the potential scope for patient self-management has assumed increased importance.

Much of the work on chronic-disease patient self-management programs has been conducted in the United States, where there are many examples of education programs for specific chronic conditions that have increased helpful behaviors, improved health status, and/or decreased health care costs of their participants. A bibliography of more than 400 such patient educational studies has been published.¹⁸¹ The components incorporated into such programs are diverse: cognitive symptom management; exercise; nutrition; fatigue and sleep management; use of community resources; use of medication; dealing with the emotions of fear, anger, and depression; communication with others, including health professionals; problem-solving; and decision making. These components can be specific to different chronic diseases. One study provided a self-management program for patients with heart disease, lung disease, stroke, or arthritis: improved outcomes in terms of health behaviors, health status, and health resource use resulted.¹⁸²

The caregivers

Despite the wider recognition that a large component of support for disabled elderly people is provided by informal caregivers,¹⁸³ the needs of caregivers are still frequently overlooked.¹⁸⁴ The stated intention of the U.K. government as expressed in the National Strategy for Carers is to

"support people who choose to be carers."¹⁸⁵ The reality, however, is that exercising such choice can be extremely difficult. Many caregivers either drift insidiously into their role or take up their duties in a state of "initial innocence."¹⁸⁶ Caregivers who take on their role suddenly, or who feel poorly prepared, often experience higher levels of burden.¹⁸⁷ It is therefore important to consider the preparation for caregiving.¹⁸⁸

Since 1996, local authorities in the United Kingdom have had a statutory duty to recognize the needs of caregivers independently during a community-care assessment of a client.¹⁸⁹ A focused approach with attention to four main areas is recommended: practical training for the physical aspects of care; preparing for the emotional aspects of care; learning how to deal with stress; and negotiating access to services.¹⁹⁰ A systematic review of 31 studies addressing the issue of stroke and informal caregivers concluded that caregivers' ability to cope with stroke was enhanced both by the use of positive coping strategies (for example, self-control skills) and by more concrete measures (such as stroke information).¹⁹¹ Overall, the literature indicates that time should be allocated specifically to caregivers for separate needs assessment and appropriate supportive and practical interventions. Providing support routinely to caregivers of stroke patients appears well received and is effective.^{192,193}

Undetected psychological and physical health problems in caregivers,^{194,195} and deficiencies in training in safe handling skills with consequent risk of injury,¹⁹⁶ are particular concerns. The underprovision of aids and equipment leads some caregivers to improvise with potentially dangerous home-made gadgets designed to assist with transfers, toileting, and self-care.¹⁹⁷

Daily living aids and adaptations

The use of aids and adaptations is an important component of rehabilitation content.^{198,199} When carefully and correctly identified, they have potential to close "the ecologic gap" between what the patient is able to do and what he or she is required to do. Unfortunately, inappropriate prescribing is common,²⁰⁰ and there is no substitute for individual assessment so that equipment meets a clearly defined objective within a wider rehabilitation program.

Walking aids,¹⁰⁴ bath and toilet aids,²⁰¹ chairs,²⁰² and special kitchen equipment are commonly needed by elderly people with disabilities. Bathing difficulties are common, so it seems perverse that painful joints should be denied the helpful soothing of hot water because of the ergonomics of a "standard" bath. A home assessment visit by an occupational therapist to select and order the appropriate bathing aid, followed by a second visit after delivery for patient instruction, significantly improved the number of arthritic sufferers who were able to bath independently.²⁰³ This finding has special relevance in the light of a study reviewing the frequency with which elderly people get stuck in the bath—an unnerving and undignified situation.²⁰⁴

A range of simple aids (raised toilet seat, teapot tipper, tap turner, shoehorn, elastic laces, and double-handed saucepans) made a major impact in maintaining the independence of elderly people.²⁰⁵ For patients with rheumatoid arthritis, home-based occupational therapy advice, treatment, and aids provision resulted in a significant improvement in daily living skills.²⁰⁶

The provision and organization of even simple aids and adaptations is poor in the United Kingdom. The mean delay between requesting and fitting an access ramp for wheelchair users in one study was 14 weeks, with the longest delay reported of 11 months.²⁰ Many patients experience multiple waiting lists for essential equipment and adaptations. Such waiting lists are less visible than the more politically sensitive surgical waiting lists. A global indicator that incorporates waiting times for aids and adaptations has been proposed as a mechanism to promote a more user-focused service.¹⁹ The current situation for the provision of aids and adaptations is clearly unsatisfactory, and a recent Audit Commission report was highly critical.²⁰⁷ It investigated the five equipment services that are the largest in terms of user numbers and cost: orthotics, prosthetics, wheelchair services, community equipment, and audiology. In some sites, and some services, the situation was well-organized; but for most it was shambolic and the main findings of the audit were: lack of involvement of users; low priority afforded by senior managers; underinvestment; and geographic variations in people eligible to receive services, in the range and quantity of equipment provided, in the time spent waiting for its delivery, and in the number of staff trained.²⁰⁷

REHABILITATION SERVICES

Rehabilitation is the most complex of all health interventions. There is no other type of service that is required to provide such highly individualized treatments on a scale dictated by the highly prevalent conditions that underlie disability. The complexity appears intrinsic to effectiveness—on the whole, single, or simple standardized rehabilitation interventions are unsuccessful.⁶⁰ In the face of this process complexity, the structure of services becomes a critical issue. Structure is the cement that binds the process elements and prevents dissipation of effectiveness. The term “packages of care” can be misleading as it can give the impression of production-line sameness. It is the variability that needs to be stressed: each package should have a different content dictated by the needs of the individual elderly person. Structures that have facilitated the complexity and variability of the rehabilitation process for older people include day hospitals, stroke units, rehabilitation wards, and orthogeriatric units. In these examples, the structure is explicit in as much as patients are geographically brought together. For community rehabilitation teams, the structure is more virtual and arises through a common team purpose and shared service objectives.

Location of rehabilitation

Arguments between service providers or professionals about location of rehabilitation tend to be emotionally charged. The currently available research evidence (a systematic review of 45 trials) strongly favors hospital-based rehabilitation.²⁰⁸ Improved outcomes are reported for hospital stroke-unit care compared with general medical wards (19 trials), and for geriatric assessment units compared with nonspecialist care (11 trials). Early discharge schemes provide similar outcomes to extended hospital stay but have associated hospital bed-releasing potential. The former group of trials (12 trials) include early discharge for surgical, orthopedic, and medical elderly patients, but the predominant evidence is for stroke (7 trials). Orthogeriatric units—where improved

coordination between surgical, geriatric, and rehabilitation staff is the aim—have been widely promoted²⁰⁹ and are accepted as good practice.²¹⁰ However, the overview evidence for effectiveness is inconclusive (7 studies).¹⁶⁴ One reason may be the considerable variation in need of elderly patients with fractures. “Old age” spans three decades and patients range from relatively fit elders with single pathology (osteoporosis) to frail older people with multiple pathology. A systematic review demonstrated that depression, delirium, and dementia are common comorbidities in patients with a fractured neck of femur and have a detrimental effect on outcome.²¹¹ A single trial has reported that patients with dementia are a particular subgroup who may obtain improved outcomes from an orthogeriatric unit.²¹²

One argument against hospital care for elderly people is the complexity of hospital health care pathways and systems. These fail routinely and regularly and constitute a greater hazard than we commonly acknowledge. Much of the evidence comes from North America and Australia, but a recent report in the United Kingdom by the Chief Medical Officer has openly accepted that similar circumstances apply to U.K. hospitals.²¹³ The report estimates there could be 85,000 serious adverse health care events per year at a cost of more than \$2.9 billion (£2 billion). Half of these adverse events are considered preventable. This represents a genuine challenge for clinical governance. A rationale for services designed to avoid hospital admission for elderly people has been demonstrated²¹⁴ but are not yet adequately investigated (three trials).²⁰⁸ There is only one randomized trial comparing the effectiveness of stroke unit against domiciliary care for early stroke rehabilitation.²¹⁵ Stroke unit care was more effective in reducing mortality, the need for institutional care, and dependence. Thus best evidence continues to support the stroke unit to optimize outcomes following early stroke rehabilitation.²¹⁶

Although the evidence base is stronger for hospital-based rehabilitation for elderly people, this is to simplify and polarize a complex service situation. The location of rehabilitation is not an either/or situation. The requirement is for the provision of rehabilitation opportunities for elderly people at whatever point they contact health and social care services.¹⁸ The best hospital-based rehabilitation should be multidisciplinary and intensive, and should offer 24-hour supportive care; but it is short-term, disability-orientated, and expensive. Home-based rehabilitation, on the other hand, is less intensive and more likely to be uniprofessional, but has the potential to be more handicap-orientated, involve caregivers more, take a longer-term perspective, and is cheaper. In a qualitative comparison study of patients treated at home or in a hospital, the major difference was that patients at home took the initiative and were more able to express and determine their own goals.²¹⁷

Home-based rehabilitation

The general concept of home-based rehabilitation has attracted widespread support for many years, but it has remained a vague intent rather than a clearly developed set of services. There has recently been an important shift in emphasis from a begrudging alternative to hospital care to a greater recognition of the primacy of home rehabilitation within the wider context of community care. Thus the perception of home-based rehabilitation as a subsidiary,

supporting role (for example, to allow patients to leave the hospital more quickly) is changing. It seems common sense that enabling disabled people to do more for themselves in their own homes is eminently more desirable than simply supplying ever-more supportive care; that a therapeutic approach is preferable to a prosthetic one.

Joseph Sheldon was arguably the first to recognize the potential of home-based rehabilitation.²¹⁸ His insights were the product of the first systematic survey of disabled older people living in their own homes in which he observed their practical struggles and difficulties. Against this background he reflected on the most appropriate help and services and came to recognize the special relevance and applicability of home-based rehabilitation to address these problems. The United Kingdom has needed a full half-century of the National Health Service to endorse Sheldon's conclusions. Even 15 years ago, little home-based physiotherapy was available.²¹⁹ Home-based rehabilitation could be relevant to most of the common disabling conditions facing older people.

A systematic review identified 36 randomized controlled trials, which evaluated interventions designed to reduce falls.²⁴ These included short-term exercise programs and home environmental assessments. Clear conclusions were hampered by variability in the interventions and in the outcomes studied. However, there was "reasonable evidence" that exercise programs offer benefit in reducing risk of falls. How such programs should be implemented in routine practice requires more study; but given the recipient patient group, the coverage needed, and the nature of the exercise programs, locality-based services would be a practical way forward. Indeed, the review identified several trials in which the initial falls risk assessment was undertaken in the elderly person's home because this allowed an environmental appraisal and resulted in risk-reduction measures such as home safety modification. In general, the higher the risk of falling, and the more multifaceted the interventions, the greater the benefit.²⁴

Osteoarthritis of hip and knee is a major public health problem affecting elderly people in the United Kingdom, with many patients being referred to outpatient physiotherapy departments. However, it is clear from the literature that the main treatment emphasis should be on exercise programs that can readily be delivered in the patient's own home.^{220,221} These programs are easy, cheap, and effective; and there is no evidence that routinely used electrotherapies have additional advantages.²²² The principal practical task is to encourage patients to comply with their exercise programs, as those who persevere do best.²²⁰

Given that hospital stroke unit care confers proven benefits,²¹⁷ this model of care should be seen as the gold standard by service commissioners. Nevertheless, the need to continue the rehabilitation process beyond the hospital period has been recognized for many years.²²³ This important area has been considerably underresearched,²²⁴ but recent studies have shown that community rehabilitation does have an important role to play. Several studies^{225–230} have selected patients after discharge from a stroke unit where rehabilitation care is optimized and where it might be considered that additional function and improvements improbable. The natural phase of intrinsic, neuroplastic recovery should have long past. Yet, improvements in dressing ability,²²⁷

daily living skills,^{225,226} leisure activities,²²⁸ mobility,²²⁹ and reduced readmission²²⁵ have all been reported. However, one trial, the largest occupational therapy trial, reported no benefit.²³⁰

Perhaps the most surprising finding has been the modest levels of therapy input required. For example, between 15 and 20 home physiotherapy visits to a patient over the 6 months following discharge from the hospital appears to be a level of treatment associated with benefit.²³¹ This modest intervention intensity supports the special relevance of home-based rehabilitation where individual patient and caregiver problems are more readily identified and addressed. The therapy team operates to minimize handicap and can maximally involve caregivers (formal and informal). This is in contrast to outpatient therapy when caregiver involvement is minimal (left at home) and the interventions are at the lower level of disability rather than handicap. Moreover, outpatient attendance for stroke patients has low acceptability.²³²

The geriatric day hospital

The first geriatric day hospital was opened in the United Kingdom in 1952.²³³ Day hospitals then developed rapidly during the 1960s as an important component of elderly care provision designed to complement inpatient services.^{234,235} The model has since been widely applied in New Zealand, Australia, Canada, the United States, and several European countries.

The objective of day hospital attendance has been succinctly summarized as "to facilitate prolonged independent living for the elderly in the community."²³⁶ There is a strong emphasis on rehabilitation, reflected in the multidisciplinary staffing structure. Reasonable amounts of therapy input can be achieved during a day hospital attendance and provided in repeated short sessions—a form of delivery particularly suitable to older people with decreased stamina and exercise tolerance.^{237,238} The service is sufficiently flexible to respond to a wide range of conditions and associated varying disabilities²³⁷ and needs²³⁹ of the attenders. Patients enjoy attending,²⁴⁰ and caregivers find the day hospital helpful.²⁴¹ Indirect supportive evidence for the day hospital concept comes from instances of sudden day hospital closure precipitated by industrial action: a short-term closure produced only marginal effects,²⁴² but a 16-week closure produced an appreciable increase in acute hospital admissions and deaths.²⁴³ A retrospective review estimated that day hospital attendance had shortened inpatient treatment in 8% of patients but had delayed or prevented admission in 42%.²⁴⁴

Day hospitals are an expensive form of patient care,^{244–247} and the National Audit Office has raised concerns about their cost-effectiveness.²⁴⁸ More than twice-weekly attendance may be more costly than inpatient care.²⁴⁹ Patients therefore need to be selected carefully so that only those with potential benefit are asked to attend. One study showed that up to 50% of general practitioner referrals to a day hospital could be managed by alternative and cheaper services.²⁵⁰ Another study showed that nearly half the day hospital attenders failed to complete their planned course of treatment.²⁵¹ Up to 20% may be unable to attend owing to motion sickness.²⁵²

The day hospital trials have now been synthesized in a systematic review of 12 trials.²⁵³ It was concluded that day hospital care was an effective outpatient service for

older people but was no more effective, and possibly more expensive, than other forms of well-organized elderly care. It appears to be less cost-effective than home-based physiotherapy for stroke aftercare.²⁵⁴ Attempts have been made to refocus the day hospital concept and use the multidisciplinary team structure to provide rapid assessment of elderly people and so avoid hospital admission.¹²⁷ A continuing role for the day hospital is likely to depend on the development of more flexible operational policies to encompass rehabilitation outreach, brief outpatient attendance, and problem-based assessment clinics (e.g., falls, continence, movement disorders).²⁵⁵

CONCLUSION

Despite the impressive unraveling of the genetic and molecular pathophysiologic bases for disease, a simple fact remains that a large proportion of the ill-health faced by elderly people is not amenable to a "cure." Worse, these chronic and (usually) progressive conditions adversely impact on, and limit, personal independence. The role of rehabilitation is to use a diverse collection of interventions to reduce this impact and maximize independence.

ACKNOWLEDGMENTS

Material in this chapter contains contributions from the fifth edition, and we are grateful to the previous author for the work done.

Part of this chapter is based on Young, Brown, Forster, and Clare. An overview of rehabilitation for older people, reviews in clinical gerontology 1999,9:183–96, with permission from the coauthors, editor, and publisher.

KEY POINTS

Rehabilitation

- The burden of disability is considerable for elderly people, with an estimated 4.3 million people over 60 years in the United Kingdom reporting disability, which represents 46% of all older people.
- Rehabilitation is concerned with maximizing functional independence at the level of the whole person set in the context of his or her personal circumstances: family, social, and home environment.
- The World Health Organization's International Classification of Impairments, Disability and Handicap (ICIDH) is a useful model of disease consequence upon which to base the rehabilitation process.
- The practice of rehabilitation requires multidisciplinary assessment and teamwork with a mixture of "hard" approaches (e.g., physical treatments, daily living aids) and "soft" approaches (e.g., educational programs, counseling).

Geriatric Pharmacotherapy and Polypharmacy

Joseph T. Hanlon
Steven M. Handler
Robert L. Maher
Kenneth E. Schmader

INTRODUCTION

Medications are the most frequently used and misused form of therapy for the medical problems of the aged. Geriatric health care professionals and their patients rely heavily on pharmacotherapy to palliate symptoms, improve functional status and quality of life, cure or manage diseases, and potentially prolong survival. There has been a major increase in our knowledge about the epidemiology and the clinical pharmacology of drugs in the elderly (see Chapter 23). This chapter examines efficacy and safety problems (including medication-related problems) of pharmacotherapy in aged populations, measures to reduce medication-related problems including polypharmacy in the elderly, and principles of optimal geriatric pharmacotherapy.

EFFICACY AND SAFETY OF PHARMACOTHERAPY FOR ELDERLY PATIENTS

The evidence for the efficacy of medication therapy in elderly patients has been bolstered by a number of seminal randomized controlled clinical trials for geriatric conditions (e.g., behavioral complications with dementia) and diseases (e.g., hypertension).^{1,2} Moreover, a number of new and improved therapeutic medication entities have come to market and improved the ability of health care professionals to treat certain conditions (e.g., cholinesterase inhibitors for Alzheimer's disease, α -blockers for prostatic hyperplasia, and bisphosphonates for osteoporosis). In addition, the future seems bright for further medication discoveries that may benefit elderly people, as nearly 900 new medicines are currently in phase I to phase III testing.³

Despite these optimistic trends, there are still major limitations in our knowledge regarding the efficacy and safety of geriatric pharmacotherapy. Elderly patients are still underrepresented in premarketing clinical drug trials.⁴ Although regulatory authorities have developed guidelines for pharmaceutical companies regarding new molecular entities that are likely to have significant use in elderly patients, the full impact of these guidelines has yet to be realized.⁵ In addition, those trials that do include elders rarely include the "oldest-old" (i.e., 85+), those with multiple comorbidities, or those taking multiple medications.⁴ These exclusions raise questions about the generalizability of the results to frail elderly people. Moreover, there is a paucity of postmarketing studies designed to compare the effectiveness of two drugs in the treatment of common conditions (e.g., duloxetine vs. gabapentin in management of postherpetic neuralgia). In addition, formal postmarketing surveillance of medications to determine adverse effects varies from country to country, but usually it consists of case reports of potential adverse effects—reports written by practitioners and published in medical journals or spontaneous reports written by practitioners, patients, or pharmaceutical companies and submitted to regulatory agencies.⁶ These methods are limited by underreporting and the lack of denominator information

about the population at risk. Thus, most safety information must come from formal postmarketing observational studies of specific therapeutic classes or conditions. This makes it difficult for prescribers to use evidence-based medicine to choose the "best" drug therapy for their frail elderly patients. Hopefully these deficiencies in pre- and postmarketing evaluation of efficacy and safety will be addressed in part by the Agency for Healthcare Research and Quality (funded by the University of Iowa), Older Adults Centers for Education and Research on Therapeutics in the United States (see www.iowacert.org for more details), and research utilizing national pharmacy dispensing data such as the Medicare Part D claims data in the United States (see http://www.cms.hhs.gov/PrescriptionDrugCovGenIn/08_PartDData.asp for more details).

MEDICATION-RELATED PROBLEMS IN ELDERLY PATIENTS

As mentioned previously, most information about medication-related problems must come from postmarketing observational studies of specific therapeutic classes or conditions. Problems commonly associated with medication use include medication errors and medication-related adverse events (Figure 104-1).⁷ Medication errors can be defined as "a preventable event that may cause or lead to inappropriate medication use or patient harm while the medication is in the control of the health care professional, patient, or consumer."⁷⁻⁹ These errors can occur at various stages of the medication use process—including the prescribing, order communication, dispensing, administering, and monitoring stages.

Medication errors may result in three different types of medication-related adverse patient events. The first type is an adverse drug reaction (ADR), which is defined as

"a response to a drug that is noxious and unintended and occurs at doses normally used for the prophylaxis, diagnosis, or therapy of disease, or for modification of physiologic function,"¹⁰ pg. 289

The second is an adverse drug withdrawal event (ADWE), defined as

"a clinical set of symptoms or signs that are related to the removal of a drug,"⁶ pg. 30

The third is a therapeutic failure (TF), defined as

"a failure to accomplish the goals of treatment resulting from inadequate drug therapy and not related to the natural progression of disease (e.g., omission of necessary medication therapy, inadequate medication dose or duration, and medication non-adherence),"¹¹ pg. 1092

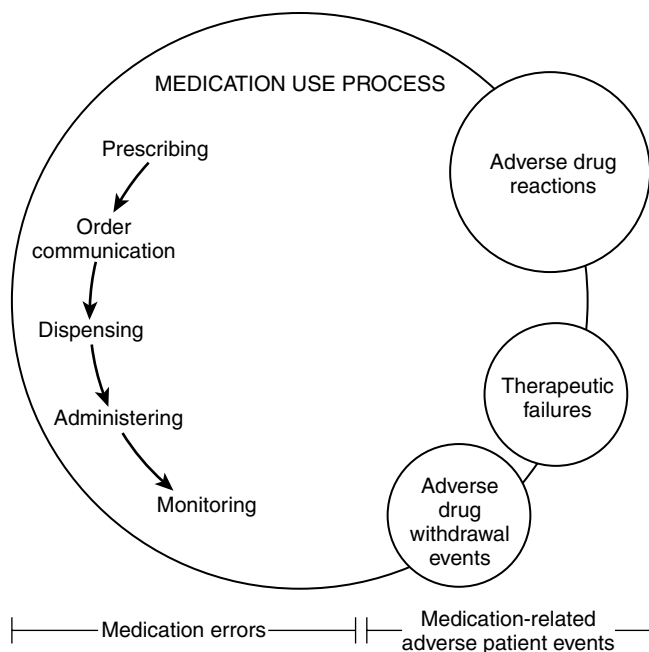

Figure 104-1. Conceptual model for medication-related problems in older adults. (Adapted from Handler SM, Wright RM, Ruby CM, et al. *Epidemiology of medication-related adverse events in nursing homes*. *Am J Geriatr Pharmacother* 2006;4:264–72.)

Medication-related patient adverse events were cited in an Institute of Medicine report as a major patient-safety concern in a variety of clinical settings including hospitals, ambulatory care, and nursing homes.⁸ Two cost-of-illness analyses done in the United States suggest that morbidity and mortality associated with drug-related problems cost an estimated \$177.4 billion per year in ambulatory patients and an estimated \$4 billion per year in nursing home residents.^{12,13} Next we describe the epidemiology of these three distinct medication-related adverse patient events.

EPIDEMIOLOGY OF ADVERSE DRUG REACTIONS

Several authors have reviewed the epidemiology of ADRs.^{6,7,14} Here we summarize some studies published most recently. One of the worst adverse consequences of pharmacotherapy is emergency department evaluation and hospitalization. Budnitz et al evaluated the frequency and characteristics of ADRs that lead to emergency department visits in the United States over a 2-year period.¹⁵ Using 21,298 ADR case reports, the authors concluded that 5.9% of all emergency department visits for adults over the age of 65 were for ADRs. Yee et al conducted a retrospective chart review of all older patients who visited the emergency department and found that 12.6% of all encounters were associated with an ADR.¹⁶ Pirmohamed et al conducted a prospective evaluation of 18,820 patients who presented to large general hospitals in England.¹⁷ The authors found that 6.5% (1225) of emergency department evaluations required hospital admission because of an ADR. The median age of a patient admitted for an ADR was 76 years, and the authors concluded that most ADRs were definitely or possibly avoidable.

Few investigators have studied ADRs in elderly outpatients or nursing home residents. In a large cohort study of older ambulatory adults, 5.5% (1523 of 27,617) experienced an ADR over a 12-month study period.¹⁸ Of those that experienced an ADR, 27.6% (421) were considered preventable. In a group of 808 frail elderly outpatients, Hanlon et al documented that 33% experienced an adverse drug event over a 1-year follow-up period.¹⁹ Of those that experienced an ADR, 37.6% (187/497) were considered preventable. Gurwitz et al studied the occurrence of ADRs in 18 Massachusetts nursing homes.²⁰ Over a 1-year period, they found that 2916 nursing home residents had 546 ADRs, an incidence rate of 1.89 ADRs per 100 resident-months. Overall, nearly 44% of the ADRs were fatal, life threatening or serious, and 51% were preventable. In a more recent study, Gurwitz et al examined the combined incidence of ADRs in two academic nursing homes.²¹ In this 9-month prospective observational study, 815 ADRs were detected among 1247 nursing home residents, an incidence rate of 9.8 ADRs per 100 resident-months. As in their previous study, Gurwitz et al found that the majority (80%) of ADRs occurred at the monitoring stage of the medication-use process and a large proportion (42%) were considered preventable. Collectively, these studies from a variety of settings document that ADRs are a common phenomenon in elderly patients.

ADVERSE DRUG REACTION RISK FACTORS

Investigators have attempted to identify a uniform set of patient-level risk factors for the development of ADRs in order to direct prevention efforts at high-risk individuals.^{15–21}

Only four risk factors were uniformly found to increase the likelihood of developing an ADR: presence of polypharmacy, use of central nervous system agents, anti-infectives, and anticoagulants. Multiple medication use or polypharmacy is an important factor because it is potentially modifiable. However, the reduction in number of medications in elderly patients with multiple diseases may be difficult because the diseases often require pharmacotherapy. It is also difficult to avoid the drug classes most associated with ADRs, because these drug classes are essential to the management of older persons.

Investigators have suspected that age-related alterations in pharmacokinetics and pharmacodynamics, fragmented medical care, suboptimal prescribing, suboptimal medication monitoring, and medication adherence influence the risk of ADRs.^{22–30} The latter three items are clinically important and will be discussed further in this chapter.

There are two major categories of suboptimal prescribing that may contribute to ADRs: (1) overuse or polypharmacy and (2) inappropriate use.^{26,27} Operational definitions of polypharmacy differ by clinical setting. One common definition (9+ drugs) in U.S. nursing homes is found in nearly 60% of patients.³¹ There is limited information about polypharmacy defined as the administration of more medications than are clinically indicated.^{26,27} Two studies showed that between 44% and 59% of outpatients were prescribed more than one unnecessary drug.^{32,33}

Inappropriate prescribing can be defined as prescribing a medication whose risks outweigh the benefits.^{26,27}

A common medical standard that has been applied and studied in a variety of care settings has been the Beers explicit criteria.^{34–36} Results of recent epidemiologic studies suggest that the prevalence of prescribing a Beers criteria medication is 12% in the ambulatory care setting, 29% in the hospital setting, and 47% in the nursing home setting.^{37–39}

Alternatively, inappropriate prescribing can be defined as prescribing that does not agree with accepted medical standards.^{26,27} Hanlon et al found that 91.9% of 365 elderly ambulatory patients in the United States had one or more prescribing problems as evaluated by the Medication Appropriateness Index (MAI).⁴⁰ A study by Steinman et al found in a sample of 170 older patients very little concordance between those with polypharmacy (9+) drugs, or taking an inappropriate drug as per the Beers criteria, or taking an inappropriate drug as per the MAI.⁴¹ Of note, the MAI was the most comprehensive approach, missing only 10% of patients identified as having either polypharmacy or taking a Beers criteria drug.⁴¹

Studies are starting to emerge describing problems associated with suboptimal medication monitoring and its relationship to ADRs in a variety of care settings. For example, two thirds of the ADRs experienced by older adults in the emergency department were due to toxicity from a relatively small set of drugs for which regular monitoring is commonly required to prevent acute toxicity.¹⁵ In the ambulatory care setting, a substantial proportion of older adults do not receive appropriate laboratory monitoring while being prescribed chronic medications, which also leads to an increased risk of developing an ADR.^{28,29,42} Finally, as many as 70% of the ADRs in nursing homes are related to a failure to appropriately monitor medications.^{20,21}

Medication adherence may also be a risk factor for ADRs. However, the contribution of medication nonadherence to ADRs is likely to be minor as elderly patients may be adherent with up to 75% of their total number of medications overall.³⁰ Moreover, the most common type of medication adherence problems is underuse.³⁰

EPIDEMIOLOGY OF ADVERSE DRUG WITHDRAWAL EVENTS

Adverse drug withdrawal events (ADWEs) are not formally examined in premarketing clinical trials so one must rely on clinical experience and published data in the post-marketing period to glean information about these problems. The clinical manifestation of ADWEs may appear either as a physiologic withdrawal reaction of the drug (e.g., β -blocker withdrawal syndrome) or as an exacerbation of the underlying disease itself.^{43,44} There have been few studies of this phenomenon in elderly patients. Gerety et al investigated ADWEs in a single nursing home in Texas over an 18-month time period and found that 62 nursing home patients experienced a total of 94 ADWEs (mean 0.54 per patient), corresponding to an incidence of 0.32 reactions per patient-month.⁴⁵ Cardiovascular (37%), central nervous system (22%), and gastrointestinal drug classes were the most frequently associated with an ADWE. Over 27% of ADWEs were rated as severe. A study of ambulatory elderly patients by Graves et al in the United States investigated ADWEs in 124 patients and discovered that out of 238 drugs stopped, 62 (26%)

resulted in 72 ADWEs in 38 patients.⁴⁶ Cardiovascular (42%) and central nervous system (18%) drug classes were the most frequently associated with an ADWE. In 26 of the ADWEs (36%), patients required hospitalization, emergency room admission, or urgent care clinic visits. Most of the ADWEs were exacerbations of an underlying disease, and some withdrawal events occurred up to 4 months after the medication was discontinued. Finally, in a study by Kennedy et al, ADWEs were investigated in the postoperative period in a single hospital.⁴⁷ Of 1025 patients studied, 50% were over the age of 60 years. Thirty-four patients suffered postsurgical complications resulting from drug therapy withdrawal. Specific drug classes involved in ADWEs included antihypertensives (especially angiotensin-converting-enzyme inhibitors), antiparkinson medications (especially levodopa/carbidopa), benzodiazepines, and antidepressants.

ADVERSE DRUG WITHDRAWAL RISK FACTORS

Little is known about the risk factors for ADWEs. In the study by Gerety et al, ADWEs were associated with multiple diagnoses, multiple medications, longer nursing home stays, and being hospitalized.⁴⁵ Graves et al found that the number of medications stopped was a significant predictor of ADWEs.⁴⁶ Analyses by Kennedy et al revealed that the risk of an ADWE increased as the length of time off the medication increased.⁴⁷

EPIDEMIOLOGY OF THERAPEUTIC FAILURE

There have been few studies of this phenomenon in elderly patients. In a U.S. study of therapeutic failure leading to hospitalization, investigators used the reliable Therapeutic Failure Questionnaire (TFQ) to measure therapeutic failure in 106 frail older adults who were admitted to 11 Veterans Affairs hospitals.⁴⁸ Eleven percent of these individuals had probable therapeutic failure leading to hospitalization. The most common conditions associated with therapeutic failure involved congestive heart failure and chronic obstructive pulmonary disease. In the emergency department, Italian investigators found that 6.8% of patients had evidence of therapeutic failure with nearly two thirds occurring in patients over the age of 65 years old.⁴⁹ A U.S. investigation of drug-related emergency department visits in elderly patients found that 28% of drug-related visits were due to therapeutic failure.¹⁶

THERAPEUTIC FAILURE RISK FACTORS

Little is known about the risk factors for TFs. Reasons for therapeutic failure may include low prescribed dose, drug-drug interaction, drug resistance or nonresponse, inadequate therapeutic monitoring, nonadherence, or underprescribing of necessary drug therapy. We discuss the latter two reasons next.

Nonadherence was the most common reason for therapeutic failure in the U.S. TFQ hospitalization study (58%) and in the U.S. emergency department visit study (66%).^{16,48} Older patients may not fill the prescription, not take a filled prescription, skip doses, take the drug erratically, or reduce doses.

These behaviors may be intentional (e.g., adverse effects, health beliefs, concerns about taking too many drugs) or unintentional (e.g., cognitive impairment, poor vision or dexterity, lack of transportation).⁵⁰ Cost-related nonadherence is a particularly important and prevalent subtype of intentional nonadherence among older adults with limited means.^{51,52}

Another major factor related to therapeutic failure is the underprescribing of medications, which can be defined as the omission of drug therapy that is indicated for the treatment or prevention of a disease or condition.^{26,27} A study that applied the explicit Assessing Care of Vulnerable Elders criteria found that 50% of 372 vulnerable adults were not prescribed an indicated medication.⁴² The most common problems were no gastroprotective agent for high-risk nonsteroidal anti-inflammatory drug (NSAID) users, no angiotensin-converting enzyme inhibitor (ACE-I) in diabetics with proteinuria, and no calcium or vitamin D for those with osteoporosis.⁴² A group of U.S. investigators using the Assessment of Underutilization of Medication (AOU) measure found evidence of underuse of medications in 62% of 384 frail elderly patients at hospital discharge.⁵³ The necessary medication classes most likely to be omitted were cardiovascular (e.g., antianginal), blood modifiers (e.g., antiplatelet), vitamins (e.g., multivitamin), and central nervous system (e.g., antidepressant) agents. Patients with limited ability to perform basic activities of daily living and greater comorbidity were at higher risk for undertreatment. Clinical researchers have consistently detected underuse of medications for specific diseases or conditions in older adults, including congestive heart failure, myocardial infarction, hypertension, hyperlipidemia, osteoporosis, depression, diabetes mellitus, and pain. For example, one study found that only half of a large cohort of 21,138 elderly patients with diabetes who also had hypertension or proteinuria received recommended therapy with an angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB) to retard progression of chronic kidney disease.⁵⁴

MEASURES TO REDUCE MEDICATION-RELATED PROBLEMS IN ELDERLY PATIENTS

Given that medication-related problems are common, costly, and clinically important, how can they be reduced? The specific answer to this question is surprisingly difficult because there are few health services intervention clinical trials in elderly patients that examine measures to reduce ADRs, ADWEs, or TFs. Therefore, health policy makers and clinicians must look to reasonable, empirical approaches that are based on existing epidemiologic and clinical information. These approaches, to be discussed here, include better health systems design, improved health services, and patient/caregiver education. Health professional education will be discussed in the last section on the principles of geriatric pharmacotherapy.

Health systems design

Medication-related problems can be reduced by designing health care systems that make it difficult for individuals to do the wrong thing and easy to do the right thing.⁵⁵ In the latest Institute of Medicine Report, *Reducing Medication Errors*, the authors provide a number of specific recommendations to

improve medication safety.⁸ One recommendation is that all health care organizations should immediately make complete patient-information and decision-support tools available to clinicians and patients. Another recommendation is that health care systems should capture information on medication safety and use this information to improve safety. Health care organizations should also implement the appropriate systems to enable providers to have (1) access to comprehensive reference information concerning medications and related health data, (2) assess the safety of medication use through active monitoring and use these monitoring data to inform the implementation of prevention strategies, (3) write prescriptions electronically, and (4) subject prescriptions to evidence-based, current clinical decision support. A recent systematic review assessed the effects that computerized physician order entry and clinical decision support systems have on the quality, efficiency and cost of health care for elders.^{56,57} These studies suggest that although the amount of research available is limited, studies have been able to demonstrate improvements in the quality and efficiency of the medication use process. It is likely that the continued development and refinement of clinical decision support systems will lead to a reduction in medication errors and medication-related adverse events in a variety of care settings.

Health services approaches

Four reviews summarize clinical trials where two health services approaches, clinical pharmacist services and geriatric medicine services, have shown an improvement in suboptimal prescribing and medication adherence and reduced ADRs in older adults.^{26,27,58,59} Clinical pharmacy is a health science discipline that is concerned with the science and practice of rational medication use. One study by Leape et al showed that clinical pharmacist activities reduced ADRs in intensive care unit patients.⁶⁰ Geriatric medicine services, also known as geriatric evaluation and management (GEM), utilizes a multidisciplinary team of specialists in geriatrics to manage patient care. The teams generally consist of a geriatrician, physician, nurse, social worker and pharmacist. An important component of GEM is the assessment and optimal management of medications. One study by Schmader et al showed that GEM care reduced the risk of serious ADRs in frail outpatients.⁶¹ Additional large, multicenter controlled trials are needed to determine the effectiveness of these and other approaches to optimizing medication use in older adults on medication-related adverse patient events.

Patient/caregiver education

Systematic education of patients and caregivers about ADRs may increase their ability to better report or avoid potential adverse drug events, thereby allowing clinicians to make medication changes before these adverse events become too serious. In addition, one study showed that when the pharmacist counsels patients about their medications upon hospital discharge, it can reduce the rate of adverse drug reactions.⁶² One review summarized randomized controlled trials designed to enhance medication adherence and related outcomes in the elderly.⁶³ Patient education and compliance aids can improve medication adherence, which could potentially reduce therapeutic failure that may lead to hospitalization because of a patient or caregiver's decision to stop

a beneficial medication.⁶³ Although not definitively shown, it is sensible that patient and caregiver education about ADWEs could prevent a patient or caregiver from stopping a medication abruptly that should be withdrawn slowly.

PRINCIPLES OF GERIATRIC PHARMACOTHERAPY

Clinicians who care for elderly patients need to know and apply principles of geriatric pharmacotherapy in order to maximize the benefits of medications in their elderly patients and minimize medication-related problems (Table 104-1). The first step in prescribing is to decide whether medication therapy is really necessary, as many medical problems in elderly patients do not require a pharmacologic solution. If the clinician decides that a medication is indicated and its benefits outweigh its risks, then the choice of the medication must factor in the medication's pharmacokinetics, the patient's renal and hepatic function, the medication's main potential adverse effects, and the patient's other medications and diseases. The starting dose for most medications in

elderly patients must be lower, and the interval before modifying the dosage often must be extended. Cost and establishment of clear therapeutic end points are also important.

In the ongoing management of the patient and his or her medications, the clinician should monitor for potential ADRs via the history, physical examination, and, where appropriate, laboratory data.⁶ The identification of ADRs can be a challenging task in elderly patients because their ADRs may present in a vague or atypical fashion and the causal link can be difficult to establish. The first step is to consider ADRs in the differential diagnosis of most geriatric syndromes. If the adverse event is a known side effect of one or more of the patient's medications, the clinician can further enhance his or her confidence in establishing ADR causality by considering the temporal relationship of onset of medication use to onset of event, competing causes, rechallenge, dechallenge, and other factors.⁶⁴ Nonetheless, in some cases, the clinician may find it difficult, and sometimes impossible, to establish the ADR causal link between medication effect and illness in elderly patients.

In patients who have recently stopped a medication, it is important to consider the possibility of an ADWE. ADWEs in elderly patients can be overlooked when the withdrawal event is mistaken for a patient's disease state. Common events that may happen in the everyday care of an elderly patient such as discontinuation of unwanted medications, intentional noncompliance, stopping medications before a surgical procedure, and managed care practices of medication substitution within classes of medications may lead to an ADWE. Table 104-2 lists medications commonly used by elderly patients that may be associated with withdrawal syndromes or exacerbation of the underlying disease.^{43-46,65} To prevent ADWEs, the clinician should take into account the dose of the medication, the length of therapy of the medication, and the pharmacokinetics of the medication. Risk can be minimized or eliminated by a slow, careful tapering of the medication over a period of time. This approach is similar to the time taken in the initiation and titration of a new medication. Unfortunately, precise tapering schedules have not been established for most medications.

Table 104-1. Principles of Geriatric Pharmacotherapy

1. Consider whether medication therapy is necessary.
2. Know the pharmacology of the medication in relation to age.
3. Know the adverse effect profile of the medication in relation to the patient's other medication(s) and disease(s).
4. Choose initial dose, and adjust it carefully (doses will often need to be smaller in elderly people).
5. Select the least costly alternative.
6. Establish clear, feasible therapeutic end points.
7. Monitor for adverse drug reactions, an important cause of geriatric illness.
8. Slowly taper medications to prevent/minimize adverse drug withdrawal events (if possible).
9. Regularly review the need for chronic medications and discontinue unnecessary ones.
10. Assess whether there is omission of needed medication for the established diagnosis/condition.
11. Review adherence, simplify the medication regimen, if possible, and consider use of aids.

Table 104-2. Medications Associated With Adverse Drug Withdrawal Events in the Elderly

Medications	Type of Withdrawal*	Withdrawal Syndrome
Alpha-antagonist antihypertensives	P	Hypertension, palpitations, headache, agitation
Angiotensin-converting enzyme inhibitors	P, D	Hypertension, heart failure
Antianginal agents	D	Myocardial ischemia
Anticonvulsants	P, D	Seizures
Antidepressants	P, D	Akathisia, anxiety, irritability, gastrointestinal distress, malaise, myalgia, headache, coryza, chills, insomnia, recurrence of depression
Antiparkinson agents	P, D	Rigidity, tremor, pulmonary embolism, psychosis, hypotension
Antipsychotics	P	Nausea, restlessness, insomnia, dyskinesia
Baclofen	P	Hallucinations, paranoia, insomnia, nightmares, mania, depression, anxiety, agitation, confusion, seizures, hypertonia
Benzodiazepines	P	Agitation, confusion, delirium, seizures, insomnia
Beta-blockers	P	Angina, myocardial infarction, anxiety, tachycardia, hypertension
Corticosteroids	P	Weakness, anorexia, nausea, hypotension
Digoxin	D	Heart failure, palpitations
Diuretics	D	Hypertension, heart failure
Histamine-2 blockers	D	Recurrence of esophagitis and indigestion symptoms
Narcotic analgesics	P	Restlessness, anxiety, anger, insomnia, chills, abdominal cramping, diarrhea, diaphoresis
Nonsteroidal anti-inflammatory drugs	P	Recurrence of arthritis and gout inflammatory symptoms
Sedative/hypnotics (e.g., barbiturates)	P	Anxiety, muscle twitches, tremor, dizziness

*P, Physiologic withdrawal; D, exacerbation of underlying disease.

Table 104-3. Medication Appropriateness Index**Questions to Ask About Each Individual Medication**

1. Is there an indication for the medication?
2. Is the medication effective for the condition?
3. Is the dosage correct?
4. Are the directions correct?
5. Are the directions practical?
6. Are there clinically significant drug-drug interactions?
7. Are there clinically significant drug-disease/condition interactions?
8. Is there unnecessary duplication with other medication(s)?
9. Is the duration of therapy acceptable?
10. Is this medication the least expensive alternative compared to others of equal utility?

At every visit, it is necessary to review and, if possible, simplify the patient's medication regimen. This may be achieved by altering the dosing schedule or discontinuing medicines that are no longer needed. To conduct the review when faced with an elderly patient taking multiple medications, the clinician can utilize any of the standardized approaches such as the Medication Appropriateness Index (MAI) (Table 104-3).⁶⁶ The clinician should also consider whether necessary medications have been omitted. A standardized tool such as the Assessment of Underutilization of Medication (AOU) can be used, which requires having a health professional match the complete list of chronic medical conditions to the prescribed medications after reviewing the medical record.⁶⁷ In this manner, one can determine whether there was an omission of a needed medication for an established disease or condition based on the scientific literature. For each condition, one of three ratings can be made: omission, marginal omission (e.g., have used appropriate nonpharmacologic approach), or no omission.

The clinician should also consider providing adherence aids for elderly patients. However, before providing the patient with methods to enhance adherence, it is important for the clinician to improve suboptimal prescribing and then to talk to the patient about how he or she takes the medications so that an individualized plan can be developed. It is also important to identify risk factors for poor adherence (e.g., impaired hearing, vision, and cognition).³⁰ Health care professionals should also follow up with compliance recommendations by monitoring their patients. Some general methods to enhance adherence in elderly patients include simplifying regimens, providing written instructions, and considering generic formulations to reduce costs. More specifically, pill boxes, increased font size on prescription labels, calendars, easy-to-swallow dosage forms, pill cutters, oral dosing syringes, insulin syringe magnification, tube spacer for inhalers, and easy-open caps may increase adherence in elderly patients. There are also some electronic devices

available as compliance aids (e.g., alarm watches with messages, automated pill delivery systems, medication bottles with alarms) that may prove to be beneficial. Finally, active patient and family involvement should be encouraged.

SUMMARY

Geriatric pharmacotherapy may greatly enhance the quality of life of elderly patients by effectively palliating, preventing, or treating many diseases and conditions in late life. The evidence for the efficacy of medications in elderly patients has significantly increased over past decades thanks to some clinical trials, and many more potentially beneficial medications are in development. However, clinical trial data may be limited by the underrepresentation of older patients in many trials, the exclusion of frail elderly or oldest-old patients, and the lack of postmarketing studies designed to assess the effectiveness of competing medications. In addition, the benefits of medication therapy can be offset by ADRs, ADWEs, and therapeutic failure. Although variable in their estimates of the frequency of these medication-related problems, many epidemiologic studies agree that these are common, costly, and clinically important problems in elderly patients. Potential solutions to these problems include better health systems design, health services approaches, and patient and caregiver education. More research is needed to determine the feasibility and effectiveness of these approaches. Clinicians who care for elderly patients need to know and apply principles of geriatric pharmacotherapy in order to maximize the benefits of medications and minimize medication-related problems.

KEY POINTS**Geriatric Pharmacotherapy and Polypharmacy**

- There are limitations in our knowledge about the efficacy and safety of medications in the elderly.
- Medication-related adverse patient events such as therapeutic failure, adverse drug withdrawal reactions, and adverse drug reactions are common and result in considerable morbidity in the elderly.
- Strategies to modify or reduce medication-related problems including polypharmacy will require that health systems design/institute new approaches to delivering care to elders.
- Clinicians should strive to conduct periodic systematic reviews of elderly patients' medication regimens as well as adhere to other principles to optimize geriatric pharmacotherapy.

INTRODUCTION

In the popular imagination and in the scientific literature, impaired mobility and balance are each associated with aging. The association between aging and mobility impairment occurs because with age, there is an accumulation of deficits, including those that affect motor performance. This is not just a matter of diseases that give rise to disorders of mobility and balance. It is worth considering that even among elite athletes, performance is age-related. When assessing the metabolic power required to achieve running world records, sprint and endurance events show a relatively uniform decline with age across the different events.¹

Chapter 106 considers the problem of falling. Here we focus on impaired mobility, although noting its relationship with balance; essential aspects of that will be covered here, too. To begin, we briefly review some essential features of how gait changes with age. Next we describe some common gait disorders and other common problems that can give rise to impaired mobility (e.g., joint and foot disorders), which can be assessed with reasonable efficiency. Moving from such specific problems, we consider how impaired mobility and balance affects older people in the hospital and in the community. Finally, we explore the relationship between impaired mobility and frailty, recognizing that the integrative aspects of reviewing high-order functions can be combined with a reductionist approach to particular disorders to make the care of frail older people better.

AGE-RELATED CHANGES IN MOBILITY

Changes in mobility and abnormalities of gait increase with increasing age; perhaps this is why the attribution of locomotion abnormalities to “old age” is a frequent occurrence among both older people and their physicians. The proportion of people with a normal gait falls from 85% of those aged 60 years to 18% aged 85 years.² Normal gait is dependent on the integrity and interaction of three components³:

- Locomotion, including initiation and maintenance of rhythmic stepping
- Balance, which engages *peripheral sensory receptors* for input, *central nervous system* structures for processing sensory input and planning motor output, and *effector organs* to carry out the movement plan (as reviewed in detail in Chapter 106).
- The ability to adapt to the environment

With aging, deficits accumulate across one or all of these systems, reducing the locomotor capability of most older adults. However, the extent to which this is due to “normal” aging is currently controversial.

The changing conceptualization of a phenomenon from normal-for-age to pathologic is exemplified by senile gait disorder. This slow, shuffling, cautious walking pattern is common in old age with no clear cause on clinical examination. And yet compared with age-matched individuals who walk normally, those with senile gait disorder have a

significantly increased risk of developing dementia⁴ and significantly reduced survival.⁵ Similarly, gait or posture impairment, present in 25% to 30% of cognitively unimpaired older people, is associated with an increased risk of cognitive decline and dementia.⁶ It is now thought that such gait abnormalities are a manifestation of subtle white-matter changes or vestibular, visual, or oculomotor dysfunction.³ In consequence, it seems reasonable as a starting stance (pardon the pun) that little should be written off as “normal gait for age.” Evaluation and treatment—stopping meds, starting exercise, etc.—should generally be considered. From an assessment standpoint, that might mean screening apparently high level people—if a geriatrician should care about them at all—with demanding tasks.⁷

Executive function

Walking was traditionally seen as an automatic task requiring little input from higher mental functions. However, an intricate interaction between gait and cognition is now recognized. The prediction of cognitive decline by senile gait disorder is matched by a converse relationship: those with established dementia are more likely to have gait abnormalities and have a significantly increased risk of falls.⁸

The link between cognition and walking may be mediated by executive function. In community-dwelling older adults after mild stroke, executive functioning is independently associated with performances of balance and mobility.⁹ The prefrontal cortex, which plays a crucial role in executive functioning, seems to be particularly vulnerable to change with “normal aging.”¹⁰ Studies investigating dual tasks, which are dependent on intact executive function, provide further supportive evidence. Older people are less able to maintain normal ambulation while performing an additional task, particularly talking.^{11,12} Even in physically fit older people, dual tasks influence balance during walking through a direct effect on body sway and stride variability and an indirect effect on gait velocity.¹³ Task shifting when multitasking is also impaired with aging. Younger people prioritize walking safely when challenged with a secondary task, but this prudent strategy is diminished in older people.¹²

Walking speed

Most quantitative studies have found that “healthy” older people walk more slowly than young adults. Gait analyses suggest their 20% slower natural velocity is secondary to reduction in stride length and that cadence (steps per minute) is well maintained.¹⁴ However, a slow gait should not be considered benign. In well-functioning community-dwelling older people, there is a continuous relationship between usual gait speed over a short course and subsequent risk of disability, hospitalization, and death.¹⁵ Indeed, reduced gait speed has been advocated as a marker of frailty—either exclusively^{15,16} or in combination with other markers of strength and vitality.¹⁷ The dynamic nature of frailty has also been explored and underpinned by measurement of mobility changes.^{18,19}

Gait initiation

Gait initiation requires the integrated control of limb movement and posture and is achieved with purposeful postural shifts (including relaxation of the triceps surae, synergistic contraction of the ventral muscles, swing hip abduction, and a few degrees of flexion in the support hip and knee). These culminate in a forward step, steady state velocity being achieved in less than two steps.¹⁴ Gait initiation is well preserved in healthy older people.²⁰ Abnormalities of gait initiation are a sensitive but not specific sign of disease processes in older people, such as Parkinson's disease, multiple cerebral infarcts, normal-pressure hydrocephalus, progressive supranuclear palsy, and cervical myelopathy.

Rising from a chair

The ability to rise from a chair is a critical aspect of normal mobility. To carry out this so-called "chair stands" test, a straight-backed chair should be placed next to a wall so it cannot slip backwards. Participants should be asked to fold their arms across their chest and to stand up from the chair one time. A second assistant should be on hand if the participant seems at high risk of instability. If successful in standing once, participants can be asked to stand up and down five times as quickly as possible and timed from the initial sitting position to the final standing position.²¹

Before standing, flexion of the knees brings the feet closer to the chair to reduce the distance that the center of mass must move anteriorly. This important preparatory movement is often omitted by patients with Parkinson's disease and other neurologic disturbances of gait.¹⁴ Standing proceeds with bilateral hip flexion, ankle dorsiflexion, and anterior rotation of the trunk and pelvis, with reversal of these dynamic events when sitting. Reduced range of motion in the hips, pelvis, knees, and spine is common with aging and impedes the initial shift of the total body center of mass over the feet. Weakness of the hip girdle muscles is also a frequent finding in older people, a manifestation of general deconditioning, and those affected may need to use their arms to help themselves upwards. Chair stands are therefore sensitive to changes in postural control, strength, and coordination and have been included in physical performance measures to stratify highly functioning older adults. The Short Physical Performance Battery (SPPB), for example, includes walking, balance, and chair stands tests and independently predicts mobility disability and activities of daily living disability in community-dwelling older people.²¹⁻²³

COMMON DISORDERS OF GAIT

Pragmatically, disorders of gait may be divided into those that are clinically obvious and others that are less so. The following gait patterns would be evident to experienced clinicians and are classified according to level of impairment/interaction with the nervous system²⁴:

Middle level disorders

- The slow and shuffling gait of parkinsonism
- The stiff limb with clumsy circumduction and scuffing of footwear due to hemiparesis, most commonly observed in stroke

- Sensory and cerebellar ataxia and vestibular pathology share unsteadiness as a core feature but can be discriminated clinically by isolating and unmasking the affected organ
- Other middle level disorders include cervical spine disease and normal pressure hydrocephalus

Lowest level disorders

- The antalgic gait pattern in which a phase of the gait is shortened on the injured side to alleviate the pain experienced when bearing weight on that side, often secondary to disease in the ankle, hip, or knee.
- Arthritis or arthrodesis of the ankle may lead to a combination of lowest level disorders with altered load bearing and secondary stress in adjacent joints (antalgic gait), subsequent muscle weakness of the tibialis anterior (slap-foot or toe-drag gait), and compensatory gait patterns (steppage gait), and recruitment of long toe extensors with hammer toe deformity a consequence.²⁵
- Other lower level disorders include peripheral neuropathy and myopathy.

Since these disorders are covered in other chapters, here we shall concentrate more on gait disorders that may present more of a diagnostic challenge.

The term gait apraxia has largely been superseded by higher-level gait disorder. This is based on "abnormalities of the highest sensorimotor systems" and assumes integrity in basic sensorimotor circuitry.²⁴ Gait pattern in higher level disorders is attributed to a motor programming failure comparable to the problems encountered in Parkinson's disease. These abnormalities can be classified according to their functional or neuroanatomic associations. Even so, the exact nature of these correlates is still debated; the present uncertainty is reflected by the many classification systems that have been proposed (Table 105-1).

It may be worthwhile reviewing just what higher level functioning achieves in relation to locomotion. Interrelated higher level structures (the cortico-basal ganglia-thalamocortical loop) meet the demands of personal desire to move and the maintenance of posture within the confines of environmental limitations.²⁶ Pathology in any of these regions or their connections therefore results in an array of gait disorders:

- Suppression of conversion of personal will into task execution manifesting as hesitation or freezing and problems initiating gait or making turns (particularly affected by abnormalities of the supplementary motor area and its connections).^{26,27}
- Dysfunctional processing with gait adversely influenced by both emotional and environmental information
- Dysfunctional or absent postural righting reflexes resulting in injurious falls
- In contrast to hypokinesia implicit in basal ganglia underactivity, disturbance in basal ganglia function may also lead to excessive, involuntary and uncontrolled limb movements²⁸

Classifications of gait have been criticized for their lack of consistency.²⁹ The Nutt classification, for instance,

Table 105-1. Classification of Higher-Level Gait Disorders

	LOCATION CLASSIFICATION*			
	Frontal Gait Disorder	Frontal Dysequilibrium	Subcortical Dysequilibrium	Speculative
Phenomenology classification [†]				Isolated gait ignition failure
Clinical findings	Extrapyramidal features, some postural imbalance	Bizarre ineffective gait	Loss of postural balance reflexes	Inability to initiate or continue movement
Liston classification [‡]	Mixed gait apraxia	← Equilibrium apraxia →		Ignition apraxia
		← Mixed gait apraxia →		
Elble classification [‡]	← Dysfunctional or absent postural righting →			Gait ignition failure

Cautious gait, psychogenic gait, and extrapyramidal overactivity probably retain their separate identities and have been omitted from the table.

*Nutt JG, Marsden CD, Thompson PD. Human walking and higher-level gait disorders, particularly in the elderly. *Neurology* 1993;43:268–79.

†Liston R, Mickelborough J, Bene J et al. A new classification of higher level gait disorders in patients with cerebral multiinfarct states. *Age Ageing* 2003;32(3):252–8.

‡Elble RJ. Gait and dementia: moving beyond the notion of gait apraxia. *J Neural Transm* 2007;114(10):1253–8.

included frontal gait disorder, cautious gait, frontal dysequilibrium and cortical dysequilibrium as distinct entities.²⁴ The older person, with accumulation and overlap of pathology, may exhibit problems of higher gait, which are not reducible to such discrete categories. Distinct gait parameters were identified by Liston et al according to their own clinically proposed subtypes. This allowed for the theoretical inclusion of mixed pathology and gait subtypes.²⁹ The amalgamation of disordered balance in conjunction with ineffective gait by Elble²⁶ seems a sensible if not altogether precise way to overcome the lack of connection between the site of pathology and the physical characteristics of gait disturbance.

The phenomenological entanglement of cautious gait is worthy of consideration. This entity may be considered multifactorial and reflects the common pathway for expression of deficits anywhere within the locomotor system in an older person. Cautious gait may be entirely appropriate in the setting of a recent fall with loss of confidence or a perceived fear of falling.³⁰ Cross-sectional studies suggest that a cautious gait is common³¹ and associated with poor standing balance, depression, anxiety, fear of falling, and reduced strength.³² It is these properties that cite a cautious gait as a high risk group but one potentially amenable to targeted interventions. The distinction between dysfunctional/excessive compensatory mechanisms and a primary disturbance of gait is important.³² Cautious gait should therefore not be labeled as a higher-level disturbance without first excluding and attempting to correct a primary disorder of locomotion.³¹

In direct contrast to cautious gait, those with careless gait³ exhibit disinhibition of movement with an inability to match their judgment to their physical limitations or the hazards posed by the external environment. Though many studies report that older people with dementia walk slowly,³³ if their overall degree of physical impairment is taken into account (e.g., use of walking aids and functional impairment), they may actually walk too quickly.³⁴ Such recklessness implicates frontal lobe disturbance, as noted, and may account for the high level of injurious falls observed in dementia. Similarly, in hospitalized older people, those with delirium are at high risk of falls because of excessive ambulation and lack of insight into mobility problems.³⁵ Mismatch in confidence and ability, while difficult to measure, remain an important clinical indicator of gait stability.

Drugs can influence mobility and balance in as many ways as there are pathways involved.³⁶ The resulting gait disorder depends on the site of drug action and may be further complicated by polypharmacy, drug/drug interaction, and altered pharmacodynamics and kinetics associated with aging.³⁷ Since cognitive impairment is associated with disturbance in mobility and balance, it is not hard to conceptualize the careless gait of dementia or delirium becoming more precarious when disinhibiting sedatives or neuroleptics are prescribed.³⁸

CLINICAL ASSESSMENT OF BALANCE AND MOBILITY

Mobility and balance provide an insight into the speed, stability, and adaptability of locomotion. Balance may be static (preserving upright posture while standing still) or dynamic (in response to an internal or external stressor). Contemporary studies have shown impairments in balance to be common and associated with adverse outcomes, particularly falls.³⁹ Performance measures have therefore been developed to quantify balance impairments, including:

- The Berg balance test.⁴⁰ This provides an ordinal measure of static and functional balance, has been validated in older patients in wide range of settings⁴¹ and correlates with outcome and disability.⁴² Although easy to use, it is limited by floor and ceiling effects.⁴³
- The timed get-up-and-go is an integral measure of gait speed and balance in widespread clinical use.⁴⁴ It is reliable⁴⁵ and also correlates well with Barthel Index.⁴⁶ It seems to predict the patient's ability to go outside alone safely.⁴⁷
- The Tinetti balance and mobility scale⁴⁸ tests for performance of balance and mobility across a wide range of tasks. The Tinetti scale is a valid predictor of future falls in older patients.⁴⁹ It is a reliable instrument across a range of rater experience.⁵⁰

However, these tests lack well-described "norms" and it is not clear how much change to expect under different circumstances.⁴³ Performance-based measures also need to be sensitive to change to be informative. Yet if a patient is unable to complete the task asked of him or her

by a performance-based measure then this results in missing data. For example, once a patient is unable to stand or walk then their abilities cannot be rated. This may exclude the very patients on whom more information would be helpful, the most frail.⁵¹ Failure to complete performance-based measures is associated with poor health status and increased risk of death.⁵²

Another method to assess mobility and balance involves observation of usual rather than extended performance. This may better represent the abilities of the frailest individuals. And being more inclusive of the functional abilities of a patient in the context of a geriatric service, the assessment of mobility incorporating a low functioning individual shines a light on overall state of health. The Hierarchical Assessment of Balance And Mobility^{53–55} has been developed as a global means of tracking progression and recovery in frail older adults who become ill. By displaying changes in static and dynamic balance and in mobility graphically, it provides a standardized and transparent description of levels of mobility and balance in three areas: in bed mobility, transfers, and walking. In each area higher scores indicate greater mobility. Patients are observed and scored at their highest level of observed safe function using their usual aid. Despite a possible ceiling effect, which may be less relevant to the population group of interest, the HABAM (hierarchical assessment of balance and mobility) has demonstrated its validity, reliability, responsiveness, and sensibility as a measure of mobility and balance. The Elderly Mobility Scale⁵⁶ and the Physical Performance Mobility Examination⁵⁷ are other tools that are tailored to the assessment of older acutely unwell patients based on evaluation of the patients usual activity. Only the HABAM has been shown to represent a unidimensional measure of mobility and is validated as an interval measure. It has superiority in terms of ease and acceptability to users.⁵⁸

The assessment of mobility in this way offers numerous clinical benefits:

- A risk stratification marker: using mobility and balance as a noninvasive tool to identify physiologic decline before conventional means of evaluation register such concern
- The opportunity to explore the relationship between specific diagnoses and/or geriatric syndromes with mobility and balance
- An objective threshold of improvement rather than gestalt can determine suitability and timing of more intensive rehabilitation techniques
- A visual prognostic tool with which to inform patients and caregivers, facilitate teaching and learning opportunities, and ease multidisciplinary working
- Assessment of mobility and balance provides a culture of clinically meaningful patient contact without redress to expensive technologies

Given the importance of mobility and balance as an overall correlate of an individual's state of health, the HABAM can be used to track daily changes in a patient's health. This has particular usefulness in elderly patients who are frail, in whom many of the traditional signs of illness often are not present. Consider, for example, a patient with pyelonephritis, whose presentation was one of being "off legs" or "taking

to bed." In a younger patient it would be reasonable to track successful treatment of the infection by noting defervescence, the amelioration of the neutrophilic leukocytosis and settling of flank pain. If none of these was present at the start of the illness in a frail older adult, then their resolution can hardly be tracked as signs of recovery. Changes in mobility and balance, however, follow a reliable hierarchy, as illustrated in Figure 105-1. In the first patient (Panel A) mobility and balance had deteriorated considerably from baseline, so that one person could only move from side to side in bed, and required the assistance of two people to transfer and to walk even to the bathroom in one person hospital room. By the second hospital day, however, recovery had begun and accelerated after day 5. In another patient with a similar level of decline, however, continued worsening on the second and third hospital days signaled a rapidly fatal course that ended in death by day 6 (Panel B). In our experience, these observations can readily be taught to house staff and to other learners, who find it a useful way to quantify their nascent clinical judgment and so gain confidence in their ability to care for frail older adults who are acutely ill.

IMMOBILITY IN OLDER PEOPLE: IMPACT AND INTERVENTIONS

Older people in hospital

Prevention of age-associated decline in mobility is a major clinical and public health priority.²³ In the early 1940s, curative operations and antibiotics replaced bed rest as therapeutic strategies and pioneers of geriatric medicine were among the most vociferous advocates of early ambulation. Working in "chronic sick" wards where older people had spent years in the hospital because they had nowhere else to go, geriatricians found that rehabilitation and mobilization enabled many patients to be discharged home.⁵⁹ Asher famously expressed the disadvantages of bed rest in a 1947 BMJ paper: "Look at the patient lying in bed. What a pathetic picture he makes! The blood clotting in his veins, the lime draining from his bones, the scybala stacking up in his colon, the flesh rotting from his seat, the urine leaking from his distended bladder and the spirit evaporating from his soul".⁶⁰ The accuracy of Asher's observations has subsequently been confirmed. Prolonged bed rest in healthy young men has deleterious effects on nearly every organ system⁶¹ and in older people in the hospital, bed rest contributes to deep vein thromboses, pressure sores, and incontinence.⁶² Bed rest has such a major role in the pathogenesis of neuromuscular weakness in critically ill patients that a new approach for managing mechanically ventilated patients includes reducing deep sedation and early rehabilitation therapy and mobilization.⁶³ Finally, but by no means least importantly, Asher seems to have recognized the adverse psychological impact of immobilization,⁶⁴ though a minority argue that "the spirit evaporating from his soul" is more likely to result from enforced mobilization than judicious bed rest.⁶⁵

Interventions to improve outcomes in hospitalized older people have centered on exercise. A recent Cochrane systematic review⁶⁶ determined the effect of exercise interventions for acutely hospitalized older medical patients on functional status, adverse events, and hospital outcomes. Of 3138 potentially relevant articles screened, 7 randomized controlled trials and 2 controlled clinical trials were

Notes for scoring the HABAM.

- Baseline (-14) is taken as 2 weeks prior to the current assessment.
- Each domain (balance, transfers, mobility) is scored at the highest level attained.
- In Balance, “**dynamic**” refers to withstanding a force, either administered externally (e.g. a sternal nudge) or internally (e.g. reaching forward).
- In Transfers, **standby assist** refers to no hands-on assistance but presence of an aide for security; **minimal assist** refers to hands on with little force, chiefly for guidance.
- In Mobility, **<8m** corresponds to not being able to walk outside the room; **8-50m** mobility is being able to get to the nursing station and back; **>50m** is more than one trip around the ward.
- The HABAM should be scored using the patient’s usual walking aid.

included. Although the effect of exercise on functional outcome measures was unclear, there was “silver” level evidence that multidisciplinary intervention that includes exercise may increase the proportion of patients discharged home and reduced length and cost of hospital stay for acutely hospitalized older medical patients.

Nutritional support also improves outcomes of hospitalized older people. Though mobility outcomes were not explicitly reported, dietetic assistance significantly reduced patients’ risk of dying after hip fracture.⁶⁷ Randomized trials are underway to establish whether the combination of a 6-month, individualized exercise and nutrition program improves mobility and function after hip fracture.⁶⁸ Anabolic agents are theoretically attractive as therapeutic agents in hospitalized older people, reducing the negative nitrogen balance and improving body composition, but small randomized controlled trials have shown no effect on mobility or function and further studies with longer follow-up periods are needed.⁶⁹

Community-dwelling older people

The impact of immobility for community-dwelling people has been investigated by Gill’s group at Yale University. In a prospective study, illnesses and injuries leading to either hospitalization or restricted activity were strongly associated with the development of a disability, including the need for personal assistance walking inside the house or transferring from a chair.⁷⁰ The associations were present both in those who were and were not frail (with frailty defined on the basis of slow gait speed). In the same patient cohort, episodes of bed rest (staying in bed for at least one half a day due to illness, injury, or other problem) were associated with decline in function, including mobility impairment.⁷¹ Additional research was called for to identify precipitants of bed rest and determine whether intervention or aggressive treatment would reduce functional decline.

Exercise programs of varying design have diverse positive effects in community-dwelling older people including improved muscle strength and gait speed,^{72,73} reduction in falls,^{74,75} and improved balance.^{76,77} In longitudinal cohort studies, physical activity is protective of impaired physical function.^{78–80} Participation in frequent and intense training can result in even greater improvements in reactive balance performance: older athletes undertaking long-term high intensity training demonstrate better and more rapid stabilization of posture following perturbation than healthy older adults under challenging conditions.⁸¹

Exercise programs for frail older people, however, have yielded conflicting results. A systematic review of physical training in institutionalized elderly patients indicated positive effects on muscle strength but effects on gait, disability, balance, and endurance were inconclusive.⁸² In some studies, exercise programs in very frail older people result in no improvements in physical health or function⁸³ and increase musculoskeletal injury⁸⁴ and falls.⁸⁵ In contrast, other studies conclude that exercise improves physical performance scores⁸⁶ and reduces falls.⁸⁷ In an international observational study, physical activity in frail older people seemed to slow further functional decline.⁸⁸

These conflicting results may be secondary to the use of different definitions of frailty and controversy about which outcomes have the best measurement characteristics.²³

IMPAIRED MOBILITY AND FRAILTY

The most consistent independent predictors of future falls in older adults are gait or balance deficits.⁸⁹ This is consistent with the paradigm of frailty in older people as failure of a complex system. Walking on two legs is not exceptional to humans (birds and some lizards do it, too) but the complexity of this task, the kinematic features of our gait, and its dependence on central nervous system control makes human bipedalism unique and distinct from that found in animals.^{90,91} Normal ambulation in people requires the coordination of many different muscles acting on multiple joints and is accomplished by the integration of activity in spinal neuronal circuitries with sensory feedback signals and with descending commands from the motor cortex.⁹⁰ The central nervous system coordinates this activity, adjusts it to fit environmental conditions, and refines it when required, all the while maintaining a remarkable degree of precision. For example, the position of the human foot during normal walking depends on the coordination of five joints and 15 muscles acting on the knee joint alone and yet with every step the foot is elevated by only 1 to 2 cm above the ground and its position varies by less than 4 mm.^{92,93} The computational task solved by the human brain to accomplish this feat is extraordinary given the infinite number of combinations of joint and muscle positions that have to be attuned relative to each other to arrive at the desired outcome. Bipedalism is indeed a higher order function that requires a significant degree of connectivity and coordination between several interdependent components (muscular, skeletal, and nervous) of the complex system that is the human body. Consequently, it should not be surprising that frail individuals who have gait and balance deficits and who have lost the ability to integrate multiple inputs in the face of stress often experience impaired mobility and falls.⁹⁴

There is a tension between this approach, and one that aims to tease out influence of the component parts. Several groups have emphasized the importance of sarcopenia (the reduction of muscle mass and function) in the pathogenesis of frailty.^{95–97} Since immobility and lack of exercise are major factors responsible for sarcopenia, self-report and objective evaluation of physical performance are advocated as the best indicators of frailty in elderly subjects, a poor performance characterizing those who may benefit from intervention.⁹⁸

Some components of frailty may be more predictive of adverse outcomes. Among very frail older people, those with mobility disability had a higher risk of mortality and nursing home placement than those without, and incidence of hip fracture and hospitalization was associated with severity of mobility limitations.⁹⁹ Similarly, mobility impairment is also of determining importance in high-functioning older women, with lower performances in mobility and balance tests (along with increasing age, poor perceived health, lower muscle strength, higher body mass index, lower educational level, and lower reported physical activity) being strong predictors of disability.¹⁰⁰ Furthermore, recent studies suggest the combination of certain frailty components may be critical. In participants of the MacArthur Study of Successful Aging, six frailty subdimensions were identified (different combinations of 4 or

more of 10 criteria: weight loss, weak grip, exhaustion, slow gait, low physical activity, cognitive impairment, high interleukin-6, high C-reactive protein, subjective weakness, anorexia). Each had a different predictive validity for disability and mortality, suggesting “that pathways to frailty differ and that subdimension-adapted care might enhance care of frail seniors.”¹⁰¹

Other groups have investigated component parts of frailty with even greater precision. For example, contributors to leg power (muscle strength and limb velocity) are each associated with different elements of balance performance in older people.¹⁰²

So while some researchers in the aging field emphasize the conceptualization of frailty as a risk state and while others aim to clarify components of the risk state, the importance of mobility impairment is universally recognized. Both approaches to frailty are motivated by the need to increase our understanding of the pathways to poor health in old age and they are not irreconcilable. Inouye et al,¹⁰³ for example, identified impaired mobility as one of four shared risk factors (along with older age, baseline cognitive impairment, and baseline functional impairment) for five common geriatric syndromes (delirium, pressure ulcers, incontinence, falls, and functional decline) and for the “overarching geriatric syndrome of frailty.” Pleiotropic interventions with effects on many different cells and tissues (such as antioxidants or exercise or improved nutrition) were advocated as the most promising preventive strategies. Thus it is feasible to unite the two different approaches to frailty, recognizing and investigating the importance of components of frailty yet managing it as a complex condition.

CONCLUSION

Mobility impairment is integral to frailty, however defined.^{104–106} What is more, the clinical assessment of changes in mobility is an important aspect of evaluating change in physical frailty.^{18,19} Since “you can’t manage what you can’t measure,” the use of a standardized means of describing mobility can help improve the otherwise curiously moral language commonly employed at the bedside (e.g., mobility being “not too good”). Even though the dangers of going to bed have been known for generations,⁶⁰ it persists as the default method for providing care in many settings. Clearly, there is much that geriatricians need to do both to better understand mobility and balance and to better communicate why and how it should be assessed routinely in frail older adults, especially when they are ill.

KEY POINTS

Impaired Mobility

- Impaired mobility and balance are common in older adults who are frail.
- Impaired mobility and balance should be investigated as signs of illness, and not accepted as inevitable parts of aging.
- Exercise has a particular role in the treatment of impaired mobility and balance in elderly people.
- Though the dangers of going to bed have been known for generations, it persists as the default method for providing care in many settings.

INTRODUCTION

Falls are a major focus of geriatric medicine because they are common among older adults and have complex interacting causes, serious consequences, and require multiple disciplines for effective management. The goals of this chapter are to present the scope and impact of the problem, explore various perspectives on causation, provide guidance about clinical evaluation and treatment, and examine opportunities to implement programs across health care settings and communities.

EPIDEMIOLOGY

Falls are common among older adults. Up to one third of community-dwelling persons over the age of 65 fall every year and about one fourth to one fifth of them will fall repeatedly.¹ Falling is more common among women than men and increases in prevalence with advancing age. In acute care settings, falls are the most commonly reported adverse incident with rates varying from 3 to 13 falls per 1000 bed days.² In chronic care settings, falls are so common that typically over half of residents are fallers and average rates can run from 1.5 falls per bed per year to two to six falls per resident per year.³ The most obvious adverse consequence of falls are injuries, which develop in about 10% of community fallers and 30% of fallers in acute and chronic care.^{1,2} Injuries are more likely in recurrent fallers.¹ Falls can be fatal; they are the fifth leading cause of death among older adults.¹ Falls are a major contributor to serious injuries, including not only hip fractures, but also other fractures, cervical spine injuries, and severe head trauma.^{4,5} Falls are a common precipitator of hospitalization and contribute to the need for long-term institutionalization.^{1,6} Falls in acute and chronic care institutions are also a source of complaints from families and even the source of litigation.⁷ Although injuries and health care use are serious concerns, falling also creates other serious problems for the older adult, including functional limitations, fear of falling, restricted activity, and social isolation.^{1,7} Falling can be a precipitator of a vicious cycle of failing health and function leading to death.

In the past, there has been no widely agreed-upon definition of falls. More recently, ProFaNE (Prevention of Falls Network Europe, www.profane.eu.org), a multinational work group dedicated to reducing falls and injuries through research and implementation of evidence-based interventions, has proposed the following as the most reliable and valid definition⁸:

"A fall is an unexpected event in which the participant comes to rest on the ground, floor or lower level."

Although this definition provides some consistency for reporting, there are still areas of confusion. It is not clear if it is appropriate to include in the definition of falls those events associated with loss of consciousness or overwhelming external forces such as being hit by a moving vehicle. Similarly, it may or may not be important to include events such as a "near" fall where the individual barely avoids a fall to the floor by suddenly grabbing for furniture or walls, or

is caught by another person. Frequent near-falls, such as "stumbles" and "trips," are risk factors for future falls. There are also problems with fall reporting. Fall events may not be remembered retrospectively, especially if there were no injuries. Prospective monitoring improves accuracy but can be burdensome. Although falls in general are important, it is possible that the most clinically relevant concern is the recurrent faller or a fall injury. There are also serious health-related concerns for the population that does not actually fall because they have restricted their own activity. This group may also be at high risk for future falls, injuries, and social isolation.

CAUSATION

Falling is considered a classic geriatric syndrome because it is often due to multiple interacting conditions that create an organism with reduced tolerance to any type of external stress. The evidence base that has been used to define the causes of falls is highly dependent on the perspective and priorities of the researchers, the definitions of falling and fallers, the time frame and approach to monitoring for falls, the characteristics of the population under study, what factors were measured, and how interactions between factors were assessed in the analyses. Whatever the focus of the research, it is clear that many fallers demonstrate multiple abnormalities, and that the interactions among these abnormalities influence fall risk.

Epidemiologic perspective

Epidemiologic observational studies of older adults in community, acute, and chronic care institutions have identified risk factors for falls and all suggest that risk increases as the number of risk factors increases. [Table 106-1](#) summarizes risk factor profiles by the setting in which older people were studied. Across settings, altered mobility and cognition are major risk factors for falls. Interestingly, it is possible to be too immobile to fall.⁹ For example, in one chronic care setting, residents with fair standing balance had the highest fall rates, those with good standing balance had intermediate fall rates, and persons with poor standing balance had the lowest

Table 106-1. Predisposing Risk Factors for Falls in Older Persons in Three Types of Settings Based on Observational Studies

Community Dweller	Acute Care	Chronic Care
Fall history	Gait instability	Cognitive impairment
Weakness	Agitated confusion	Visual impairment
Balance problem	Urinary incontinence/frequency	Weakness
Gait problem	Fall history	Neurologic problems
Visual problem	High-risk medications	Gait/balance problems
Mobility limitation		Cardiovascular problem
Cognitive impairment		
Decreased functional status		
Postural hypotension		

fall rates.¹⁰ Risk factor patterns and appropriate preventive interventions may differ substantially by overall mobility capacity; active older adults may experience falls and injuries for very different reasons than persons who stand and walk with difficulty, who in turn may fall for very different reasons than persons who cannot stand. Risk factors for injurious falls may differ from risk factors for all falls. In a recent study of older people in residential care facilities, fracture risk among fallers was higher in persons with better balance and no history of falls, perhaps suggesting that in some persons, activity increased the risk of producing sufficient force to fracture.¹¹ Risk factor profiles are also limited in that they generally only identify chronic and stable risk factors, sometimes called predisposing risk factors. Many falls might occur because an individual with predisposing risk confronts additional acute precipitating factors.¹² For example, an older adult with limited mobility and cognition might not become a faller until he or she develops diarrhea, becomes dehydrated and dizzy, and tries to rush to the bathroom. Because risk factor studies have rarely accounted for these more transient and dynamic precipitating contributors, much less is known about them.

Risk factors for falls overlap substantially with risk factors for other geriatric syndromes.¹³ Older age and impairments in cognition, mobility, and function are risk factors for falls, incontinence, delirium, and frailty.¹³ Thus there is a population of older adults with multiple impairments who are at risk for numerous geriatric syndromes, including falls and injuries. There may be other populations of older adults who are at risk for different types of falls; active older adults may fall and injure themselves during demanding activities, whereas very immobile older adults may fall out of bed and chairs or even be dropped by care providers. In the future, more distinct risk factor profiles might be defined based on overall mobility status.

Epidemiologic studies have also identified environmental risk factors for falls. Virtually all falls can be considered the result of interactions between a person and the environment. The individual has some level of ability to move and the environment has some level of challenge. The task of the moment is the context in which the person and the environment interact. The risk factors identified in Table 106-1 are sometimes called “intrinsic” factors because they relate to the individual. Risk factors associated with the environment are sometimes called “extrinsic” factors. The typical aged faller experiences a fall in an environment and while performing tasks that would not cause a healthy young person to fall. This phenomenon of falling under low challenge is the rationale for believing that many falls in older people are due largely to intrinsic factors. If an older adult has many intrinsic risk factors, it is possible that only modest problems with the environment or modest degrees of challenge in a task will precipitate a fall. Table 106-2 lists environmental risk factors for falls. Commonly reported indoor environmental factors are uneven walkways, loose rugs, absence of grab bars in the bathroom, and poor lighting.^{14,15} Outdoor hazards are less frequently assessed but might be important, especially for more active older adults. Other extrinsic elements, such as the availability of human help, may be an important factor in falls among persons living in the community, and are even more likely to contribute to falls in the institutional setting.¹⁰ Additional risk factors for falls include psychological and

Table 106-2. Environmental Risk Factors for Falls

Indoor Falls	Outdoor Falls
Poor lighting	Uneven and broken sidewalks
Loose or absent railings	Wet surfaces
Throw rugs	Poor lighting
Trailing cords and wires	Irregular steps
Uneven transitions such as level change between rooms	Unpredictable level changes
Lack of bars in the bathroom	
Slippery floors	
Cluttered walkways	

attitudinal characteristics such as risk preference.^{9,16} Other risk factors for injury include osteoporosis, low body weight, and fall direction.¹⁷

Physiologic perspective

Contributors to falls can be examined from the perspective of physiologic systems that contribute to balance. The rationale for using a framework of organ-based physiologic systems that affect balance is founded in models of disablement. These models draw links between pathologic processes and altered organ system performance (termed impairments), which combine to affect body movements (termed functional or performance limitations), then affect functional abilities and disability, and ultimately interfere with social roles, such as homemaker or volunteer (termed handicap). There are several disablement models. When assessing causation of problems of aging, these multisystem physiologic approaches are helpful for several reasons. First such approaches can address interactions between systems. Second, they can include mild or subclinical impairments that might affect function without being individually clinically obvious. Third, well-functioning systems might actually serve to compensate for problems with other systems. Thus both individual organ systems and even overall functions such as balance exist on a continuum; they might be obviously abnormal, subclinically abnormal under usual conditions, abnormal only under stressful conditions, normal, or even have “back up” or “reserve” excess capacity.

From a physiologic perspective, balance dysfunction results from impairment in one or more of the following systems: *peripheral sensory receptors* for input, *central nervous system* structures for processing sensory input and planning motor output, and *effector organs* to carry out the movement plan (Table 106-3). In many situations, it is the combination of deficits across these systems that produces instability and falls.

There are three main sensory systems used for balance: vision, somatosensation, and vestibular function. Visual functions such as acuity, depth perception, dark adaptation, contrast sensitivity, and peripheral vision help determine body position and trajectory in space and monitor the environment. Since bifocal glasses prioritize two focal lengths—one in the lower field at about 20 inches for reading and one in the upper visual field at about 20 feet for distance—bifocals can limit acuity in the critical zone in front of the feet while walking.¹⁸ Diseases of the aging eye that affect multiple visual functions are common and include glaucoma, macular degeneration, and cataracts. Medications that cause miosis, or constriction of the pupil, can reduce dark adaptation.

Table 106-3. Components of Postural Control

Peripheral sensation is important for balance. These sensors provide information about the position of the body relative to the support surface and gravity, and reflect the relationship of one body part to another during rest and movement. Peripheral sensation is the most important system for monitoring the characteristics of the weight-bearing surface and the distribution of body weight onto the feet. Peripheral sensory loss is common in older adults because of diabetes and peripheral vascular disease. In the face of peripheral sensory loss, visual systems can compensate by supplementing information about body position. Thus a combination of vision loss and peripheral sensory loss can create serious problems with ability to monitor body position.

The vestibular system detects the position of the head with respect to gravity, monitors linear and angular acceleration of the head, and coordinates head and eye movements to maintain gaze and visual field stability while moving. Vestibular system impairments can occur with usual aging and are affected by ischemia or head trauma. Several widely recognized vestibular conditions, such as benign paroxysmal vertigo and perhaps Meniere disease, are common in older people. Others are also common but less well recognized, such as chronic bilateral vestibular hypofunction.

The central nervous system has numerous structures that contribute to balance. Structures in the brainstem and spinal cord are considered central pattern generators that produce stepping behaviors. Balance is further controlled by higher level brain structures including the frontal cortex, basal ganglia, cerebellum, motor cortex, and other areas. Degeneration of brain regions can affect balance, as in the basal ganglia in Parkinson disease and in cerebellar degeneration. All brain processes are dependent on adequate levels of brain perfusion, so any threats to perfusion affect central processes of gait and balance. Thus many of the conditions that produce syncope or presyncope can cause transient cerebral hypoperfusion and falls. Examples include orthostatic hypotension, tachy- and bradyarrhythmias, and critical aortic stenosis.¹⁹ In recent years, there has been increased awareness of the role of more diffuse microvascular brain disease as a contributor to balance disorders and falls.²⁰ This mechanism is posited to involve ischemia in vulnerable brain areas, especially the frontal lobes and in important white matter tracts connecting the frontal lobes to critical subcortical areas. Radiologically this ischemia is manifested as leukoaraiosis or white matter disease on magnetic resonance imaging. White matter disease has been associated with specific patterns of cognitive dysfunction involving psychomotor slowing, and

altered attention and executive functions such as sequencing and visual spatial organization.^{20,21} These cognitive abnormalities have been associated with alterations in gait, especially excessively variable length and timing of stepping and with falls.^{22,23} Thus there is an emerging concept of altered balance and gait due to abnormal nonamnestic cognitive functions and movement planning produced by regional microvascular brain disease. This condition may be manifested by irregular walking patterns and may be exacerbated by placing stress on cognition and movement. Tasks that simultaneously stress cognition and movement are part of an emerging conceptual approach to balance assessment called "dual tasking." Older persons whose performance worsens substantially when asked to walk and solve cognitive problems simultaneously may be at increased risk for falls.²⁴

The central nervous system also operates a multisynaptic "righting reflex" that produces automatic correcting movements when balance is lost. Classically appearing as a stepping response that occurs much more quickly than can be done voluntarily, this righting reflex is lost in many central nervous system disorders including extrapyramidal diseases and other forms of multisystem atrophy. Sedation, either clinical or subclinical, may further reduce alertness and attention. Thus both sleepiness and sedative medications have been found to increase fall risk.^{25,26} Less specific but potentially important are psychological factors such as fear of falling and risk preferences.^{9,27}

Muscles and joints are effector organs that are critical for balance and mobility. Muscle weakness is widespread in older adults and can be due to primary muscle mass loss (sarcopenia), disorders of peripheral nerves or neuromuscular junctions, or to inactivity. Specific muscle diseases such as inflammatory myositis or steroid myopathy can produce proximal muscle and trunk weakness that occurs with falls. Lower motor neuron conditions, radicular nerve deficits due to spinal stenosis, or peripheral nerve damage can result in localizing strength deficits that affect specific muscle groups and more distinct functional movements. For example, a foot drop due to damage to the peroneal nerve prevents the forefoot from lifting to clear obstacles and can induce trips and stumbles. Recent evidence suggests that low vitamin D levels may contribute to muscle weakness and falls.²⁸ Low testosterone levels have been found to be associated with falls in men under age 80.²⁹ Other common conditions such as arthritis can reduce range of motion and produce pain that alters stepping and weight bearing.³⁰ Deformities distort the weight bearing surfaces of the foot and cause pain. Fatigue, either generalized or localized to muscle, can contribute to loss of balance. Thus acute conditions such as overworked muscles or chronic conditions associated with fatigue such as anemia³¹ or congestive heart failure might increase risk for falls.

When fall onset is abrupt or there is a major change in balance, the likelihood is higher that there is a medical event that has affected the central nervous system. Any illness or episode that reduces cerebral perfusion through hypoxia, decreased oxygen carrying capacity, or hypotension could present as dizziness, lightheadedness, unsteadiness, and falls. Toxic or metabolic abnormalities due to medications, infection, or electrolyte disorders could present as unsteadiness and falls through effects on attention. New focal neurologic deficits due to stroke can also present as unsteadiness. Older

Figure 106-1. Terms used to describe normal walking (1: step length; 2: step width; 3: stride length).

adults with predisposing subclinical balance disorders could be more vulnerable to such precipitating factors. These types of physiologic acute and sometimes transient changes are harder to include in research studies because stable chronic effects are usually the focus of the investigation.

Biomechanical perspective

A biomechanical approach to fall risk is based on concepts of mass, force, momentum, and acceleration of the body as a whole and of body segments. The human body in standing is a long tall column that rests over a small base of support. The main task of movement is to displace and recover this column while the base of support changes. Thus the assessment of balance includes two main conditions, (1) static balance, defined as steadiness of the fixed column over a constant base of support and (2) dynamic balance, defined as control of the column and supporting structures during movement. The most essential and classic dynamic balance task is walking. Walking involves alternating use of one leg to support the body while the other swings from behind to in front of the body. There is an extensive knowledge base about normal and abnormal walking that is based on a set of biomechanical characteristics and uses a specialized terminology (Figure 106-1). Walking can be characterized by the pattern of steps using spatial factors such as step length, stride length (the distance between two heel contacts from the same foot), and step width. Walking can also be characterized by temporal factors such as double support time (the duration of the stride when both feet are on the ground at the same time) and cadence (step frequency). Walking has been described as “controlled falling” because the body column moves forward past the base of support and the feet must be timed to contact the support surface at the right location and time in anticipation of the moving location of the trunk.³² When this timing is altered by disease, gait becomes irregular and trunk movement can be altered. Walking can also be characterized by changes in other body segments and joints. During normal walking, the foot begins a step with a push off from the toe, then lifting the foot to swing through and ending with a heel strike and forward rolling foot contact to initiate the next push off. The knee is in full extension at the time of toe push off, swings forward with slight flexion to aid foot clearance and then returns to full extension at the point of heel contact. The hip is in extension behind the trunk at push off and swings into flexion at heel contact. The arms swing alternately and in a sequence opposite to the step sequence of the legs. Biomechanical factors that have been found to be abnormal in fallers encompass both static and dynamic balance. Abnormal static balance associated with falling is manifested as increased sway during quiet standing. Some recent studies suggest that increased sway to the side, or medial-lateral plane, is especially associated with falls.³³ Alterations in dynamic balance among fallers

are diverse depending on the underlying cause. Frequently observed abnormalities include prolonged double support time during walking, increased step width, increased trunk sway during movement, increased or decreased toe clearance, reduced hip extension, abnormal lateral stepping, and delayed correcting movements at the hip or ankle when the trunk is displaced.^{34,35}

SCREENING

Screening for fall risk has two main goals: to identify persons at high risk and to identify remediable factors for intervention. Screening for risk alone can be more efficient than assessment for modifiable factors, so screening sequences that first identify risk and then assess remediable factors may make the best use of scarce resources. Since fall risk varies by population and type of fall, there is unlikely to be a single screening approach that works well in all settings. Certainly in diverse community populations, it makes sense to identify groups who are at low risk and who therefore can be spared more detailed, time-consuming assessments. Thus the American Geriatrics Society and the British Geriatrics Society have recommended falls screens that identify risk as (1) more than one fall in the last year, (2) one or more falls with injury, (3) self-report of unsteadiness, or (4) unsteadiness on performance testing.³⁶ Many older adults do not complain about falling to health care providers, so it is important to explicitly ask about falls. Some older adults fail to report falls because they forgot them. Some older adults may actively hide the fact that they are falling because they worry that family or providers will insist on relocation or activity restrictions. Screening in chronic care settings differs from screening in primary care. In chronic care settings, fall rates are often high and screening tools are more likely to have high false-negative rates. If prevalence is very high, it may be sensible to consider almost everyone as high risk and act accordingly. Fall risk screening in acute care is a high priority, but recently some have argued that no screening tool has high enough accuracy to justify the current investment in detailed admission fall screening since it consumes much nursing staff time with little real benefit.³⁷ In addition, general screens for functional problems in acutely ill hospitalized older adults may do as well at predicting falls as more specific falls screens and general screens can be used for multiple nursing issues.³⁸ There is some evidence that nursing global judgement is comparable in accuracy to formal screening tests in some chronic care settings.³⁹

There are two main types of screening tools: those that are based on professional assessments of various historical and health factors and those that are based on observed performance of mobility and balance tasks. Some of the more common tools are described in Table 106-4. There are no clearly superior tools that have been shown to have high

Table 106-4. Scales Used for Fall Risk Screening and Balance Assessment

Instrument	Items	SETTING		
		Community	Acute	Chronic
Multifactorial Reports				
STRATIFY ⁵⁵	Five items: history of falls, agitation, visual impairment, frequent toileting, able to stand but needs assistance with moving		x	x
Morse falls scale ⁵⁶	Six items: history of falls, secondary diagnoses, parenteral therapy, use of ambulation aids, gait, mental status		x	x
FROP-Com ⁵⁷	13 risk factors in 26 items, fall and fall injury history, medications, medical conditions, sensory loss, feet, cognitive status, toileting, nutrition, environment, function, behavior, balance, gait (total score 0 to 60, fall risk high with score >24)	x		
Fall risk for residential care ⁵⁸	Among persons who can stand without assistance, poor balance, or (2 of 3 of fall history, nursing home residence, urinary incontinence) Among persons who cannot stand without assistance, any 1 of 3 (fall history, hostel residence, use of 9 or more medications)			x
Functional Mobility				
Berg balance test ^{40,59}	14 tasks scored 0 to 4; total range 0 to 56; fall risk increases as score decreases	x	x	x
Functional reach ⁶⁰	Distance reached in inches without moving the feet; fall risk <7 inches	x	x	x
Performance oriented mobility and balance ⁶¹	Balance subscale score 0 to 16, gait subscale 0 to 12, summary score 0 to 28; summary score below 19 indicates high fall risk	x		x
Timed up-and-go ⁶²	Time in seconds to rise from a chair, walk 3 m, turn, walk back and sit down. <10 sec is normal. Fall risk increases with time >13.5 sec.	x		x
Dynamic gait index ⁴¹	8 walking tasks scored 0 to 3, total score 0 to 24; <18 or 19 indicates fall risk	x		
Functional mobility tests ⁶³	Time to complete 8 step-ups (Alternate Step Test) >10 sec, timed sit to stand five times >12 sec, 6 m walk time >6 sec increased fall risk	x		
Physiologic profile assessment ⁶⁴	Performance in five domains: sway, reaction time, strength, proprioception, contrast sensitivity; total score 0 to >3. Fall risk increases with score of 2 or more.	x		

accuracy in multiple settings, so the optimal tool must be tailored to the population, the goals of screening, and the time and other resources available.

EVALUATION AND MANAGEMENT

Evaluation

When an individual has been identified as high risk for falls, then a more detailed evaluation is needed. The goals of evaluation are to (1) identify impairments that contribute to the problem, (2) gain an overall sense of mobility and balance capacity, and (3) consider special risk factors for injury. Since falling is multifactorial, multidisciplinary teams can provide a range of expertise. Disciplines that can make valuable contributions include physicians, nurses, physical therapists, occupational therapists, social workers, pharmacists, and others. Although the older adult should always be interviewed, other informants may be helpful. [Table 106-5](#) illustrates elements of the history and physical examination that can be used to evaluate potential impairments. It is important to recall that older adults often have more than one impairment, so that finding one problem does not mean that there are not others as well. The history should include circumstances of one or more recent falls, history of injuries from falls, the course of the problem over time, associated symptoms and effect on overall mobility and activity. A fall description should include location, time of day, activity, symptoms, use of assistive devices, and ability to get up again. It is sometimes helpful to explore potential relationships to medication dosing schedules. Various patterns may suggest differing clusters of contributors. Recurrent backward falls tend to be associated with degenerative

brain diseases. Acute onset is more likely to be due to a toxic or metabolic effect or perhaps an acute cerebrovascular or cardiac condition. Fear of falling can develop with or without a history of falling and can lead to severe activity restriction. Falls associated with dizziness may suggest some specific diagnoses ([Table 106-6](#)). Dizziness is common and nonspecific, so the interviewer must probe more deeply to distinguish potential contributors. True vertigo is defined as a hallucination of rotatory motion and is generally due to vestibular problems. Lightheadedness sometimes implies a sense of imminent loss of consciousness or presyncope. In this case, consider contributors to decreased cerebral perfusion. A third type of dizziness is perceived as “not in the head” and only occurs when upright. It may be an indicator of multisensory dysequilibrium, when more than one sensory impairment reduces the ability to monitor body position.

Medications are sometimes implicated in falls and can be among the most treatable contributors, so a thorough medication history is essential. Although there are long lists of medications with adverse effects on balance, there are just a handful of major mechanisms by which they cause falls. Common mechanisms include sedation, orthostatic hypotension, extrapyramidal effects, myopathy, and altered dark adaptation of vision. See [Table 106-7](#) for examples of medications listed by potential mechanism. Persons who take multiple medications that alter balance are especially vulnerable.

Functional status should be assessed because mobility and balance are central to the ability to care for oneself and live independently. Many older adults use assistive devices for walking so it is important to explore when and how they were obtained, where they are used and not used,

Table 106-5. Clinical Assessment Based on Components of Postural Control

Organ System	Impairment	Clinical Evaluation	Potential Cause
Eye	Decreased acuity	Vision chart	Presbyopia, macular degeneration, cataracts
	Reduced visual fields	Confrontation, perimetry	Glaucoma, posterior circulation stroke
Vestibular apparatus	Decreased depth perception	Stereo or depth testing	Monocular vision
	Decreased dark adaptation	Self-report, inability to dilate pupil in low light	Aging, miotic agents for glaucoma
	Otoliths	Ability to detect true vertical, Hallpike maneuver	Benign positional vertigo
Peripheral nerve	Semicircular canals	Ability to detect position during rotation with eyes closed, nystagmus, visual acuity during head motion	Meniere's disease, vestibular hypofunction
	Peripheral neuropathy	Light touch, filaments, two point discrimination, vibratory sense	Diabetes, peripheral vascular disease, B ₁₂ deficiency
Circulation	Reduced cerebral perfusion	Low blood pressure, altered level of consciousness, lightheadedness	Medications, arrhythmias, postprandial hypotension
	Orthostatic hypotension	Positional change in blood pressure	Medications, autonomic dysfunction, dehydration
Brain	Reduced attention	Ability to perform dual tasks such as timed up-and-go with cup of water, executive function tasks	Mild cognitive impairment, dementia, medications
	Psychomotor slowing	Timed tapping, timed finger to nose test, trails A test (connect the dots)	Medications, degenerative and vascular brain diseases
	Altered postural reflexes	Absent or slowed righting reflexes	Parkinson's disease, other extrapyramidal and degenerative brain diseases
Muscle	Reduced strength	Manual muscle testing, strength-based functional performance (chair rise, squat)	Generalized: inactivity, sarcopenia, vitamin D deficiency, myopathies Focal deficits: spinal cord and peripheral motor nerve conditions
Musculoskeletal pain	Loss of flexibility	Contractures, decreased range of motion	Arthritis, inactivity
	Bone and joint deficits	Weight-bearing pain	Arthritis, fractures, periarticular conditions, foot problems
	Disturbance of spinal cord, roots, nerves	Leg and back pain with activity	Spinal stenosis, radiculopathies, peripheral neuropathies

Table 106-6. Differential Diagnosis and Management of Dizziness

Condition	Symptoms	Evaluation	Management
Orthostatic hypotension	Lightheadedness with change in position	Measure blood pressure in multiple positions, both immediately after change and then again after several minutes. Clinically important systolic drop is not well defined but is more likely to be significant if greater than 20 mm Hg or drops below 100	Taper or eliminate medications, fluorinated corticosteroids, salt loading, lower extremity muscle contractions before arising, compression hose
Arrhythmia, especially tachyarrhythmia or bradyarrhythmia	Lightheadedness or syncope not associated with position, occasionally with palpitations	Rhythm monitoring is important to capture symptomatic episode so monitoring may be prolonged.	Antiarrhythmic agents, medications for heart rate control, pacemakers
Benign paroxysmal positional vertigo (BPPV)	Short periods of true vertigo with head movement, even without upright body movement, such as rolling over in bed or looking up	Dix-Hallpike reproduces symptoms when in the head-down position and precipitates rotatory nystagmus in the direction of the involved ear.	Epley maneuver to reposition otolith debris; Brandt Daroff exercises
Meniere's disease	Severe episodes of vertigo with perceived ear pressure, decreased hearing, nausea, and vomiting	Usually diagnosed based on classic presentation, often incorrectly diagnosed when the true cause is not known	Diuretics, dietary modifications to reduce salt intake
Uncompensated vestibular hypofunction	Unsteadiness that worsens when vision is reduced, blurred vision with head motion	Rotational chair testing, caloric testing, dynamic visual acuity testing	Vestibular rehabilitation, optokinetic stimulation
Multisensory dysequilibrium	Sensation of lack of confidence in body position that only occurs when upright	Decreased sensory function in more than one sensory system (e.g., vision, vestibular, and peripheral sensation)	Treat sensory disorders, rehabilitation for use of sensory aids

and if there are areas of problem or concern. Since balance and mobility problems can limit function, it is important to determine if able and willing helpers are available. Older adults without access to helpers may be at special risk as they attempt to perform tasks that have become difficult.

Since the environment influences mobility and safety, a home assessment is an important element of falls evaluation. Although some aspects of the environment can be explored through an interview, a direct home assessment by professionals from a home visit agency can be invaluable. Key aspects of home assessment are described in Table 106-8.

Table 106-7. Medications That Affect Components of Postural Control

System Affected	Examples
CNS: attention and psychomotor speed	Benzodiazepines, sedating antihistamines, narcotic analgesics, tricyclic antidepressants, SSRIs, antipsychotics, anticonvulsants, ethanol
Basal ganglia and extrapyramidal system in general	Antipsychotics, metoclopramide, phenothiazines, SSRIs
Blood pressure regulation	Antihypertensives, antianginals, Parkinson drugs, tricyclic antidepressants, antipsychotics
Muscle: myopathy	Corticosteroids, colchicine, statins, ethanol, interferon
Pupil: miosis	Some glaucoma medications, especially pilocarpine

Table 106-8. Modifications for the Physical Environment

Area	Modifications
Lighting	<ul style="list-style-type: none"> Nightlights in the bedroom, bathroom, and hallways leading to the bathroom Keep a flashlight next to the bed Timer or motion-activated lighting systems Locate light switches near all doors and both ends of stairways
Flooring	<ul style="list-style-type: none"> Nonglare, nonskid flooring Avoid loose area rugs or used nonskid backing Nonskid strips on steps Bevel/ramp uneven transitions between rooms
Stairwells	<ul style="list-style-type: none"> Increase contrast at level changes Sturdy handrails, sometimes on both sides of steps Chair lift (Stair Glide) Rearrange rooms to achieve single-floor living
Bathroom	<ul style="list-style-type: none"> Elevated toilet seat Grab bars Nonskid strips or mat on floor of shower or bathtub Shower chairs Tub bench
Kitchen	<ul style="list-style-type: none"> Put common items at easily accessible height Clear countertop clutter to maximize working space
Walkways	<ul style="list-style-type: none"> Clear and straight as possible Increase width by removing obstacles and furniture to accommodate walkers Eliminate tripping hazards such as cords and tubing

The physical examination is useful to detect impairments that contribute to poor balance and to assess overall functional performance. Table 106-5 describes maneuvers that can be performed during the physical examination to detect impairments. Most of these assessments are familiar to health care providers, but a few are somewhat unique to balance assessment. Peripheral sensory testing is important since neuropathy is common among older adults. Although proprioception (joint position sense) is important for balance, testing is insensitive. Since proprioception and vibratory sensation use similar nerve fibers, testing vibratory sense may be more sensitive. A common strategy is to evaluate vibration detection using a 128 Hz tuning fork applied over a bony prominence such as the medial malleolus. The Romberg test,

in which standing balance is compared with eyes open and closed, is a useful strategy for detecting visual dependence. An abnormal result suggests peripheral nerve or vestibular disorders. Abnormal muscle tone can indicate a variety of conditions. Increased tone implies upper motor neuron disease whereas decreased tone suggests lower motor neuron dysfunction. Increased tone can exist throughout the range of motion (lead pipe rigidity), or intermittently (cogwheeling rigidity). Coordination should be assessed in both the upper and lower extremities using tests of rapid alternating movements. Every balance assessment should include a test of righting reflexes. To perform the assessment, the examiner stands behind the patient, and asks the patient to prepare to respond to a push or pull with any reaction they prefer. The examiner pulls the patient's pelvis backwards sufficiently to displace the body outside the base of support. A normal response is a brisk step backwards. An abnormal response is a complete lack of stepping, called a "timber reaction." The patient can also be displaced to the side.

The evaluation is also used to determine functional mobility and balance capacity. Physical performance measures can serve as a guide, but it is important to target the performance assessment to the mobility capacity of the individual. Thus an older adult who is wheelchair-bound needs detailed assessment of bed mobility, transfers, and standing balance, whereas an active older adult may need more of a focus on high-level skills such as obstacle avoidance, dual tasks, and stair climbing. Table 106-4 includes commonly used functional performance assessment tools for mobility and balance. The Berg balance scale has been used to predict fall risk⁴⁰ but does not assess balance during walking. The dynamic gait index is especially helpful for detecting subtle higher level problems because it includes challenging conditions.⁴¹ The performance-oriented mobility assessment (POMA) assesses static balance and gait and is widely used, but does not assess higher level functions.⁴² Recently, balance assessments have added dual task tests that combine mobility assessment with distraction or a cognitive task. These divided attention tasks can sometimes uncover abnormal gait or balance not seen under usual simple conditions. Being unable to walk and talk at the same time is a risk factor for falls.⁴³ Reduced endurance during walking can create a sense of fatigue and leg weakness, so a long walk might be a useful element of the examination.

The third element of evaluation is to determine special risk factors for injury. Since fractures are a major cause of morbidity in fallers, every unsteady person should be assessed for osteoporosis. Another special concern is the risk of bleeding in persons who take anticoagulants. Loss of protective reflexes also increases the risk of injury. Since normal protective responses involve use of the upper extremity to moderate impact force and protect the head, injuries to the head, face, and orbit are especially worrisome. An absent righting reflex on physical examination is a significant indicator of increased risk of injury.

Management

The goals of management are to (1) treat impairments where possible, (2) build on systems that work well to compensate for deficits, and (3) provide physical and human resources to assist where necessary. Table 106-9 provides suggestions for management strategies based on the impairments

Table 106-9. Management of Impairments That Contribute to Instability and Falls

	Organ System	Impairment	Medical Management	Restorative Services	Environmental Modifications
	Eye	Decreased acuity Reduced visual fields	Corrective lenses Prisms in spectacles	Low vision rehabilitation Low vision rehabilitation, teach to scan using head rotation	Lighting
		Loss of depth perception	Cataract removal if indicated	Teach to use shadows to detect depth	Lighting to accent shadows, contrast lighting
		Poor dark adaptation	Switch to glaucoma medications that do not cause miosis		
	Vestibular system	BPPV Meniere disease	Epley maneuver. Cautious use of meclizine, diuretics, rarely surgery	Vestibular rehabilitation Vestibular rehabilitation	
Central	Peripheral nerve	Neuropathy	Footwear to protect foot and maximize sensation	Assistive devices for haptic enhancement	Handholds, railings
	Circulation	Reduced brain perfusion	Treatment varies by cause Arrhythmias: medications to control rate and rhythm, pacemakers Postprandial hypotension: frequent small meals		
		Orthostatic hypotension	Treatment varies by cause Adjust offending medications Autonomic neuropathy: salt loading, fluorinated corticosteroids Dehydration: hydration, reduce diuretic dose	Compression hose, calf muscle contractions	
	Brain	Reduced attention Psychomotor slowing	Medication adjustment Medication adjustment	Practice dual tasks Practice movement speed	
Effector	Muscle	Abnormal righting reflexes	Antiparkinsonian medication helps bradykinesia more than balance	Assistive devices, practice getting up after a fall	Protective clothing
		Weakness	Reduced activity: treat contributing causes such as CHF, anemia, COPD, arthritis Focal motor deficit due to spinal stenosis: sometimes surgery Myopathy: adjust offending medications, possibly steroids for myositis	Strength-training exercise Orthotics, exercise, assistive devices	Raise chair height
	Musculoskeletal	Decreased range of motion		Active and passive range-of-motion exercise, orthotics	
		Bone and joint pain	Analgesics, injections	Physical modalities such as heat, massage, assistive devices, orthoses, adaptive equipment	Place items within easy reach
		Spinal cord, roots, nerves	Injections, surgery, analgesics	Orthoses, assistive devices	Place items within easy reach

detected during the evaluation. As always, it is important to engage the older adult and family in the discussion of management options and to incorporate patient preferences into the plan.

Assistive devices can promote mobility in persons with balance problems through several mechanisms. In general, they all increase the base of support, thus increasing stability. Assistive devices can also provide sensory information about the walking surface directly to the upper extremity, and are especially helpful in this way to people with sensory loss in the feet. This ability to use sensory information from any part of the body to promote awareness of body position is called haptic sensation. Assistive devices should be professionally assessed and patients need training in proper use. Older adults notoriously acquire poorly fitting devices from family and friends. Canes increase the base of support and take up much less space than walkers. Walkers provide much more stability than canes but are more bulky and difficult to maneuver in tight spaces. Newer four-wheeled walkers are

light weight and have hand-activated wheel locks, seats, and baskets that make them an attractive option for older adults. The larger wheels also make them more maneuverable on uneven sidewalks, grass, and gravel than the small wheels found on traditional walkers. Wheeled walkers also are easier to learn to use than traditional pick-up walkers.

Inappropriate footwear can be modified but there is no clear evidence to guide optimal characteristics of the shoe for falls reduction. Shoes with low wide heels promote stability. Shoes should fit comfortably but snugly so that the foot and the shoe move together. There is controversy about the optimal characteristics of the bottom of the shoe. Rubber soled shoes reduce pressure areas in persons with insensitive feet but also decrease sensory information about the walking surface. Hard leather soled shoes provide better sensory information and reduce tripping because they do not catch on surfaces, but increase the risk of slipping.

It is important to attend to the needs of the caregiver as well. Caregivers should receive training in body mechanics

and transfer assists. They can also be educated about how to help get the older adult up after a fall.

Injury prevention is an important element of falls care. If a faller has had a fracture or is found to have osteoporosis, serious consideration should be given to prescribing appropriate medications. Hip protectors have been found to reduce injury in some studies but more recent data has shown less benefit.^{44,45}

There is now a body of clinical trial evidence that supports the effectiveness of interventions to prevent falls.⁴⁶ Interventions that have been found to reduce falls include multiple risk factor reduction, professionally directed and individualized balance and strength rehabilitation, professionally led home hazard assessment and remediation, psychotropic medication withdrawal, Tai Chi group exercise, and cardiac pacemakers for fallers with cardioinhibitory carotid sinus hypersensitivity. Overall interventions yield about a 20% relative risk reduction and 10% absolute risk reduction, so there is certainly room for further improvement.

SYSTEMWIDE IMPLEMENTATION

There is now sufficient evidence from formal clinical trials to suggest that interventions to reduce falls may be effective in some settings.^{7,47–49} Despite the evidence, these programs have not yet translated into systemwide changes in practice. Recent research suggests that translation to practice may be feasible and effective. A large nonrandomized study compared fall injury rates and medical service use between two comparable geographic regions before and after a systemwide intervention was implemented in one of the regions.⁵⁰ The intervention consisted of recommendations for medication reduction, management of postural hypotension, vision and foot problems, hazard reduction and training for balance, gait, and strength. Using multiple media, seminars, opinion leaders, and site visits, the intervention was targeted

at primary care physicians, home health agencies, and emergency departments. Injury rates were lower in the intervention region and medical use increased less than in the usual care region. Other system interventions have been effective in emergency departments⁵¹ but not nursing homes^{52,53} or public health departments.⁵⁴ Keys to widespread implementation require that system barriers such as provider time limits, lack of knowledge, care fragmentation, and lack of reimbursement be addressed.¹

SUMMARY

Falling is common and has serious consequences among older adults. Fallers often have multiple contributing impairments that interact to affect balance. Multidisciplinary interventions have been effective in some settings but evidence from research has not yet translated into usual clinical practice.

KEY POINTS

Falls

- Falling, especially recurrent falling, is a signal that health and function are failing in older adults.
- Most older adults who fall have multiple interacting impairments in the components of postural control.
- Systematic assessment and treatment planning is multidisciplinary and incorporates medical, rehabilitative, and psychosocial perspectives.
- The next major step in fall prevention is to disseminate evidence-based practices into health care systems.

INTRODUCTION

Delirium is typically an acute onset fluctuating disorder of consciousness. Profound alterations in the mental state of the affected person are manifest as impairments in arousal, attention, orientation, thinking, perception, and memory. Delirium often occurs in the setting of multiple physical illnesses and problems with a reciprocal impact on function. Not just a temporary suspension of cognitive abilities, delirium represents the susceptibility to adverse event through increasing functional dependence and aberrant behavior. Impaired mobility, falls, and fractures or pressure ulceration therefore add to the burden of illness.

Delirium is derived from the Latin *delirare*, meaning “to leave the furrow” and has long been recognized as a disturbance in the train of thinking.¹ The meaning of the term delirium has undergone many fluctuations over the last 200 years, but descriptions of delirium have maintained considerable stability over time with references to it in the writings of Hippocrates and,² in the Talmud,³ and the Pancatantra.⁴

Delirium most commonly develops in frail elderly people. Thus rates of delirium are higher wherever there are greater numbers of frail elderly people, in other words, in hospitals and in long-term care settings such as nursing homes. However, despite equally greater density of health professionals in these settings delirium remains commonly unrecognized and thus poorly managed leading to a variety of adverse outcomes. By contrast, the prevalence of delirium in the community is low and may herald the presence of an underlying dementia.^{5,6}

Evolution of the delirium concept and diagnostic criteria

Disturbance of consciousness is a characteristic feature of delirium that distinguishes it from the classical form of Alzheimer's disease and has also been the hardest to operationalize. It has been conceptualized in three different ways: as disruptions of the sleep-wake cycle; as part of continuum between alertness and coma; and as a disorder of attention.⁷ Although sleep disturbances have long been recognized as a feature of delirium,² the evolution of consciousness and attention as features of delirium are relatively recent. Greiner's development of the concept “clouding of consciousness” in delirium⁸ can be understood in the context of nineteenth century view that impairments in consciousness represented “organic” brain disease.⁹ Clouding has come to refer to both a state of lowered arousal between alertness and coma¹⁰ and a denseness of the medium in which psychic events occur,¹¹ leading to imprecision in its meaning. Geschwind's influential views,¹² based mainly on studies of delirium in younger adults,¹³ paved the way for operationalization of delirium as an attentional disorder in modern classificatory systems.^{14,15} However, disturbance of attention is not the sole cognitive disorder seen in, neither is it the sole preserve of delirium.¹⁶ So it remains that disturbance of consciousness is the defining criterion for delirium.^{17,18}

The international diagnostic criteria require different numbers and combinations of factors to diagnose delirium.

For example the International Classification of Diseases-Tenth Edition (ICD-10)¹⁸ requires five symptom characteristics to be present whereas the Diagnostic and Statistical Manual-Fourth Edition (DSM-IV)¹⁷ requires only three and also specifies onset and causation more clearly. Unsurprisingly, DSM-IV is more inclusive and sensitive than ICD-10 in identifying delirium.^{19–21} However, prognosis of delirium by different criteria sets of outcomes such as mortality and rates of institutionalization appear to be no different.²²

Clinical features of delirium

Consciousness, or time-ordered serial awareness of self and the environment,²³ and its impairment may not be easily measured. Unable to gaze directly into the seat of consciousness, we can at least measure its component parts: arousal and attention. Alterations in arousal, or level of consciousness, may range from a hyperalert-hyperactive state—often accompanied by hallucinations, illusions, and delusions²⁴—to a state of somnolence where the person is hypoalert and hypoactive.²⁵ Although the typical image of a delirious patient is one of a hyperactive and psychotic younger adult experiencing delirium tremens, older patients are more likely to be withdrawn and lying in bed or fluctuating between states of hyperalertness and somnolence.²⁶ This spectrum of psychomotor activity associated with delirium has been described since antiquity by terms such as *lethargus* and *phrenitis*.² The usefulness of the distinction has been called into question and is only of value if it relates to separate clinical outcomes.⁷ In this regard, hypoactive delirium may represent a clinical casualty from the lack of an established definition; lack of archetypal “activated” features leaves it most vulnerable to misdiagnosis.^{27,28} This poses a problem. The subtype of delirium that is most easily missed may also be associated with the worst outcome.^{8,29} However, key components of established rating scales, namely delusions, variability, and mood lability have been shown to reproducibly discriminate between delirium subtypes.^{30,31} The prospect of clinically systematizing psychomotor activity³² may help to resolve some of the heterogeneity in delirium and improve the focus for future therapeutic interventions. Notwithstanding the abundant descriptive data concerning subtypes, the absence of standardized criteria represents a challenge and estimation of subtype frequency suffers.

As one of the core symptoms of delirium, the ability to focus, sustain and shift attention¹² forms a valuable, if incomplete, insight into the “sentry gate to consciousness.”³³ Staff involved in daily care of older people often have difficulty in formally assessing inattention.³⁴ Accessibility to interview over a 2-minute period may be a simpler yet well validated measure to test attention.³⁵ Without formal assessment, cognitive decline may be unobserved and contributes to poor recognition of delirium in a variety of settings.^{36–39}

Phenomenologic studies of delirium offer fresh insight into the development of psychopathology in delirium.⁴¹ In their study Andersson et al⁴² found that many patients simultaneously encountered past, present, and the realm of imagination as reality leading to apprehending these experiences

both real and existing and unreal and nonexistent. Commonly patients think that they are being drugged, that there is a party going on or are in great danger. Patients may have visions of dead and yet not recognize family.⁴¹ Within psychosis, hallucinations—visual or auditory—and delusions may be elicited and may be disturbing to patients and those around them.

Acuity of onset, usually over hours to days, is a core feature of delirium but is not peculiar to it.¹⁷ Vascular dementia may share abrupt changes.^{42,43} This may pose a diagnostic challenge as cerebrovascular insults are especially important in the occurrence of delirium in the elderly without significant predisposing factors.⁴⁴ Prevalence rates of these conditions may vary in acute settings⁴⁵ and may help in determining the likelihood of the diagnosis. Accurate history taking is helpful when patients come to the hospital as are serial cognitive assessments once patients are admitted.⁴⁶ Nursing staff may observe troublesome nocturnal behavior while their colleagues encounter with incredulity the same patient placid by day. Fluctuation of symptoms also is a characteristic of dementia with Lewy bodies (DLB)⁴⁷; once again prevalence rates are helpful in determining the likelihood of the condition. Acuity of onset, fluctuating course, and classically but contentiously short lived and reversible, delirium is a consequence of underlying illness.⁴⁸ Early recognition then becomes important to addressing the cause and optimizing the outcome.

Differential diagnoses

Most patients with dementia that arrive acutely to the hospital will have, or will develop, a delirium (32% to 89%)⁴⁹ and represents a large, growing yet uncharted portion of hospital care.^{49,50} As the clinical features may be similar, behavioral changes in an individual with dementia can be mistakenly normalized by the contribution of environmental change or perceived as a natural sequelae of dementia.⁵¹ Greater than expected deterioration of cognition, along with new onset of hallucinations and delusions, is suggestive of a superimposed delirium.⁵² Rating tools discriminate from dementia,⁵³ although they may not be entirely helpful in daily practice.⁵⁴

Investigations, in particular the electroencephalogram (EEG), offer an adjunct to clinical assessment. Well described and replicated, the pattern of “diffuse slowing”⁵⁵ on EEG can help to distinguish a delirium from the following conditions: delirium superimposed on dementia,⁵⁶ temporal lobe epilepsy, and nonconvulsive status. Undoubtedly useful even in older patients,⁵⁷ an EEG requires a level of patient compliance and therefore becomes of questionable value where behavioral problems supervene. Further, it is supplementary to and not a replacement for the less invasive and more achievable focus of robust, bedside clinical and cognitive assessment.

Of all the dementias, DLB is perhaps the closest mimic of delirium with many features common to both the disorders. The sharply contrasting treatment strategies between both conditions make this a difficult but important distinction to make. The cause and natural history provides guidance to this predicament. DLB is a neurodegenerative disorder, and has an insidious onset in contrast to the acute onset with underlying systematic upset in delirium. Parkinsonian features should also alert the clinician to the possibility of underlying DLB. Delirium is an unwelcome but often frequented visitor

among the dementias. DLB is no exception to the hazard of delirium, and dopaminergic therapies may potentiate this risk.⁵⁸ Careful follow-up and avoidance of precipitants for either condition is a pragmatic approach to management in the context of ongoing clinical uncertainty.

Depression and delirium may share “negative symptoms” and even a broad range of cognitive deficits.⁵⁹ The mood changes observed as part of the delirium syndrome, particularly hypoactive delirium, may account for the tendency to misdiagnose the two conditions. However, acute onset of mood change, particularly in a hospitalized older patient, represents a delirious event until proven otherwise. Failure to systematically exclude delirium may result in such patients receiving antidepressants mistakenly leading to a worsening of the condition both by the addition of a psychotropic⁶⁰ and the resultant inadequate treatment of delirium.

Prevalence

Delirium afflicts most acutely hospitalized, frail, older patients. The setting of the emergency department mixes increasing presentations of older patients with acute illness.⁴⁵ Such risk factors translate to a high prevalence of delirium within the emergency department of between 26% and 40% in older patients.⁶¹ Clinicians who are more removed from the distal consequences of delirium often fail to undertake cognitive assessment.⁶¹ Furthermore, even when cognitive assessment is performed, it does not always register with a diagnosis of delirium or affect management.⁶² Pressures within an emergency department represent barriers to appropriate care for individuals at risk of delirium. These are not insurmountable; an education program and geriatrician support may help to realign the inequity of emergency health care provision to those most vulnerable.⁶¹ In-hospital nonstandardized reported rates of delirium vary widely, typically 20% to 30%.⁶³ Delirium frequency is dependent on the hospital population under study with higher prevalence of 43% to 61% noted following hip fracture.⁶⁴ Prevalent delirium, encountered on admission and incident delirium, precipitated during the hospital stay, may represent different populations with the same syndrome. Both may occur with a similar frequency of around one third of acutely hospitalized patients.⁶³ The intensive care unit is a potent conflagration of illness severity and iatrogenic insult as to be inevitably bound with delirium⁶⁵ with a prevalence of around 70% in patients over 60 years of age.⁶⁶ Validated screening tools^{67,68} have been developed for use even when individuals are unable to speak. As with all other clinical arenas that encounter delirium, mandatory screening has been recommended,⁶⁹ although the role of intervention strategies is as yet uncertain.

Delirium permeates beyond the acute sector. Prevalence of delirium in nursing homes varies from 32% to 62%.⁷⁰ Even with a conservative estimate, delirium and subsyndromal delirium⁷¹ still represent a significant and largely unexplored health burden in postacute facilities. Chronicity of symptoms in these settings neither alleviates the consequences of delirium nor defines the best management for those in institutionalized care.⁷² Many, if not most, individuals dying from chronic illness experience delirium.^{73,74} The inextricable link between the two has called into question the poor outcome associated with delirium by not controlling for delirium experienced as part of the dying process.⁷⁵

And yet the end stage of any chronic illness does not always have a predictable path nor does delirium impose an imminent sentence of death.⁷³ As yet, nothing within the delirium syndrome offers the ability to distinguish a temporarily recoverable process from a "terminal drop" but is worthy of future enquiry. In the meantime, an interdisciplinary focus with consensus driven management is advised.⁷⁶ A common pathway and range of causes is probable. General prevention and management strategies should be considered when an individual has not entered the terminal stage of illness or if they can be implemented without adding to the suffering of the dying process.

Causes and risk factors

Delirium is caused by multiple factors. Cause in medicine is often associated with the idea of a single cause that arose from the success of the germ theory in the nineteenth century.⁷⁷ There have been two major areas of focus on the pathophysiology of delirium: the cholinergic hypothesis^{78,79} and more recently the role of proinflammatory cytokines.⁸⁰ The cholinergic hypothesis essentially attributes causation to reduced cholinergic input in the brain⁷⁹ and has led to useful measures that offer the prospect of a role in delirium prevention.^{81–83} However, this does not account for the other major player in delirium: infections, a problem addressed by proinflammatory cytokines. Recent studies have found an association generally between cytokines and delirium⁸⁴ and specifically with their rising levels and to onset of delirium.⁸⁵ The hypothesis is that with increased inflammatory activity in the dementing brain, peripheral cytokines lead to delirium.⁸⁰ In the end these remain unsatisfactory because they do not account for the multifactorial nature of delirium causation. Rationalizing the wealth of potential and multiple causes into commonly associated groups may assist in learning⁸⁶ and translate to better management. Despite its pragmatic appeal, this version lacks the ability to determine a hierarchy of cause and fails to offer a testable model of causation.

Given the conceptual limitations, development of a model of delirium has been refined to incorporate predisposing and precipitating factors.⁸⁷ Consistently identified, independently associated predisposing factors include older age, male gender, visual impairment, dementia and cognitive impairment, depression, functional dependence, immobility, fracture on admission, dehydration, alcoholism, increased comorbid conditions, previous stroke, and azotemia. Frailty is an underlying theme. Similarly, independently associated precipitating factors include medications, such as sedative hypnotics and narcotics; severe acute illness; infections, especially urinary tract infections; metabolic abnormalities especially hyponatremia; hypoxemia; shock; anemia; pain; physical restraint use; bladder catheter use; any iatrogenic event; intensive care unit treatment; surgeries; and high number of procedures in hospital.^{88–91} From this list it is then possible to identify individuals who are predisposed to delirium upon whom preventative interventions have been successfully implemented.⁹² However, this model while superficially similar to the vulnerability-stress models used in psychiatry,⁹³ has implicit assumptions which may not hold true in the context of delirium. Risk factors such as male gender are useful in predicting delirium but unlike vulnerabilities,⁹³ do not provide a template for causal mechanism.

Moreover, the temporal separation between predisposing and precipitating factors may be relatively short, making separation of vulnerability and stress an arbitrary distinction. Finally, the model fails to provide an account for the multiple interactions between illnesses, physiologic states, and interventions that typically occur in the setting of delirium.

So how may we speculate on cause in delirium and under what conceptual framework? Illness can be considered as the somatic anomaly and its current or potential manifestations.⁹⁴ In older patients, each somatic anomaly individually is not sufficiently provocative enough to generate a delirium. Geriatric syndromes, such as delirium, are disorders of higher order function that are impaired because of complex interactions between multiple remote but interrelated components. This accounts for why tracking other higher state variables such as mobility and balance as markers of delirium progress makes sense. In the case of delirium, consciousness and its "clouding" is the victim of such physiologic disarray. The components of consciousness that are relevant in delirium are arousal, attention, and time perception.⁹⁵ In this untested model, delirium results when a critical number of mechanisms responsible for these functions in potentially different combinations fail.⁹⁵ This model accommodates the cholinergic and inflammatory cytokines because both these factors can significantly affect arousal mechanisms.^{96–98}

Prevention of delirium

Is the occurrence of delirium in frail older individuals who are medically unwell an inevitability or can it be prevented? Landmark multicomponent intervention studies by Inouye et al^{99,100} built on their predictive model have evolved to address multiple factors with favorable outcome unsurprisingly dependent upon adherence.¹⁰¹

The evidence for prevention of delirium is most compelling within a surgical setting.¹⁰² A large study of proactive geriatric consultation versus usual care was undertaken in the setting of hip fracture.¹⁰³ The recommendations made, essentially basic aspects of good care, achieved a reduction of 33% in cases of delirium compared with usual care.¹⁰³ Delirium severity was also reduced with the greatest benefits extending to those without dementia and least functional limitations. Lundström et al¹⁰⁴ have since replicated these findings with reduced incidence, duration, and complication rate of multidisciplinary care in an orthopedic setting.

The benefits may extend to a reduced delirium rate in a cost-effective manner within a geriatric unit¹⁰⁵ associated with an improvement in outcome. What remains unanswered is the part of geriatricians' intervention that promotes success. The elixir may owe its healing properties to comprehensive geriatric assessment. If this is the case, then uptake relies on little more than initiative, support, and a basic skill set to be adopted by other disciplines.

The role of factors before engagement with acute care has up until recently received scant attention. The future is promising; exercise reduces the incidence of both dementia¹⁰⁶ and delirium¹⁰⁷ and promotes an active lifestyle for the maintenance of healthy cognition into midlife and beyond.

These studies endorse the function of geriatricians within a variety of settings and oppose the perception that delirium is inevitable, even in frail individuals who have experienced a grave insult such as a hip fracture. Clinicians, and in particular geriatricians, are in a position to direct education and

implement multicomponent strategies with a deliverable reduction in delirium.

Delirium education can arguably play a role in delirium prevention. Nurses and personal care workers (nursing assistants or aides) are involved in the day-to-day care of many elderly, both in hospitals and residential care facilities, with doctors and specialists having intermittent contact. Training requirements, scope of practice, and philosophical orientation of these groups differ between themselves and from medical doctors and may contribute to different rates of delirium recognition. It has been suggested that philosophical orientation of nurses to health and aging may influence recognition.¹⁰⁸ Nurses using a healthful perspective, that is regarding “good health” in aging as normal, were most likely to differentiate between acute confusion and chronic confusion.⁵¹ Delirium nonrecognition in this group may also be related to insufficient knowledge of cognitive deficits.¹⁰⁹ Studies of recognition of delirium by nurses have shown that nurses assessed disorientation the best or limit their assessment of cognition to disorientation^{110–112} and failed to recognize behavioral aspects of delirium because of a tendency to normalize such behaviors.¹¹⁰ Delirium education may thus have to address both teaching of clinical skills and enhancing the ability to question stereotypes.

Delirium evaluation

The identification and treatment of the underlying cause affords the only possibility of vanquishing delirium. Untreated delirium represents a high risk of adverse event through pressure ulcers, falls, and fractures¹¹³ made worse by overbearing or constrictive medical endeavors to reduce behavioral problems. Great zeal may be given over to describing the array of possible causes.¹¹⁴ However, ruthlessly pursuing pathology in an older patient with delirium, allowing for exceptions, may be inappropriate, threaten dignity,¹¹⁵ and ultimately misses the point. In delirium, as with other geriatric syndromes, multiple common pathologies associated with aging and their treatments are most often responsible¹¹⁶ and can be evaluated in the main without redress for invasive procedures. Firstly, recognizing that delirium is a sensitive marker of illness should trigger a sensible and proportionate screen for underlying causes. The presence of multiple co-morbidity and polypharmacy challenges standardized treatment regimes and an individualized approach to management of the cause in a frail, older patient should be considered. It should be recognized that delirium may persist even after discharge and highlights the need to track the course of delirium to resolution.

A few exceptions should be noted. Delirium in the older patient is sometimes a consequence of disease of the brain, such as stroke or infection, and should be considered, particularly when the clinical picture is associated with focal neurologic signs. In addition, drug withdrawal states, such as delirium tremens, usually comprise a different natural history and management strategy and are important to recognize and screen for. Regular cognitive assessment is important⁴⁶ to track the delirium, in addition to measurement of other higher state variables, such as mobility and balance that share sensitivity to disturbance of higher order failure.⁵⁴

Rating scales in the evaluation of delirium have at least a couple of roles: identification of delirium and delineation of severity (see Table 107-1). The first allows for more systematic assessment of older people, such that delirium is clearly identified and the latter can help in evaluating change over time. In the absence of biologic markers, rating scales are dependent on operationalization of core features of a disorder. Delirium rating scales without some of the core features such as impaired attention have performed well in expert or trained hands in the identification of delirium. How can this be so? It may be that it is the systematic assessment of an older patient's mental state that is important because it allows for recognition of change in presentation based on clinical observation rather than reactions to patient behaviors. The research requirements of delirium rating scales are slightly but not vastly different to that in clinical practice. The issues of reliability and validity become more important. Many delirium rating scales have not been adequately tested for interrater reliability (IRR) and it has been suggested that IRR should be tested on all occasions when these scales are used in research.¹¹⁷ The validity that is tested is often construct validity because delirium is a well-described but not well-validated entity.

Drug treatment

Not without promise, the role of cholinesterase inhibitors in delirium has been studied with the hope of correcting the central cholinergic deficit described as part of the syndrome.^{78,79,118} Donepezil has failed to demonstrate a benefit¹¹⁹ in terms of reduction in the incidence of delirium although larger studies are called for. Antipsychotic medications such as haloperidol have no preventative role in delirium.^{120–121} However, low dose haloperidol (<3.0 mg/day) associated with decreased severity and duration but not incidence of delirium in postoperative patients compared with placebo controls in one study. Although haloperidol may be equally efficacious as risperidone or olanzapine,¹²¹ it can pose a risk if DLB is mistaken for delirium. Atypical antipsychotics, by contrast, offer

Table 107-1. Clinical Tools and Their Role in Delirium Evaluation

Screening and Diagnosis	Screening, Diagnosis and Severity	Severity
Brief cognitive tests (Abbreviated Mental Test; Mini Mental State Examination)	Confusional State Evaluation (CSE)	Confusion Rating Scale (CRS)

Organic Brain Syndrome Scale (OBS)		
Saskatoon Delirium Checklist (SDC)		

less in the way of extrapyramidal side effects¹²² but some may be associated with hyperglycemia¹²³ and increased risk of stroke.¹²⁴ Consideration should also be given to the inability to metabolize drugs in individuals who are frail^{125,126} or delirious.¹²⁷ Drugs are not a replacement for good care and should be deliberated over only when adequate nonpharmacologic management strategies have been implemented. Neuroleptic agents may have a potentially justifiable role in the diminution of recall distress¹²⁸ but this is as yet without evidence.

Management of delirium

Recognition of delirium is half the battle yet one that is often poorly fought. Untreated delirium may have dire consequences. Educational strategies provide an improved knowledge base for clinicians¹²⁹ and better detection rates for delirium.^{129,130} Unfortunately, consensus-based clinical guidelines fail to generate improvement in the management of delirium.¹³¹ Interventions for other disorders that visibly impact on patient outcome have revolutionized how such conditions are perceived. Before thrombolysis, stroke received little interest compared to today, despite its ever present burden on disability and death. Delirium may lack a single dramatic intervention with which to inspire prescribers but this does not diminish its impact. Knowledge translation has the task of overcoming the obstacles to taking delirium seriously and challenge current attitudes and processes of care (see Table 107-2).

Multicomponent intervention has a sound basis on the grounds of the multifactorial nature of the condition (see Table 107-2). However, the evidence is far less clear than

for preventative strategies.¹³² Delirium, in a surgical setting, is amenable to reduction in duration and severity, but these benefits do not extend to the medical population.¹³³ Good geriatric care may hasten recovery from delirium with sustained cognitive outcomes at 1 year.¹³⁴ Any other health benefits observed have not extended to the longer term¹⁰⁰ and may only be cost-effective for targeted populations.¹³⁵ As yet, there is no robust evidence to direct management strategies for delirium superimposed on dementia.¹³⁶

What is to be made of the limited body of evidence based recommendations in the management of delirium? It may simply reflect that such strategies do not work but does not excuse efforts to institute what makes sense and is good medicine.¹³⁷ The optimization of a patient's environment has a sound basis and is worthy of consideration. Orientation represents assimilation of information acquired through sensory information from the outside world. Sensory deficits, accrued with advancing age, may be compensated for in a person's familiar environment to maintain orientation. Hospitals present a myriad of novel sensory stimulation. Inability to selectively process this external information as part of attention deficit within delirium may lead to misperception of sensory input, such as hallucinations or illusions, and worsen an already unravelled state of orientation. The interaction between the individual and his or her environment becomes readily appreciated as important for modulating the course of delirium. The role of optimization of sensory function is a standard of care in older hospitalized patients made more crucial by its speculated role in delirium.

Table 107-2. Strategies for Optimizing Care at an Institutional and Individual Patient Level in the Prevention and Management of Delirium

DELIRIUM PREVENTION AND MANAGEMENT			
SYSTEM APPROACH		INDIVIDUAL MANAGEMENT	
Challenge	Management	Factor	Intervention
Delirium knowledge gap	<ul style="list-style-type: none"> • Knowledge translation of established clinical guidelines to multidisciplinary team • Implementation of education strategies 	Clinical uncertainty	<ul style="list-style-type: none"> • Intensity of management proportional to likely cause and commensurate with degree of frailty/expected outcome
Poor detection rate of delirium	<ul style="list-style-type: none"> • Mandatory screening in high risk and prevalence settings • Specialist delirium liaison services 	Drugs	<ul style="list-style-type: none"> • Rationalize anticholinergic and other central nervous system acting medications
Postdelirium risk of dementia	<ul style="list-style-type: none"> • Development of memory clinics • Partnerships with other disciplines • Links with voluntary support groups • Raising the public awareness of delirium 	Interventions	<ul style="list-style-type: none"> • Avoid if possible: integrate risk of delirium into judgment of best interests • Incorporate risk of delirium into informed consent/assent process
Inappropriate ward placement	<ul style="list-style-type: none"> • Prioritize timely transfer from acute to geriatric care • Reduce total ward transfers 	Nutrition and hydration	<ul style="list-style-type: none"> • Assess and monitor • Consider guidance for feeding
Inappropriate ward environment	<ul style="list-style-type: none"> • Plan ward layout individual rooms and nursing input 	Sensory abilities	<ul style="list-style-type: none"> • Screen visual and hearing abilities • Provide and optimize function of any aids used
Inadequate prior health care planning	<ul style="list-style-type: none"> • Encourage formal living will in frail/vulnerable individuals to assist future management and goals of care 	Orientation	<ul style="list-style-type: none"> • Provide reorientation strategies: photographs, day-night lighting entrainment, encourage family involvement
Insufficient evidence to guide management	<ul style="list-style-type: none"> • Investigate the role of targeted intervention strategies • Flexibility to identify and pursue best location for management of the individual patient (e.g., palliative care, home, geriatrics) 	Medical care	<ul style="list-style-type: none"> • Consider and correct multiple potential contributors • Track delirium with serial cognitive assessment, mobility, balance, and function • Early rehabilitation

The dearth of rigorous studies has prompted the evolution of largely consensus-based guidelines in the management of delirium.¹³⁸ Nevertheless, experts have a high level of agreement over recommendations¹³⁹ in the absence of supportive data that have a basis beyond just common sense.

Consideration of risk of delirium accompanying a procedure, while not always quantifiable,¹⁴⁰ should be integral to the informed consent process in an older patient.¹⁴¹ The breakdown in cognitive abilities may affect the reliability of the history but also the competency of an individual with delirium to make decisions regarding their medical care and participation in research.^{142–144} Proxy decision makers, because of the acute nature of onset, may not adjust easily to the gravitas of the decision-making process required by the condition. Nevertheless, collateral history is essential to ascertain the history, presence of prior cognitive impairment, and to clarify goals of treatment.¹³⁸ Comprehensive geriatric assessment provides an ideal framework with which to capture this information and affect outcomes.¹⁴⁵

Prognosis

Delirium has profound and wide reaching consequences, including increased length of hospital stay,¹⁴⁶ higher rates of institutionalisation¹⁴⁷ and deaths,^{20,72,148–150} cognitive impairment,^{147,150} psychiatric morbidity,¹⁵¹ patient distress,¹²⁸ functional decline,^{152,153} and caregiver stress.^{154,155}

As the demographic burden of delirium increases, so too will the number of survivors with impairment, the caregiver requirements, and economic cost of their care.¹⁵⁶ This may negate postdelirium interventions to affect outcome, which remains an unexplored area. Interdisciplinary services, despite the absence of evidence-based management strategies, should adapt to the perceived increase in need that follows in the wake of delirium.¹³⁸

Conclusions and future directions

Delirium imposes a toll on the individual, caregiver, and society with personal, health care, and economic consequences. Delirium is well described and despite clinical tools, educational strategies, and clinical guidelines, its recognition is consistently poor and its burden continues to grow. It is no accident that delirium is most commonly seen within a hospital setting and illness severity offers some insight into this. Hospital process—fragmented care, multiple transfers, and iatrogenic events—provide the catalyst for much of delirium witnessed in this group of older, cognitively vulnerable individuals.⁸⁷ Yet delirium can be prevented by using a constellation of interventions that boils down to individualized but basic care without redress for additional high technology therapies. Prevention becomes all the more important when it is considered that management is based on unclear evidence. The lack of knowledge concerning management reinforces

the need for regular screening for delirium because this affords the best prospect of diagnosing underlying illness that can be treated. Such insults should be sought and treated in the context of the patient and in the majority of cases will reflect commonly seen conditions.

Recognizing delirium is a challenge but by systematic application of validated tools in at risk older patients we can do better. Furthermore using the resources that are at hand, namely relatives and the multidisciplinary team, to gather a complete picture of an individual over time may enhance capture of this dynamic condition.

As frailty advances and death approaches, delirium becomes a common theme. Seen in nursing homes and the palliative care setting alike, interventions to prevent or dampen the course of delirium in the dying should be considered and implemented when not adding to the burden of suffering.

Understanding the interaction of pathophysiologic mechanisms in the determination of a deliriant threshold offers the prospect of using targeted strategies to prevent and manage delirium.

Geriatricians, psychiatrists, and the multidisciplinary teams are the groups with the greatest impact on outcomes in delirium. However, the growing burden of delirium is too overwhelming to deal with alone. Only by the dissemination of our skills beyond our conventional boundaries, including the community, can delirium be dealt a blow. Policy, inspiration, and knowledge translation have become the next frontier for geriatricians in the battle for minds in delirium.

KEY POINTS

Delirium

- Delirium is a common, underrecognized disorder among institutionalized and frail older patients.
- Education strategies improve knowledge and recognition of delirium and should be tailored to the health professional.
- Standardized assessment tools incorporating cognitive evaluation are an essential part of screening for delirium and monitoring its progress.
- Delirium is often multifactorial in etiology and the causes reflect common problems in older individuals.
- Delirium can be prevented by promoting good basic care in the form of multicomponent intervention strategies.
- Delirium is associated with a poor outcome and cognitive follow-up is recommended.

Constipation and Fecal Incontinence in Old Age

Danielle Harari

This chapter describes the epidemiology, risk factors, clinical presentation, assessment, and treatment of constipation and fecal incontinence (FI) in older adults. Data sources were a PUBMED/MEDLINE database was searched (1966 to 2008) for relevant abstracts and papers using the following keywords: constipation, impaction, anal, bowel, faecal, fecal, incontinence, urinary, laxatives, enemas, suppositories, and other relevant phrases such as “comprehensive geriatric assessment,” “stroke,” etc. Additional articles were identified by examining reference lists, Cochrane, and other recent systematic reviews. Levels of evidence are as used by the U.S. Preventive Task Force¹:

- Good evidence: Level 1 - consistent results from well-designed, well-conducted studies
- Fair evidence: Level 2 - results show benefit, but strength limited by number, quality, or consistency of studies
- Poor evidence: Level 3 - insufficient because of limited number, power, or quality of studies

INTRODUCTION

Fecal incontinence (FI) in older people is a distressing and socially isolating symptom and increases the risk of morbidity,^{2,3} mortality,^{4,5} and dependency.^{3,5} Many older individuals with FI will not volunteer the problem to their general practitioner or nurse. Regrettably, health care providers do not routinely inquire about the symptom, which is why it is a routine prompt in a standard comprehensive geriatric assessment. This “hidden problem” can lead to a downward spiral of psychological distress, dependency, and poor health. The condition can especially take its toll on informal caregivers of home-dwelling patients,⁶ with FI being a leading reason for requesting nursing home placement.^{7,8} Even when older people are noted by health care professionals to have FI, the condition is often managed passively (e.g., pads provision without assessment). Current surveys show limited awareness of appropriate assessment and treatment options among primary care physicians.⁹ The importance of identifying treatable causes of FI in frail older people is strongly emphasized in national and international guidance,^{8,10,11} but audit shows that adherence to such guidance is generally poor, with nonintegrated services, and suboptimal delivery by professionals of even basic assessment and care.^{12,13}

Constipation is a common concern for adults as they age beyond 60, reflected by a notable increase in primary care consultations and burgeoning laxative use. Older people reporting constipation are more likely to have anxiety, depression, and poor health perception. Qualitative studies show they feel doctors can be dismissive about the problem, and that useful and empathic professional advice is hard to find,¹⁴ and this is confirmed in primary care studies where GPs view constipation as less important than other conditions (such as

diabetes).¹⁵ Clinical constipation in frail individuals can lead to significant complications such as fecal impaction, FI, and urinary retention precipitating hospital admission. Constipation and FI are costly conditions, with high expenditure including laxative spending and nursing time.⁶ For instance, it is estimated that 80% of community nurses working with older people in the United Kingdom are managing constipation (particularly fecal impaction) as part of their case-load.

DEFINITIONS

The WHO International Consultation on Incontinence defines FI as “involuntary loss of liquid or solid stool that is a social or hygienic problem.”¹¹ There is, however, a lack of standardization in defining FI in published prevalence studies hindering cross-study comparisons. Most community-based studies examine prevalence of FI occurring at least once over the previous year, which may overestimate prevalence, but does also provide the upper limit for FI occurrence. Nursing home studies mostly measure weekly or monthly occurrence. Systematic reviews examining FI prevalence have highlighted the need for consensus on definitions.^{16,17}

Definitions of constipation in older people in medical and nursing literature have also been inconsistent. Studies of older people have defined constipation by subjective self-report, specific bowel-related symptoms, or by daily laxative use. Self-reported constipation (e.g., “Do you have recurrent constipation?”) often means different things to different individuals.¹⁵ It is now increasingly required in both clinical practice and research to use standardized definitions for constipation based on specific symptoms (Rome II and III criteria)^{18–20} (Table 108-1). Important constipation subtypes affecting older people such as rectal outlet delay are easier to identify by using standard definitions.^{18,20} Rome criteria are symptom-based: objective assessment relies on finding fecal loading in the rectum and/or colon. Such objective assessment is particularly important in frail older people in whom constipation can be underestimated (Table 108-2).

PREVALENCE OF CONSTIPATION AND CONSTIPATION-RELATED SYMPTOMS

Constipation is a hugely prevalent problem in older people. Approximately 63 million people in North America meet the Rome II criteria for constipation, with a disproportionate number being over 65 years old.²¹ Age is strongly associated with nonspecific self-reporting of constipation.^{22–24} It is therefore striking that the report of infrequent bowel movements (≤ 2 per week) is no more prevalent in older than younger people in community-based studies:

- Only 1% to 7% of both younger and older people report ≤ 2 bowel movements a week.^{22,24,25}

- This consistent bowel pattern across age groups persists even after statistical adjustment for greater laxative use among older people.²²
- Of older people complaining of constipation, less than 10% report ≤ 2 weekly bowel movements, and more than 50% move their bowels daily.^{24,26}
- In contrast, two thirds have persistent straining and 39% report passage of hard stools.²⁶

The symptoms predominantly underlying self-reported constipation in older people tend therefore to not be infrequent bowel movements, but straining and passing hard stools. Difficult rectal evacuation is a primary cause of constipation in older people. Twenty-one percent of community-dwelling people aged 65 and over have rectal outlet delay (Table 108-1),²⁷ and many describe the need to self-evacuate.^{14,27} Two thirds of nursing home residents taking laxatives still report frequent straining.²⁸ Among these frailer individuals, difficult evacuation can lead to recurrent rectal impaction and overflow. Fecal impaction was a primary diagnosis in 27% of acutely hospitalized geriatric patients admitted over the course of 1 year in the United Kingdom,²⁹ and a survey of patients with FI found that fecal loading was present in 57% of older acute hospital inpatients and 70% of care home residents.³⁰ Frail older people do have a higher prevalence of ≤ 2 weekly bowel

movements, affecting one third of care home residents reporting constipation.³¹ Up to 80% of care home residents are constipated according to Rome III criteria,³² a surprising figure considering that 50% to 74% of long-term care residents use daily laxatives.^{31,32}

PREVALENCE OF FECAL INCONTINENCE IN OLDER PEOPLE

Table 108-3 summarizes data on prevalence and risk factors in FI. Meta-regression analysis of prevalence studies in community-dwelling people shows that age has a significant influence on rates of solid and liquid FI.¹⁷ Prevalence is equal between genders in older people, except in the care home setting where it is greater in men.³³⁻³⁶ One prospective study conducted in French nursing home residents⁴ found a baseline FI prevalence of 54%, and a 10-month incidence in those continent at baseline of 20%. New-onset FI was transient (<5 days) in 62%, and long-standing in 38%. In the latter group, 1-year mortality was 26% compared with 7% in those who remained continent. The prevalence of FI varies according to the general health of the study population and therefore by proxy to the study setting:

- Community: 6% to 12% age over 65 and 18% to 29% age over 80^{5,6,33,37-41}
- Acute hospital: 14% to 33% age over 65^{42,43}
- Long-term care: 37% to 54%.^{4,31,35,36,42}

Of note, United Kingdom care home studies have shown wide variations in prevalence between individual homes,^{35,41} that may well be more reflective of different standards of care, rather than of different patient characteristics.

These prevalence data represent case-finding statistics within epidemiologic studies, but in real clinical settings FI is often overlooked. This is through both older people not help-seeking ("it is embarrassing" and "nothing that can be done"), and providers not case-finding and not following through when the problem is identified. Less than 50% of home-dwelling older people with FI (or their caregivers) have discussed the problem with a health care professional in British primary care surveys.⁴⁴ Younger women are more likely to seek help for less severe FI symptoms than older women,⁴⁵ yet even in younger cohorts in most cases of FI are still unrecognized by GPs.⁴⁶ Poor provider awareness of FI is just as prevalent in institutions despite greater opportunity for patient observation. In the acute hospital setting, only 1 in 6 of patients reporting FI have the symptom documented by ward nursing staff,⁴⁷ and care home nursing staff are aware of FI in only half of those residents self-reporting the condition.³¹ Professional ignorance about how to treat FI may in part underlie this: a recent UK care home survey found that trained staff cited advanced age as the main cause of both urinary and fecal incontinence.⁴⁸ Auditing bowel care in care homes to improve quality of care may seem a solution but this proved challenging in a recent United Kingdom high profile nationwide audit of urinary and fecal incontinence care in older people.¹³ Many care homes declined participation, and those who did partake generally reported hampered data collection due to limited access to clinical records and information technology, and staff shortages. The audit did however show that patients admitted to

Table 108-1. Definitions of Constipation

Definition
Constipation (Rome III criteria) Two or more of the following symptoms present on more than 25% of occasions for at least 12 weeks in the last 12 months: 2 or less bowel movements per week Straining at stool Hard stools Feeling of incomplete evacuation
Rectal outlet delay (Rome II criteria) Feeling of anal blockage at least a quarter of the time and Prolonged defecation (>10 minutes to complete bowel movement); or Need for self-digitation (pressing in or around the anus to aid evacuation) on any occasion
Clinical constipation Large amount of feces (hard or soft) in rectum on digital examination and/or Colonic fecal loading on abdominal radiograph

Table 108-2. Factors Potentially Leading to Underestimation of Constipation and FI in Frail Older People

Frail older people may:
<ul style="list-style-type: none"> • Be unable to report bowel-related symptoms due to communication or cognitive difficulties • Have regular bowel movements despite having rectal or colonic fecal impaction • Have impaired rectal sensation and inhibited urge to go and so be unaware of rectal stool impaction • Have nonspecific symptoms associated with colonic fecal impaction (e.g., delirium, anorexia, functional decline) • Be less likely to have symptoms of urgency associated with FI and more likely to have passive leakage

Table 108-3. Epidemiology of FI in Older People and Recommendations for Identifying Cases**Epidemiologic Data Summary**

- FI affects 1 in 5 older people (aged 65 and over) living in the community, and half of those resident in care homes.¹
- Prevalence of FI increases with age alone, particularly in the eighth decade and beyond.¹
- The prevalence of FI is higher in the acute hospital and nursing home setting than in the community,¹ thus the group most affected is frail older people.
- The prevalence of FI in frail older people is equal to or greater in men than women.² This predominance of older men over women with FI is most striking among nursing home residents.²
- The prevalence of FI varies dramatically between institutions in nursing home studies.²
- FI coexists with urinary incontinence in the majority of frail older people.¹
- Aside from age, the following are primary risk factors for FI in older people²:
 - Loose stool
 - Impaired mobility
 - Dementia
 - Neurologic disease
 - Chronic medical conditions
 - Depression
- Fecal loading and constipation are clinically linked to FI, but there is little epidemiologic work assessing this association.
- Physicians and nurses in primary care, acute hospital, and long-term health care settings do not have a high awareness of FI in older people.²
- Within nursing homes, there is a low rate of referral by nursing staff of residents to primary care physicians or continence nurse specialists for further assessment of FI² and there is a tendency toward passive management (e.g., use of pads only without further evaluation).² Fecal loading is often present in older care home residents with FI.²
- Older people may be reluctant to volunteer the symptoms of FI to their health care provider² for social or cultural reasons, or due to a popular misperception that the condition is part of the aging process and therefore “nothing can be done about it.”
- FI is associated with reduced quality of life and poor health perception.²

Recommendations: Identifying FI in Older People

- Bowel continence status should be established by direct questioning and/or direct observation in:
 - All nursing and residential home residents
 - Hospital inpatients aged 65 and over
 - People aged 80 and beyond living at home
 - Older adults with impaired mobility
 - Older adults with impaired cognition
 - Older adults with neurologic disease
 - Older adults with chronic disease
- Primary care staff, hospital ward staff, and long-term care staff should routinely inquire about fecal incontinence in frail older patients.
- Inquiry about FI should be systematic and include stool consistency, severity of FI, and impact on activities of daily living and quality of life.
- Health care providers should be sensitive to cultural and social barriers discouraging patients from talking about the condition.
- Frail older patients with restricted ability to access primary care, such as nursing home residents, and those with mobility, chronic illness, or cognitive impairments, should be screened for FI through systematic case-finding methods.
- Systematic outreach program that make it easier for frail older people and those who care for them to volunteer the problem to their primary care provider should be implemented.
- There are significant geographic variations in provision of specialist expertise in bowel care (both medical and nursing) nationally and globally, which may affect case-finding in older people.
- Further examination of underlying reasons for the variations in prevalence of FI between nursing homes (standards of care, patient case-mix, reporting) is needed.
- Urinary and fecal incontinence often coexist; continence care workers (e.g., nurse specialists) should be trained in identification and management of fecal and urinary incontinence in older people.
- Key requirements to improving detection in the practice setting should be implemented:
 - Education of health care workers to embed both a sense of value in identifying FI, plus confidence that the condition can be treated
 - Protocols should be in place clarifying all details of screening inquiry (who will ask, how to ask, when to ask, and who to ask)
 - Patients and caregivers should have access to educational materials at the point of inquiry

these care homes with preexisting FI tended to be placed on a containment management plan rather than being assessed for causes and possible treatment, and this was despite having good access to continence specialist care. On a similar theme, a recent U.S. National Institutes of Health State-of-the-Science Statement commented that health care provider education alone is not enough to improve the identification of adults with FI and recommended key requirements to improve detection in the practice setting (Table 108-3).⁸

RISK FACTORS FOR FI AND CONSTIPATION IN OLDER PEOPLE

Urinary incontinence is strongly linked to FI, with 50% to 70% coexistence in community-based studies.^{2,34,39,49} Perhaps unsurprisingly, diarrhea or loose stool is a strong

predictor for FI in all settings, but what is striking is the prevalence of chronic diarrhea in frail older people.^{2,6,36,41} Medical comorbidity and physical disability are equivalent or greater than age in strength of association.^{2,3,6,34,49} A cohort study of community-dwelling patients aged 65 and over found that severe FI (at least once weekly) was associated with increased mortality after 42 months, independent of age, gender, and poor general health.⁵ Depression is repeatedly linked, though cause or effect is clearly impossible to discern from cross-sectional analyses.^{2,49,34} Independent factors for FI in acutely hospitalized patients (in order of strength of association) are loose/liquid stool consistency, illness severity, and older age.⁴³ In elderly hospital inpatients, contributing factors are fecal loading (57%), functional disability (83%), loose stools (67%), and cognitive impairment (43%)³⁰; those with loose stools and less

comorbidity are more likely to have transient FI with resolution after 3 months.

Most risk factor studies for constipation are cross-sectional, but one prospective study examined baseline characteristics predictive of new-onset constipation (≤ 2 bowel movements per week or persistent straining) in elderly U.S. nursing home patients.⁵⁰ Seven percent ($n = 1291$) developed constipation over a 3-month period. Independent predictors were poor consumption of fluids, pneumonia, parkinson's disease, decreased bed mobility, greater than 5 medications, dementia, hypothyroidism, white race, allergies, arthritis, and hypertension (the latter 3 conditions were postulated to be associated primarily because of the constipating effect of drugs used to treat them). What is evident is that many of these factors are potentially modifiable. Table 108-4 summarizes practice guidance in constipation based on the epidemiologic data described below.

Reduced mobility

Greater physical activity (including regular walking) is associated with less constipation symptoms in older people living at home.^{23,51} Reduced mobility is the strongest independent correlate (following adjustment for age and comorbidities) of heavy laxative use among nursing home residents,⁵² and gut transit time in bedridden elderly subjects can be as long as 3 weeks.⁵³ Exercise increases colonic propulsive activity ("joggers diarrhea"), especially when measured postprandially.⁵⁴ In a survey of younger women (36 to 61 years), daily physical activity was associated with less constipation (≤ 2 bowel movements per week), and the association strengthened with increased frequency of physical activity.⁵⁵ This leads to speculation that increasing physical activity in adulthood may reduce the likelihood of constipation problems in older age. Epidemiologic studies in older people have repeatedly shown that poor mobility is also a strong risk factor for FI after adjustment for other variables.^{3,4,6,34,36}

Polypharmacy/drug side effects

Polypharmacy itself increases the risk of constipation in older patients, particularly in nursing homes where each individual takes an average of six prescribed medications per day.⁵³ Certain drug classes are particularly implicated. Anticholinergic medications reduce contractility of the smooth muscle of the gut via an antimuscarinic effect at acetylcholine receptor sites, and in some cases (e.g., patients with schizophrenia taking neuroleptics), long-term use may result in chronic megacolon. Anticholinergic medications have been independently associated with daily laxative use in nursing home studies,⁵³ symptomatic constipation in community-dwelling older U.S. veterans,⁵⁶ and FI in elderly stroke survivors.⁵⁷ Although older people are certainly susceptible to the constipating effects of opiate analgesia, a study of nursing home residents with persistent nonmalignant pain showed equivalent constipation rates in chronic opiate users and nonusers over a 6 month period; those taking opiates showed improved function and social engagement.⁵⁸ Chronic pain is often undertreated in frailer older people, possibly through fear of adverse effects of analgesic drugs, so it is important to note that constipation in this context can be effectively managed by laxative and suppository coprescribing. Transdermal patches (e.g., fentanyl) are associated with lower constipation risk than sustained-release oral morphine.⁵⁹ All types of iron supplements (sulfate, fumarate,

Table 108-4. Practice Guidance for Constipation Based on Epidemiologic Evidence

Screening

- Constipation symptoms should be routinely asked about in patients aged 65 and over in view of the high prevalence of the condition in this population.
- Men and women in their eighth decade and beyond should be regularly screened for constipation symptoms, as prevalence increases with advancing age.
- Periodic objective assessment for constipation in elderly nursing home residents should be incorporated into routine nursing and medical care. Patients unable to report symptoms due to cognitive or communication difficulties should be especially targeted. Such an assessment should occur at minimum every 3 months (3 monthly incidence rate of new-onset constipation is 7% in nursing home residents), and optimally monthly.

Identifying Risk Factors

- The identification of risk factors for constipation in older people is critical to effectively managing the condition.
- The following are risk factors for constipation in older people: Polypharmacy (5 medications)²
Anticholinergic drugs (tricyclics, antipsychotics, antihistamines, antiemetics, drugs for detrusor hyperactivity)¹
Opiates²
Iron supplements³
Calcium channel antagonists (nifedipine and verapamil)²
Calcium supplements²
Nonsteroidal antiinflammatory drugs²
Impaired mobility²
Nursing home residency²
Dementia²
Parkinson's disease¹
Diabetes mellitus¹
Autonomic neuropathy²
Stroke³
Spinal cord injury or disease¹
Depression³
Dehydration²
Low dietary fiber³
Hypothyroidism
Hypercalcemia
Hypokalemia
Uremia
Renal dialysis³
Mechanical obstruction (e.g., tumor, rectocele)
Lack of privacy or comfort
Poor toilet access³
- Systematic identification of multiple risk factors in vulnerable older people with constipation should be incorporated into good practice guidelines in all health care settings
- Patients at increased risk of constipation from recognized comorbidities (e.g., Parkinson's disease, diabetes) should be regularly assessed for the condition

Assessment

- Identifying specific bowel symptoms in older individuals reporting constipation is important to guide appropriate management of this common complaint.
- Reduced bowel movement frequency is not a sensitive symptom indicator for constipation in community-dwelling older people, though it is specific.
- Difficulty with evacuation and rectal outlet delay are primary symptoms in older individuals.
- An objective assessment should be undertaken in frail older people with constipation because these patients are at increased risk of developing complications.
- Increased wandering and agitation in patients unable to communicate due to dementia should prompt an assessment for constipation.
- Older patients being prescribed laxatives on a daily basis should be regularly reviewed for symptoms of constipation and rectal outlet delay, and treatment should be appropriately adjusted.

and gluconate) cause constipation in adults, the constipating factor being the amount of elemental iron absorbed.⁶⁰ Slow-release preparations have a lesser impact on the bowel because they carry the iron past the first part of the duodenum into an area of the gut where elemental iron absorption is poorer. Intravenous iron does not cause constipation and can be an alternative in patients with chronic anemia (e.g., chronic kidney disease) who become constipated on oral iron. Constipation was the main side effect in a 5-year study of calcium supplementation in older women (treatment 13.4% versus placebo 9.1%).⁶¹ Calcium supplementation reduced bone turnover and fracture rates in women who took it, but long-term compliance was poor, and constipation may have contributed to this. Calcium channel antagonists impair lower gut motility, particularly in the rectosigmoid.⁶² Severe constipation has been reported in older patients taking calcium channel antagonists, with nifedipine and verapamil being the most potent inhibitors of gut motility within this class. Nonsteroidal anti-inflammatory drugs (NSAIDs) increase the risk of constipation in older people, most likely through prostaglandin inhibition. In a large primary care study, constipation and straining were more prevalent reasons for stopping NSAIDs than dyspepsia.⁶³ NSAIDs have also been implicated in increasing the risk of stercoral perforation in patients with chronic constipation. Aluminium antacids have been associated with constipation in both nursing home⁵² and community settings.⁶⁴

Dietary factors

Low consumption of fiber in the form of wheat bran, vegetables, and fruit predisposes toward constipation, and in the United Kingdom, consumption of all of these decreases with advancing age. Community studies of older Europeans who eat a Mediterranean diet rich in fruit, vegetables, and olive oil show lower rates of constipation (4.4% in people aged 50 and over).⁶⁵ A study of nutritional factors within all the nursing homes in Helsinki found an association between malnutrition and constipation.⁶⁶ This may be two-way in that marked constipation can cause anorexia, whereas low calorie intake can promote constipation. Constipation is a recognized problem in patients receiving enteral nutrition. A prospective survey of older hospitalized patients receiving nasogastric tube feeding identified constipation as a complication of treatment in 30% of patients.⁶⁷ Enteric feeding products containing fiber are available, though there are no data on whether constipation is any less of a problem with their use.

Low fluid intake in older adults has been related to symptomatic and slow-transit constipation.^{50,68} Withholding fluids over a 1-week period in young male volunteers significantly reduced stool output.⁶⁹ Elderly people are generally at risk of dehydration because of:

- Impaired thirst sensation
- Less effective hormonal responses to hypertonicity
- Limited access to drinks because of coexisting physical or cognitive impairments
- Voluntary fluid restriction in an attempt to control urinary incontinence

Population studies have suggested that alcohol consumption is a preventive factor for constipation symptoms in both men and women.^{51,55}

Diabetes mellitus

Over half of diabetic outpatients report constipation symptoms, with neuropathy symptom scores correlating with laxative usage and straining.⁷⁰ Diabetic autonomic neuropathy can result in slow colonic transit and impairment of the gastrocolic reflex.⁷¹ However, one third of diabetic patients with constipation do not have neuropathic symptoms,⁷⁰ so unrelated reversible factors (e.g., drugs, mobility, fluids) should be considered, particularly in older people. Colonic transit time in frail older people with diabetes and constipation is extremely prolonged at a mean of 200 hours.⁷² Administering acarbose, an alpha-glucosidase inhibitor with a potential adverse effect of causing diarrhea significantly reduced transit in these patients.⁷² Diabetes is a risk factor for the development of FI, especially in men.⁷³ FI may occur through mechanisms of¹ bacterial overgrowth resulting from prolonged gut transit causing characteristic nocturnal diarrhea and² multifactorial anorectal dysfunction (reduced basal and squeeze pressures, spontaneous relaxation of the internal anal sphincter, reduced rectal compliance, abnormal rectal sensation).^{71,74} Acute hyperglycemia can further inhibit anorectal function and colonic peristalsis.

Neurologic diseases

Patients with Parkinson's disease (PD) suffer from multiple primary pathologies that lead to constipation:¹ dopaminergic neuron degeneration and increased presence of Lewy bodies in the myenteric plexus prolonging colonic transit (independent of age, physical activity, medications),^{75,2} pelvic dyssynergia causing rectal outlet delay and prolonged straining,^{75,3} and small increases in intraabdominal pressures on straining. Constipation can become prominent early in the course of the disease, even before motor symptoms developing. In a 24-year longitudinal study, less than one bowel movement a day was associated with a threefold risk of future PD in men.⁷⁶ Fifty-nine percent of PD patients report constipation according to Rome criteria, with 33% being very concerned by their bowel problem.⁷⁷ Antiparkinsonian drugs may further exacerbate constipation. Pelvic dyssynergia affects 60% of people with PD, and may be hard to treat. Botulinum toxin injected into the puborectalis muscle has been used to improve rectal emptying in PD patients with good effect, though repeat injections every 3 months are required to maintain clinical benefit.⁷⁸

Dementia predisposes individuals to rectal dysmotility,²⁹ partly through ignoring the urge to defecate. Epidemiologic studies show a significant association between cognitive impairment and nurse-documented constipation in nursing home residents. Patients with non-Alzheimer's dementias (PD, Lewy body, vascular dementia) compared with those with Alzheimer's are more likely to suffer from constipation as part of autonomic symptoms.⁷⁹ Constipation in long-term care residents unable to communicate due to dementia has been linked to physically aggressive behavior⁸⁰ and development of wandering behavior⁸¹ by independent association.

Depression, psychological distress, and anxiety are all associated with increased self-reporting of constipation and with FI in older persons. The symptom of constipation can also be somatic manifestation of psychiatric illness. A careful assessment is required to differentiate subjective complaints from clinical constipation in depressed or anxious patients.

Constipation affects 60% of those recovering from stroke on rehabilitation wards,⁸² and a high number of these have combined rectal outlet delay and slow transit constipation.⁸³ Major FI is 4½ times more prevalent in stroke survivors than the nonstroke population.⁸⁴ FI may develop months after acute stroke and can be transient, consistent with constipation with overflow as one possible cause.⁵⁷ Epidemiologic data suggest that FI is associated more with disability-related factors (particularly functional difficulties in using the toilet, and anticholinergic medications) than stroke-related factors (e.g., severity and lesion location).^{57,84,85} Weak abdominal and pelvic muscles following stroke also contribute to problems with evacuation.

Metabolic disorders

Hypokalemia and hypomagnesemia produce neuronal dysfunction that minimizes acetylcholine stimulation of gut smooth muscle, and so prolongs transit through the gut. This should especially be looked for and corrected in acute colonic pseudo-obstruction. Hypercalcemia causes conduction delay within the extrinsic and intrinsic gut innervation of the gut neuromuscular bowel dysfunction (which may be reversed following parathyroidectomy). Constipation is not an unusual presentation for clinical hypothyroidism, particularly in older women. Patients on long-term renal hemodialysis have prolonged age-adjusted transit time⁸⁶; 63% complain of constipation, with important contributors being high (49%) use of resin to prevent hyperkalemia, suppression of the defecation urge while undergoing dialysis, and low fiber intake.⁸⁷ Resin administration can increase the risk of impaction in frail older patients also.

Colorectal cancer

Following adjustment for age and potential confounders, ≤ 2 reported bowel movements a week was associated with a greater than twofold risk of colon cancer in a U.S. study, with the association being stronger in women than men; no association was seen with laxatives.⁸⁸ Comparing underlying causes for FI in younger and older men shows colon and prostate cancer to be significantly more common in the older group,⁸⁹ so the index of suspicion for colorectal cancer should be higher in older adults with bowel symptoms.⁹⁰

Diverticular disease

A case-control study of patients (mean age 68) with acute uncomplicated diverticulitis showed 74% to have prolonged transit.⁹¹ Left-sided diverticulosis coli affects 30% to 60% of people over the age of 60 in developed countries. High intraluminal pressures while straining at stool in people who have a low fiber diet contributes to the cause of the condition.

PATHOPHYSIOLOGY OF CONSTIPATION AND FI IN OLDER PEOPLE

Physiologic studies suggest that changes in the lower bowel predisposing toward constipation in older people are not primarily age-related. This is compatible with the epidemiology showing that bowel movement frequency does alter with aging, and that constipation symptoms are more prevalent in older people with comorbidities. Extrinsic causes such as reduced mobility, fluid intake, dietary fiber, comorbidities,

and medication all impact colonic motility and transit, and influence the pathophysiology of constipation. Studies of anorectal function do, however, show age-related changes predisposing to FI.

Colonic function

Colonic motility depends on the integrity of the central and autonomic nervous systems, gut wall innervation and receptors, circular smooth muscle, and gastrointestinal hormones. Propagating motor complexes in the colon are stimulated by increased intraluminal pressure generated by bulky fecal content. Studies of total gut transit time (passage of radiopaque markers from mouth to anus, normally 80% passed within 5 days), colonic motor activity, and postprandial gastrocolic reflex show no differences between healthy older and younger people.^{92–94} Conversely, older people with chronic constipation do have prolonged transit of up to 9 days.^{92,95} Markers pass especially slowly through the left colon with striking delay in the rectosigmoid, suggesting that total transit time is prolonged because of segmental dysmotility in the hindgut.⁹⁶ The prolongation is even greater in institutionalized or bedridden older patients with constipation, with transit time ranging from 6 to greater than 14 days.⁵³ Slow transit results in a cycle of worsening constipation by reducing stool water content (normally 75%) and shrinking fecal bulk, which then diminishes intraluminal pressures, and hence the generation of propagating motor complexes and propulsive activity. Aging is associated with some intrinsic physiologic mechanisms that may alter colonic function, predisposing older people to this “constipation cycle”:

- Reduced number of neurons in the myenteric plexus and impaired response to direct stimulation,^{96,97} leading to intrinsic myenteric dysfunction
- Increased collagen deposit in left colon leading to altered compliance and motility⁹⁷
- Reduced amplitude of inhibitory junction potentials and hence inhibitory nerve input to circular colonic muscle causing segmental motor incoordination⁹⁸
- Increased binding of plasma endorphins to gut receptors after age 60⁹⁹

Anorectal function

In normal defecation, colonic activity propels stool into the rectal ampulla causing distention and reflexic intrinsically mediated relaxation of the smooth muscle of the internal anal sphincter (or anal canal). This is followed promptly by reflex contraction of the external anal sphincter and pelvic floor muscles, which are skeletal muscles innervated by the pudendal nerve. The brain registers a desire to defecate, the external sphincter is voluntarily relaxed, and the rectum evacuated with assistance from abdominal wall muscle contraction. There is a tendency toward an age-related decline in internal sphincter tone and thickness particularly beyond the eighth decade.^{94,100–102} This reduction in internal anal sphincter pressure lowers the threshold for balloon (stimulated stool) expulsion, and is much more notable in frail older people with FI.^{103,104} There is a clear age-related decline (greater in women than men) in external anal sphincter and pelvic muscle strength,^{100,101} which may contribute to both incontinence and evacuation difficulties. Rectal

motility appears to be unaffected by healthy aging,⁹⁴ but an age-related increase in anorectal sensitivity thresholds, and reduced rectal compliance has been observed, starting at an earlier age in women than men.¹⁰⁵ Patients with dementia and FI tend to exhibit multiple uninhibited rectal contractions in response to rectal distention.¹⁰³ Younger women with FI are more likely to have isolated anal sphincter defects (often child-bearing related),¹⁰⁶ whereas the anorectal pathology is more multifactorial in older women, including pudendal neuropathy, hemorrhoidectomy, diabetes, and rectal and vaginal prolapse.^{45,107} Failure of the anorectal angle to open and excessive perineal descent in older women can also lead to constipation,⁹⁷ and consequent prolonged straining may compress the pudendal nerve further exacerbating any pre-existing neuropathy. Table 108-5 describes the three main types of anorectal dysfunction that predispose older people to rectal outlet delay.

CLINICAL EVALUATION

The causes of FI and constipation in older people are usually multifactorial. Comprehensive geriatric assessment (evaluating medical, functional, and psychosocial factors in addition to the bowel) is key to identifying all contributing causes and developing a goal-focused management plan. There is much room for improving standards of bowel assessment in older people in current routine practice; surveys indicate a lack of thoroughness by doctors and nurses in all settings, with failure to obtain an accurate symptom history or to perform rectal examinations.^{13,108} A recent U.K. audit in older patients with FI in primary care, acute hospital, and care home settings showed that only 50% of individuals within each setting had a history taken, only 22% to 33% had a basic examination documented (history and rectal), and cause(s) for FI was documented in only 27% to 49%, the 27% being in the acute hospital sector.¹³

Clinical history

It is helpful to have patients or caregivers keep a stool chart for 1 week to document bowel pattern and episodes of FI. Self-report of bowel symptoms are generally reliable and reproducible in older cohorts, including those in long-term

care.^{109–111} Proxy responses by informal caregivers for questions concerning FI have also been shown to concord well with index responses given by older patients.¹¹²

Documentation of stool consistency is diagnostically critical⁸ for both FI and constipation, and the pictorial Bristol stool chart is commonly used to aid patients in describing their stool. Overflow fecal incontinence typically presents as frequent passive leakage of watery stool, sometimes confusing patients and caregivers (and occasionally health care providers) into thinking they have "diarrhea" rather than constipation. Patients with anal sphincter dysfunction tend to leak small amounts of stool, with urgency before leaking where external anal sphincter weakness predominates, and more passive (unconscious) leakage when internal sphincter dysfunction is the main cause.¹¹³ Fecal urgency and/or loose stool should prompt investigation for diarrheal disease (see FI treatment). Patients with dementia-related incontinence tend to pass complete formed bowel movements, usually after meals. A recent history of altered bowel habit should prompt an exploration of precipitants (e.g., medications, stroke), and where unexplained, an evaluation for colorectal cancer. Abdominal pain, rectal bleeding, and certainly any systemic features such as weight loss and anemia should prompt further investigations for underlying neoplasm. IBS should be a diagnosis of exclusion in older people, and only made in those with a long history of IBS symptoms (Table 108-6). Abdominal pain is a warning symptom for constipation complications such as impaction with obstruction, stercoral perforation, sigmoid volvulus, or urinary retention. Rectal pain associated with defecation in older people may be due to rectal ischemia and other more common anorectal conditions. Urinary incontinence and lower urinary tract symptoms (frequency, urgency, straining and hesitancy, dysuria, nocturia) frequently coexist with FI and constipation^{107,114} and should be characterized, and urinalysis and postvoid bladder residual volume measurement (preferably by hand-held scan) undertaken if present.

Fecal impaction

In frail patients, fecal impaction may present as a nonspecific clinical deterioration; more specific symptoms are anorexia, vomiting, and abdominal pain. Findings on physical

Table 108-5. Types of Anorectal Dysfunction Causing Rectal Outlet Delay in Older People

	Pathophysiology	Clinical Picture
Rectal dysmotility	<ul style="list-style-type: none"> Reduced rectal motility and contractions Increased rectal compliance Variable degree of rectal dilation Impaired rectal sensation with blunting of urge to pass stool Over time, increasing rectal distention required to reflexively trigger the defecation mechanism 	<ul style="list-style-type: none"> Rectal hard or soft stool retention on digital examination of which patient may be unaware Chronic rectal distention leads to relaxation of the internal sphincter and fecal soiling One postulated cause is diminished parasympathetic outflow as a result of impaired sacral cord function (e.g., from ischemia or spinal stenosis). May also develop through persistent disregard or suppression of the urge to defecate as a result of dementia, depression, immobility, or painful anorectal conditions.
Pelvic floor dyssynergia	<ul style="list-style-type: none"> Paradoxical contraction or failure to relax the pelvic floor and external anal sphincter muscles during defecation Manometric studies show paradoxical increases in anal canal pressure on straining 	<ul style="list-style-type: none"> Severe and longstanding symptoms of rectal outlet delay Parkinson's disease More common in younger women
Irritable bowel syndrome (IBS)	<ul style="list-style-type: none"> Increased rectal tone and reduced compliance Lower pain threshold on distending the rectum during anorectal function tests 	<ul style="list-style-type: none"> Usually constipation-predominant in older people Rome criteria symptoms: abdominal distention or pain relieved by defecation, passage of mucus, and feeling of incomplete emptying

Table 108-6. Diagnosis of Constipation and FI in Older People**Bowel History**

Number of bowel movements per week
 Stool consistency
 Straining/symptoms of rectal outlet delay
 Fecal incontinence/soiling - frequency
 Duration of constipation symptoms or FI
 Irritable bowel syndrome symptoms (abdominal pain, bloating, passage of mucus)
 Rectal pain or bleeding
 Laxative use, prior and current
 Psychological and quality of life impact of bowel problem
 Urinary incontinence/lower urinary tract symptoms
 Pad use and laundry changes

General History

Mood/cognition
 Symptoms of systemic illness (weight loss, anemia)
 Relevant comorbidities (e.g., diabetes, neurologic disease)
 Mobility
 Diet
 Medications
 Toilet access (location of bathroom, manual dexterity, vision)

Specific Physical Examination

Digital rectal examination including external and internal sphincter tone
 Perianal sensation/cutaneous anal reflex
 Rectal prolapse/hemorrhoids
 Pelvic floor descent/rectocele
 Abdominal palpation, auscultation
 Postvoid residual volume
 Neurologic, cognitive, and functional examination

Tests**Indications for plain abdominal radiograph**

Empty rectum with clinical suspicion of fecal impaction
 Persistent fecal incontinence despite clearing of any rectal impaction
 Evaluation of abdominal distention, pain, or acute discomfort
 Persisting complaints of constipation with increasing laxative usage
 Indications for colonoscopy
 Systemic illness (weight loss, anemia, etc.)
 Bleeding per rectum
 Recent change in bowel habit without obvious risk factors
 Indications for anorectal function tests
 Severe or persistent symptoms of rectal outlet delay, suggesting pelvic dyssynergia
 Persistent FI with preserved anorectal sensation and clinically weak anal sphincter

examination may include fever, delirium, abdominal distention, reduced bowel sounds, arrhythmias, and tachypnea secondary to splinting of the diaphragm. The mechanism for the fever and leucocytosis response is thought to be microscopic stercoral ulcerations of the colon. A plain abdominal radiograph will show colonic or rectal fecal retention associated with lower bowel dilation (Figure 108-2). Presence of fluid levels in the large or small bowel suggests advanced obstruction; the closer the fecal impaction is to the ileocecal valve, the greater the number of fluid levels seen in the small bowel.

Rectal and pelvic examination

Stool impaction on digital rectal examination does not have to be hard; soft stool retention is commonly seen in older people taking laxatives who have problems with rectal outlet delay. Absence of stool on rectal examination does not exclude the diagnosis of constipation.²³ A dilated

Figure 108-1. Abdominal radiograph of a 73-year-old man with chronic schizophrenia who has taken anticholinergic neuroleptics for many years. This was his third hospital admission for colonic impaction. The arrow points to the cecum, which is full of stool, indicative of slow transit. Fecaliths are visible in the pelvic region.

rectum with diminished sensation and retained stool suggests rectal dysmotility. Digital assessment of squeeze and basal tone has been shown to be as sensitive and specific as manometry in discriminating sphincter function between continent and incontinent patients aged over 50.¹¹⁵ Easy finger insertion with gaping of the anus on finger removal indicates poor internal sphincter tone, whereas reduced squeeze pressure around the finger when asking the patient to "squeeze and pull up" suggests external sphincter weakness. Preserved sensation (urge to stool, awareness of wind) improves likelihood of response to anal strengthening maneuvers. Absent cutaneous-anal reflex (gentle scratching of the anal margin should normally induce a visible contraction of the external sphincter) and, in particular, perianal anesthesia points to sacral cord dysfunction with possible related gut neuropathy. Proctoscopy is a simple, quick, and useful test for diagnosing internal hemorrhoids, and abnormalities of the rectal wall.

Perineal examination is relevant in view of the association between urogenital prolapse (particularly rectocele) and FI in older women.¹⁰⁷ An examination for posterior vaginal prolapse (bearing down in the gynecologic position) is appropriate in all women with constipation, especially those reporting incomplete rectal emptying. Excessive perineal descent is observed by asking the patient to bear down while lying in the lateral position. Normal perineal descent is less than 4 cm (can be eye-balled by drawing an imaginary line between that ischial prominences). Rectal prolapse may also be observed in this manner, though lesser degrees of prolapse may be only identified by having the patient strain while sitting on a toilet or commode. FI is a primary independent risk factor for pressure sores in older people,^{6,116} so

Figure 108-2. Abdominal radiograph of an 83-year-old man with Parkinson's disease and long-standing symptoms of continuous fecal leakage. As his caregiver at home, his wife was changing his clothing up to six times a day. The rectosigmoid colon is completely impacted, and the dilated bowel loop implies obstruction. He was briefly hospitalized for disimpaction with enemas and laxatives, resulting in complete resolution of incontinence. He and his wife were educated in regular use of laxatives and suppositories, and in lifestyle measures.

evaluation of skin integrity (with pressure ulcer risk assessment) is important.

Rectosigmoid fecal loading may impinge on the bladder neck causing a degree of urinary retention.^{117,118} Constipation increased the risk of urinary retention fourfold (other predictors being urinary tract infection and previous urinary retention) in hospitalized women aged 65 and over.¹¹⁸ Urinary symptoms of difficult voiding are unreliable in diagnosing retention in older people, so is good practice to do screening postvoid residual volumes in the setting of constipation and FI.

Plain abdominal x-ray

Incontinent patients without evidence of rectal stool impaction should ideally undergo a plain abdominal radiograph to establish or rule out the diagnosis of overflow. Abdominal x-ray is required in the presence of abdominal pain or dilation to identify impaction with obstruction and more severe complications, such as sigmoid volvulus, colonic pseudo-obstruction, and stercoral perforation.⁹⁵ Acute colonic pseudo-obstruction (Ogilvie's syndrome) is most likely to occur in hospitalized frail older people with a history of chronic constipation who are acutely medically ill or post-operative. It occurs with abdominal distention and colonic dilation on x-ray, with a cecal diameter of ≥ 10 cm. Marked fecal loading in the descending and sigmoid colon correlates well with prolonged transit time, as does the presence of feces rather than air in the cecum (Figure 108-2). Dilation of the colon (>6.5 cm maximum diameter) in the absence

Table 108-7. Bowel Preparation in Older People

- Older age, constipation, reported laxative use, tricyclic antidepressants, stroke, and dementia are associated with inadequate preparation and thus taking longer to instrument the cecum
- Even in those who take 75%–100% of their prescribed treatment, bowel preparation is satisfactory in only 50%

Guidance

- Give regular laxatives (e.g., Movicol 2 sachets daily) and enemas or suppositories for at least 1 week before the procedure, with a longer run up period in patients known to have constipation, or with comorbidities such as diabetes
- Individualize the cathartic regimen (e.g., 1–2 L of GoLYTELY daily over 2 to 3 days in those unable to drink 4 L, or use of alternative preparations such as sodium picosulfate)
- Identify potential nonadherence ("Can the patient drink 4 L of GoLYTELY in 24 hours?")
- Preempt unpleasant side effects ("Will the patient be able to reach the toilet in time to avoid fecal leakage?")
- Use oral phosphosoda with caution as administration in older people increases in serum phosphate, even in patients with normal creatinine clearance
- Consider preprocedure plain abdominal x-ray for evaluation of persisting fecal loading
- Where possible give clear fluid diet before administration of bowel preparation

of acute obstruction points to a neurogenic component to bowel dysfunction, and thus identifies patients at risk of recurrent colonic impaction. Rectal dilation (>4 cm) implies dysmotility and evacuation problems.

Colonoscopy/bowel preparation

Chronic constipation alone is generally not considered an appropriate indication for colonoscopy; the range of neoplasia found is similar to that in asymptomatic patients undergoing primary colorectal cancer screening.¹¹⁹ A review of 400 colonoscopies in people aged 80 and over showed a good safety profile but low cancer detection rate for symptoms (e.g., constipation, abdominal pain) other than bleeding (2% versus 12%).¹²⁰ Further investigation is of course warranted in the context of rectal bleeding, systemic illness, or laboratory abnormalities. Barium enema has now largely been superseded by colonoscopy in older patients. Colonoscopy causes significantly less discomfort than a barium enema and is diagnostically more sensitive. Inadequate colonoscopies are common in older people because of poor bowel preparation (Table 108-7).

Anorectal function tests

Anorectal physiology tests are not generally required in older people with constipation or FI because they do not tend to alter the clinical examination conclusions or the management plan.¹²¹ They have a role in confirming pelvic dyssynergia in people with persistent rectal outlet delay, a condition amenable to biofeedback. Endoanal ultrasound or MRI measure the integrity of the anal sphincters and thus guide management of incontinence toward biofeedback therapy, or surgical intervention (sphincter reconstruction). This investigation is appropriate in those patients with clinically weak sphincters and preserved sensation whose FI persists after behavioral measures (pelvic floor exercises, loperamide).

Physical function and toilet access

Functional FI can occur in individuals who are unable to access the toilet in time due to impairments in mobility, dexterity, or vision, but who may even have normal lower gut function. Withholding evacuation because of access problems can lead to constipation. Evaluation of toilet access should ideally be multidisciplinary and include assessment of function (e.g., Barthel Index), mobility (e.g., "timed up-and-go"), visual acuity, upper limb dexterity (e.g., undoing buttons), and cognition. A practical assessment is to watch someone transfer and manage clothing on the toilet or commode. Toilet or commode design should be adapted to each individual (e.g., trunk support, adaptability, mobility, foot support).¹²² For patients with functional difficulties, the physical layout of their home in relation to the bathroom should be assessed (location, distance from main living area, width of doorway for accommodating walking aids, presence of grab rails or raised toilet seat, lighting levels).

Psychological impact/quality of life

Constipation and FI affect quality of life, daily living, and morale in older people, even following adjustment for other chronic illnesses.^{40,123} The Patient Assessment of Constipation Quality of Life questionnaire is a self-report tool that has been validated in elderly long-term care residents (QOL scores correlate with abdominal pain and constipation severity).¹¹⁹ In routine practice, a person's attitude toward their bowel problem (positive, acceptance, denial, distress, apathy) and the impact on their quality of life (changes in usual family, social, physical, and work-related activities) should at least be included when taking a history.

TREATMENT OF CONSTIPATION IN OLDER PEOPLE

Nonpharmacologic treatment

The consultation between a general practitioner and an older person reporting constipation will more often than not result in a laxative being prescribed. Nursing home studies show high rates of self-reported constipation, despite very substantial levels of laxative prescribing. These observations suggest that nonpharmacologic treatments for constipation are underused. They should be first-line treatment in nonsevere constipation and combined with laxative treatment. A 1997 systematic review of nonpharmacologic treatment of chronic constipation in older people found no studies evaluating the effect of exercise therapy and only a few nonrandomized trials examining fiber and fluid supplementation,¹²⁴ and there has been little further robust research in this area since then. Available data, expert opinion, and practical recommendations are summarized below.

EDUCATION OF PATIENTS AND CAREGIVERS

Educating patients as to what constitutes normal bowel habit is helpful, and those with no or mild symptoms of constipation should be encouraged to discontinue laxative therapy. Patients who do require laxative treatment for constipation should be advised to aim for regular, comfortable evacuation rather than daily evacuation, which is often their preconceived norm.

Educational interventions promoting lifestyle changes should include written educational materials (ideally produced with input from users). A single nurse assessment and education session including provision of booklet in older stroke patients with constipation and FI showed that 1 year later they were still more likely to be altering their diet and fluid intake to control their bowel problem.⁸³ Table 108-8 illustrates some of the patient-centered instructions from this study booklet, which are relevant to all older people with constipation and FI.

Other RCTs have sought to influence fiber intake at a population level. Nutrition newsletters sent to older Americans in their homes significantly improved their dietary fiber intake. Another community intervention used media and social marketing in educational targeting of small retirement communities under the theme "Bread: It's a Great Way to Go," and reported a 49% decrease in laxative sales and 58% increase in sales of whole meal bread.

Educating home caregivers on maintaining fecal continence in patients with dementia (focusing on constipation and other contributors) increases knowledge levels,¹²⁵ though impact on FI is unknown. However, home caregiver involvement in bowel care plans is crucial in patients with FI, and should include awareness of caregiver needs.

DIET

Evidence for the effectiveness of fiber in treating constipation in elderly people is somewhat equivocal. In one community study, higher fiber intake was associated with lower laxative use among older women,¹²⁶ but in another study, higher intake of bran was associated with no reduction in constipation symptoms and greater fecal loading in the colon on abdominal radiography.²³ There have been several "before and after" studies in nursing home residents reporting that addition of dietary fiber (ranging from bran to processed pea hull) or fruit mixtures (apple puree to fruit porridge) to the daily diet improved bowel movement frequency and consistency, and reduced laxative intake and need for nursing intervention; despite the possibility of bias, these observational studies demonstrate the usefulness of increasing dietary fiber, fluid, and fruit in older people at high risk of constipation. In practical terms, at least 10 g of fiber with additional fluids should be recommended to patients. Although coarse bran rather than more refined fiber is more effective in increasing stool fluid weight, it is far less palatable, and is more likely to cause initial symptoms of increased bloating, flatulence, and irregular bowel movements. Fiber should therefore be recommended in the form of food, such as whole meal bread, porridge, fresh fruit (preferably unpeeled), seeded berries, kiwi,¹²⁷ raw or cooked vegetables, beans, and lentils.

FLUIDS

An RCT in adults with chronic constipation showed that the beneficial effect of increased dietary fiber was significantly enhanced by increasing fluid intake to 1.5 to 2 L daily.¹²⁸ Upping fluid intake by two 8-oz beverages a day for 5 weeks in dependent nursing home residents significantly increased bowel movement frequency and reduced laxative use.¹²⁹ This "hydration program" used a colorful beverage cart and four beverage choices to stimulate residents' interest in drinking. An RCT found that drinking carbonated versus tap

Table 108-8. Patient Education**Toilet Habits and Positioning**

Do not delay having a bowel movement when you feel the urge.
 Put aside a particular time each day (we would advise after breakfast) when you can sit on the toilet without being in a hurry.
 A relaxed attitude to bowel evacuation will especially help if you have problems with straining or a feeling of anal blockage.
 If straining is a problem, it is helpful to have a foot stool under your feet while sitting on the toilet because this increases the ability of your abdominal muscles to help evacuation of stool.

Abdominal Massage

Lie on the bed with pillows under your head and shoulders.
 Your knees should be bent up with a pillow underneath them for support.
 Cover your abdomen with a light sheet.
 Massage your abdomen with firm but gentle circular movements starting at the right side and working across to the left side.
 Continue the massage for about 10 minutes.
 This massage should be a pleasant experience; if you feel any discomfort then stop.

Diet

To help prevent constipation, you should eat more of the food from List A and less of the food from List B. Food in list A tends to make the stool softer and easier to pass because they are high in fiber. Food in list B tend to make the stool harder because they bind together the contents of the bowel.

List A: Fresh fruit, prunes and other dried fruit, whole meal bread, bran cereals and porridge, salad, cooked vegetables (with skin where possible), beans, lentils

List B: Milk, hard cheese, yogurt, white bread or crackers, refined cereals, cakes, pancakes, noodles, white rice, chocolate, creamed soups

You should increase your fiber intake gradually because sudden change in fiber content may cause temporary bloating and irregularity. It is important to eat the food that contains fiber all through the day and not just at one meal such as breakfast

Increase the amount of fluid that you drink gradually up to 8–10 glasses a day. Try to drink more water, fruit juices, and fizzy drinks.

Sphincter Strengthening

Learning to do your exercises

Sit in a comfortable position with your knees slightly apart. Now imagine that you are trying to stop yourself passing wind from the bowel. To do this you must squeeze the muscle around the back passage. Try squeezing and lifting that muscle as tightly as you can. You should be able to feel the muscle move. Your buttocks, abdomen, and legs should not move at all. You should be aware of the skin around the back passage tightening and being pulled up and away from your chair. Really try to feel this. You are now exercising you anal sphincter muscles. (You do not need to hold your breath when you tighten the muscles!)

Practicing your exercises

Tighten and pull up the anal sphincter muscles as tightly as you can. Hold tightened for at least 5 seconds, then relax for at least 10 seconds.

Repeat this exercise at least 5 times. This will work on the strength of your muscles.

Next, pull the muscles to about half of their maximum squeeze. See how long you can hold this for. Then relax for at least 10 seconds.

Repeat at least 5 times. This will work on the endurance or staying power of your muscles.

Pull up the muscles as quickly and tightly as you can and then relax and then pull up again, and see how many times you can do this before you get tired. Try for at least 5 quick pull-ups. Try this quick pull-up exercise at least 10 times each day.

Do all these exercises as hard as you can and at least 5 times a day. As the muscles get stronger, you will find that you can do more pull-ups each time without the muscle getting tired.

It takes time for exercises to make muscle stronger. You may need to exercise regularly for several months before the muscles gain their full strength.

Instructions for Using Suppositories

These may be inserted into your rectum (back passage) by your nurse or caregiver or yourself if you are physically able to do it.

If necessary go to the toilet and empty your bowels if you can.

Wash your hands.

Remove any foil or wrapping from the suppository.

Either lie on your side with your lower leg straight and your upper leg bent toward your waist or squat.

Gently but firmly insert the suppository, narrow end first, into the rectum using a finger. Push far enough (about 1 inch) so that it does not come out again.

You may find you body wanting to push out the suppository. Close your legs and keep still for a few minutes.

Try not to empty your bowels for at least 10–20 minutes.

water significantly improved constipation scores, along with benefiting functional dyspepsia and gallbladder emptying.¹³⁰ Probiotic drinks have been shown to increase defecation frequency in older people.¹³¹

PHYSICAL ACTIVITY

An RCT in middle-aged inactive patients with chronic constipation showed that daily physical activity (30-minute brisk walk and 11-minute home exercises) decreased transit time and improved constipation, according to Rome II criteria.¹³² Physical activity interventions in older adults are generally most effective if incorporated naturally into a person's day. Exercise interventions in older nursing home patients have shown disappointingly modest impact on

constipation,^{133,134} but existing evidence would support exercise programs (e.g., prompting to walk to toilet, bed exercises for chairbound¹³⁵ within context of addressing other risk factors also).

ABDOMINAL MASSAGE

There is some evidence to support abdominal massage in alleviating chronic constipation in spinal cord patients and older people.¹³⁵ A vibrating device that applied kneading force to the abdomen daily for 20 minutes in elderly constipated nursing home residents resulted in softening of stool, increased bowel movement frequency, and a 47% reduction in transit time after 3 months.¹³⁶ Patients can self-administer with training (Table 108-8).

TOILETING HABITS

Small nonrandomized studies show that regular scheduled toileting habits restore comfortable evacuation in stroke survivors¹³⁷ and in older postoperative inpatients. The preservation of the gastrocolic reflex with aging supports the rationale for postprandial toilet visits. Voluntary increase in intraabdominal pressure during defecation can compensate for rectal dysmotility to produce enough of an increase in rectal pressure for evacuation to occur, but older people are often limited by weakened abdominal musculature. Supporting the feet (on footstool or toilet block) can optimize the Valsalva maneuver.¹¹

TOILETING ACCESS—PRIVACY AND DIGNITY

A U.K. study asked frail older patients with FI about privacy during defecation.¹³⁸ Adequate privacy was reported by 23% of nursing home residents, and 50% of hospital inpatients. Lack of privacy, particularly in dependent older people in institutions, is a major care issue. Reluctance to use the toilet in institutional settings has been linked to residents developing severe fecal impaction in case reports. [Table 108-9](#) summarizes basic but important recommendations relating to toileting and maintaining privacy and dignity.

PHARMACOLOGIC TREATMENT

Many reported trials of laxative treatment in older people are low quality, limited by unclear definitions for constipation, inconsistent outcome measurement, and underreporting of potential confounding factors during the trial period (e.g., fiber intake). The absence of good level evidence may in part underlie the somewhat empirical way in which laxatives are prescribed to older people. A 1997 systematic review of effective laxative treatment in elderly persons found that the few randomized controlled trials were potentially flawed,¹²⁴ and in the decade since there has been little new research in this area. The following evidence-based conclusions are

drawn from recent meta-analytical reviews^{124,139,140} of efficacy of laxatives in treating chronic constipation in adults:

- Availability of published evidence is poor for many commonly used agents including senna, magnesium hydroxide, bisacodyl, and stool softeners
- In trials conducted in older people, significant improvements in bowel movement frequency were observed with a stimulant laxative (cascara)³ and lactulose,² while psyllium² and lactulose² were individually reported to improve stool consistency and related symptoms in placebo-controlled trials
- Level 1 evidence supports the use of PEG in adults
- Level 2 evidence supports the use of lactulose and psyllium in adults
- In trials conducted in older adults (>55 years), there is little evidence of differences in effectiveness between categories of laxatives
- A stepped approach to laxative treatment in older people is justified, starting with cheaper laxatives before proceeding to more expensive alternatives ([Table 108-11](#))

[Table 108-10](#) lists the indications, efficacy, and safety of laxatives, and [Table 108-11](#) provides guidance to pharmacologic treatment of constipation in older people based on available evidence and best practice. Ineffective patterns of prescribing, such as giving docusate to care home residents,¹⁴¹ may partly explain the reports of high constipation rates despite heavy laxative use. Another factor may be undertreatment of rectal outlet delay by enemas and suppositories.

Enemas have a role in both acute disimpaction and in preventing recurrent impactions in susceptible patients.^{142,143} They induce evacuation as a response to colonic distention and by plain lavage; the commonest reason for a poor result from an enema is inadequate administration. Frail elderly patients with recurrent episodes of overflow FI despite regular laxative and suppository use can benefit from weekly enemas. In one study of nursing home residents with overflow incontinence associated with fecal impaction on rectal examination, daily phosphate enemas continued until no further result was effective in completely resolving incontinence in 94% of patients.¹⁴³ Regular use of phosphate enemas should be avoided in patients with renal impairment because dangerous hyperphosphatemia may occur.¹⁴⁴ Tap water enemas are the safest type for regular use, although they take more nursing administration time, and are not available in certain countries. Arachis oil retention enemas are particularly useful in loosening colonic impactions. In patients who have a firm and large rectal impaction, manual evacuation should be performed before inserting enemas or suppositories, using local anesthetic gel if needed to reduce discomfort.

The predominance of rectal outlet delay (including manual evacuation) in older people, many of whom take regular laxatives, is likely to be linked to underuse of *suppositories*. Although research data is lacking, in clinical practice suppositories are useful in symptoms of prolonged straining and incomplete rectal emptying. Regular suppository administration (usually three times a week, and ideally after breakfast) may be needed. With appropriate education, many older people can themselves use suppositories (see [Table 108-8](#) for patient instructions). People with impaired dexterity can be

Table 108-9. Toilets and Toileting: Maintaining Privacy and Dignity

<p>A multidisciplinary assessment should be made of older persons ability to access and use the toilet.³</p> <p>Commodes/sani-chairs/shower chairs:</p> <p>Should be available to residents in institutional settings.³</p> <p>Should provide a safe seated position for prolonged use by older people with skin vulnerability and trunk support problems (e.g., padded seat, footstool if feet are unsupported, back and arm support, grab rails, etc.).³</p> <p>Older people should be given the opportunity to use the toilet (either directly or by using a sani-chair or shower chair) rather than a bedside commode.³</p> <p>Bedpans should be avoided for defecation purposes.</p> <p>Transportation to the toilet and use of the toilet or commode should be carried out with due regard to privacy and dignity.</p> <p>A direct method of calling for assistance should be provided when an older person is left on the toilet/commode.</p> <p>When using a commode:</p> <p>Methods to reduce noise and odor should be offered.</p> <p>Methods to facilitate bottom wiping should be available.</p> <p>If in living area and cannot be emptied immediately, a chemical toilet should be offered instead.³</p>

Table 108-10. Summary of Laxatives

Type and Agent	Indication, Action, Administration, Side Effects
Stimulant Senna (alternate is bisacodyl)	Cheap, safe and effective for use in chronic constipation (ref) Improves propulsive action (direct stimulation of myenteric plexus) and softens stool (Prostaglandin E-like effect) Onset 8–12 hr. Give at bedtime Long-term use associated with melanosis coli (mucosal pigmentation with no clinical significance) does not cause “cathartic colon”
Bulk Psyllium Ispaghula husk Methyl cellulose Calcium polycarbophil	First-line laxative in ambulant older people with mild-moderate constipation, safe long-term, underprescribed in older people First-line in diverticular disease (limits flare-ups of diverticulitis), facilitates painful defecation with hemorrhoids, reduces abdominal pain in IBS Reduces incontinent episodes in FI associated with loose stool Psyllium lowers cholesterol (binds bile acids in intestine) Hydrophilic fibers resistant to bacterial degradation, leads to bulkier and softer stool and peristaltic stimulation Onset 12–72 hr May initially cause bloating and unpredictable bowel habit, increased risk of impaction with poor fluid intake Unsuitable for treatment of chronic constipation Rapid onset, so commonly prescribed to older hospital inpatients Stimulates release of cholecystokinin, increases secretion of electrolytes and water into gut lumen May cause watery stool, dehydration, FI, hypermagnesemia in renal insufficiency
Magnesium hydroxide (Milk of Magnesia)	Second-line laxative for chronic constipation, relatively expensive Nonabsorbable disaccharide degraded into low molecular weight acids, which osmotically draws water into the colon causing reflex prolonged tonic gut contractions. Shortens transit time, and softens stool Onset 24–48 hr May cause abdominal cramps and flatulence especially with fruit diet
Hyperosmolar Lactulose	Useful for acute disimpaction (effective in care home residents and hospitalized patients)(refs) and rapid clear out for bowel preparation Reduces recurrence of acute pseudo-obstruction if administered after initial resolution of colonic dilation Long-term use only in patients with neuropathic bowel or resistant constipation Potent hyperosmotic action, shortens transit time Onset 30–60 min, low starting dose and titrate against effect May cause nausea, abdominal cramps, FI and loose stool
Hyperosmolar Polyethylene glycol (PEG) “Movicol”, GoLYTELY	Ineffective in treating constipation though commonly prescribed Reduces surface tension and promotes penetration of water into stool No effect on colonic motility or bowel movement frequency Increases risk of FI in care home residents Can cause perianal dermatitis in incontinent patients
Stool softener Docusate	No specific research in older people, so not recommended for routine use Altered serotonin (5-HT) signaling may predispose to chronic constipation. 5-HT4 agonists (e.g., Tegaserod) stimulate gastrointestinal motility and increase stool water content. Efficacy and safety of Tegaserod in treating chronic constipation shown in RCT where 13% of participants were aged 65 and over, but no subgroup analysis. Tegaserod improves symptoms of constipation in IBS. Side effects includes headaches and diarrhea, postmarketing reports of ischemic colitis.
Enterokinetic agents 5-HT4 agonists (e.g., Tegaserod)	

helped with suppository inserters designed for spinal cord injured patients. Glycerin, a hyperosmolar laxative used solely in suppository form, should be used first-line. If ineffective, bisacodyl suppositories in PEG base (effective in spinal cord injured patients)¹⁴⁵ should be substituted. Suppository onset of action varies by individual from 5 to 45 minutes (most likely influenced by the neurogenicity of the rectum), and so patients should be advised to set a quiet time aside for effective evacuation.

TREATMENT OF FECAL INCONTINENCE IN OLDER ADULTS

The algorithm summarizes the clinical evaluation and management of FI in this population emphasizing the structured comprehensive clinical approach, which can be undertaken by doctor or nurse specialist.¹¹ Table 108-12 provides a summary.

Multicomponent treatment of FI in frail older people

Although a multidimensional approach to FI treatment would clearly be indicated in view of the multifactorial causation in older people, there are few published studies

of multicomponent interventions. An RCT in elderly stroke survivors with constipation and/or FI evaluated a one-off assessment according to the algorithm in Figure 108-3, leading to patient/caregiver education, and treatment recommendations to routine health care provider⁸³ showed benefit at 6 months in percent of “normal” defecations. A nursing home RCT found that a structured daily exercise program, combined with increased fluid intake and regular toiletting opportunities, significantly improved FI and increased appropriate toilet use.¹⁴⁶ These types of evaluations do not identify any specific action to have a particular benefit, but do test a multicomponent approach that nonspecialist doctors and nurses could feasibly apply in various settings.

Lifestyle and diet

A U.S. study of self-care practices among home-dwelling older people with FI found that most commonly used strategies for managing FI were dietary change, wearing pads, and limiting activity.¹⁴⁷ Women, more so than men, altered their diet and missed meals to prevent FI. Reducing intake of fiber foods (whole grain bread, fruits, etc.) can limit FI in some people. Likewise, some individuals may benefit from limiting dairy products and sorbitol sweeteners. In the context of FI

Table 108-11. Pharmacologic Treatment of Constipation in Older People - Guidance**Chronic Constipation**

In ambulant older people

Bulk laxative (psyllium) 1–3 times daily with fluids as required

If symptoms persist add senna 1–3 tablets at bedtime

In individuals with questionable fluid intake or those intolerant of bulk laxatives, start with senna 1–2 tablets at bedtime

If symptoms persist, add sorbitol or lactulose 15 mL daily as needed, titrating the dose to achieve regular (≥ 3 times a week) and comfortable evacuation

In high risk patients

- Bedridden individuals
- Patients with neurologic disease
- Patients with history of fecal impaction

Senna 2–3 tablets at bedtime and sorbitol or lactulose 30 mL daily, titrating upwards as needed

If symptoms persist, give PEG ($\frac{1}{2}$ –2 sachets of Movicol daily)

Colonic Fecal Impaction

Clinical or radiologic obstruction

Daily retention enemas (e.g. arachis oil) until obstruction resolves, before starting oral laxatives

Colonic disimpaction

Daily enemas (preferably tap water) until no further washout result

PEG ($\frac{1}{2}$ –2 L daily or 2–3 sachets of Movicol) with fluids

Ensure that patient has easy access to toilet to avoid fecal incontinence

When impaction resolves, give laxative regimen for chronic constipation in high-risk patients long-term to avoid recurrence

Rectal Outlet Delay

Rectal disimpaction

Manual disimpaction where necessary, followed by phosphate enema(s) for initial complete clearance of rectal impaction

Regular treatment

Glycerin suppositories at least once a week and as required to relieve symptoms

For persistent symptoms, use bisacodyl suppositories instead of glycerin suppositories

In patients at high risk of rectal impaction (rectal dysmotility, neurologic disease) give regular enemas (usually once weekly) and daily suppositories

If stool is hard or infrequent, add daily laxative as for chronic constipation

associated specifically with loose stool, an RCT of dietary fiber supplementation (psyllium or gum agar) significantly reduced incontinent episodes.¹⁴⁸ Caffeine reduction can also help—black coffee increased rectosigmoid motility within 4 minutes of ingestion in young healthy volunteers (a reaction not observed with ingestion of hot water), implying that caffeine triggers the gastrocolic reflex.¹⁴⁹ Caffeine has also been shown to stimulate defecation urgency in some patients with FI.¹¹

TREATMENT OF OVERFLOW FI IN OLDER PEOPLE

An effective therapeutic program for overflow incontinence depends on:

- Regular toileting (ideally 2 hourly, which also promotes mobility)
- Monitoring of treatment effect by rectal examination and bowel chart
- Responsive stepwise drug and dosage changes
- Prolonged treatment (at least 2 weeks)
- Subsequent maintenance regimen to prevent recurrences

There are only two trials evaluating treatment of overflow FI, both involving frail elderly care home residents.

Table 108-12. Treatment of FI in Older People: Evidence-Based Summary and Recommendations**Overflow FI**

- Stimulant laxatives, osmolar laxatives (PEG and lactulose), suppositories and enemas can be effective in treating fecal impaction in older people at risk of overflow²
- Complete rectal clearance is required to reduce overflow FI² but may be hard to achieve in frail older patients.² Weekly digital rectal examination and prolonged treatment is helpful in increasing effectiveness of a bowel clearance program.²

Frail Older People and Dementia-related FI

- Structured approaches to bowel care can reduce the frequency of FI in the nursing home setting.²
- Prompted toileting can be effective in reducing FI in patients with dementia within a structured bowel care plan.²
- Multicomponent structured nurse-led assessment and intervention can improve bowel symptoms and alter bowel-related habits in older stroke patients.²

FI Associated With Loose Stool

- Treatable causes of loose stool (e.g., infection) must first be identified.
- Dietary fiber supplementation can reduce episodes of FI associated with loose stool.¹
- Caffeine reduction can reduce FI and urgency.³
- Some patients with FI benefit from limiting dietary dairy products, fiber (e.g., unpeeled fruit, vegetable, whole meal, etc.), sorbitol, and alcohol.
- Loperamide can reduce frequency of FI, particularly when associated with loose stool.²

FI Associated With Weak Anal Sphincters

- Older people with FI associated with weak sphincters and preserved sensation can benefit from sphincter strengthening exercises³ and biofeedback.²

Lifestyle and Education

- Self-care practices are prevalent in older people with FI.² Women are more likely to alter their diet than men.
- Patient and caregiver education (using verbal and written materials) should be undertaken to promote self-efficacy and other coping mechanisms, and where appropriate self-management (e.g., reducing risk of constipation and impaction through dietary and lifestyle measures, advice on how to take loperamide). Advice on skin care, odor control, and continence aids is also important.

Privacy and Dignity

- Dependent older people with FI in care homes and hospitals often lack privacy during defecation.³
- Privacy and dignity of care during defecation should be afforded to all older people in institutionalized settings. Particular attention should be paid to this in patients with FI because privacy may be relatively overlooked in their care.

One U.K. trial evaluated an intervention based on treatment recommendations to general practitioners.¹⁴³ Patients with rectal impaction and continuous fecal soiling were classed as having overflow and the recommended treatment was giving enemas until no further response, followed by lactulose. Complete resolution of incontinence was achieved in 94% of those who were fully treated, but GP and care home staff compliance with the recommended treatment was obtained in only 67% of patients. A French study found that treatment of constipation was only effective in improving overflow FI (incontinence at least once weekly associated with impaired rectal emptying) when long-lasting and complete rectal emptying (monitored by weekly rectal examinations) was achieved using daily lactulose plus daily suppositories, plus weekly tap water enemas.¹⁴² The number of FI episodes was reduced by 35% and staff workload (based on soiled laundry

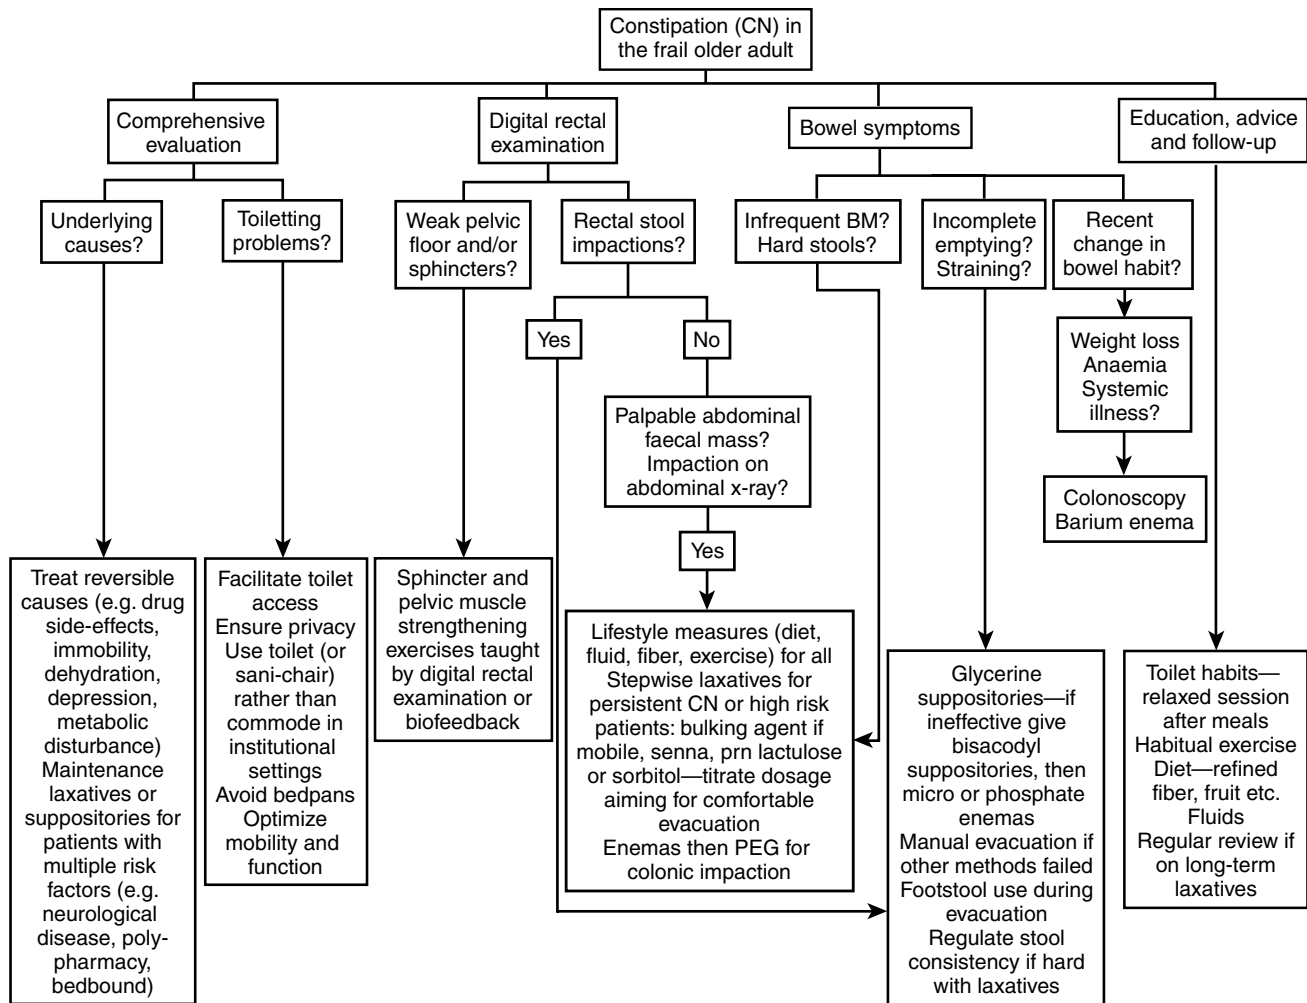

Figure 108-3. An algorithmic approach to assessment and treatment of constipation in older people.

counts) fell by 42% in those with complete rectal emptying; complete clearance was, however, only achieved in 40% of study subjects. These trials demonstrate the challenges of treating overflow FI in care homes where it is highly prevalent, both in terms of delivering the right care, and of needing to persevere with treatment to achieve good clear out and restoration of continence. They also emphasize the need for combined laxative and enema or suppositories, and for treatment persistence (lasting weeks rather than days) to achieve effective bowel clearance.

TREATMENT OF LOOSE STOOL

Treatable conditions affecting older people are:

- * Excessive laxative use - Stool softeners in particular have been linked to FI in frail older people.³⁵
- * Drug side effects (e.g., proton-pump inhibitors [also increase risk of *Clostridium difficile*]¹⁵⁰ selective serotonin reuptake inhibitors, magnesium-containing antacids, cholinesterase inhibitors)
- * Lactose intolerance - Lactose malabsorption affects 50% of healthy women aged 60 and over compared with 15% in women aged 40 to 59 years.¹⁵¹ Only certain individuals will develop a clinical intolerance to dairy products.

- * Antibiotic-related diarrhea - Among hospitalized patients, age, female gender, and nursing home residency significantly increases the risk for antibiotic-related *C. difficile* diarrhea.¹⁵² The diarrhea also takes longer to resolve following treatment of *C. difficile* in more frail older patients.¹⁵² Preliminary RCT data support the use of probiotic drinks in preventing *C. difficile* in older hospitalized patients on antibiotics.¹⁵³ Infective causes of loose stool should always be ruled out before settling on a chronic FI management plan (e.g., with loperamide or fiber).
- * Diabetes - Treatment with erythromycin and metoclopramide is indicated where slow-transit with bacterial overgrowth is diagnosed. Acarbose may also be beneficial.⁷²
- * Crohn's disease - This condition has a second incidence peak in the sixth decade and beyond.

TREATMENT OF DEMENTIA-RELATED FECAL INCONTINENCE

It is important to look for all other causes of FI (e.g., constipation, drugs, reduced function) in patients with cognitive impairment because only those with severe cortical deficit will have FI-related primarily to dementia. Prompted

Table 108-13. What We Don't Know - Research Ideas**Constipation – Areas for Further Research**

- What are the different characteristics between constipation sufferers who seek help and those who do not? (Case-control study)
- What drives constipation sufferers to seek help? (Qualitative research)
- How can standardized "constipation protocols" for case-finding and risk assessment be implemented across community and institutional health care setting where frail older patients are cared for? (Action Research, Quality Improvement Study)
- Why is the prevalence of constipation in nursing homes so high despite heavy laxative use? Is it:
- ineffective laxative prescribing?
 - substandard assessment of patients?
 - underuse of nonpharmacologic treatments? (Observational)
- What is the impact of nonpharmacologic interventions targeting constipation risk factors on bowel and health-related outcomes in frail older people? (RCT)
- What are the barriers to older people adopting bowel-related lifestyle measures? (Qualitative research)
- What are the psychosocial and quality of life effects of chronic constipation on older individuals and caregivers? (Questionnaire population studies, qualitative research)
- What is the effectiveness of enemas and suppositories in treating constipation and rectal outlet delay in older people? (RCT)
- Is biofeedback an effective treatment for pelvic dyssynergia in older people with rectal outlet delay? (RCT)
- How common is manual self-evacuation in older people, and does prolonged use affect anal sphincter function? (Questionnaire survey, anorectal function study)
- What is the cost-effectiveness of a stepwise approach to laxative treatment in older people with constipation in different health care settings (community, hospital, long-term care) (RCT)
- How effective and safe are new enterokinetic agents (serotonin agonists) in treatment of chronic constipation in older people, including frail individuals? (RCT)

FI – Areas for Further Research

- Trials of laxative and nonpharmacologic treatment and prevention of fecal impaction and overflow are needed to optimize standards of prescribing and care
- Multicomponent interventions to treat FI in frail older people should be evaluated as applied research to assess effective ways of delivering this type of intervention within routine health care settings
- There are challenges to undertaking RCT's in this area in frail older people. In particular, it is important to balance feasibility and practicality versus high strength intervention (i.e., a team of specialist continence nurses in nursing homes are likely to have an impact, but at what cost, and what carry-over will there be when they are gone). Methodologies other than RCTs (e.g., prepost with multivariate case-mix adjustment) should also be considered.
- Evaluation of case-finding methods for FI in different settings including the fundamentals of staff education, screening protocols, patient educational information
- Testing the feasibility of providing an integrative pathway approach to assessment of FI in the frail older person, including a range of health and social care providers and different health care settings (acute, intermediate, long-term care, community)
- Examination of the variability of FI rates between nursing homes within single nation states, (taking into consideration case-mix) to highlight problems areas both organizationally and clinically. Nursing home administrative factors such as resident:nurse staff ratios should be evaluated as a contributing factor to FI.
- Further epidemiologic studies are required to document causes of FI in frail older people in different health care settings. Such studies should include evaluation of the unmet need for patients and caregivers.
- Evaluation of etiologies, and in particular the pathophysiologic basis for high prevalence of FI in older men.
- Evaluation of potentially preventable causes of loose stools in institutionalized older people, and impact of their treatment on FI.
- Examine the research question, "Do educational interventions by health care providers to informal caregivers of home-dwelling older people with FI reduce caregiver burden and improve quality of life for patient and caregiver?"

toileting (by reminder or by accompaniment depending on cognition) is the mainstay approach in these patients and has been evaluated in two care home resident RCTs. One significantly increased the number of continent bowel movements but had no impact on FI frequency,¹⁵⁴ whereas the other significantly reduced the frequency of FI and increased the rate of appropriate toilet use, but interestingly did not impact the primary outcome measure of pressure ulcers.¹⁴⁶ Prompted toileting is also an appropriate intervention in hospital and at home, though it has not been evaluated in those settings. Pharmacologic control of disinhibited bowels in patients with dementia was demonstrated in a small care home study using daily codeine phosphate and twice weekly enemas; continence was achieved in 75% of those treated.¹⁴³ This approach can be effective in practice, but requires careful bowel planning and monitoring to prevent impaction.

TREATMENT OF ANORECTAL FI IN OLDER ADULTS

Older patients with a FI pattern suggestive of anorectal incontinence (small amounts of leakage, weak anal sphincters) should be taught sphincter strengthening exercises

(Table 108-8). These are similar to pelvic floor exercises, a treatment shown to be effective in older women with urinary incontinence.¹⁵⁵ It is helpful to teach the exercises while placing the examining hand resting on the posterior vaginal wall, so that verbal feedback can be given as the patient contracts the pelvic floor; an RCT in older women with urge urinary incontinence showed that this teaching method was just as effective as formal biofeedback.¹⁵⁵ Similar verbal feedback can be given to men during digital examination of the anal sphincter. There is no evidence to suggest that frail older people without severe cognitive problems are any less able to adhere to such programs. Combined with the exercises should be advice to reduce caffeine intake and to increase fiber (psyllium can be prescribed). If FI persists after several months of this approach, biofeedback treatment should be considered. There is limited data on biofeedback in older people, but in one small study of older patients with no cognitive impairment, good motivation, and intact anorectal sensation, there was a 75% reduction in incontinent episodes short term.¹⁵⁶ There is no evidence to suggest that older patients selected by these criteria will not benefit.

KEY POINTS

Constipation and Fecal Incontinence in Old Age

- Constipation is a common problem as people age; the definition of constipation includes both quantitative (2 or fewer bowel movements per week; >10 minutes to complete bowel movements) and qualitative (straining, hard stools) components.
- Fecal incontinence is common among elderly people who are frail, but can be missed if not inquired about routinely. Such inquiry properly forms part of a comprehensive geriatric assessment.
- A wide range of problems can give rise to fecal incontinence in older adults, including problems in cognition, mobility, gastrointestinal motility, and anorectal dysfunction. A systematic approach is therefore essential.
- Common precipitants of constipation include low fluid volume intake, neurologic disorders, anticholinergic medications, iron supplementation, and dysautonomia.
- Fecal impaction can result in overflow diarrhea, so that the presenting complaint can be entirely at odds with the diagnosis. Note, too, that stool impaction on digital rectal examination does not have to be hard.
- In treating constipation, there is evidence for a variety of nonpharmacologic maneuvers, including increased fluid intake, dietary fiber, physical exercise, and abdominal massage although more research is needed, especially in relation to elderly people who are frail.
- A stepped approach to laxative treatment in older people is justified, starting with cheaper laxatives before proceeding to more expensive alternatives.
- Treatment of fecal incontinence starts with understanding the type (overflow, diarrheal, anorectal, functional, neurogenic)
- Many frail older adults will have more than one cause of fecal incontinence, and while a multidimensional approach would be indicated, there are few published studies of multicomponent interventions.

LOPERAMIDE

The most extensively tested drug treatment for FI associated with loose stools is loperamide. In one adult study loperamide significantly reduced FI, with no additional benefit when combined with fiber supplementation.¹⁵⁷ A small placebo-drug crossover trial in older adults showed that loperamide significantly reduced visual analogue scores for incontinence and urgency, prolonged colonic transit, and increased basal tone.¹⁵⁸ It is appropriate to start at low doses in older people (1 mg available in liquid form), with monitoring for impaction, and instruction on titration. Self-titration of loperamide can greatly restore confidence in older people whose social activities have been restricted because of FI.

FURTHER RESEARCH

Table 108-13 lists what we do not know about constipation and FI in older people, and ideas for further research. The overall aim in both clinical practice and research should be to develop common evidence-based policies, procedures, guidelines, and targets to promote integrated bowel care for older people within all health care settings.

For a complete list of references, please visit online only at www.expertconsult.com

Urinary incontinence is one of the giants of geriatric medicine. Despite this lofty status, however, it remains along with management of other associated lower urinary tract symptoms an entity largely neglected by geriatricians. Nevertheless, research-based evidence for the management of incontinence, even in the most frail elderly exists. Incontinence should not be a Cinderella subject, relegated to the realms of palliative nursing and should be approached seriously.

In the United Kingdom the prevalence of urinary incontinence increases in association with increasing age such that at age 60 moderate or more severe incontinence affects 22.3% of women and 10.2% of men and at age 80 and above, 33.4% of women and 23.5% of men are affected.¹ A recent survey has supported these observations and noted the increasing prevalence of lower urinary tract symptoms with advancing age.² The increased prevalence of incontinence in late life reflects a combination of physiologic change, an increased incidence of lower urinary tract disease, and the influence of associated morbidity in older people. It is both a marker of dependency of poorer health-related outcomes and also leads to an increased likelihood of institutionalization.³ Incontinence also has a measureable negative impact on quality of life, although this appears not to be of the magnitude of that expressed by younger adults despite having a more severe extent of disease.⁴ This may be because the coping mechanisms that people adopt become habituated, lessening the perceived impact. Older cohorts are generally more accepting of these or may expect conditions that they may associate with aging to afflict them and simply cope.

ANATOMY AND PHYSIOLOGY

The smooth muscle fibers of the detrusor muscle of the bladder appear to be randomly arranged over the dome of the bladder but funnel at the bladder neck to be continued into the urethra as longitudinal fibers forming a tube. In the male these fibers are inserted into the verumontanum, but in the female they terminate in the distal urethra. Contraction of the detrusor results in a rise in bladder pressure associated with shortening of the urethra. Contraction of the muscle of the trigone, the triangular baseplate with its apex at the bladder neck, and base running between both ureters results in funneling of the bladder neck. There are some fibers that are inserted into the external surface of the trigone distally. These pull the distal margins of the trigone apart, thus opening the bladder neck.

In normal circumstances the detrusor is highly compliant. This means that it is normal for a bladder to be filled to 500 mL and more, without an increase in intravesical pressure, other than the pressure head resulting from the volume of the fluid in the bladder, which would be approximately 8 cm H₂O at 500 mL. If the wall tension in the detrusor increases in association with filling, but then fails to relax (stress relaxation), the bladder is said to "lack compliance." "Low compliance" may result from fibrosis, detrusor hypertrophy, or an increased resting tone secondary to reduced neural inhibition.⁵

Control of the bladder and urethra depends upon a complex supraspinal neuronal network, which allows voluntary postponement of voiding and the ability to empty the bladder at a socially convenient time, even if there is little need to void. Animal studies and clinical observation have suggested that the main levels of control over the lower urinary tract are cortical (inhibitory), hypothalamic (excitatory), midbrain (inhibitory), and pontine (excitatory). With the advent of modern functional brain imaging, the sites of these control systems have been further identified. In adults, the normal mechanism for activating contraction of the detrusor is the release of acetylcholine from parasympathetic nerves, stimulated by a spino bulbospinal micturition reflex,⁶ the main micturition reflex. Tension receptors in the detrusor activate afferents traveling in the pelvic nerves. These afferents pass through the lumbosacral dorsal roots to ascending tracts where they synapse in the midbrain periaqueductal gray (PAG). Their signaling intensity increases as the bladder fills and fibers from the PAG descend to the pontine micturition center (PMC), causing excitation. If left unmodulated, fibers from the PMC excitation causes activation of the descending motor efferents, which cause coordinated detrusor contraction and urethral relaxation.⁷ However, afferent signals from the bladder do not automatically trigger the micturition reflex, but are relayed via the forebrain where a voluntary decision to empty the bladder can be made.⁸

Although much of the functional neuroanatomy of the lower urinary tract has been explored by animal experiments, the advent of functional imaging, (positron emission tomography, functional magnetic resonance imaging, single photon emission computed tomography) has allowed some impressive studies on humans, these methods map regional cerebral metabolism or blood flow and this is assumed to reflect neuronal activity. Many areas of the brain become active as the bladder is filled and studies have shown that humans and cats have remarkably similar arrangements. They show that micturition is associated with activity in the hypothalamus, periaqueductal gray matter, the right prefrontal cortex, anterior cingulate gyrus, and the dorsomedial pontine tegmentum.⁹

Since higher cerebral centers tend to inhibit the pontine micturition center, lesions above this area associated with detrusor overactivity of neurogenic origin. Frontal lobe lesions are associated with frequency, urgency, and urgency incontinence with a loss of warning of impending micturition. Strokes are often associated with detrusor overactivity, excepting those which primarily affect the occipital lobes. Any spinal cord injury that disrupts the normal connection between the sacral spinal cord and the supraspinal pathways controlling micturition will cause bladder dysfunction. Lesions of the spinal cord below the pons, but rostral to the sacral nuclei, result in bladder areflexia initially, lasting days to weeks before detrusor overactivity develops. However, if a spinal lesion involves complete destruction of the sacral nuclei, bladder areflexia will be permanent.^{10,11}

The internal urethral sphincter is present only in the male, forming a circular collar continuous with the smooth muscle

of the prostate. This sphincter is not part of the continence mechanism but contracts during ejaculation to prevent the retrograde flow of semen into the bladder. Failure of this sphincter leads to infertility, dry ejaculation, and seminuria. The internal sphincter is cut during transurethral resection of the prostate; however, continence is maintained.¹²

The external urethral sphincter is the principal mechanism for maintaining urethral continence in both sexes, although the smooth muscle and epithelium of the urethra is also important, particularly in women.⁵ The urethra consists of an internal layer of longitudinal smooth muscle and an outer thinner layer of circular smooth muscle controlled by the action of adrenergic and cholinergic receptors and under modulation of NO and CO. Sympathetic control predominates, mediated by α_{1A} α -adrenoceptors.^{13–16}

The striated muscles of the pelvic floor and the external sphincter are supplied by somatic efferents originating in the anterior horns of the sacral cord segments S2–S4. The motor neurons are grouped in a specific region called the Onuf's nucleus. This nucleus differs from other somatic motor nuclei, with histochemical appearances similar to sacral parasympathetic nuclei along with evidence of adrenergic innervation. The axons, originating from the Onuf's nucleus pass to the periphery through the pudendal nerve and the pelvic nerves. External sphincter activity is supported by the adrenergic smooth muscle of the urethra.

The sympathetic innervation for the lower urinary tract comes from postganglionic nerves traveling in the hypogastric plexus, the pelvic nerves, and the pudendal nerves. This sympathetic innervation inhibits the detrusor, providing an active component to relaxation and also stimulates the urethral smooth muscle and the sphincters. The inhibitory noradrenergic receptors on detrusor cells are β_3 subtype.^{17–20} Motor activation of the detrusor in healthy humans is achieved by the stimulation of muscarinic receptors by acetylcholine; this activates second messengers causing release of Ca^{2+} ions from intracellular stores in the sarcoplasmic reticulum and an inward flow of Ca^{2+} ions through L-type Ca^{2+} channels. The rise in intracellular Ca^{2+} ion concentration activates actin and myosin, thereby promoting contraction. The detrusor cell can depolarize with an inward current consisting of Ca^{2+} ions passing through L-type channels in sufficient magnitude to support depolarization, but the normal physiologic role of the L-type Ca^{2+} channel appears to be regulation of the filling of intracellular stores during the resting state. Cholinergic activation occurs independently of depolarization; its limited influence may explain the lack of efficacy of calcium channel blockers in the treatment of detrusor overactivity.^{21–23} Ligand studies of the M_2 and M_3 muscarinic receptors in the bladder have shown that the greater proportion (85%) are M_2 receptors with only 15% being M_3 . All of the contractile activity appears to be attributed to the M_3 receptor in healthy humans. However, the M_2 receptor is of increasing interest as its role in the appreciation and modulation of sensory inputs in both the detrusor and the urothelium have become apparent.^{24,25}

It has been found that some muscarinic antagonists prove selective for the bladder, but this tissue specificity does not appear to be associated with either M_2 selectivity or lack of M_3 selectivity.^{26–28}

It is now known that acetylcholine and noradrenaline are not the only significant neurotransmitters in the lower

urinary tract. Nonadrenergic noncholinergic (NANC) neurotransmitters are neuropeptides that modulate the actions of the classical transmitters and may act as transmitters themselves. Neuropeptide-Y (NPY) and vasoactive intestinal polypeptides (VIP) are important neuromodulators, which are released at neuromuscular junctions so as to influence the release and uptake of acetylcholine and noradrenaline. Adenosine triphosphate (ATP) is thought to be an important neurotransmitter, coreleased with acetylcholine and it is known to cause depolarization of the detrusor. Although in the normal human bladder ATP is not important, there is evidence that in diseased states the activating mechanisms of the detrusor change and that NANC transmitters exert a much greater influence on the bladder, the ATP being broken down less effectively in the overactive detrusor.^{29–31} More recently, an appreciation of the role of the sensory afferents in the detrusor and the role of the urothelium as an active, rather than a passive component of detrusor function has led to a greater understanding of the generation of detrusor overactivity, but not yet to therapeutic manipulation. Of resurgent interest is the concept of spontaneous detrusor activity and the role of the interstitial cell in the regulation of this.³² These cells lie in the suburothelial space or within the detrusor and, indeed, throughout the lower urinary tract, and it has variously been postulated that these cells act as pacemaker cells, analogous to the interstitial cells of Cajal in the gastrointestinal tract.³³

PRESENTATION

There is an outdated quote, often used, which states that the bladder is an unreliable witness and that the symptoms that a patient describes do not point to the true pathology.³⁴ This belief has arisen from the dubious assumption that patients can be fitted into clearly separate diagnostic categories where a set of unique symptoms leads to distinct diagnoses. Given that there is likely to be a spectrum of disease, reflecting the variability inherent in any biologic system, diagnostic categories most likely form intersecting continua that share some symptoms. Such faith in diagnostic absolutes is dangerous because it leads to dismissal of the significance of symptoms, which are the patients' experience of disease. The great majority of symptoms can be explained by the physiologic and mechanical principles that govern the lower urinary tract, and what the patients say usually makes sense. Experimental data have supported this thesis,³⁶ but there is a continual search for classification, discrimination, and scoring of disease variables that largely leads to no gain in terms of understanding of disease or advances in treatment.

Frequency, urgency, urgency incontinence, nocturia, and enuresis are symptoms associated with detrusor overactivity (DO) and have been observed to be associated with the involuntary detrusor contractions of DO,³⁷ and to reduce with documented resolution of the overactivity.^{38,39}

Frequency and urgency may be more noticeable when out and about, when putting the key in the door on returning home, in cold weather, in anxiety-provoking situations, and to be subject to diurnal and seasonal variation. Intercurrent illness, particularly urinary infection, will exacerbate the symptoms. The subjective experience that is urinary urgency also varies between individuals, and probably, within the same individual. Some describe the idea of a

growing potential for loss of bladder control, whereas others tell of a wholly physical sense of near incontinence. Clinically, the symptom complex is called the overactive bladder, or frequency-urgency syndrome, and it is defined as urinary urgency, with or without urgency incontinence, usually with frequency and nocturia in the absence of other lower urinary tract pathology that might lead to similar symptoms (such as bladder stones, tumor, or infection).⁴⁰

Stress urinary incontinence is associated with coughing, sneezing, or other physical exertion. The term “genuine stress incontinence” is no longer used to describe stress incontinence caused by an incompetent urethral sphincter. The symptom of stress incontinence, which often coexists with varying degrees of overactivity, particularly in older people, is clearly associated with reduced sphincter function.^{41,42} Where overactivity coexists, treatment of this may result in resolution of both urgency and stress-induced incontinence. This should be expected if the two pathologies work synergistically. Response to treatment of one pathology does not exclude the presence of the other.⁴³ On current evidence, if a woman describes stress incontinence, then there is a 78% probability that sphincter dysfunction exists. Although there is a reduction in the maximum closing pressure that can be generated in the urethra in association with increasing age, this closing pressure must exceed the pressure of urine at the bladder neck for continence to be maintained. As the bladder fills, a pressure will develop equal to the hydrostatic pressure of urine in the bladder plus the weight of any viscera pressing on it. If the maximum urethral closure pressure is reduced below this, then the woman will develop a sense of pending incontinence as the hydrostatic pressure rises; positional changes may exacerbate this. The woman will thus be forced to maintain a bladder capacity below the threshold. Frequency, urgency, and urge incontinence may all therefore be induced by an incompetent urethral sphincter. Additionally, rising during or at the end of the night with a full bladder, and suddenly applying an increased hydrostatic pressure to the faulty sphincter, will lead to very severe urgency and precipitancy.

Hesitancy, a reduced stream, intermittency of stream, straining to void, manual abdominal compression during voiding, terminal dribbling, postmicturition dribbling, and incomplete emptying are recognized symptoms of a voiding problem, be it obstructive or due to a failure of detrusor emptying function. Their presence correctly points to a requirement to check voiding efficiency. However, the physiology of micturition indicates that a high frequency will lead to similar symptoms. The bladder empties more efficiently from a higher capacity, but voiding efficiency is compromised by overdistention.^{44,45} Elongation of the detrusor fibers in response to filling promotes optimum contact between the actin and myosin so that a better contraction can be obtained.⁴⁶ Flow rates are well known to be related to the voiding bladder volume. People with frequency and low-volume voids therefore commonly describe symptoms of poor voiding in the absence of either detrusor underactivity or obstruction.

Dysuria is the experience of pain in association with micturition. The classical symptom of a burning in the urethra during voiding, caused by infection, is well known. Less appreciated is the external dysuria experienced by women with vaginitis when urine passes over the labia.⁴⁷

Table 109-1. Factors Associated with and Consequent upon Urinary Incontinence on Older People

Incontinence can be Associated with the Following:

- Falls
- Depression
- Pressure ulcers
- Bowel problems
- Skin infection
- Isolation
- Impaired quality of life
- Increased likelihood of institutional care

Incontinence is also a Consequence of the Following:

- Lower urinary tract disease
- Musculoskeletal disease
- arthritis/contractures
- Peripheral vascular disease
- Stroke
- Parkinson's disease
- The dementias
- Diabetes mellitus
- Venous insufficiency
- Chronic lung disease
- Congestive heart failure
- Neurologic disorders, for example: multiple sclerosis, spinal cord injury, and motor neuron disease

There are a number of conditions, labeled by the International Continence Society as painful bladder syndromes, which are beyond the scope of this chapter, that are poorly defined and require specialist management.

There are a variety of factors, unrelated to bladder physiology, relevant to older people that should be explored at the time of presentation. These commonly interact with a greater propensity for incontinence so as to cause it, such that correction will lead to continence. Conditions related to incontinence are listed in [Table 109-1](#).

The importance of a medication review and alteration in the management of urinary incontinence in the elderly should not be underestimated. [Table 109-2](#) lists the medications that may either precipitate or contribute to incontinence. Data from the National Audit of Continence Care for Older People suggest that, at best, this is only done for 33% of older people in primary care⁴⁸ but there is undoubted value in this.

MULTICHANNEL CYSTOMETRY

Multichannel cystometry “urodynamics” has been the principal method used to explore the physiologic changes in the lower urinary tract particularly seen in elderly people, but is also used, sometimes erroneously, as a diagnostic tool. A urodynamic study is not necessary for the initial conservative management of anyone presenting with urinary incontinence, be they young or old, and age should not influence the decision to use the investigation. However, an understanding of the test is certainly worthwhile.

The study describes a number of aspects of lower urinary tract function extremely accurately; for example, a urodynamic study measures urinary outflow obstruction precisely.⁴⁹

However, the majority of urologists operate on the basis of symptoms rather than the physical demonstration of obstruction and do not routinely perform cystometry.⁵⁰ Because similar symptoms are found in roughly as many urodynamically obstructed and unobstructed men, it is inevitable that the

Table 109-2. Medications That May Either Precipitate or Contribute to Incontinence

Medications	Effects on Continence
α -adrenergic agonists	Increase smooth muscle tone in urethra and prostatic capsule and may precipitate obstruction, urinary retention, and related symptoms
α -adrenergic antagonists	Decrease smooth muscle tone in the urethra and may precipitate stress urinary incontinence in women
Angiotensin-converting enzyme (ACE) inhibitors Agents with antimuscarinic properties	Cause cough that can exacerbate incontinence May cause urinary retention and constipation that can contribute to incontinence; may cause cognitive impairment and reduce effective toileting ability
Calcium channel blockers	May cause urinary retention and constipation that can contribute to incontinence May cause dependent edema, which can contribute to nocturnal polyuria
Cholinesterase inhibitors (cognitive enhancers)	Increase bladder contractility and may precipitate urgency incontinence
Diuretics	Cause diuresis and precipitate incontinence
Lithium	Polyuria due to diabetes insipidus-like state
Opioid analgesics	May cause urinary retention, constipation, confusion, and immobility—all of which can contribute to incontinence
Psychotropic drugs	May cause confusion and impaired mobility and precipitate incontinence
Sedatives	Some agents have anticholinergic effects
Hypnotics	
Antipsychotics	
Histamine ₁ receptor antagonists	
Selective serotonin re-uptake inhibitors	Increase cholinergic transmission and may lead to urgency urinary incontinence
Other drugs	Can cause edema, which can lead to polyuria while supine and exacerbate nocturia and nighttime incontinence
Gabapentin	
Glitazones	
Nonsteroidal antiinflammatory agents	

clinical syndrome bearing the name “obstruction” is divorced from the urodynamic measure. Likewise, the requirement to demonstrate involuntary contractile behavior of the detrusor in association with symptoms to make the urodynamic diagnosis of detrusor overactivity also leads to up to 25% of subjects with urgency and urgency incontinence not having a diagnosis made. This is not a problem with the measure, but with the preoccupation that diagnoses should occupy specific “boxes” without overlap.⁵¹

On presentation, patients are asked to empty their bladders while urine flow rate is measured by means of a flow meter positioned in an adapted commode. A Jaques catheter (French gauge 10) and a nylon catheter (16 G) are placed in the bladder via the urethra, which is usually anesthetized with lidocaine gel. The postmicturition residual urine is drained off and measured. Another catheter (French gauge 10) tipped with a perforated latex sheath to prevent fecal plugging, is introduced into the rectum. The smaller bladder catheter and the rectal catheter are filled with normal saline and then connected to force displacement transducers mounted at the level of the superior ramus of the pubic bone. This reference point is used to establish atmospheric pressure. The detrusor pressure, generated by the walls of the bladder, is calculated by subtracting the intraabdominal pressure (measured via the rectal catheter) from the intravesical pressure (measured via the bladder catheter). The bladder is filled with a fluid at a rate of between 50 and 100 mL min⁻¹. The subject is asked to cough at intervals during the study to assess the quality of abdominal pressure subtraction and to report sensations of filling and urgency. The bladder is filled until either a maximum of 500 mL has been infused, or unstable detrusor activity prohibits further filling, or the patient is found to be unable to tolerate any further infusion. Unfortunately, filling rate, fluid temperature, and content are not standardized and vary with department preference. Videourodynamics uses radio-opaque contrast to fill the bladder. There has been an attempt to standardize the methods

used for cystometry by both the international continence society and the British Society for Urogynaecology in the United Kingdom. Clearly some standardization is useful as this allows comparison of results and a quality assurance of the method by which these were obtained.

On completion of the filling study, the filling catheter is withdrawn from the bladder leaving the pressure measuring catheter in situ. The patient is then asked to void to completion. During voiding, the bladder and rectal pressure and the flow rate are recorded simultaneously.

During normal filling the detrusor pressure should only rise an amount consistent with the pressure head of the volume of fluid within it. If the detrusor contracts while the patient is attempting to inhibit micturition, then urodynamic detrusor overactivity is diagnosed. This should usually occur at the same time as the subjective sensation of urinary urgency, but the magnitude of the contraction may be small and not be associated with any sensation. In a subject with neurological disease, such as spinal cord injury or multiple sclerosis, this observation is termed detrusor overactivity of neurological origin.⁴⁰

There is little evidence that the use of cystometry adds anything to history taking or makes a difference in outcome from treatment. When NICE made its recommendations on the rational, evidence-based use of cystometry, there was considerable adverse reaction from “clinical experts” often citing anecdotal evidence or conflating arguments about the utility of an additional investigation in the assessment of incontinent patients.⁵²

AGE-RELATED PATHOPHYSIOLOGY

Early studies of age-related urodynamic findings were conducted on samples of elderly people without younger comparisons.^{53–55}

In more recent studies, people with lower urinary tract symptoms have been compared across all age groups.^{56–59}

Urgency incontinence is the commonest cause of urinary incontinence in elderly people, this being due chiefly to detrusor overactivity. This is particularly the case in elderly people living in institutions.^{60,61} Among outpatients having lower urinary tract symptoms, between 75% and 85% of women aged 75 and over and 85% and 95% of similarly aged men will be found to have detrusor overactivity.⁶² The observed changes associated with greater age in men and women with lower urinary tract symptoms undergoing cystometry are listed in Table 109-3 and illustrated in Figures 109-1 through 109-5.

It is interesting to note that men with lower urinary tract symptoms do not demonstrate all of the age-related changes associated with women. This probably relates to the higher urethral resistance caused by the prostate gland, causing detrusor muscle hypertrophy. The influence of this "obstructive" organ may dominate the evolution of bladder physiology.⁶³ In elderly people of both sexes, detrusor overactivity is associated with lower bladder capacities than in those with normal bladders. Contrary to expectations, lower bladder capacities, more aggressive detrusor overactivity, and older age do not appear to be associated with a poorer therapeutic prognosis. In fact, there do not appear to be any urodynamic variables indicative of a poorer outcome from treatment.³⁶

Both sexes void less successfully in late life and voiding is associated with higher residual urine volumes and a higher proportion of patients with incomplete bladder emptying.

Table 109-3. Changes Associated With Greater Age in Men and Women With Lower Urinary Tract Symptoms Undergoing Cystometry

Decreased
Urinary flow rate
Speed of contraction of detrusor
Collagen:detrusor ratio (♀ only)
Maximum bladder capacity
Functional bladder capacity
Sensation of filling
Increased
Postvoid residual volume of urine
Urinary frequency
Outflow tract obstruction (♂ only)

The explanations for this are probably complex. Obstruction will play a part in men but it is by no means the only explanation. There is evidence for a reduced speed of detrusor shortening in late life and problems in sustaining adequate voiding contractions. The transmission of force from the detrusor in later life is damped by an accumulation of collagen and connective tissue, giving the impression of "impaired contractility" a common misnomer.

The combination of detrusor instability and incomplete bladder emptying in elderly people raises the controversy of "detrusor hyperactivity and impaired contractility" (DHIC). This was described by Resnick and Yalla when reporting on 32 elderly nursing home residents in 1987.⁶⁴ They identified a specific physiologic entity, being a subset of detrusor hyperreflexia in elderly people. The characteristics were involuntary detrusor contractions, a postmicturition residual urine volume, and a reduced speed and amplitude of isometric detrusor contractions. In studying a much larger sample of elderly people, such a distinct physiologic subgroup has not been identified. Voiding problems and detrusor overactivity, often coexist in elderly people but seem to be independent of each other.

Additionally, Elbadawi et al⁶⁵ have published data from electron microscopy studies of bladder biopsy specimens from elderly men (*n* = 11) and women (*n* = 24), which are in support of distinct pathophysiologic subgroups of detrusor function. They reported four structural patterns precisely matching four urodynamic groups with no overlap. Additionally two subsets, "normal contractility" (*n* = 11) and "impaired contractility" (*n* = 24) matched histologic subsets exactly. These findings have not been corroborated despite Carey et al⁶⁶ having reported finding some of the defining histologic characteristics described by Elbadawi et al⁶⁷ evenly distributed between normal women (*n* = 15) and women with detrusor overactivity (*n* = 22). In vitro studies of detrusor muscle contraction reveal a lower level of acetylcholine release in association with increasing age,⁶⁸ there are also data showing a reduction in the number of acetylcholinesterase containing nerves within the muscle.⁶⁹

There are additionally changes in urethral function associated with aging in women. Figure 109-6 demonstrates a plot of the voiding detrusor pressure against flow rate recorded

Figure 109-1. Urinary flow rate by decade of life in men and women with lower urinary tract symptoms.

Figure 109-2. Speed of detrusor muscle shortening, calculated from the voiding pressure-flow plot in men and women with lower urinary tract symptoms in association with age.

Figure 109-3. Maximum cystometric bladder capacity for women with lower urinary tract symptoms in association with age.

BLADDER CAPACITY AT FIRST DESIRE TO VOID AS A PROPORTION OF MAXIMUM BLADDER CAPACITY IN ASSOCIATION WITH AGE

Figure 109-4. First desire to void, plotted as a proportion of maximum bladder capacity in women with lower urinary tract symptoms associated with age.

from a urodynamic study. The two pressure intercepts shown, $p_{\text{det.clos}}$ and $p_{\text{det.open}}$, are invariably elevated in the presence of detrusor overactivity and lower in the presence of stress urinary incontinence. Where both conditions exist, the values take the middle ground. Highest values are seen in neurologic diseases such as multiple sclerosis. Greater age in women is associated with lower values of both $p_{\text{det.clos}}$ and $p_{\text{det.open}}$, even in the presence of detrusor overactivity (Figure 109-7). Data from studies measuring the maximum urethral closure pressure also show a similar decline in association with increasing age. Histologically, there is evidence of an age-related apoptosis of striated muscle cells of the urethral sphincter.^{70,71}

ASSESSMENT OF THE ELDERLY INCONTINENT PATIENT

A screening question about bladder and bowel care as part of any interaction between an older person and a clinician is recommended. Many of the single assessment processes mandated by the National Service Framework for Older People contain a simple question such as "Do you have any problems with either your bladder or bowel?" A validated

screening or case-finding questionnaire could be used in appropriate settings.⁷²

Should the answer to that question be positive, then an assessment should be offered. However, this is not always the case. Essentially, problems can be divided into those relating to the storage of urine and those of emptying. Incontinence might be as a result of failure of either functions of the bladder. Useful questions are shown in Table 109-4.

Additional questions that should be asked relate to obstetric history (for example, the number of deliveries and if these were by forceps or were very prolonged), surgery, and bowel function, especially constipation and fecal incontinence because this can commonly coexist in frail, older people. Underlying causes of urinary incontinence may readily be identified. Characteristic features are shown in Table 109-5.

Assessing cognitive function

Older, cognitively impaired people are less able to cooperate in lifestyle interventions for their incontinence. They may also be at risk of developing further impaired cognition in response to drug therapy for their problem. Many older people are taking medication with antimuscarinic properties and

Figure 109-5. Postvoid residual volume of urine for men and women with lower urinary tract symptoms associated with age.

Figure 109-6. A voiding pressure-flow plot.

are at risk of subclinical cognitive impairment.⁷³ Oxybutynin, used for the treatment of overactive bladder, is associated with an impairment of cognition in normal older people.⁷⁴ There are also case reports of acute delirium in patients with preexisting cognitive impairment.^{75,76} Therefore it is a good idea to assess this formally. Simple, robust, and reliable scoring such as the Folstein MMSE may be employed but, as yet, it is not known if this is sensitive enough to detect what might be subtle change. It can be performed in a short time and may serve as a baseline measure against which to judge

the impact of treatment interventions or to assess what level of complexity of management the patient might tolerate.

Bladder diaries

Where possible, a bladder diary should be obtained to gain an understanding of the person's bladder habits and associated symptoms. A 3-day diary is usually sufficient. This can either be a tick chart of voiding frequency and incontinence episodes, or can include volume measurements at each void. This is most useful when polyuria or nocturnal polyuria is

suspected (excessive nighttime voiding or enuresis). A bladder diary is difficult to obtain for the very old, frail, and cognitively impaired and obtaining a reliable recording requires considerable effort and observation, particularly if there are a considerable number of incontinent voids. The process will involve observation and regular "wet checks" to allow building up a pattern of voiding. Involvement of an informal caregiver, where one is available may be beneficial.

Examination

A physical examination should be performed for all people complaining of urinary incontinence. This at a minimum should consist of urinalysis to exclude infection and the presence of hematuria, and a rectal examination to exclude fecal loading as a precipitating factor for the incontinence. A digital rectal examination also allows the assessment of the prostate in men. Palpation of the abdomen will detect large volumes of urine in the bladder and can exclude large volume

retention. For a more detailed examination and estimation of a postmicturition residual volume of urine, a portable ultrasound bladder scanner should be used.

Vaginal examination

This is considered to be an important part of a continence assessment, however, this should only be undertaken by a professional with the necessary competence and probably as part of a specialist rather than generalist assessment. A visual examination though might reveal conditions such as urogenital atrophy or prolapse that can cause urinary symptoms. Typically, women complain of the presence of the "lump" in their vagina that may sometimes be visible, a dragging sensation or discomfort especially when sitting. The prolapse itself may cause voiding difficulty, leading to a postmicturition residual volume or occasionally may mask underlying stress urinary incontinence. What the generalist can do, though, is easily identify a significant urogenital prolapse — certainly those that protrude beyond the introitus should be referred for a specialist examination. Visual inspection of the skin will also help in the planning of treatment to maintain skin integrity where this is threatened.

Urinalysis

This should be done for all patients with urinary incontinence at first presentation, or if there is a change in symptoms suggesting infection of the urine. The presence of frank blood indicates the need for action to be taken. The best dipstick tests to use are those with leucocytes and nitrite test pads; if both tests are negative, the chance of there being an infection is low when compared with laboratory evidence of a UTI based upon microscopic pyuria and bacteruria.⁷⁷ Large amounts of glucose or ketones in the urine can make the nitrite test falsely negative and the utility of this test has recently been called into question.⁷⁸ If there are lower

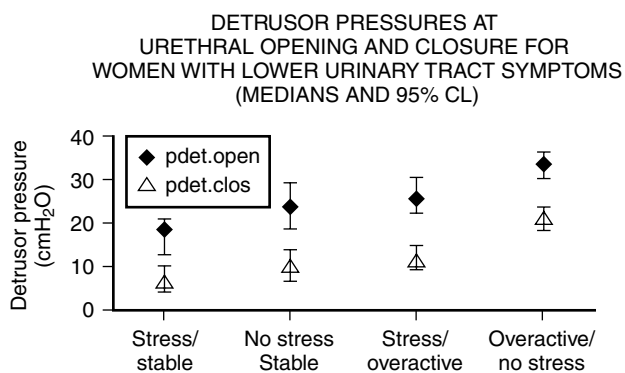

Figure 109-7. $p_{det.open}$ and $p_{det.clos}$ associated with detrusor overactivity, normal cystometry, and urodynamic stress incontinence.

Table 109-4. Questions About Urine Storage Symptoms

Symptom	Questions to Ask
Daytime frequency	How many times do you have to pass water in the day?
Nighttime frequency (nocturia)	How many times do you have to pass water at night?
Urgency	Do you get a desperate need to pass water that you find hard to hold?
Urgency incontinence	Do you wet yourself by accident because you do not reach the lavatory in time?
Stress urinary incontinence	Do you wet yourself if you cough, laugh, or exert yourself?
Aggravating factors	Do any of the following aggravate your symptoms: running water, cold weather, putting the key in the door and/or psychological stress.
The presence of the following symptoms should lead to specific action:	
Dysuria	Urinalysis and collect a urine sample for microscopy; treat according to findings
Hematuria	Assess for underlying pathology
Pain	
Questions About Voiding Symptoms	
Symptom	
Continual (passive) urine loss	Does your urine leak continually by night and day? (Suggests either a fistula [women] or retention and overflow incontinence [men >> women])
Hesitancy or straining to void	Do you have to wait a long time in the lavatory before the urine flows? Do you have to push or strain to pass urine?
Poor or intermittent stream - indicating bladder outflow tract obstruction	Is the flow weak or does it stop and start as you empty your bladder?
Terminal dribbling - related to outflow tract obstruction	Do you continue to leak urine even after you have finished emptying your bladder?
Postmicturition dribbling - dribble from the penis due to urine staying in the urethra after bladder emptying	Do you leak urine a while after you have left the toilet? (men >> women)
Incomplete emptying	Do you feel that after you have emptied your bladder there is more to pass?
Prolapse	Do you feel a lump coming down your vagina when you pass water?

Table 109-5. Making a Distinction Between Stress and Urgency Incontinence

Factor	Stress	Urge/Urgency
Loss of urine with exertion (e.g., coughing, sneezing, lifting, or exercise)	Typical	Uncommon
Nocturia	Uncommon	Typical
Frequency - voiding >8 times in a 24-hr period	Uncommon	Typical
Sudden uncontrollable urge to urinate	Uncommon	Typical
Volume of urine lost with each incontinence episode	Small	Moderate/large

Adapted from: Fantl JA, Newman DK, Colling J et al. Urinary incontinence in adults: acute and chronic management: clinical practice guideline, No. 2, 1996 Update. Rockville, Md: US Department of Health and Human Services, Public Health Service, Agency for Health Care Policy and Research; March 1996. AHCPR Publication No. 96-0682.

urinary tract symptoms or the patient has a delirium, then a midstream specimen of urine should be obtained if at all possible. For the very frail, there are pads that are similar to those used in pediatric practice that enable the collection of urine. For those doubly incontinent, an in and out catheter may be the only way of reliably obtaining a specimen.

Asymptomatic bacteriuria (the presence of bacteria in the urine that occurs without symptoms) is common in older women (in excess of 15%)⁷⁹ and treating this will have no effect on incontinence or on the general health of the individual. Antibiotic treatment will merely add to the likelihood of developing resistance to the antibiotic and expose the individual to antibiotic-related side effects. If the patient is already known to be chronically incontinent, then eradicating the bacteria will not help.⁸⁰ Women who do not have symptoms, and whose urine is negative for leukocyte esterase and nitrites, are most unlikely to have a UTI and do not require urine culture.

If dipstick-positive blood is found, it should be followed up by sending a sample for microscopy. If there is true microscopic hematuria, then a referral for investigation should be made because this can result from having urinary tract stones or a tumor. Clearly glycosuria, indicating either a low renal threshold for glucose or poorly controlled diabetes mellitus, requires further investigation and will cause polyuria.

Rectal examination

Whether or not a rectal examination should be routinely performed for all older people with urinary incontinence continues to promote discussion and opinion.

Although there is no published evidence that performing a rectal examination alters outcomes for the treatment of incontinence in women, expert opinion suggests that a loaded rectum may, because of its size, lead to voiding difficulty or the presence of a significant postvoid residual volume. Additionally, an assessment of prostate size and consistency in men will help to guide medical treatment. Occasionally, fecal impaction will lead to acute retention, resolution of which will lead to normal voiding.

THE TREATMENT OF URINARY INCONTINENCE

The overall aim in managing and treating incontinence is not cure; an absolute cure is seldom achieved and the best that any clinician might aim for is resolution of symptoms leading to a return to normal bladder habits and a normal lifestyle. Data from randomized, controlled studies of interventions for older people in this area are available but often exclude the frail elderly, thus extrapolations have to be made. In some instances, these may be perfectly valid

but sometimes caution needs to be taken. This section will outline evidence based treatment interventions for the main incontinence syndromes in older people.

General measures

Fluid balance - Although many older people restrict the amount of fluid they drink, there are data to suggest that the achievement of a "normal" fluid balance (1 to 1.5 L/day in a temperate climate) and awareness of bladder habits can lead to an improvement in lower urinary tract symptoms.

Weight loss - In epidemiologic studies, more women with incontinence report themselves as being short for their weight or overweight. Evidence for the improvement of symptoms comes from two studies: one in which the intervention was a 3-month liquid only diet, achieving a median weight loss of 16 kg in the intervention group and resulting in a greater than 50% resolution of urinary tract symptoms, which was sustained for the 6 months of the study.⁸¹ A more recent U.K. study⁸² showed that 5% weight loss can improve incontinence severity and have a beneficial effect on quality of life in obese women with urinary incontinence.

Caffeine - There are conflicting epidemiologic data about the effect of caffeinated drinks on lower urinary tract symptoms but reduction is supported by one RCT.⁸³ There are no specific data for the elderly, but should a patient express the sentiment that tea or coffee appears to worsen their symptoms then it would seem sensible to attempt reduction.

Bladder retraining

The purpose of bladder retraining is to extend the intervoid interval, increase bladder capacity, and overcome urinary urgency. There are many methods espoused, and none are superior to others. Bladder diaries are often used as an adjunct to retraining, making people aware of their bladder habits and reinforcing change. The patient uses the chart to keep a record of episodes of micturition, while gradual efforts are made to delay micturition after the urge to void is experienced. The technique is effective.⁸⁴⁻⁸⁶ However, it is not necessarily easy and clinical trial evidence illustrates the need for appropriate support in achieving a good outcome. Some patients with detrusor overactivity will experience pain while delaying micturition, and there is a real possibility of urge incontinence while working with the regime. Stretching the bladder can be augmented by encouraging higher fluid intake while at home, when an episode of incontinence can be dealt with in private. Increasing incontinence is more likely if the urethral sphincter is incompetent as the larger bladder volumes will increase pressure on the sphincter. As the bladder empties more efficiently from a capacity between 3 and 500 mL, it is logical to use a bladder

retraining regime to treat voiding problems secondary to detrusor muscle lesions. Excessive delay, so that the bladder capacity rises substantially above 500 mL, should be avoided as such overdistention is associated with ineffective voiding. Should bladder retraining and lifestyle measures fail to achieve satisfactory symptom control, then pharmacologic options for treatment are available.

Up to 70% of people in their eighth decade of life report at least one life limiting coexistent medical condition, even those who report themselves as "fit." However, frailer and older men and women are often excluded from clinical studies in this field by virtue of these or the treatments for them.⁸⁷ Seldom do published papers report the number of people who were screened for inclusion in a study but were ineligible. Such studies that are published then include data on the physiologically, if not chronologically, younger group of older people. The results of these studies should thus be considered in this light.

The hypotheses underlying drug treatment for OAB have undergone a revolution over the last 8 years; it was widely held that the action of antimuscarinic agents was to suppress overactive contractions of the bladder acting via M₃ receptors, although data to support this were inconsistent.⁸⁸ It has become established that there is considerable sensory dysfunction associated with OAB and that M₂ receptors, found in the suburothelium, have a significant effect on the appreciation of urinary urgency. Newer drugs are now targeted to control urinary urgency, a central feature of the symptom complex that has a major impact on quality of life.^{89,90} The role of antimuscarinics in patients with cognitive impairment is discussed later.

Oxybutynin is the most established antimuscarinic drug in use today. Trials comparing oxybutynin with placebo have consistently shown a reduction in symptoms with the active drug. Studies in older people, using lower doses of the drug than the usual licensed dose of 5 mg three times daily, have some efficacy with a concomitant reduction in the adverse effects and an enhanced level of tolerability of the drug, which at normal dosing resulted in up to 60% of subjects being unable to take it.^{85,91,92} Oxybutynin is also effective when used in combination with prompted voiding schedules in the nursing-home environment. However, the drug had no effect on the requirement for nursing intervention in the management of incontinence, and the authors concluded that there was little justification for its use.⁹³ Extended-release oxybutynin was also reported to be an effective compound in the elderly, with 31% remaining free of urge incontinence in one 12-week study. However, 58.6% of subjects reported dry mouth, with 23.0% rating it moderate or severe; but despite this, only 1.6% of subjects withdrew.⁹⁴ There are two studies of extended release oxybutynin, one examining the effect of the drug on the management of cognitively impaired nursing home residents with urgency incontinence and the other covering women over the age of 65.^{95,96}

Oxybutynin is also available in a transdermal preparation that is effective and avoids most antimuscarinic side effects associated with the oral preparation, and fewer systemic side effects than oral extended-release tolterodine. Side effects associated with transdermal delivery include local application-site irritation or erythema, generally managed by appropriate rotation of the application site, but described as severe in 2.5% of subjects.^{97,98} Published analyses of the

efficacy of transdermal oxybutynin included subjects of up to 100 years of age and those in institutional care settings.⁹⁹

Solifenacin is a long-acting once-daily antimuscarinic agent that is effective in the treatment of OAB. A pooled analysis of results from older subjects taking solifenacin showed the drug to be effective in reducing urinary frequency, the number of urgency episodes, and sensation of urgency, with a restoration of continence in up to 49% of people.¹⁰⁰ In the pooled analysis, 13.5% of people on 5 mg reported dry mouth, which was mild to moderate. At the higher dose, a third of people complained of dry mouth, and in 1.9% this was reported as severe. In a randomized controlled trial versus tolterodine extended-release, solifenacin was shown to be equivalent in terms of reduction in micturition frequency and, in an analysis of secondary end points, better than tolterodine in several key indicators. There appeared to be no lessening of effect in those subjects aged over 65 years.¹⁰¹

Tolterodine is a nonselective antimuscarinic agent that appears to have some functional selectivity and greater affinity for bladder muscarinic receptors over those in the salivary glands. This appears to explain the lower incidence of dry mouth, 12.9% in one long-term study,¹⁰² and the reduction in withdrawals from treatment seen with the use of the drug. The extended-release form of the drug gives greater tolerability and better efficacy than the immediate-release compound, which should be reserved for those older people with significant hepatic impairment. An effect of therapy can be seen within a week but the maximum effect is seen after 5 to 8 weeks of treatment.^{103,104} There are published data specifically relating to the elderly that show efficacy, but there appears to be some diminution of effect in older people in some studies, although the clinical relevance of this is unclear.^{105–107} Tolterodine does not appear to significantly worsen the postvoid residual urine volume and has been effective in treating men with both OAB and bladder outflow tract obstruction.^{108,109} An evening dose of the drug is effective in reducing nocturnal voids and has been shown to be more tolerable.¹¹⁰

Imipramine appears to have a strong inhibitory effect on detrusor muscle. In the treatment of 10 elderly patients with detrusor instability, the use of imipramine was effective in achieving continence in six at doses of 25 to 150 mg. However, the existing evidence is of only moderate quality, and the incidence of side effects, particularly severe dry mouth, make it difficult to titrate to an effective dose.¹¹¹

Propiverine hydrochloride has combined antimuscarinic and calcium channel blocking actions. Comparative trials against flavoxate and a placebo, and oxybutynin and a placebo, showed that propiverine has a similar efficacy to oxybutynin. Propiverine has a similar efficacy in treatment of symptoms to oxybutynin 5 mg twice daily, but with a statistically significantly milder and less common incidence of dry mouth. Although there are no specific data in older people, the elderly were not specifically excluded from studies. However, up to 20% of patients have adverse effects, which are mainly anticholinergic.^{112,113}

Trospium chloride is a quaternary ammonium salt derived from atropine; it was effective in treating DO in several randomized controlled trials using urodynamic measures of diagnosis and extent of disease, and clinical and quality-of-life outcomes.^{114–116} These studies included patients aged over 70 years, and there are no data to suggest that the elderly do less well. The drug was assessed in studies versus placebo and

standard release oxybutynin, and was better in effect to placebo and equivalent in efficacy to oxybutynin, when treating DO at doses of 5 mg three times daily. Adverse effects occur less commonly with trospium than with oxybutynin. The drug has no significant drug-drug interactions and does not cross the blood-brain barrier, and thus it is unlikely to have an adverse effect on cognition. Except for one study on driving ability, changes in alpha wave activity on the electroencephalogram have been used as a surrogate end point.^{117,118} Trospium might therefore be a useful drug where there is coexisting polypharmacy or concern about significant cognitive dysfunction.

Darifenacin is an antimuscarinic agent that has fiftyfold selectivity for M₃ over M₂ receptors, but only ninefold for M₃ over M₁. The drug has been specifically tested in older people in randomized controlled trials, and is effective in terms of objective and subjective variables and quality of life. Pooled data from the population aged over 65 years show a similar effect size to the younger groups.^{119,120} In cognitively intact older people, darifenacin does not adversely affect cognition, probably due to its lack of M₁ receptor activity, and its CNS tolerability appears to be similar to a placebo.¹²¹ The results of a study of darifenacin in the more elderly (over 75 years) failed to reach its primary end point, but more people on the drug than a placebo experienced a response to treatment.¹²² The major side effects are constipation, affecting at most 23.6% of subjects at a dose of 15 mg, 10% of whom required treatment for this (although only 2.7% withdrew from treatment because of this) and dry mouth.

Fesoterodine, a prodrug that is converted into the active metabolite of tolterodine (5-hydroxymethyl tolterodine) has recently been launched in Europe and is due for launch in the United States in 2009. It is statistically significantly better than a placebo in all of the objective disease variables and has a favorable effect on quality of life.^{123,124} For some outcome measures, the 8 mg dose appears to be more effective than the 4 mg dose. The side effect profile appears much the same as other available antimuscarinics with the exception of a lower incidence of reported constipation; whether this is borne out in current trials and clinical use remains to be seen.

OTHER PHARMACOLOGIC MEASURES

Although there is no evidence for estrogen therapy being of use in the treatment of incontinence in women, there are data to support the use of topical estrogens for treating OAB in postmenopausal women. One systematic review of studies involving 430 subjects found benefits in all of the relevant symptoms associated with the condition.¹²⁵ It may, however, have a role in the management of recurrent urinary infection. Estrogen withdrawal is associated with a fall in the levels of intravaginal glycogen on which lactobacilli depend. These bacteria cease to colonize the vagina, which is then occupied by colonic organisms that thrive in the higher pH associated with this change.¹²⁶ The atrophy of the urothelium encourages colonization by gram-negative fecal organisms and the bacteria adhere more easily. There is some evidence that estrogen replacement therapy may reverse this process and give protection to elderly women with recurrent urinary tract infection.¹²⁷⁻¹³⁰

Topical estrogen therapy appears to be associated with a negligible risk of endometrial hyperplasia and certainly, our

oncologists are happy for its use even in those women with a previous breast cancer. A minimum of 3-months use is required as a trial of efficacy. Those women on systemic HRT are also just as likely to have urogenital atrophy as not; they should not be excluded from either an examination or treatment.

Desmopressin (synthetic antidiuretic hormone with no effect on blood pressure) can be useful in those individuals with nocturnal frequency or nocturnal polyuria. Its use might be hampered by drug-drug interactions, predisposing to hyponatremia or excessive drinking habits.¹³¹ More recent data have been offered in support of careful, supervised use of desmopressin in older individuals.¹³² In one meta-analysis of available trial data, dilutional hyponatremia occurred in 7% of patients, all within the initial phase of dose titration.¹³³ Given that this decrease in serum sodium may occur within 72 hours, it is worthwhile checking the levels before and 72 hours after initiation. Levels should be then checked again if there is any change to the disease state or treatment taken by the patient.

FLAVOXATE HYDROCHLORIDE (URISPAS)

At one time this drug was used extensively for treating the overactive bladder but its efficacy has not been shown in data from controlled clinical trials versus placebo. It is no longer considered to be an effective drug for the overactive bladder or detrusor overactivity.¹³⁴⁻¹³⁶ There are no data from studies including the frailer elderly.

Surgery for detrusor overactivity

Surgical measures for the treatment of detrusor overactivity have developed over the years but there are, needless to say, few data on the elderly. There has been a rapid expansion in the intradetrusor usage of botulinum toxin, although an unlicensed indication, for both people with spinal cord injury and those with idiopathic detrusor overactivity, although evidence for the latter from randomized trials is lacking. The treatment appears to be efficacious, and the beneficial effect lasts up to 9 months per injection. The main adverse effect is voiding dysfunction, requiring the patient to revert to clean intermittent catheterization. In some studies of middle-aged women, the rate of this has reached 43%.¹³⁷ The elderly, with a higher prevalence of impaired voiding, may be at a higher risk of developing this complication. There are randomized, controlled trials underway.

For severe cases of urgency urinary incontinence not responding to conventional medical therapy, potential surgical approaches are sacral nerve modulation and the clam ileocystoplasty. Sacral neuromodulation appears effective for carefully selected individuals and some series have reported results in a few subjects over the age of 65. Approximately a third of subjects appear to require re-operation and reimplantation of the stimulator. Age over 55 years appears to be associated with a poorer outcome.^{138,139} The precise mechanism by which neuromodulation has its effect still remains to be ascertained. Patients are committed to lifelong follow-up and many will require reoperation during the lifetime of the device.¹⁴⁰ Finally, the Clam ileocystoplasty is probably the only operation for detrusor overactivity for which there is evidence of efficacy. Some series have reported on patients in their eighth decade with good results.¹⁴¹ However, since the procedure makes voluntary bladder emptying

ineffective, patients require clean intermittent self-catheterization to empty.¹⁴² Some elderly patients can cope with this, but the prevalence of multiple disabilities in late life demand careful selection and counseling.

Correcting sphincter incompetence

Pelvic floor muscle therapy remains the mainstay of conservative therapy for stress urinary incontinence. The evidence for their efficacy is limited in terms of quality but they are recommended by the Cochrane collaboration systematic reviews, and in England and Wales by NICE. Data are mostly from open studies or within group analyses of comparative trial data.¹⁴¹ Data on pelvic floor exercises (PFE) in the elderly, however, are somewhat lacking, as might be expected but there are data from Japan, combining PFE with general physiotherapy for walking speed and muscle strength resulting in overall improvement in incontinence, although this may have been related to the loss of weight and greater ability to toilet effectively rather than any direct LVT effect.¹⁴² The effect size for PFE in terms of incontinent episodes, leakage amount, and perceived severity for women older than 60 years of age was less than younger women but was still beneficial overall rather than but still is of statistically significant benefit.¹⁴³ Exercise programs need to be supervised and supported, and last for at least 3 months, with the minimal amount of effective exercises to achieve any benefit appearing to be 24 to 32 daily. PFE have not been found to be superior to surgery. Although they are advocated for the treatment of stress incontinence in older women, there is no specific evidence to support any specific efficacy in this group. It is regrettable that no large-scale studies of efficacy, which include age comparisons, have been conducted, so doubt hangs over their application. For men, PFE are used in the context of postprostatectomy incontinence where stress incontinence may affect up to 10% following a radical procedure. Evidence for their long-term efficacy is lacking and has been subjected to a Cochrane review.¹⁴⁴

MEDICATION

Until recently there were no drug treatments with evidence of efficacy in the treatment of stress urinary incontinence. However, duloxetine, a combined serotonin and noradrenaline reuptake inhibitor was licensed in Europe in 2004. It is thought to act by increasing the tone of the urethral sphincter. There are data from randomized, controlled trials supporting its efficacy in women (it is not licensed for use in men) but there are no specific data in the elderly. The main side effect of the drug in clinical practice is nausea in 24% of women that caused 6.4% of all withdrawals within trials.¹⁴⁵ In clinical practice, even with slow titration of the dose, the withdrawal rate is higher.¹⁴⁶ The drug has not been considered by the FDA. In England and Wales, NICE does not recommend the drug for the treatment of stress urinary incontinence in women on pharmacoeconomic grounds.

SURGERY

Surgery for stress urinary incontinence has been revolutionized over the past 7 years by the wholesale adoption of the midurethral tapes, such as the tension-free vaginal tape (TVT). These have supplanted colposuspension as the primary procedure for urethral incompetence. There are now 10-year data showing efficacy and data also exist for older women¹⁴⁷ who, while not achieving the same extent

of cure as younger women, did gain meaningful reductions in incontinence and were satisfied with their result. Other approaches to insertion of the tapes are possible; the transobturator route is often used in more obese women, with similar efficacy to the TVT, but a higher incidence of leg pain. The open Burch colposuspension remains the "gold standard" procedure for stress urinary incontinence with a sustained improvement up to 20 years postoperation.¹⁴⁸ For frailer, older women, the use of agents to bulk the urethral sphincter have been used with acceptable short- to medium-term results but these diminish with time and repeat injection may be required to achieve efficacy.¹⁴⁹

THE AS ARTIFICIAL URINARY SPHINCTER

This is an option for the management of urethral sphincter failure in both sexes. It is best suited to people who do not have detrusor overactivity, but needless to say, there are no data in older people. The operation involves the insertion of a cuff around the urethra. This cuff is passively inflated from a reservoir of fluid placed in the pelvis. The cuff can be deflated, so as to allow voiding, by activating a pump placed in the scrotum or labia majora. After voiding, the cuff reinflates spontaneously. Complications include infection, displacement of the device, and mechanical failure. In one series with a 9 year follow-up, 35% of patients required a surgical revision.¹⁵⁰ In correctly selected patients, this prosthetic sphincter is highly effective.¹⁵¹

Treating voiding disorders

Intermittent self-catheterization is now the mainstay of management of voiding disorders associated with neurologic disease.^{152,153}

Older people of both sexes have an increased tendency toward incomplete bladder emptying and this frequently coexists with detrusor overactivity. Voiding disorders may occur in the absence of symptoms but where there are symptoms, such as urinary frequency, recurrent urinary tract infection, or renal impairment, this can be managed by intermittent catheterization.¹⁵⁴

There are no outcome data with regard to this technique in elderly people. It is clear, though, that asymptomatic individuals can probably be left alone. An assessment of the postmicturition residual urine volume is a routine part of our standard management protocol in men. There are data to suggest that women without voiding symptoms are unlikely to have a significant residual volume of urine. When we discover a significant problem, which we define as a residual of 200 mL or more, we institute a temporary, once daily intermittent catheterization program; this can be delivered by community nursing services if required. If this results in a rapid and significant improvement in symptoms, we then establish a more permanent regime, otherwise we take no further action.

The procedure may be difficult because of cognitive impairment and poor dexterity. It is more usual for us to enlist the services of a spouse or partner to administer the procedure, although a number of elderly people can self-catheterize. We have found that the fluid output in elderly people tends to be lower so that a less frequent regime of daily or twice daily catheterizations may prove adequate. Some older women, with delicate atrophic urethras, appear to be able to reduce urethral trauma by using estrogen replacement therapy.

Maintenance products

Pads continue to play an important role in the management of uncontrolled urinary or fecal incontinence. However, ambulant patients will need to use these devices while awaiting a surgical cure, or more likely as “an insurance policy” in case of incontinence. The design, technology, function, and performance of incontinence pads have been reviewed with meticulous detail elsewhere. Nowadays, there are some very effective products available, but care needs to be taken when choosing a suitable range.¹⁵⁵ There are now considerable data on which to base an informed judgment of the most suitable products and most guidelines suggest that patient preference should guide choice.¹⁵⁶ Too often decisions on the aids to provide for people are not given sufficient importance and tend to be based primarily on cost considerations.¹⁵⁷

INDWELLING CATHETERS

These have a role in the management of some patients. They are best reserved for people with voiding problems, with or without controllable overactivity, who are unable to manage intermittent catheterization. They may also be employed for the frailest oldest group who are either not suitable for outflow tract surgery or for whom the frequent changing of pads may cause distress or considerable discomfort. A suprapubic catheter may be preferable because it is easier to maintain and does not traumatize the urethra.

Recurrent blocking and infections are complications of permanent catheterization; this tends to occur following the formation of a biofilm on the outside of the catheter, which is more likely to form in alkaline urine. Anecdotal reports favor the use of vitamin C, 1 g tds and cranberry juice to combat blockage and infection, but there are no clinical trial data to support this, although cranberry juice seems to have urinary antiseptic properties.¹⁵⁸ There are no data to support the use of silver-coated catheters in preventing urinary tract infection, only short-term bacteriuria.¹⁵⁹ A successful indwelling catheter need be changed only once every 3 months. Asymptomatic bacteriuria should be left untreated.^{160,161} The use of a flip-flow valve instead of an external drainage bag is often very acceptable to many, but requires cognitive and manual dexterity to operate. They are

unsuitable for those with high pressure detrusor overactivity or those with upper renal tract damage.

EXTERNAL SHEATH DRAINAGE

Condom catheters, which are fixed to the penis using adhesives specifically developed for this purpose, may also be acceptable to men and are attractive as an alternative to pads. Urine drains from a tube connected at the apex of the sheath. The main problem is difficulty in attaching them because of penile retraction into the suprapubic fat pad. There are special attachments that can deal with this problem. Additionally, some patients have problems with displacement in response to the physical stresses of movement. A small randomized controlled trial versus indwelling catheters in men averaging 73 years of age resulted in a reduction in symptomatic UTI or bacteriuria, increased level of comfort, and a reduction in the amount of associated pain.¹⁶²

KEY POINTS

Urinary Incontinence

- Urinary incontinence is a highly prevalent condition in older people.
- Careful history, examination, and assessment is sufficient to make a diagnosis of the underlying cause of the urinary incontinence in the majority of cases.
- An assessment of coexisting medications and medical conditions is essential in the evaluation of an older person with urinary incontinence.
- Both asymptomatic bacteriuria and an asymptomatic postvoid residual volume of urine do not require treatment.
- The most common underlying cause of LUTS in the older person is the overactive bladder, regardless of the presence or absence of bladder outflow tract obstruction.
- There is evidence for the conservative management of UI in frail older people by the use of prompted voiding, individualized toileting, and scheduled voiding.

Five centuries ago, French physician Ambroise Paré described one of the earliest pressure ulcers in the medical literature, noting that “the bedsore on the buttock has come from having been too long a time lying on it, without moving himself.”¹ Today, pressure ulcers continue to be a significant problem, costing billions of dollars annually.^{2,3} The United States, the United Kingdom, and the European medical community spent significant time and effort creating staging guidelines, identifying risk factors, and outlining prevention strategies.^{4,5,6} Even with these guidelines, pressure ulcers continue to haunt medicine in the twenty-first century. The older adult population is especially at risk. Incidence rates of pressure ulcer in the United States approach 38% in acute care, 40% in critical care units, and 24% in long-term care facilities.⁴ Prevalence rates in the United Kingdom range from 8% to 20% for hospitalized patients.^{7,8} For fiscal year 2006, there were 322,426 pressure ulcers reported as a secondary diagnosis for hospitalized Medicare beneficiaries, at an average cost per stay of \$40,381.⁹ As a result, the Centers for Medicare and Medicaid will be making significant payment adjustments for this high cost and high volume hospital complication in October 2008.⁹ This chapter will describe how normal aging affects the known risk factors for pressure ulcer development, review the pathophysiology of pressure ulcers, describe new staging classification, and discuss prevention and treatment options.

NORMAL AGING

With increasing age, several changes occur throughout the skin, resulting in increased risk of pressure ulcer development. Epidermal turnover rates decrease by 30% to 50% by the age of 70, resulting in rougher skin with decreased barrier function.¹⁰ Theoretically, this change plays a role in decreased healing of epidermal wounds. The dermal-epidermal junction flattens resulting in decreased contact between the two layers. As a result the two layers may easily separate, making older skin more likely to tear and blister.

The dermis provides the basic structure of the skin between the epidermis and the deeper structures (muscle and bone). The dermis is a complex connective tissue matrix consisting of collagenous, elastic, and reticular fibers, which provide strength and elasticity. The blood vessels, lymphatics, nerves, and deeper portions of the hair follicles are located in the dermis. Normal aging changes the structure of and function of the dermis. Basal and peak levels of cutaneous blood flow are reduced by about 60%, resulting in compromised vascular responsiveness during injury or infection.¹⁰ This change may be mediated by endothelial dysfunction.¹¹ With age, collagen synthesis decreases and degradation increases, resulting in a loss of the connective tissue matrix and impaired wound healing.¹⁰ Elastic fibers decrease in number and size, resulting in decreased skin elasticity. Photo aging may worsen these normal changes.

Subcutaneous fat decreases with age, decreasing its ability to protect deeper structures from injury. Distribution of subcutaneous fat changes (decreasing in face and hands,

increasing in thighs and abdomen), which decreases pressure diffusion over bony prominences.

PATHOPHYSIOLOGY OF PRESSURE ULCERS

Pressure that disrupts normal circulation to the skin and deep structures is the primary factor in the development of pressure ulcers. A complex vascular system, consisting of large vessels and a network of capillaries, courses through the dermis to supply the skin with oxygen, nutrition, and remove waste. Motor nerves monitor arterioles and excretion production.¹² Blood flow through the macrocirculatory system is controlled by the microcirculatory system. Small conductance vessels in between these two systems conduct blood and resist flow.^{13,14} Dermis capillary blood flow pressures range from 11 mm Hg at the venule side to 32 mm Hg on the arterial side. If capillary pressures rise above 32 mm Hg, blood flow will be disrupted, causing ischemia within hours.^{15,16} An elderly patient, supine on a bed, generates pressure between 50 to 90 mm Hg at the location of the heel and greater trochanter, well above the capillary filling pressure. Animal skin studies suggest damage can begin in 2 hours in the presence of only 100 mm Hg pressure.¹⁷

However pressure is not the only extrinsic factor that influences ulcer development. Friction and shear also are extrinsic factors. Friction causes epidermal injury, which can increase damage already present by pressure. This often occurs when objects such as bed linen or clothes are allowed to rub on the skin, removing the epidermis. The age associated decrease in epidermal turnover rate may delay repair. Moisturizer use can decrease effects of friction.

Shear is the internal force that is generated when a body shifts or moves in a direction parallel to the plane of contact.¹⁸ As an elderly person slides down in the bed, the skin adheres to the bed surface but the underlying structures move with the body. This causes tearing of capillaries and disruption in blood flow. Now less pressure is needed to occlude blood flow. These phenomena may be worsened by the loss of subcutaneous fat seen with normal aging. Using a draw sheet and keeping a low head of bed elevation can minimize shear.

The final extrinsic factor is excessive moisture. Moisture from urinary or fecal incontinence or profuse sweating can lead to skin maceration and perhaps increased friction and shear forces when left sticky and wet. Absorbent pads can improve moisture.

Aside from extrinsic forces, several intrinsic forces also impact the development of pressure ulcers. These factors include immobility, poor nutrition, decreased sensory perception, and low body mass.¹⁶ Older adults are at increased risk for immobility because of increased rates of cerebral vascular disease, hip fracture, and increased recovery time from acute illness or surgery. If these comorbidities are present, physical therapy and occupational therapy consults may minimize the effects of immobility. Decreased sensory perception may be due to diabetic neuropathy or cerebral

vascular disease, which may prevent an older adult from feeling the pain associated with damage from extrinsic forces. Inadequate nutrition increases risk for ulcer development and impairs healing.¹⁹ Large wounds may require twice the normal protein intake to heal.²⁰ Tube feeding has not been associated with preventing or healing pressure ulcers in advanced dementia.²¹

Although the above extrinsic and intrinsic factors may initiate pressure ulcer formation, cell death results from ischemia-reperfusion (I/R) injury.¹⁸ The initial ischemic injury occurs when blood flow ceases. Deeper structures such as skeletal muscle can tolerate only short periods of ischemia, compared to the epidermis, which can tolerate longer periods. Initially, the microcirculation dilates and releases histamine (blanchable erythema). Next the capillaries and venules engorge with red blood cells and then hemorrhage (nonblanchable erythema). Necrosis of all skin structures is seen by Stage III.²² Reperfusion begins with removal of pressure. Damage seen with blanchable and nonblanchable erythema may be reversible. Nitrous oxide (NO) production decreases during ischemic periods, causing blood vessel constriction. During reperfusion, blood vessels dilate as NO production increases. If damage is extensive, the reperfusion spreads toxic metabolites and oxygen free radicals, destroying surrounding tissue.¹⁸

RISK ASSESSMENT

Prevention remains the mainstay of pressure ulcer treatment. The health care provider should carefully examine high-risk areas for pressure ulcer development, such as the occiput, spine, sacrum, ischium, heels, trochanter, knee, and ankle. Several scales exist to assess patients at risk for pressure ulcer development: the Norton, Braden, and Waterlow scales. The Norton scale assesses five areas on a four point scale: physical condition, mental condition, activity, mobility, and incontinence. A modified scale deducts one point for each of the following: comorbidities (diabetes, hypertension), low hemoglobin, low hematocrit, low albumin (<3.3 mg/dL), fever greater than 99.6° F, polypharmacy, and mental status changes/lethargy in the past 24 hours. A score of 10 is high risk.²³ The Braden scale is used both in research and clinic settings. This scale assesses risks in six categories: sensory perception, activity, mobility, nutrition, moisture level, and friction/shear (three point scale). The maximum score is 23. A score of 18 indicates increased risk for elderly patients.^{24,25} The Waterlow scale is a modification of the Norton scale and assesses eight factors: build, sex and age, continence, mobility, appetite, medication, and special risk factors.²⁶ The higher the score on this complex scale indicates an increased risk. A 2007 review and study using the three scales in an inpatient geriatric setting showed that sensitivity and specificity of all scales depended on selected cutoff points sample changes.²⁷ The positive predictive value of the Braden and Norton scales is approximately 37%.²⁸ As a result it is recommended that the scales be used in conjugation with a good physical examination by a nurse or physician.^{9,27} Recently, the Cochrane Database of Systemic Reviews attempted to determine whether using structured, systematic pressure ulcer risk assessment tools in any health care setting reduces the incidence of pressure ulcers. However, it found no randomized trials exist that compare assessment tools with clinical judgment or no risk assessment in terms

of rates of pressure ulceration. Therefore, Cochrane could not conclude that assessment tools reduced the incidence of pressure ulcers.

PRESSURE ULCER CLASSIFICATION

The National Pressure Ulcer Advisory Panel (NPUAP) defines a pressure ulcer as localized injury to the skin and/or underlying tissue usually over a bony prominence as a result of pressure, or pressure in combination with shear and/or friction. Blanchable erythema or reactive hyperemia often precede pressure ulcer development and can resolve in 24 hours if treatment starts. However, once the skin changes go beyond the initial stage, pressure ulcer formation has started. The NPUAP uses a four-stage system of pressure ulcer classification.²⁹ In 2007, two new stages were added: suspected deep tissue injury and unstageable.³⁰

Suspected deep tissue injury is a purple or maroon localized area of discolored intact skin or blood-filled blister because of damage of underlying soft tissue. The skin may be painful, different temperature compared to surrounding skin. Deep tissue injury may progress rapidly to a pressure ulcer, despite treatment. Stage I is intact skin with nonblanchable erythema of a localized area usually over a bony prominence. The skin may be painful, and a different temperature compared with surrounding skin. This indicates that there is inadequate perfusion to the cutaneous microcirculation. Stage II is a partial thickness loss of dermis presenting as a shallow open ulcer with a red-pink wound bed, without slough or bruising. An open or ruptured blister may also be present. At this stage, tissue anoxia has progressed to such an extent that the epidermis starts to necrose. Stage III is full thickness tissue loss associated with undermining and tunneling. Subcutaneous fat may be visible but bone, tendon, or muscle is not exposed. Ulcers on areas with no subcutaneous tissue (nose, ear, malleolus) may be very shallow compared with areas with significant subcutaneous tissue such as the sacrum. Stage IV is full thickness tissue loss with exposed bone, tendon, or muscle. It is often associated with slough or eschar, undermining and tunneling, and osteomyelitis. An unstageable ulcer is full thickness tissue loss in which the base of the ulcer is covered by slough (yellow, tan, gray, green, or brown) and/or eschar (tan, brown, or black) in the wound bed. The slough and/or eschar must be removed before the true stage can be determined. However, an eschar on the heels is considered stable if it is dry, adherent, and intact without erythema and should not be removed.

Once staging of the ulcer is completed, ulcer progression must be documented. One method of documenting a wound is as follows³¹: (1) stage the ulcer, time present, setting where occurred; (2) describe the location anatomically; (3) measure ulcer in centimeters (length × width × base); (4) describe percent of ulcer covered by granulation tissue versus yellow slough versus necrotic tissue/eschar; (5) note any odor; (6) describe the surrounding tissue; (7) document undermining or tunneling (use clock as reference point).

MANAGEMENT AND TREATMENT

As described earlier, pressure ulcer development occurs from a combination of extrinsic and intrinsic factors. Pressure ulcers are chronic wounds and amount of time to heal is very variable.³² Management and treatment should focus

on (1) pressure relief, (2) wound care, and (3) complications. In 2006, *Wound Repair and Regeneration* published *Guidelines for the treatment of pressure ulcers (GTPU)*, which were evidence and consensus based.⁴¹ Evidence level (EL) were classified as I (multiple clinical trials supporting use), II (at least one trial), or III (suggestive but lacking sufficient data).

Pressure relief is the first line of treatment. According to the NPUAP, patients should be turned every 2 hours while in bed or 1 hour while seated. Patients should be positioned or padded as to minimize pressure on at-risk areas or minimize pressure on existing ulcers (GTPU EL II). Support surfaces can reduce pressure but not eliminate pressure, so repositioning is still important. Static support surfaces are usually foam, air, or water overlays and can reduce pressure, especially for stage I and stage II ulcers and if the patient can move.^{33,34} (GTPU EL I). These surfaces lie over the existing mattress or replace the existing mattress and can be used in the home.

Dynamic support surfaces are low air loss beds, alternating pressure beds, and air fluidized beds. These devices are usually reserved for stage III and stage IV ulcers. (GTPU EL I) The low air loss beds and air fluidized beds reduce pressure by keeping the person floating on a bed of air or fluidized beads. By contrast, alternating pressure beds reduce pressure by reproducing the alternation of high and low pressure in the weight-bearing areas, which occurs in normal people as a result of postural changes in response to pressure pain. They consist of two alternating systems of air cells powered by a pump, which causes them to inflate and deflate reciprocally over a 5- to 10-minute cycle, thus continually changing the supporting areas of pressure on the body. These beds are expensive and large, so are difficult to use in the home setting and may increase immobility for older patients. One dynamic surface has not been shown to be superior to another one in treatment of pressure ulcers.³⁵

Pressure ulcers require consistent wound care, which includes débridement, cleansing, and dressing. Necrotic tissue or slough may require débridement to promote healing (GTPU EL I). Sharp débridement uses a scalpel and scissors, removing only the dead tissue. Mechanical débridement uses wet to dry dressings, whirlpool, and irrigation. It is a nonselective method and may remove healthy tissue. Enzymatic débridement uses enzymes to slowly break down the fibrin and collagen in the necrotic tissue. The enzymatic ointments are expensive. Autolytic débridement uses the wounds own enzymes to slowly remove the necrotic tissue through use of an occlusive dressing.

Wound cleansing should be done with tap water or saline. Antiseptics should be avoided as their use will destroy healthy tissue (GTPU EL III).

The purpose of the dressing is to manage fluid balance in the ulcer by adding moisture or absorbing excess moisture (GTPU EL I). Films are semioclusive or occlusive, usually transparent, promote autolytic débridement, and often used on stage II ulcers. Hydrogels provide moisture to the ulcer and are best used for ulcers that have adequate granulation tissue and minimal necrotic tissue. Hydrocolloid dressings are occlusive, adhere to the wound, and promote autolytic débridement. Alginate dressings are derived from seaweed and can absorb 20 times their weight in fluid, so are good for draining ulcers. Silver impregnated dressings are used to decrease microbial count and improve healing. Although they have been used in infection-prone wounds, such as

burns and leg vein graft sites, their use in chronic wounds such as pressure ulcers is unclear, although data suggests that dressings may be changed less frequently saving clinician time, which offsets their expense. If stage III or IV pressure ulcers fail to progress from these therapies, consider using a negative pressure wound therapy such as a wound vac (GTPU EL I). However, hyperbaric oxygen therapy has not been shown to improve healing (GTPU EL I).

The primary complication of pressure ulcers is infection, resulting in poor healing, sepsis, or osteomyelitis. All ulcers are colonized and do not require antibiotics. However, if an ulcer does not progress in 14 days, infection should be considered (GTPU EL II). To prevent contamination with colonizing organisms, a culture should be obtained by deep aspiration or biopsy. Initiate treatment if greater than 10^5 colonies are present.³⁶

QUALITY INDICATOR AND LITIGATION

Google "pressure ulcer" and the search will return a list of law firm Web sites. Since pressure ulcers are considered preventable, their development is used as a quality indicator for long-term care facilities, hospitals, and effectiveness of a physician's care. It is argued that some pressure ulcers are unavoidable if the facility assessed the risk and implemented interventions or if the patient's medical condition (cachexia, metastatic cancer, severe peripheral vascular disease, or terminal illness) impedes healing or promotes development of ulcers.³⁷ Yet litigation over pressure ulcers in the United States continues to grow. A review of pressure ulcer cases against long-term care facilities showed that the number of cases increased 2.6 times from 1984 to 2002, with 87% of the plaintiffs receiving some type of recovery from the facility.³⁸ The mean recovery for the period 1984 to 1999 was \$3,359,259 compared to a mean of \$13,554,168 for the period 1999 to 2002.³⁸ In Great Britain, there is usually little to be gained in litigation as there would be little payable compensation. However, the National Health Service has a statutory procedure for handling pressure ulcer complaints in coordination with the Patient Advocacy and Liaison Service.³⁹

Today when a family appears with a digital camera to photograph a pressure ulcer, one can conclude that the photo will be used in future litigation. When it appears that a family is contemplating legal action, the entire health care team should work with the patient and family. [Table 110-1](#) summarizes risk management measures for pressure ulcers.⁴⁰ Pressure ulcer prevention programs also appear to limit litigation.³⁸

CONCLUSION

The best plan for pressure ulcer prevention and treatment continues to be informed health care providers that are always vigilant in their examination of the elderly patient's skin and assessment of risk factors. Older adults have decreased epithelial cell turnover, decreased dermal blood flow, impaired collagen synthesis, and loss of subcutaneous fat. These changes make the skin more susceptible to pressure ulcers from extrinsic factors, such as pressure, friction, shear, and moisture. Since impaired mobility often accompanies illness in elderly people who are frail, the clinical index for suspicion for pressure ulcers must be high and require pressure reducing protocols immediately.

Table 110-1. Minimizing Litigation from Pressure Ulcers

Principle	Action
Avoid defensiveness, anger, and confrontation.	If family request help in documenting pressure ulcer, immediately ask administration for assistance.
Involve the entire team, even administration.	Maintain professionalism and avoid blame and finger pointing.
Attempt to reestablish trust with the family and patient.	Meet frequently with family, try new interventions.
Educate the family and provide realistic goals.	Notify family as soon as pressure ulcer noted, inform them end stage diseases will affect healing.
Review the history and reassess the patient.	Prepare a time line of events leading up to the pressure ulcer, discuss alternative pressure relief devices.
Reevaluate the care plan.	The best care plans are individualized, clearly state the role of each discipline in treatment.
Obtain proper studies and consultations.	Doppler for evaluation of peripheral vascular disease for leg ulcers, swallow study for patient with poor nutrition
Document problem behaviors and provide appropriate interventions.	Be specific in record with date, time. When describing behaviors, be objective, consistent with terms, and nonjudgmental (family interfered with care, patient had a leave of absence during care).
Establish a feedback loop for quality improvement.	When pressure ulcer occurs, review policy and procedures.

Adapted from Levine JM, Savino F, Peterson M, et al. Risk management for pressure ulcers: when a family shows up with a camera. *J Am Med Dir Assoc* 2008;9(5):360–363.

KEY POINTS

1. As skin ages, there is decreased epithelial cell turnover, decreased dermal blood flow, impaired collagen synthesis, and loss of subcutaneous fat. These changes make the skin more susceptible to pressure ulcers.
2. Extrinsic factors causing pressure ulcers are pressure, friction, shear, and moisture.
3. An elderly patient, supine on a bed, generates pressure between 50 to 90 mm Hg at the heel and greater trochanter, well above the 32 mm Hg arterial capillary filling pressure.
4. Intrinsic factors causing pressure ulcers are poor nutrition, decreased sensory perception, low body mass, and impaired mobility and endothelial dysfunction.
5. Impaired mobility often accompanies illness in elderly people who are frail; the clinical index for suspicion for pressure ulcers must be high.
6. Pressure ulcers can be reliably staged using the National Pressure Ulcer Advisory Panel classification (from nonblanchable erythema to full thickness tissue loss with exposed bone, tendon, or muscle).
7. Management relies on relieving pressure and a variety of treatments; no one treatment has yet been reliably shown to be superior.
8. Pressure ulcer development can be considered an indication of negligent care and lead to litigation.

INSOMNIA

Epidemiology

In most,¹⁻⁶ but not all studies,⁷⁻¹⁰ the prevalence of insomnia has been found to increase with age. It has typically been reported in one quarter to one third of people aged 65 and over (see Table 111-1). However, as more stringent definitions of insomnia are increasingly being used, lower prevalence rates have been estimated, particularly when daytime impairment has been used as a criterion.^{3,4,6,11} Epidemiologic studies have also tended to show that insomnia is more common among older adult women than among older men^{1,2,6,8,12} (Table 111-1), although a few surveys have found no gender differences,^{7,10} or found differences for some but not all insomnia subtypes.¹³ However, a recent meta-analysis of gender differences in insomnia found that women were indeed at greater risk for insomnia than men, and that this discrepancy in female insomnia risk relative to males increased after age 65. Findings also suggest that insomnia is higher among lower income and lower educational attainment groups.^{1-4,8,9}

Insomnia appears to be widespread in medical settings, although it often goes unreported by patients and consequently underrecognized by providers.¹⁴⁻¹⁸ Prevalence rates of insomnia symptoms in primary care settings have ranged from 30% to 69%.^{14,15,17,18} In addition, one recent study found that 42% of new benzodiazepine prescriptions written for older adults in primary care settings were indicated for insomnia symptoms.¹⁶ In addition, those reporting sleep problems tend to show significantly higher consumption of health care resources than those who do not.¹⁹⁻²¹

Information on the incidence of insomnia in older adults (i.e., the rate of onset of new cases of insomnia) is more limited. Using strict criteria for insomnia (see Table 111-1), the U.S. National Institute for Mental Health (NIMH) catchment study found a modest age-related increase in the 1-year incidence of insomnia, with incidence rising from 5.7% among those between ages 18 to 25, to 7.3% among those aged 65 and over.¹¹ In one large study of insomnia incidence in a sample of 6899 participants, Foley et al reported age-related rises in insomnia incidence for both men and women.²² Within the age groups 65 to 74, 75 to 84, and 85 and over, this study found 3-year insomnia incidence rates of 12.4%, 15.1%, and 20.5% respectively, for men and 14.4%, 16.7%, and 13.7% for women.²² The overall annual rate was 5%. In a more recent study examining the incidence of specific insomnia subtypes in older adults, the annualized incidence of trouble falling asleep was found to be 2.8% over a mean follow-up period of 3.5 years, and significantly higher in women than in men (3.4% versus 1.9% per year).²³ The annualized incidence of frequent awakenings was noticeably higher at 12.3%, with no significant effect of gender.²³

Natural history of insomnia

The nature and duration of insomnia symptoms appear to change with advancing age. Table 111-2 shows the distribution of specific insomnia complaints among older adults (the categories are not mutually exclusive, as respondents may report more than one problem). Of the studies which report data for sleep onset, maintenance, and early morning awakenings (EMA), sleep maintenance problems are the most prevalent sleep complaint in the majority of these studies. Similar to other types of sleep complaints, rates of EMA show considerable variation across studies, ranging from 0.9% in China⁶ to 45% in Japan.⁷

Several longitudinal studies suggest that insomnia symptoms persist over time. Foley et al reported that of nearly 2000 individuals reporting insomnia at baseline, more than half continued to report symptoms at 3-year follow-up.²² One survey of general medical practice patients found that 69% of those with insomnia at baseline still had insomnia at 12-month follow-up.²⁴ Furthermore, persistence of insomnia symptoms was significantly associated with older age. Another study employing a sample of 1870 participants aged 45 to 65 years old from the general population found that at 12-year follow-up, 75% of those with insomnia at baseline still carried the diagnosis.²⁵

Changes in sleep architecture

Numerous studies have reported age-related changes in sleep architecture. However, many of these studies have reported conflicting findings about a number of sleep indices. Importantly, a recent analysis of data from the Sleep Heart Health Study (SHHS) provides normative data on sleep architecture in almost 2700 adults, including a sizeable proportion of older adults.²⁶ The SHHS employed rigorous standards for scoring and analyzing of polysomnography data, and excluded individuals using psychotropics, those with restless leg syndrome, and individuals with systemic pain conditions. Whether participants had a history of each of several common medical conditions, including cardiovascular disease, diabetes mellitus, and chronic lung disease, was also recorded. The large sample size and exclusion of individuals with comorbid conditions known to impact sleep architecture suggest that the SHHS findings may be broadly representative of normative sleep architecture data in middle-aged and older adults. Thus the SHHS data figure heavily into the discussion of structural changes in the sleep of older adults.

CONTINUITY OF SLEEP

The sleep of older adults is more fragmented than that of their younger counterparts, being characterized by more frequent shifts between sleep stages and more periods of wakefulness during sleep (see Figure 111-1). Polysomnogram (PSG) evidence suggests increased awakenings at night

¹Insomnia defined as "had trouble and was bothered a lot" by "trouble falling asleep or staying asleep"

^b... had trouble falling asleep, staying asleep, or waking too early" for a period of 2 weeks or more, and consulted a professional about it, took medication for it, or stated that it interfered with life a lot, and "... if it was not always the result of physical illness"

^c"trouble falling asleep and/or waking up too early and not being able to fall asleep again most of the time"

^d"often" or "always" has trouble getting to sleep, staying asleep, or waking too early

^emean sleep latency >30 minutes, mean wake after sleep onset >30 minutes, or waking up at least 30 minutes earlier than preferred >10 days per month, and DSM-IV criteria met for insomnia disorder

^fdifficulty falling asleep, disrupted sleep, early morning awakenings, or nonrestorative sleep, at least one of which occurs 3+ days per week

^gDSM-IV criteria met for insomnia disorder

^hdifficulty falling asleep, waking repeatedly, or "waking up and finding it difficult to fall back asleep," at least one of which occurring "often" (5–15 times per month) or "almost always" (16–30 times per month)

ⁱdifficulty falling asleep, staying asleep, or nonrestorative sleep and daytime impairment

^jsleep latency >30 minutes or (wake after sleep onset > 3 times per night or early morning awakenings > 2 hours earlier than usual), either of which occurring 3+ times per week and accompanied by either poor subjective sleep quality or a moderate or greater degree of daytime dysfunction

^ktrouble sleeping due to sleep latency >30 minutes, "night awakenings," or early morning awakenings, at least one of which occurring 3+ times per week

^lone or more insomnia symptoms and daytime consequences occurring one or more times per week

^mregularly occurring insomnia or trouble sleeping in the past 12 months

ⁿ"fitful and disturbed sleep" in the past 30 days.

even among healthy older adults who do not complain about their sleep.²⁷ Nocturnal awakenings tend to be more common among men than women.²⁶ "Microarousals" (2 to 15 second bursts of alpha activity) have also been observed in the electroencephalograms (EEG) of sleeping older adults.²⁸ Microarousals, which are not accompanied by behavioral awakenings, are associated with daytime sleepiness.²⁸ In the SHHS, the arousal index (total number of EEG arousals from sleep divided by total sleep time) increased significantly with advancing age.²⁶

DURATION OF SLEEP

Although sleep disruption becomes more pronounced with age, sleep duration appears to experience a decline. Van Cauter et al found that in a sample of men ages 16 to 83, total sleep time decreased on average by 27 minutes per decade from midlife until the eighth decade.²⁹ As a result, sleep efficiency (time spent asleep divided by time spent in bed) also tends to decrease.²⁶ A recent meta-analysis of 65 objective sleep studies representing 3577 participants ages 5 to 102 found that in adults, both total sleep time and sleep efficiency decreased with age.³⁰

DEPTH OF SLEEP

With advancing age, there is a reduction in EEG slow waves (stages 3/4 or slow wave sleep; SWS; Figure 111-1).³⁰ In addition to a decrease in SWS, increases in stages 2 (light sleep) and 1 (drowsiness) have been reported.³⁰ SHHS data suggests that there are gender differences in sleep architecture in that men have lighter sleep as they age relative to women.²⁶ Specifically, the men had more Stage 1 and 2 sleep with increasing age, whereas there was no detectable effect of age on Stage 1 and 2 percentages in women. In addition, there were gender effects on SWS. Men had proportionally less SWS compared with women in each age group, and there was a steep and significant age-related decline in SWS in men, but no significant age-related changes in percentage of SWS in women. This putative gender effect on age-related SWS changes may explain why Ohayon et al found no significant change in SWS after age 60 in their meta-analysis of relevant studies.³⁰ Therefore, while there may be changes in depth of sleep with age, these changes may be confined to men, or at least more evident in males.

In addition, studies of auditory awakening thresholds (the minimum amount of noise required to wake a sleeping

person) show qualitative changes in the depth of individual sleep stages. It has been shown, for example, that during stages 2, 4, and REM, older people are more easily awakened by noise (i.e., have lower auditory awakening thresholds) than are younger people (this despite reductions in the hearing sensitivity of older subjects).³¹ However, in a study of the effects of aircraft noise on the sleep of people living near a major airport, Horne et al³² found that while awakenings in response to aircraft noise were most common in the oldest age group (ages 50 to 70), other factors, such as having children in the household, appeared to be more influential than aging in determining arousals.

REM SLEEP

The proportion of REM sleep has also been shown to decline with age.³³ Van Cauter et al found that REM sleep was reduced by as much as 50% in older adults compared with their younger counterparts.²⁹ However, Ohayon et al did not replicate this finding; they found that while REM sleep decreased between young and middle adulthood, percentage

of REM sleep remained stable over time in adults older than 60.³⁰ A recent meta-analysis by Floyd et al, who used an analytic approach designed to detect nonlinearity in age-related REM change, found a small but significant decline in REM until the mid-70s, followed by a small increase in REM sleep percentage. Taken together, these studies suggest that REM is relatively well preserved in older adults, that if there is a decrease in REM sleep in older adults, it is modest, and that this small decline in REM sleep may begin to stabilize during the seventh decade of life.

The aging circadian rhythm

The circadian rhythm itself also shows evidence of age-related fragmentation, with sleep becoming more desynchronized and likely to impinge on daytime activities.^{34,35} Recent research suggests that an age-related reduction in sleep promotion of the circadian pacemaker, along with decreased homeostatic pressure for sleep in older adults, may be involved in this desynchronization.³⁶

Comorbidity

MEDICAL COMORBIDITY

There is a strong association between insomnia complaints and chronic medical conditions. Foley et al found that only 7% of new cases of insomnia in older adults occurred in the absence of health-related risk factors.²² In community surveys of older adults, poor self-reported health, nocturnal micturition, and chronic pain are frequently associated with increased risk of insomnia.^{3,6,8,10} In 2003, the National Sleep Foundation survey of adults aged 65 and older found a significant positive correlation between insomnia and current medical conditions, including cardiac and pulmonary disease.³⁷ In studies examining the prevalence of insomnia in specific medical conditions, it was found that 31% of arthritis and 66% of chronic pain patients report difficulty falling asleep; 33% of diabetes, 57% of end-stage renal disease, 81% of arthritis, and 85% of chronic pain patients report difficulty staying asleep; and 44% of cancer, 45% of gastroesophageal reflux disease, and 50% of patients with congestive heart failure report sleep initiation and maintenance difficulties.^{38–44} In knee pain and osteoarthritis, predictors of greater insomnia complaints included a greater number of involved joints and knee pain severity.⁴³ In chronic obstructive pulmonary

disease (COPD), insomnia also appears related to severity. A group of patients with moderate to severe COPD with demonstrated reduced oxygen saturation also reported poor sleep quality.⁴⁵

PSYCHIATRIC COMORBIDITY

Psychiatric conditions are also highly associated with insomnia. Studies estimate that over 40% of individuals with persistent hypersomnia or insomnia have a psychiatric diagnosis.¹¹ Having insomnia has been associated with increased risk of onset of depression in the future, particularly for older women.^{46,47} In one follow-up study on 1053 men who provided information on sleep habits in medical school and who had been followed since graduation, the authors found that those who went on to develop depression by 34-year follow-up were more likely to report experiencing insomnia during medical school.⁴⁸ Although the relationship between insomnia and depression has been more consistently studied, recent surveys also suggest that insomnia is also often associated with anxiety disorders in older adults.^{24,49} Recent data from Ohayon et al,⁵ which used a large community survey of individuals from four European countries, suggest that while insomnia typically precedes or cooccurs with the onset of depression, insomnia symptoms are more likely to develop at or after the onset of an anxiety disorder.

Treatment

Although pharmacologic treatments are available for insomnia, recent evidence suggests that behavioral approaches to insomnia treatment may be more effective than medications for older adults,^{50,51} and thus may be considered either as a first-line treatment, or in combination with medication.⁵² Combination treatment may allow patients to gain immediate relief from medication, whereas long-term relief of insomnia may be best achieved with behavioral treatment.

BEHAVIORAL TREATMENT

Behavioral treatment of insomnia, which involves a set of techniques collectively referred to as cognitive behavioral therapy (CBT), typically begins with psychoeducation about insomnia. During this phase, the behavioral model of insomnia is discussed, and factors that contribute to insomnia, such as heredity, medical and psychiatric comorbidity, and poor sleep hygiene, are introduced. Sleep hygiene involves promoting good sleep habits and avoiding sleep-incompatible behaviors in the bed/bedroom (e.g., establishing a set wake-up time, no napping during the day, keeping the bedroom at a cool temperature at night to promote sleep), which patients are instructed to adhere to in order to improve their sleep. Sleep hygiene instructions are tailored to each patient depending on his or her own sleep habits. The most frequently studied components of CBT for insomnia are sleep restriction and stimulus control. Although these components have sometimes been implemented as stand-alone treatments for insomnia, they are typically employed together in the context of the CBT approach to insomnia. Sleep restriction entails instructing patients to limit the time they spend in bed to the average number of hours slept per night plus 15 minutes (e.g., if a participant reports sleeping 6.5 hours per night on average over the past week, they will be instructed to spend 6.75 hours in bed per night). Time spent in bed is lengthened, typically in

15-minute increments, as sleep efficiency improves. Patients' time in bed is stabilized once their weekly sleep efficiency reaches 85% to 90% or higher, which is considered within the normal range. Stimulus control is used to decrease the alertness and arousal that many individuals with insomnia feel while in bed, and to increase the association of bed with sleepiness. It entails instructing the patient to sleep only in bed, to get out of bed whenever he or she feels alert and aroused or when awake more than 10 to 15 minutes, and to return to bed only when he or she begins to feel sleepy again. Although CBT for insomnia typically totals 6 to 8 sessions, abbreviated forms of CBT have been tested. One drawback of CBT is that clinical effects of treatment may take 2 to 4 weeks to emerge.⁵³

PHARMACOLOGIC TREATMENT

Many classes of medication have been used to treat insomnia, including sedative-hypnotics, antidepressants, antipsychotics, antihistamines, and anticonvulsants, some of which are prescribed "off-label." However, a recent state-of-the-science report on insomnia from the National Institutes of Health concluded that there is no systematic empirical support for the effectiveness of antipsychotics, antihistamines, barbiturates, anticonvulsants, or antidepressants for treating insomnia.⁵² In addition, the report expressed concern about the side effects of some of the off-label agents commonly used for insomnia, suggesting that the risks outweigh the benefits. Some of the risks associated with use of pharmacologic treatment of insomnia, such as increased risk of falls, may be particularly concerning for older adults. A newer class of medications known as type-1 γ -aminobutyric acid (GABA) benzodiazepine receptor agonists, which includes zaleplon, eszopiclone, zolpidem, and zolpidem MR, has been shown to be effective and safe in treatment of insomnia in older adults.^{54–57} A melatonin agonist, ramelteon, has also been approved for insomnia associated with difficulty falling asleep, and has shown promise in older adults.⁵⁸

Sleep-disordered breathing

Sleep-disordered breathing (SDB) refers to a range of periodic respiratory events that occur while asleep, from mild snoring to partial cessation of airflow (hypopnea) to complete airflow cessation (apnea). The severity of SDB is measured by the apnea hypopnea index (AHI). Data suggests that the prevalence of SDB increases with age.^{59,60} Older individuals with dementia, and institutionalized elderly patients, have especially high rates of SDB, although reasons for these findings are not entirely clear.⁶¹ One factor contributing to increased prevalence of sleep-disordered breathing in those with certain forms of dementia may be that areas of the brainstem involved in respiration and other autonomic functions are affected by the disease process in dementias.

Medical and behavioral risk factors for SDB include obesity, male gender, increasing age, family history, smoking, alcohol consumption, craniofacial features, and upper airway configuration.⁶² In those with SDB, primary symptoms include snoring and excessive daytime sleepiness, which arise due to recurrent arousals from sleep and sleep fragmentation. About half of regular snorers have some degree of SDB, and snoring may also be a risk factor for SDB.⁶³ Other common presentations include daytime napping and falling asleep at inopportune times during the day. Functional

impairment, particularly in social and occupational areas, is common in those with SDB. Cognitive deficits, such as short-term memory problems or difficulty concentrating, may also occur; in those with baseline cognitive impairment, these symptoms may be exacerbated.⁶⁴ SDB has been linked to cardiovascular disease, including coronary artery disease, heart failure, and stroke.^{65–67}

Of the treatment options for SDB, continuous positive airway pressure (CPAP) is considered the gold standard. CPAP improves the symptoms of SDB, along with improving cognitive function in older adults.^{68,69} However, adherence can sometimes be an issue because some patients find the mask inconvenient or uncomfortable; these patients should work with their provider to find a model that is tolerable for them. Alternatives to CPAP include dental devices and surgery; however, the outcomes for these methods are typically not as favorable as for CPAP, particularly in older adults. Patients should also be educated on the importance of healthy body weight, smoking cessation, and alcohol consumption because each contributes to favorable outcome of SDB. Medications such as long-acting benzodiazepines and narcotics should be avoided if possible because they have been shown to increase the frequency and duration of apneas.

Periodic limb movements in sleep/restless leg syndrome

Periodic limb movements in sleep (PLMS) are repetitive leg jerks or kicks that occur while asleep. These movements typically occur in clusters approximately 30 seconds apart, and can recur throughout the night, leading to brief arousals and fragmented sleep. Consequently, many of these patients may have complaints of insomnia, nonrestorative sleep, and excessive daytime sleepiness. Diagnosis is based on a periodic limb movement index (movements per hour during sleep) greater than 5. Restless leg syndrome (RLS) is commonly comorbid with PLMS, and is characterized by uncomfortable, “creepy crawly” sensations in the legs that typically occur during resting, wakeful states. Those afflicted find that moving the legs in response to these sensations temporarily relieves discomfort caused by these sensations. RLS also occurs while the patient is resting in bed, and may interfere with sleep initiation. Roughly 80% of adults with RLS also meet diagnostic criteria for PLMS.⁷⁰ The cause of both PLMS and RLS is not well understood, although RLS may be more likely to occur with iron deficiency (such as in pregnancy), radiculopathy, uremia, and peripheral neuropathy.

The prevalence of PLMS increases significantly with advancing age, with one study finding that 45% of older adults experiencing symptoms consistent with the diagnosis.⁷¹ The presence of RLS also increases with age.⁷² Although the gender distribution is roughly equal in PLMS, about twice as many older women experience RLS compared with men.⁷³

Evidence-based treatment for PLMS/RLS includes agents that target leg movements or associated arousals. At present, dopamine agonists are recommended as a first-line treatment because they have been found to reduce the number of kicks and associated arousals.^{74,75} Ropinirole and pramipexole are the only dopamine agonists currently approved by the U.S. Food and Drug Administration for the treatment of RLS.

Rapid eye movement (REM) sleep behavior disorder

Rapid eye movement sleep behavior disorder (RBD) occurs when the gross motor paralysis typically associated with REM sleep is intermittently absent. As a result, the sleeper may laugh, yell, kick, punch, or engage in other elaborate behaviors as they respond to dream content. RBD-related behavior typically occurs during the second half of the night, when REM periods are more frequent. These behaviors can often be violent or aggressive, and can result in injury to the patient or to bed partners. RBD occurs almost exclusively in older males,⁷⁶ and is highly prevalent in Parkinson's disease and related neurodegenerative conditions. In some cases, RBD may signal the onset of one of these neurologic conditions, and may occur years before diagnosis.^{76,77} In cases of acute onset, RBD has been associated with posttraumatic stress disorder.⁷⁸ The overall estimated prevalence of RBD is 0.5% in the general population.⁷⁹

Treatment of RBD is primarily pharmacologic, although strategies that decrease the likelihood of injury include placing pillows or cushions around the sleeper's bed, or having partners sleep in another room if behaviors are especially violent, can also be helpful. The pharmacologic treatment of choice is the clonazepam, a sedating benzodiazepine, which has been found to be beneficial for patients with RBD in up to 79% of cases.⁸⁰ In patients with RBD for whom clonazepam is contraindicated, melatonin has also shown promise in RBD treatment.⁸¹

Sleep in dementia

Demented patients have a high prevalence of disturbed sleep compared with healthy older adults, with 19% to 44% experiencing sleep disturbances. Sleep features in dementia can include abnormal nighttime behavior, wandering and confusion, agitation (“sundowning”), and daytime napping. These symptoms may be more prominent in institutionalized demented patients. One study showed that demented older adults living in institutions may not spend a single hour completely awake or asleep during a 24-hour period.⁸² One contributing factor to this may be inadequate light exposure because previous studies have found that institutionalized patients with adequate light exposure had fewer sleep disruptions.⁸³ Many demented older adults have a comorbid sleep disorder such as SDB or a medical condition that contributes to the sleep disturbance such as chronic pain; the effects of medications to treat medical or psychiatric conditions may also interfere with sleep. However, sleep disturbance in demented patients may also occur in the absence of any contributing comorbid condition, and may be related to the dementing process itself. Supporting evidence includes findings that severity of sleep disturbance is positively correlated with dementia severity.⁸²

After a thorough assessment of possible contributing factors to sleep disturbance, treatment should focus on the responsible sleep disorder, if one is detected. Nonpharmacologic interventions may include the introduction of increased activity via exercise or social activity, which may address the problem of unintended dozing during the day, particularly in institutionalized demented patients. Restriction of time in bed, increasing bright light exposure during the day, decreasing light at night, and making the environment more

quiet at night have all been shown to improve sleep in this population will address poor sleep hygiene and inadequate light exposure. Nonpharmacologic approaches are preferable to medications for older individuals with dementia.

SUMMARY

Aging is associated with significant changes in sleep depth, duration, and architecture. Sleep disorders are often more common in older adults and thus may contribute to insomnia complaints in aging populations. However, sleep problems may also arise as a result of changes in the circadian rhythm, medical or psychiatric comorbidity, and the side effects of medications. Diagnosis of occult sleep disorders requires a thorough sleep and medical history, supplemented by overnight sleep recording when appropriate. Treatment may include somatic interventions, behavioral strategies, or combination treatment depending on the disorder. Successful treatment may significantly improve sleep and daytime functioning in older adults.

KEY POINTS

Sleep, Aging, and Late-Life Insomnia

- Sleep disorders are common in older adults.
- Sleep architecture changes with age, with sleep becoming lighter.
- Most sleep problems are a function of medical and psychiatric illness, medications, and primary sleep disorders, and are not a function of age per se.
- Diagnosis of sleep disorders requires a thorough sleep and medical history. For some primary sleep disorders, an overnight sleep recording should be considered.
- Treatment may include behavioral strategies, pharmacologic treatment, or combination of both.

Malnutrition in Older Adults

Larry E. Johnson

Dennis H. Sullivan

Malnutrition may refer to both deficiencies (such as protein, calorie, vitamin, mineral, etc.) and excesses (e.g., obesity and hypervitaminosis).¹ This chapter will focus on common nutritional concerns in older adults: protein-energy undernutrition (PEU), hydration, artificial feeding, and end-of-life nutrition. Vitamin health will be covered in Chapter 82 and obesity (i.e., overnutrition) in Chapter 83. As people age, the risks for undernutrition increase. Five to 10% of community-dwelling older adults are undernourished.² Undernutrition in hospitalized elderly persons is frequently unrecognized and untreated,³ for example, hospitalized patients are often not fed for extended periods of time in preparation for various procedures. In one study of 700 older hospitalized men, 21% had a daily intake of less than 50% of maintenance requirements, and this low intake was associated with an eight times higher mortality risk.⁴ Estimates for the prevalence for PEU in long-term and subacute care facilities vary from 12% to 85%.^{5–8} As is true within hospitals, staff in these facilities also fail to recognize undernutrition.⁹

Weight loss is a cardinal sign for PEU and can develop in association with many disorders, including cancer, heart failure, pulmonary disease, diabetes mellitus, and thyroid disease. Detection of weight loss is important in the care of older adults. Older men who lose more than 3 kg/yr over 5 years have a 3.5 times greater mortality risk than those who have no weight change.¹⁰ Losing 5% of weight in any one month is associated with a tenfold higher risk for death in long-term care residents compared with residents who gain weight.¹¹ Even much slower weight loss, such as 5% over 1 year¹² or 10% over several decades¹³ is associated with an increased mortality risk.

Characterizing undernutrition using terms such as marasmus and kwashiorkor, clinical syndromes originally described in third-world children, has also been used with adult malnutrition. It is proposed that a distinction be made between persons who have “simple” starvation (which may be the same as what is referred to as marasmus) from those who have inadequate caloric intake in the presence of inflammatory states (which may be subclinical). This latter syndrome has variably been referred to as cachexia, kwashiorkor, hypoalbuminemic malnutrition, or wasting disease.^{14,15} Although far more needs to be learned about the metabolic basis of PEU that develops in association with other disease states, there is growing evidence that disease-induced inflammation triggers a catabolic response that is relatively refractory to nutritional support alone. Even when protein and energy intakes are higher than estimated requirements, there is often continued catabolism of both fat and lean body mass, particularly skeletal muscle (see Chapter 73).¹⁶ In addition, it is important to be wary of trying to distinguish voluntary from involuntary weight loss, particularly in the frail older adult¹⁷; any weight loss in this population, even in the obese, should be considered potentially serious. On the other hand, stable weight or weight gain in physically inactive older adults who are obese may mask muscle loss, leading to the condition of sarcopenic obesity.^{18,19}

Failure to thrive and frailty

Weight loss and malnutrition are often associated with other physiologic and functional impairments and increased mortality. “Failure to thrive” is a poorly defined term that has been variously characterized as a syndrome in older adults accompanied by weight loss, anemia of chronic disease, reduced immune function, and low albumin and cholesterol, along with functional and cognitive decline.^{20–22} This syndrome may be part of the spectrum of inflammation-induced catabolism described above with marked cachexia representing an advanced stage. Frailty is a related, but better defined, concept.²³ Indicators of frailty include unintended weight loss (defined as >5% weight loss over the previous 1 to 2 years), weakness/impaired walking, exhaustion, and poor physical activity.^{23,24} Studies of both older males and females from the Cardiovascular Health Study and the Women’s Health Initiative Observational Study have found that frailty is associated with increased risk of death, hip fracture, disability, and hospitalization.^{23,24} The importance of a dysregulated inflammatory response as a contributor to frailty in older adults is being investigated. Weight loss may also precede the diagnosis of Alzheimer’s disease.²⁵

The anorexia of aging

With advancing age, appetite and food intake steadily decline, even in the absence of serious acute or chronic disease. Paralleling the change in appetite, there is usually an associated decline in energy expenditure (i.e., level of physical activity). Whether the declines in energy intake and expenditure are causally related is not known with certainty. However, both contribute to the progressive weight loss seen in many older adults after about age 60 to 70 years. The magnitude of this problem is indicated by population-based studies that reveal a progressive decline in the prevalence of overweight and obesity, and an increase in the prevalence of underweight (BMI < 18.5) with each decade of life after age 60.²⁶ With advancing age, the physiologic processes that regulate body weight and that link nutrient intake and energy expenditure apparently lose their compensatory responsiveness to changes in energy demands.²⁷ This was demonstrated in one study of young and old adults who were placed on energy restricted diets. Both groups lost weight. However, at the end of the fast, the older adults regained their lost weight more slowly and less completely than the younger subjects.²⁸ These findings suggest that a reduced ability to regulate appetite and food intake may contribute to the progressive loss of weight that many older individuals experience as they age.

A thorough assessment of any older adult who is losing weight is mandatory to determine if there are potentially reversible causes and to assess the severity of the anorexia.²⁹ Sometimes even an extensive evaluation fails to find any contributing causes for the weight loss. The term “Anorexia of Aging” has been coined to describe such older adults with isolated anorexia. It is hypothesized that this age-associated anorexia may result from any number of physiologic changes

seen in older adults including impaired gastric motility, exaggerated adiposity signals from leptin and insulin, and/or postprandial anorexigenic signals from cholecystokinin (CCK) and peptide YY (PYY).³⁰ It may also entail a cytokine-dependent process as many older adults have elevated blood cytokine levels.^{16,31}

Protein-energy undernutrition (PEU)

There is no “gold standard” laboratory test for PEU. Laboratory tests of so-called nutritional biochemical markers (e.g., serum albumin, transthyretin/prealbumin, α -acid-1 glycoprotein, or transferrin) have poor specificity. The synthesis and distribution of all of these serum proteins are probably more strongly affected by cytokine-associated inflammation (as “acute phase reactants”) than nutrient intake. The sensitivity of these markers is also low. This is particularly true of serum albumin. The serum concentration of albumin may remain near normal during uncomplicated slow starvation. Thus it is possible to die of starvation with a normal serum albumin concentration. However, because of their responsiveness to physiologic stress, serum albumin and some of the other serum secretory proteins are important health status indicators; a low level is associated with increased morbidity and mortality, independent of nutritional status.³² No biomarker is readily available to distinguish simple starvation from cachexia, and measuring nonspecific markers for inflammation, such as erythrocyte sedimentation rate or C-reactive protein, is not recommended.

Nutritional screening

There are a variety of screening tools to assess for nutritional risk. These instruments do not necessarily confirm that an individual has malnutrition, but they are useful for identifying those who need a more thorough nutritional evaluation. The Mini Nutritional Assessment (MNA) (Figure 112-1) has a six-question screening test.³³ If an older adult scores at nutritional risk, there are 12 more questions (including estimates of consumption, self-assessment, and anthropometric measures of midarm and calf circumference) to aid in assessing the probability of malnutrition. The Malnutrition Universal Screening Tool (MUST) (Figure 112-2) has also been validated for older adults and has alternative measurements for patients whose height cannot be measured or who cannot be weighed (for detailed information: www.BAPEN.org.uk).^{34,35} In the United States, nursing home residents must have a minimum data set (MDS) completed within 14 days of admission, at any major change in condition, and at yearly intervals.³⁶ This document includes an assessment for nutritional risk, including chewing or swallowing problems, or mouth pain; complaints about the taste of food or complaints of hunger; IV fluids or hyperalimentation; feeding tube, mechanically altered or therapeutic diets, or oral syringe feeding; between meal supplements; adaptive feeding equipment; planned weight change programs; an estimate of percent calories consumed over the previous 7 days; height and weight over the previous 30 days; and weight loss or gain over the past 30 and 180 days. The MDS regulations for nursing home residents require a thorough evaluation for any resident who loses 5% of weight in 1 month or 10% in 6 months.³⁶

Accurate estimates of a patient’s height, weight, and weight loss are important. These measurements are sometimes difficult to obtain. Direct measurement of height may not be valid due to the presence of spine curvature. An older patient’s memory of current or maximum adult height is frequently inaccurate; formulas to estimate height using demippan (half total arm span), ulna length, or knee height (using special calipers) are available. Identification of weight loss, using the MDS guidelines above, and an estimate of calorie intake, are important in identifying PEU. Weight measurement accuracy is highly dependent on the skill of the examiner; weights obtained by trained persons maintaining strict adherence to protocol are more reliable and can differ substantially from those obtained routinely by nursing staff. On the other hand, relying only on a patient’s weight or body mass index (BMI) may not identify individuals who are malnourished but have fluid overload or sarcopenic obesity.

Chewing and swallowing

Healthy aging is generally associated with little clinical change in chewing and swallowing. Many medications (particularly anticholinergic and antimuscarinic drugs), Sjögren’s syndrome, and radiation therapy for head and neck cancers decrease salivation, causing xerostomia and increasing the risk of dental caries and hampering chewing and swallowing.³⁷ Poor dental hygiene, missing teeth, poorly fitting or missing dentures are common, and cause reduced food intake, and require the evaluation of a dentist.³⁸ Proper routine dental care for the uncooperative patient requires training for the family, nursing staff, and the dentist. Finding a dentist especially trained in examining and treating resistive patients can be challenging if a gerodontist is not available.

The gastrointestinal tract generally shows little dramatic change with aging, though the accumulation of multiple small changes may contribute to the development of the anorexia of aging (see previous discussion).³⁹ Esophageal motility may be impaired (“presby-esophagus”) with less efficient peristalsis. Medication transit and absorption may be affected by this change and pills may remain for a prolonged period in the esophagus of older persons who are supine. It is therefore recommended that older patients take more fluids with medications and then remain upright for at least 30 minutes rather than lying down immediately. This is a particularly important issue for older adults taking medications known to cause esophageal irritation. Gastroesophageal reflux and hiatal hernia increase with aging, with associated dyspepsia. In most cases, symptoms are managed with dietary avoidance of food that increase symptoms; universal avoidance of hot and spicy foods is not necessary. Widespread use of antacids for dyspepsia is extremely common; antacids reduce gastric symptoms but can increase the risk of pneumonia (stomach acid is valuable in killing bacteria that are swallowed) and may reduce absorption of some vitamins and minerals (e.g., B₁₂ and iron) in very frail persons.^{40,41} Further workup of uncomplicated dyspepsia is necessary only if alarm symptoms or signs appear such as weight loss, fall in hemoglobin, or gastrointestinal bleeding (see p. 623).

Dysphagia (or difficulty eating) can arise as a consequence of problems in any phase of eating including the anticipatory phase, preparatory phase, mastication (the oral phase), swallowing (pharyngeal phase), and/or passage of food or

Mini Nutritional Assessment MNA[®]

Last name:	First name:	Sex:	Date:
Age:	Weight, kg:	Height, cm:	I.D. Number:

Complete the screen by filling in the boxes with the appropriate numbers.

Add the numbers for the screen. If score is 11 or less, continue with the assessment to gain a Malnutrition Indicator Score.

Screening

A Has food intake declined over the past 3 months due to loss of appetite, digestive problems, chewing or swallowing difficulties?
0 = severe loss of appetite
1 = moderate loss of appetite
2 = no loss of appetite

B Weight loss during the last 3 months
0 = weight loss greater than 3 kg (6.6 lbs)
1 = does not know
2 = weight loss between 1 and 3 kg (2.2 and 6.6 lbs)
3 = no weight loss

C Mobility
0 = bed or chair bound
1 = able to get out of bed/chair but does not go out
2 = goes out

D Has suffered psychological stress or acute disease in the past 3 months
0 = yes
2 = no

E Neuropsychological problems
0 = severe dementia or depression
1 = mild dementia
2 = no psychological problems

F Body Mass Index (BMI) (weight in kg)/(height in m²)
0 = BMI less than 19
1 = BMI 19 to less than 21
2 = BMI 21 to less than 23
3 = BMI 23 or greater

Screening score (subtotal max. 14 points)
12 points or greater Normal – not at risk – no need to complete assessment
11 points or below Possible malnutrition – continue assessment

Assessment

G Lives independently (not in a nursing home or hospital)
0 = no
1 = yes

H Takes more than 3 prescription drugs per day
0 = yes
1 = no

I Pressure sores or skin ulcers
0 = yes
1 = no

J How many full meals does the patient eat daily?

0 = 1 meal
1 = 2 meals
2 = 3 meals

K Selected consumption markers for protein intake

• At least one serving of daily products (milk, cheese, yogurt) per day yes no
• Two or more servings of legumes or eggs per week yes no
• Meat, fish or poultry every day yes no
0.0 = if 0 or 1 yes
0.5 = if 2 yes
1.0 = if 3 yes .

L Consumes two or more servings of fruits or vegetables per day?

0 = no
1 = yes

M How much fluid (water, juice, coffee, tea, milk...) is consumed per day?

0.0 = less than 3 cups
0.5 = 3 to 5 cups
1.0 = more than 5 cups .

N Mode of feeding

0 = unable to eat without assistance
1 = self-fed with some difficulty
2 = self-fed without any problem

O Self view of nutritional status

0 = views self as being malnourished
1 = is uncertain of nutritional state
2 = views self as having no nutritional problem

P In comparison with other people of the same age, how does the patient consider his/her health status?

0.0 = not as good
0.5 = does not know
1.0 = as good
2.0 = better .

Q Mid-arm circumference (MAC) in cm

0.0 = MAC less than 21
0.5 = MAC 21 to 22
1.0 = MAC 22 or greater .

R Calf circumference (CC) in cm

0.0 = CC less than 31
1 = CC 31 or greater

Assessment (max. 16 points) .

Screening score

Total Assessment (max. 30 points) .

Malnutrition Indicator Score

17 to 23.5 points at risk of malnutrition
Less than 17 points malnourished

Figure 112-1. The Mini Nutritional Assessment (MNA). The initial assessment is a six-question screening test. If an older adult scores at nutritional risk (11 points or less), there are 12 more questions to aid in assessing the probability of malnutrition. A score of 17 to 23.5 indicates a high risk for malnutrition and less than 17 indicates probable malnutrition.^{33,130,131} (Reprinted with permission from Societe des Produits Nestle S.A., Vevey, Switzerland.)

BAPEN

Advancing Clinical Nutrition

'Malnutrition Universal Screening Tool' ('MUST')

MAG

Malnutrition Advisory Group
A Standing Committee of BAPEN

BAPEN is registered charity number 1023927 www.bapen.org.uk

'MUST'

'MUST' is a five-step screening tool to identify **adults**, who are malnourished, at risk of malnutrition (undernutrition), or obese. It also includes management guidelines which can be used to develop a care plan.

It is for use in hospitals, community and other care settings and can be used by all care workers.

This guide contains:

- A flow chart showing the 5 steps to use for screening and management
- BMI chart
- Weight loss tables
- Alternative measurements when BMI cannot be obtained by measuring weight and height.

The 5 'MUST' Steps

Step 1

Measure height and weight to get a BMI score using chart provided. *If unable to obtain height and weight, use the alternative procedures shown in this guide.*

Step 2

Note percentage unplanned weight loss and score using tables provided.

Step 3

Establish acute disease effect and score.

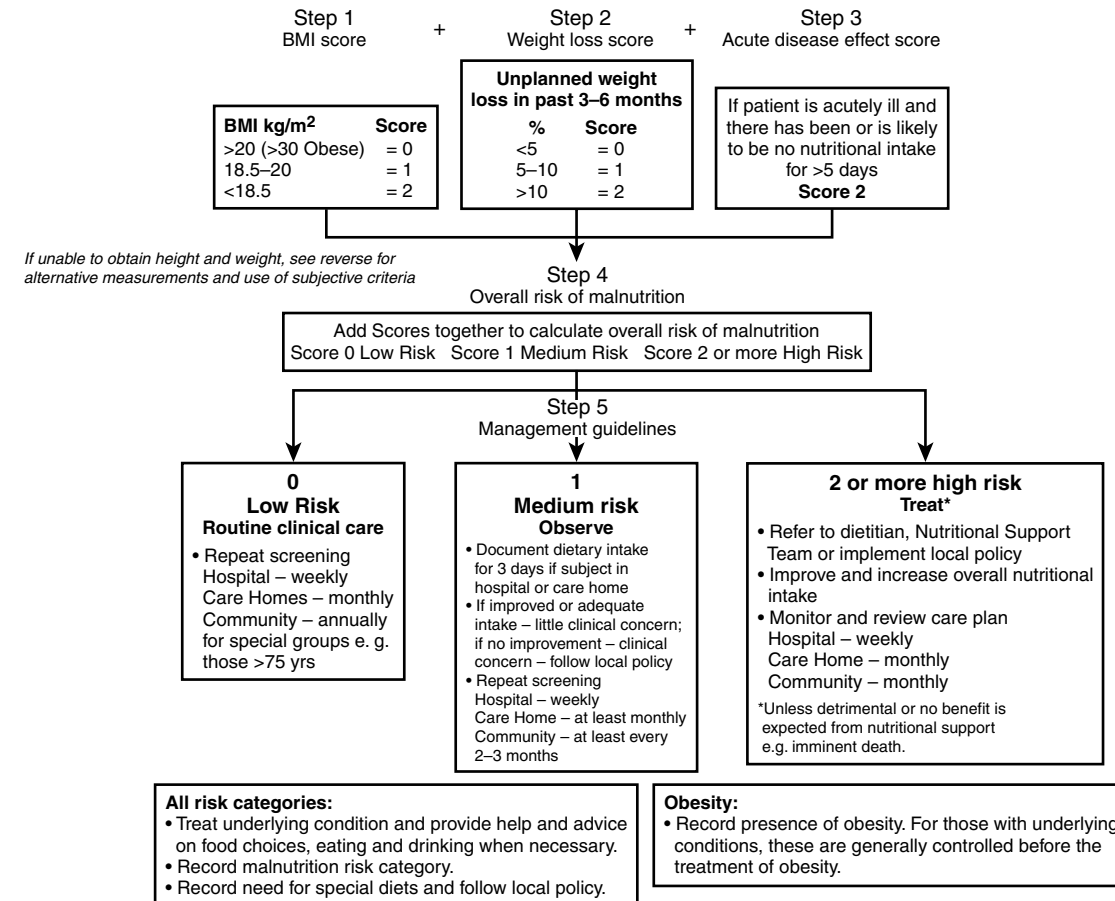

Step 4

Add scores from steps 1, 2 and 3 together to obtain overall risk of malnutrition.

Step 5

Use management guidelines and/or local policy to develop care plan.

Please refer to *The 'MUST' Explanatory Booklet* for more information when weight and height cannot be measured, and when screening patient groups in which extra care in interpretation is needed (e.g. those with fluid disturbances, plaster casts, amputations, critical illness and pregnant or lactating women). The booklet can also be used for training. See *The 'MUST' Report* for supporting evidence. Please note that 'MUST' has not been designed to detect deficiencies or excessive intakes of vitamins and minerals and is of **use only in adults**.

Re-assess subjects identified at risk as they move through care settings

See *The 'MUST' Explanatory Booklet* for further details and *The 'MUST' Report* for supporting evidence.

Figure 112-2. The Malnutrition Universal Screening Tool (MUST) has been validated for older adults, with low risk, medium risk, and high malnutrition risk.^{34,35} Reproduced with the kind permission of BAPEN (British Association for Parenteral and Enteral Nutrition). (For further information on this tool contact: www.BAPEN.org.uk)

fluids down the esophagus (esophageal phase).⁴² Details of the neurophysiology of swallowing can be found elsewhere.⁴³ Dysphagia may include signs and symptoms of difficulty chewing or swallowing, with the sensation of food getting stuck in the throat or chest and/or coughing or choking with swallowing. Patients with these symptoms require a thorough history and physical examination, especially of the head and neck regions to identify possible causes. The prevalence of dysphagia in community dwelling elderly varies from 7% to 28% (increasing with frailty)⁴⁴ but may also be relatively common even in younger adults.⁴⁵ Persons with degenerative neurologic disorders such as Alzheimer's disease and other dementias may have a tonic bite (refusing to open their mouths when fed) or hold food in the mouth for prolonged periods (swallowing apraxia). However, dysphagia may be present with less obvious symptoms, and should be considered whenever there is weight loss, decreased appetite, prolonged eating time, food falling from the mouth, food debris staying in the mouth, nasal or oral regurgitation, wet voice, or hoarseness after eating.⁴⁶ Any possible symptoms of oral or pharyngeal stage dysphagia that do not quickly resolve should be assessed by a speech-language pathologist (SLP) or an ENT (ears, nose, throat) specialist. Esophageal stage problems (e.g., esophageal cancer, candidiasis, reflux esophagitis, Zenker's diverticulum, hiatal hernia, varices, Barrett's esophagus, Schatzki's ring) will need assessment by a gastroenterologist, with esophagogastroduodenoscopy (EGD), string capsule endoscopy, or other specialized evaluations.⁴⁷ Dysphagia is an expected complication of head, neck, and esophageal cancers, and many of the therapies directed at these conditions; pretreatment swallowing exercises may benefit some of these patients.⁴⁸ There are a variety of survey instruments to screen for dysphagia; they are of limited usefulness for most clinicians but may be of benefit to SLPs.^{49,50}

Oropharyngeal dysphagia occurs commonly after strokes and during the course of many neurodegenerative diseases, such as dementia and Parkinson's disease. Chronic swallowing disorders also appear to be common in independent-living elderly; 33% of older adults in one study reported a current problem.⁵¹ Dysphagia following a stroke is associated with decreased survival in the 3 months after a stroke, and increased risk of nursing home placement.⁵² SLP assessment can be very useful in assessing persons who are not chewing or swallowing normally, who cough with eating, or who are losing weight for unknown reasons. These experts can assess chewing and swallowing using many modalities, and often provide valuable treatment suggestions, although the evidence on the effectiveness of many of these strategies is limited. The most accurate diagnostic test for dysphagia is considered to be videofluoroscopy (or the modified barium swallow), but this requires radiation exposure. Fiberoptic endoscopic evaluation of swallowing (FEES) also appears to be quite accurate and can be performed at bedside, wherein air is blown through an endoscope in the nose down to the soft palate or pressure is applied to the pharyngeal muscles to trigger an observable swallow.^{53,54} In the absence of SLP resources, several bedside tests may be useful, including the GUSS (Gugging swallow screen) (observing patients during a saliva swallow, then semisolid thickened liquids, thin liquids, and finally dry toast),⁵⁰ or the 3-oz (84 mL) water test, observing for coughing during, and for up to 1 minute

Table 112-1. Strategies to Reduce Dehydration in Older Adults

Prepare for dehydration in older adults in high risk situations (summer heat without air conditioning, acute illness, delirium, etc.) Evaluate patient for possible benefit to drink using a straw Offer a variety of fluids during recreational and social activities; "happy hours"; "tea times" Consider offering options to water (juices, soups, water-rich fruits [watermelon, grapes, peaches] and vegetables [tomatoes, lettuce, squash]) ¹³² Discuss side effects/timing of diuretics to anticipate voluntary dehydration Offer a choice of fluid options, rather than only one or two

following, drinking water.⁵⁵ A comprehensive nursing protocol to assess and manage swallowing problems in frail older adults is available.⁵⁶

A variety of treatment options are used by SLP experts to try to restore a normal swallow, including electrical stimulation, thermal stimulation, muscle exercises, and acupuncture.⁵⁷ More extreme interventions (cricopharyngeus muscle myotomy, botulinum toxin injections, etc.) have an uncertain role.⁵⁸ The use of modified diets can improve the safety of swallowing; SLPs and dietitians can provide guidance to patients, families, and staff on the use of such diets. For patients with difficulty swallowing thin liquids, adding thickening agents to provide nectar-like, honey-like, or spoon-thick, or fluids is an option.⁵⁹ However, thickened liquids are often less palatable and may increase the risk for dehydration.⁶⁰ Sitting patients upright when eating (and for some time afterwards), chin tucking when swallowing, eating more slowly, and use of various swallowing maneuvers are additional techniques (see Table 112-1). Methods that are more successful in persons with one cause for dysphagia may not work as well for another (see the "Aspiration and Aspiration Pneumonia" section).^{61,62}

Constipation

The frail older adult is prone to constipation for many reasons (anticholinergic and opioid medications, poor fluid intake, poor fiber intake, little physical exercise, etc. [see Chapter 108]). Constipation is a common cause of poor food intake in the frail or bedbound older adult, and proper monitoring of bowel movements can be very useful in assessing reasons for reduced dietary intake of these patients.

Thirst and hydration

Adequate fluid intake may be associated with fewer falls, less constipation and laxative use, improved rehabilitation outcomes, less bladder cancer, and lower rates of postprandial orthostatic hypotension.^{63,64} Risk for dehydration increases with advanced age, race (blacks have higher risk than whites), use of certain medications (diuretics, laxatives, psychotropics, and general polypharmacy), physical dependency, dementia, delirium, and chronic disease.^{63,64} Healthy older adults have an age-associated decrease in thirst sensation (hypodipsia) and consume less fluid in response to the same degree of dehydration than younger adults.⁶⁵⁻⁶⁷ Hypodipsia can be even more pronounced in older adults suffering from chronic disease; perhaps 30% of nursing home

residents are dehydrated at any point in time.⁶⁸ Darker urine color in persons with adequate renal function, blood urea nitrogen:creatinine ratio (>25:1 mg/dL), serum osmolality (>300 mmol/kg), serum sodium (>150 mEq/L), urine specific gravity (>1.029), and urine output (<800 mL/day) may aid in the detection of dehydration.^{69–71} Skin turgor is not an adequate tool to detect dehydration in older adults. Older adults at highest risk of dehydration include those who have a diminished thirst drive due to neurodegenerative conditions, those who cannot access or safely consume fluids due to physical or cognitive impairments or dysphagia, those who will not drink enough because of fears of urinary incontinence or have never consumed many fluids, and those at the end of life.⁶⁸ Distinguishing patients in this manner may aid in selecting the optimal prevention and treatment strategies.

Water requirements are not defined well for adults, let alone for older adults. In healthy adults, hydration status remains normal despite large individual differences in intake. Fluid goals should be tailored to each individual; for example, there may be competing goals with patients with fluid overload (as found with congestive heart failure) (Chapter 40), with hyponatremia with the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) (Chapter 85), and with respect to activity level or environmental temperature. A daily water intake (including free water, water in other beverages, and water in food) of 3.7 L for men and 2.7 L for women meets the needs of most healthy persons, including advanced ages.⁷² This should not be considered a minimum intake. A reasonable initial goal for sedentary older adults may begin with 30 mL/kg/day or 1500 to 2000 mL/day of fluids; this goal can then be adjusted based on blood urea nitrogen levels, urinary output, and clinical status. Possible intervention strategies are presented in Table 112-1. The poorer palatability of thickened liquids may reduce intake and not meet patients' fluid requirements.⁶⁰ In cases where oral fluid intake is temporarily decreased, for example, due to an acute infection, subcutaneous infusion of fluids (hypodermoclysis) for a day or two until adequate drinking resumes is easy to accomplish and may avoid intravenous access or hospitalization.⁷³

Refeeding syndrome

Nutritional requirements are discussed in Chapter 82, and feeding someone can be based on those recommendations. There are several formulas that may be useful in initially calculating caloric needs; none are perfect but the Harris-Benedict equations (Table 112-2) serve as a starting point for average individuals.⁷⁴ However, in patients with significant chronic undernutrition (such as prolonged starvation), feeding too much and too rapidly can cause the refeeding syndrome, with rapid falls in blood phosphorus, potassium, and magnesium; sodium and water retention leading to fluid overload; and altered glucose homeostasis.^{75,76} Electrolyte deficiencies, pulmonary edema, cardiac decompensation, and death become likely. High carbohydrate intake increases thiamine requirements and can precipitate acute Wernicke's encephalopathy in undernourished persons with unrecognized thiamine deficiency (e.g., alcoholics). It is critical to identify individuals at high risk for refeeding syndrome before beginning nutritional support, provide thiamine and other micronutrient

Table 112-2. Harris-Benedict Equations for Estimating Caloric Requirements

Men: $66.4 + [13.75 \times \text{weight (kg)}] + [5.0 \times \text{height (cm)}] - [6.8 \times \text{age}]$
Women: $655.1 + [9.6 \times \text{weight (kg)}] + [1.85 \times \text{height (cm)}] - [4.7 \times \text{age}]$

supplements immediately, and then begin feeding at about 25% of the estimated caloric goal (permissive underfeeding). As tolerated, intake can be increased slowly with the goal of reaching targeted daily intake after 3 to 5 days.^{75,76} Electrolytes should be assessed before refeeding, and then monitored every 4 to 6 hours for the first day or two. Initial fluid intake should be restricted to less than 1000 mL per day in these individuals, and weights accurately measured daily. Weight gain more than 1 kg weekly is a warning for fluid overload.

Aspiration and aspiration pneumonia

Aspiration pneumonia is common in older frail adults, particularly those who are hospitalized or institutionalized, and those with acute or chronic neurologic disease. It may also make up 5% to 15% of all community-acquired pneumonias.⁷⁷ Highest predictors of aspiration pneumonia, which vary among differing patient populations, include the need for suctioning, COPD and CHF diagnoses, presence of feeding tube, feeding or oral care dependency, and being bedfast.^{78,79} Patients on respirators are also at very high risk. Aspiration pneumonia in frail older adults frequently has few classic symptoms; delirium (confusion, agitation, lethargy), unexplained elevated white blood cell counts, or tachypnea may be the only early indicators. Aspiration itself may occur without any obvious clinical signs, or with only episodic fever or reduced oxygen saturation.^{80–82} Approaches to reducing the risk of aspiration and aspiration pneumonia are outlined in Table 112-3.

In patients who have dysphagia, it is important to assess aspiration risk and whether this risk is influenced by the texture of the food consumed. In some of these patients, thin liquids present a particular problem. For these individuals, dietary modifications and adoption of specialized swallowing techniques may be important in reducing risk (see the "Chewing and Swallowing" section).⁵⁰ A recent study⁸³ did not find any clear difference in aspiration pneumonia risk between drinking thin liquids in a chin-down posture or thicker liquids in a normal posture in patients with dementia or Parkinson's disease (PD). Honey-like liquids appear to work better than nectar-like liquids or chin-down posture for many patients with dementia or PD.⁶¹ However, half the patients receive no benefit from these maneuvers, particularly those with the most severe dementia. Many patients and their families refuse to accept thickened liquids and prefer to accept the aspiration risk of thin liquids; this decision process needs to be thoroughly documented. Videofluorographic swallow study (VFSS) currently appears to be the best test to assess aspiration risk, and is recommended before restricting intake of thin liquids.^{53,54} Debilitated patients will continue to aspirate oral secretions and reflux, which are not prevented by SLP interventions or recommendations, and this is at least as important as prandial aspiration.⁸⁴

Table 112-3. Reducing Risk of Aspiration and Aspiration Pneumonia in Older Adults*

<p>All patients: Improve oral hygiene/frequent teeth brushing/properly fitting dentures</p> <p>Hand feeding: Provide a rest period (>30 minutes) before feeding time Sit upright at 90 degrees, or highest position allowed by medical condition Avoid rushed or forced feeding; feeding by syringe is risky Alternate liquids with solids Recognize the high risks of sedatives, hypnotics, and other psychotropic meds, and try to wean or reduce dosages Speech-language-pathology referral: Evaluate patient for possible benefit of "chin down" position when swallowing or for possible benefit of adjusting liquid viscosity; thickened liquids of varying types may improve swallowing in some patients (ice cream and Jello are considered thin liquids)</p> <p>Tube feeding (both nasogastric and gastrostomy tube feeding may increase aspiration risks): Consider continuous feedings rather than intermittent (bolus) feedings Keep backrest elevated at least 30 degrees during feedings, if possible Consider pump-assisted feedings rather than gravity-controlled feedings A gastric residual volume >200 mL during continuous feeding or before intermittent feedings may increase risk (but this remains controversial)¹³⁶ Prokinetic agents such as metoclopramide or erythromycin may improve feeding tolerance, but are associated with their own serious potential side effects. Placing the feeding tube tip beyond the pylorus (jejunostomy, gastrojejunostomy) may reduce aspiration in some patients Using colored dye in tube feeding is contraindicated (it was originally felt that adding coloring to liquid tube feeding formulas would help to identify probable feeding aspiration if the coloring was found after throat and pulmonary suctioning)¹³⁷</p>
--

*(Note: most of these suggestions are consensus and expert opinions rather than evidence based¹³³⁻¹³⁵.)

Several medications have been proposed to reduce the risk of aspiration pneumonia, most notably the angiotensin-converting enzyme (ACE) inhibitors, but the evidence to support this intervention remains inadequate.⁷⁷ Improved oral hygiene and regular tooth brushing may also reduce the risk of aspiration pneumonia.^{85,86} Treatment of aspiration pneumonia will include coverage for both gram-positive and gram-negative organisms, including anaerobic mouth organisms.

Improving nutrition

Strategies to improve nutrition should be individualized, focusing on barriers specific to each person; strategies proven to be most successful entail multimodal interventions. [Table 112-4](#) provides examples of such approaches. Appetite may improve when depression, pain, and constipation are treated, so these common disorders should be searched for whenever appetite is poor. For institutionalized older adults, appropriate social stimulation, one-on-one feeding support, increasing the variety of choices at and between meals, and a liberal food substitution policy are associated with increased calorie intake.⁸⁷ Nursing home residents who are physically unable to feed themselves are at particularly high risk for weight loss if adequate care is not provided. It is well established that this risk can be reduced by the provision of feeding

assistance by appropriately trained staff. Less well recognized is that many nursing home residents assessed by the nursing staff to be physically independent are also at high risk for weight loss. Recent studies indicate that these individuals can also benefit from close supervision, verbal cuing, and other forms of staff support at mealtime.⁸⁸ Using non-nursing staff to transport patients to the dining room, deliver meals and provide substitute foods, document intake, and increase social stimulation may allow nursing staff to spend more time with mealtime feeding assistance.⁸⁸

Weight loss in patients with dementia is often due to many interacting factors: self-feeding/chewing/swallowing difficulties; loss of hunger drive; and, occasionally, higher energy expenditure due to pacing coupled with failure of intrinsic regulatory systems for maintaining body weight.⁸⁹ Unless other diseases are present, there is no consistent evidence that patients with dementia have higher resting energy expenditure or other evidence of hypermetabolism. Obstinance and feeding aversions (turning the head away when food is offered, keeping the mouth shut, pushing the spoon or hand away, and spitting out food) are common in dementia and often require individualized and creative and persistent approaches to maintain an adequate nutrient intake.⁸⁹⁻⁹²

Appetite stimulation

Medications designed to specifically improve appetite in older adults have not proven very effective, and many have considerable side effects or costs. Relatively few studies have targeted the frail older adult, and studies of cancer patients or persons with AIDS should not be presumed translatable to the aging patient. Corticosteroids, cyproheptadine, thalidomide, and human growth hormone lack proven effectiveness and are not recommended for appetite stimulation in older adults. Testosterone replacement or supplementation and other anabolic sex hormones (e.g., nandrolone) have important side effects and their use cannot be currently recommended in persons who are anorexic and losing weight without documented hypogonadism (see Chapter 58). Selective androgen receptor modulators (SARMs) have not yet been fully investigated but may play a future role.⁹³

There is some evidence indicating that the cannabinoid, dronabinol, is effective in promoting weight gain in patients with Alzheimer's disease.^{94,95} However, this medication is very expensive and many frail patients do not tolerate the dysphoria that is a common side effect. If careful monitoring can be provided, a trial of use in patients with anorexia can be considered. Megestrol acetate (MA) (a "progestagenic-corticoid-steroid") is another appetite stimulant that can be prescribed for frail older adults who are losing weight. Studies indicate that it is occasionally effective in increasing nutrient intake, inducing weight gain, and decreasing serum inflammation-associated cytokine levels.¹⁴ However, the physiologic significance of this latter effect is not known, the weight gain is primarily fat, and MA often produces several potentially serious side effects. Many of its side effects are a consequence of its corticosteroid agonist and antagonist properties and include suppression of the pituitary-adrenal axis, muscle loss, insulin resistance, and salt and water retention. MA also suppresses testosterone levels to castrate levels and may increase the risk of venous thromboembolism and death.⁹⁶⁻⁹⁸

Table 112-4. Causes and Feeding Options in Patients Who Are Not Eating Enough^{68,87,89*}

<p>All Patients</p> <p>Liberalize diet; offer variety of snacks between meals; offer food substitutions at meals</p> <p>Reduce/eliminate “therapeutic” diets (e.g., low cholesterol, low fat, low salt)</p> <p>Treat pain, constipation, depression</p> <p>Dental evaluation</p> <p>Give medications with high calorie liquid protein drinks</p> <p>Reduce/eliminate sedating and other medications that often reduce appetite, if possible (e.g., anticholinergic, NSAIDs, some antidepressants and other psychotropic medications, dementia medications)</p> <p>Train volunteers to feed patients/encourage family participation</p> <p>Physically Capable</p> <p>Independent: Educate, provide preferred/varied beverages, buffets, social stimulation, and encouragement</p> <p>Assess for depression</p> <p>Encourage exercise</p> <p>Dementia: Offer food/variety of high-energy/high-protein snacks frequently between meals; integrate fluids into activities, happy hours; roving beverage and snack carts</p> <p>Intensive dietitian involvement and staff education/awareness</p> <p>Eat out of bed, in a chair at a table, if possible</p> <p>Nonverbal and verbal cueing to encourage self-feeding, physical guidance; hand-over-hand technique to initiate and guide self-feeding; demonstrate eating movements for patient to imitate; show how to use utensils.</p> <p>Reduce distraction, turn off television</p> <p>Dentures in and eye glasses on</p> <p>Simplify: one food/plate at a time</p> <p>Observe for pocketing (cheeking) foods</p> <p>Less emphasis on “healthy” eating and more on food preferences</p> <p>Cannot Eat or Drink</p> <p>Dysphagia:</p> <p>SLP evaluation (see text)</p> <p>Assess for mouth and throat infections</p> <p>Physically dependent:</p> <p>Adequate assistance, allow sufficient time to eat a meal</p> <p>Will not eat or drink: (Patients who apathetic to eating or drinking may have frontal lobe dysfunction)</p> <p>Sippers/eating disorders: Geropsychiatry evaluation</p> <p>Fears incontinence: Adjust timing of diuretics/consider alternatives</p> <p>End of Life</p> <p>Review advance directives; discuss natural dying with patient and family, and the risks of artificial nutrition and hydration</p> <p>Treat pain/constipation/depression; avoid medication side effects</p> <p>Adequate hand feeding/assistance</p>

*More suggestions are available at www.ConsultGeriRN.org. (Note: Persons with co-existing inflammation and cachexia may respond poorly to efforts at increasing nutritional intake.)

Appetite stimulation and weight gain are potential side effects of certain antipsychotics and antidepressants. This fact may have relevance in choosing therapies. Depression is common in older adults with anorexia, and should be actively and repeatedly screened for (see Chapter 57). Although antidepressants may either increase or decrease appetite in any individual patient, there is some evidence that mirtazapine can induce weight gain. Trials of antidepressant therapy, including mirtazapine up to its maximum dose, should be considered in any older adult who has unexplained anorexia and weight loss. Assessment by geropsychiatry is also recommended for patients who do not respond to initial therapy.

Current research on appetite stimulation is targeted on cytokines as these chemicals may play a significant role in cachexia^{16,99,100}; this includes a potential role for anti-inflammatory nutrients such as n-3 polyunsaturated fatty acids. Any role for ghrelin is unknown.

Enteral nutrition and tube feeding

When oral intake is inadequate and is likely to remain so for some time, artificial nutrition support should be considered. The nutritional assessment should consider several factors including the urgency of the need, the prognosis of the underlying condition, whether the individual has a functioning gastrointestinal (GI) tract, and the individual's personal preferences. If the GI tract is not functioning properly, peripheral or total parenteral nutrition support should be considered. If it is functioning and tube feeding is appropriate, it is then necessary to choose the type of tube and formula to be used, and the rate, schedule, and method of formula delivery.

The patient's overall prognosis is a critical consideration. If the underlying condition contributing to the older adult's loss of desire or ability to eat can be treated and the individual has a reasonable expectation of recovering independent function, it is often advisable to provide nutrition support during the recovery period.¹⁰¹ This might be the case when the decline in nutrient intake occurs in association with major surgery, acute medical or psychiatric illness, or an acute and likely reversible exacerbation of a chronic medical condition. If the patient's BMI is greater than 18, the individual does not have a condition associated with exceptional metabolic demands, and volitional nutrient intake is expected to return to adequate levels within 5 days, nutrition support is probably not necessary.^{101–103} In these cases, efforts should focus on identifying and eliminating any possible contributor to the patient's low intake. Older patients who have not had any appreciable nutrient intake for more than 5 days or who are unlikely to resume oral feedings within a comparable amount of time, nutrition support is warranted.^{101–103} For patients with very little nutritional reserve (e.g., BMI <18), or high metabolic demands (e.g., extensive burns), initiate nutrition support if volitional intake cannot be restored within 2 or 3 days.^{101–103}

If it is anticipated that tube feedings will be needed for less than 6 weeks, a soft (e.g., silicone or polyurethane), small-bore, nasoenteric feeding tube can be used. These tubes can be inserted at the bedside and their use avoids the need for an invasive procedure. The disadvantages of nasoenteric feeding tubes include increased risk of aspiration, sinusitis, and local nasal irritation; need for x-ray confirmation of correct placement before use; and the possibility of the tube being dislodged with coughing, vomiting, or poor patient tolerance. Tubes that are long enough to be passed into the duodenum or jejunum are useful when there is significant gastroparesis. Placement distal to the ligament of Treitz may also lower the risk of large volume aspiration, but it is often difficult to pass a tube beyond the stomach without endoscopic or fluoroscopic assistance.¹⁰⁴ Great care is required to prevent tube obstruction.

For patients requiring long-term enteral nutrition support (i.e., >6 weeks), a tube enterostomy is preferable. Tubes can be placed either endoscopically, radiologically, or surgically. Surgical placement is usually used only when

there is a contraindication to less invasive procedures or the patient is going to surgery for another reason. Tubes placed radiologically or endoscopically can be used within hours and the procedure is often done as an outpatient. Special tubes that can be advanced into the jejunum can be used when there is pathology preventing gastric feedings, or when there is intractable intolerance to gastric feeding. Use of percutaneous jejunostomy tubes is usually limited to hospitalized patients with complex GI problems. Major complications of percutaneous endoscopic/radiologic gastrostomy occur in approximately 3% of patients and include hemorrhage, bowel perforation, fistula, aspiration, and erosion of the internal tube bumper into the abdominal wall.^{101–103}

The type of formula to be used should be determined based on the needs of the patient. In most cases, a nutritionally complete, polymeric, lactose-free formula is the best option. The polymeric formulas differ in terms of the ratio of fat, protein, and carbohydrates, caloric density, and fiber content. Although some patients, such as those whose medical condition cannot tolerate high fluid intake, may benefit from high-calorie or high-nitrogen formulas, other patients do not tolerate the higher osmolality of such formulas, which may contribute to the development of diarrhea. With very narrow tubes, it is important to avoid use of formulas of high viscosity and not to insert crushed medications into the tube.

Partially digested and elemental (e.g., amino acid) formulas are available for patients who have difficulty digesting whole nutrients. However, these formulas are rarely required and are expensive. If the infusion rate of the formula is increased slowly or pancreatic enzymes are provided when needed, standard polymeric formulas can usually be used.

For patients who are severely undernourished, tube feedings should be started slowly to prevent metabolic complications (see the "Refeeding Syndrome" section).^{75,76,105} Diarrhea, abdominal pain, and vomiting may occur when tube feedings are increased too rapidly. The use of tube feeding protocols to increase feeding rates to desired amounts, and closely monitoring laboratory values are recommended. Predictions of caloric intake are frequently inaccurate because tube feeding is frequently interrupted.

Some patients are eventually able to tolerate multiple, intragastric bolus feedings per day. This approach may be more physiologic and offers the advantage of allowing the patient to be intermittently disconnected from the feeding apparatus to enjoy more freedom of movement. This approach may also allow volitional oral feedings to be slowly introduced. Cyclic or nightly feedings may provide a similar advantage. For patients who do not tolerate bolus feedings or who need to be fed distal to the stomach, slow formula infusion by a pump is the preferred method. To minimize the risk of aspiration, the patient should be sitting upright at greater than 30 degrees during feedings, whether fed by bolus or slow infusion. Unless there is an absolute contraindication, patients receiving enteral nutrition support should always be allowed, and even encouraged, to resume volitional oral intake if tolerated. "Recreational" oral feeding, even if in small amounts, may be offered to patients with low aspiration risk to allow some of the hedonic sensations of eating.

Nutrition and hydration at the end of life (see also Chapter 116)

There are significant emotional, cultural, and religious aspects to providing nutrition and hydration to someone nearing the end of life and, in some cases, legal constraints as well.^{106,107} It is often difficult to determine when aggressive nutritional support should be pursued and when someone should be allowed to die "naturally." Ideally, an ongoing dialogue among a patient, family members, and the health care team regarding advance directives should begin at adulthood when the patient is healthy and be based on the evidence of effectiveness before a health crisis.¹⁰⁸ Preferences regarding use of nutrition support at the end of life, how the individual defines quality of life, medical futility, dying naturally, unrealistic expectations, and medically prolonged death should be part of these discussions. As age advances and health changes, these directives should be reconsidered, again based on as much current evidence as is available. Encouraging the participation of nurses and nursing aides in the hospital or nursing home, and also providing them the latest clinical evidence,¹⁰⁹ may allow the health care team to present a unified, consistent, and supportive message, and maximize the chances for a peaceful death. Palliative care team referrals often benefit patients, families, and health care workers. Referral for hospice care is often delayed or avoided until shortly before death.¹¹⁰

The role of nutrition in end-of-life care is complex and controversial. Estimating life expectancy in patients with incurable disease is imperfect.^{110,111} Average life expectancy after diagnosis differs significantly from one disease to another and there is considerable controversy as to how best to define the terminal stage of most conditions whether it be metastatic cancer, heart failure, or end-stage dementia. The issue is further complicated by the fact that the type of care provided may have a significant impact on the duration of life, but not necessarily the quality of life. This is particularly true of nutrition support. As discussed above, cancer-induced cachexia is generally resistant to increasing nutrient intake, and nutrition support is usually not effective in prolonging life. In contrast, some patients with Alzheimer's disease and other dementias can be kept alive for many years if provided adequate oral or enteral nutritional support (and excellent nursing care). However, there is no evidence that nutrition support slows the progression of the cognitive deficits or lowers the risk of aspiration, pressure sores, or infections, and it does not lead to improvement in physical function.^{112–114} One observational study found no survival advantage for hospitalized patients with advanced dementia who receive a new feeding tube.¹¹⁵ Whereas eating is associated with pleasure, enteral feedings are not felt to add to the quality of life. For these reasons, artificial nutrition and hydration are considered appropriate for reversible diseases, but decisions may become more complicated with irreversible illness and when the patient does not have advance directives and cannot make informed decisions (see Chapter 116). Complicating the issue further, clinicians' attitudes toward the role of nutrition support at the end of life differ significantly by specialty, region of the world, and personal beliefs.¹¹⁶ Many health care providers, including oncologists and SLPs, encourage artificial nutrition and hydration and may cause confusion for patients and families (along with

other staff) by using terms such as “life-sustaining” and “starvation.”^{84,117,118} Dietitians and SLPs are more likely to recommend artificial nutrition and hydration than other health care professionals.^{119,120} Diverse ethnic and religious backgrounds (of both patients and clinicians) may result in different goals and values, and different attitudes towards end of life care that are often poorly appreciated or anticipated.¹²¹ Patient-family-health care provider discussions regarding prognosis, and education about the effectiveness or potential futility of various nutrition and hydration interventions are strongly recommended. If families need continuing support and education, and insist on artificial feeding and hydration, a therapeutic and finite trial of tube feeding can be instituted and can then be discontinued if the patient’s condition has not improved or if the patient continues to be unable to consume enough food or fluids by mouth. This often allows family members to witness the futility of the purpose of the feeding and to come to terms with their depression and grief.

The dying process is often extremely stressful for families to observe. There are often many fears and unasked questions. Proactively discussing the natural dying process with patients and families can be very beneficial, including education regarding the dying patient’s naturally slow cessation of food and fluid intake, and the evidence that there is

no apparent suffering from this decline in intake.^{122,123} Families need to be educated that intravenous (IV) hydration is unlikely to provide comfort, and may actually increase secretions and respiratory difficulty in the dying patient. Patients receiving IV hydration at the end of life often require diuretics for edema, ascites, and/or respiratory distress.¹²⁴ Families and patients need reassurance that pain management and treatment side effects (such as constipation, lethargy, confusion, etc.) will be anticipated and effectively treated.

Two clinical practice guidelines, from France and Canada,^{125,126} address artificial nutrition in terminally ill cancer patients; parenteral nutrition is recommended only in selected persons with gastrointestinal obstruction due to cancer, a life expectancy of more than 6 to 12 weeks, and who have good functional status (Karnofsky score >50%). These guidelines can improve decision making and reduce the inappropriate use of these interventions.¹²⁷ Educating patients, families, and staff that artificial feeding and nutrition in persons who are terminally ill may increase suffering and not improve outcome is recommended.^{128,129}

The Mistreatment and Neglect of Older People

Anthea Tinker
Simon G. Biggs
Jill Manthorpe*

Although medical practitioners are generally informed about child abuse, elder abuse, mistreatment, and neglect have only recently developed an evidence base of any significance. In this chapter, we first examine the development of concern, definitions, prevalence, and risk factors. We then discuss ways in which they may be identified and consider prevention and responses. We write from the perspective of developments in the United Kingdom, and from studies in a wider European and North American context. The publication of "Hidden Voices" by the World Health Organization (WHO) in 2001¹ revealed widespread recognition of this problem internationally. There is scope for continuing to draw lessons from cross-national perspectives, while recognizing differences in service and legal provisions along with cultural interpretations of abuse, between countries. Throughout we are concerned that, although there are lessons to be learned from child abuse, simplistic parallels should not be drawn. For example, there are dangers in interventions narrowly focused on the *protection* of older people, if they are ageist in philosophy, or undermine autonomy and rights in civil and criminal law. The European Convention on Human Rights, now incorporated into U.K. domestic law, offers an important counter to these dangers.

HISTORICAL DEVELOPMENT

Early concerns about mistreatment of older people were raised by doctors who saw a parallel with child abuse and placed the issue in the wider context of the care of older people both in their own homes and in institutions, emphasizing the importance of awareness and of good geriatric practice.^{2,3} However, an evidence base was slow to develop with notable exceptions.^{4,5} In its absence, abuse was linked to concerns about the stress placed on family caregivers by the care of older people, particularly those with dementia. Policy in many countries has drawn on developments from the United States. In England and Wales one policy response was the development of statutory guidance ("No Secrets"⁶ and "In Safe Hands"⁷) to establish multiagency (involving mainly health services, local government, and the police) systems through which concerns about the abuse of "vulnerable adults" might be addressed. The Mental Capacity Act 2005 created offenses relating to mistreatment or willful neglect of adults with mental incapacity. In the United Kingdom, policy developments have also responded to professional and pressure group concerns that elder abuse has been insufficiently resourced and prioritized (see Action on Elder Abuse⁸ and Help the Aged⁹).

*With acknowledgments to Claudine McCreadie, who coauthored the original chapter with Anthea Tinker.

DEFINITIONS

Table 113-1 provides standard definitions and gives examples of both behavior and effect. Elder abuse, mistreatment, or neglect refer to the ill-treatment of an older person (usually defined as over age 65) by commission or omission. They may occur both in domestic settings (the older person's own home, a relative's home, or supported housing) and in institutions (care homes, nursing homes, and hospitals). Some kinds of behavior are criminal acts, such as assault and theft; others, such as verbal abuse, the restraint of someone who is aggressive, or overmedication, may be more contingent upon particular circumstances. Definitions are important because they determine "who will be counted as abused and who will not."¹⁰ Abuse and neglect refer to behavior within a relationship connoting trust. This distinguishes actions by those closely linked to the older person, such as family members, or others in positions of responsibility (such as a member of staff) for their care, from actions by strangers.

Different types of abuse and neglect

There is now widespread agreement about five categories of abuse: physical violence; psychological abuse, often measured by persistent verbal aggression; financial abuse; sexual abuse; and neglect.^{10,11} Although sexual abuse is sometimes subsumed under physical abuse, it has been increasingly recognized as a form of abuse in its own right. There is still very limited information on how much these types of abuse occur together and how much they are separate phenomena, but the research suggests that they both occur singly *and* in combination, and that the explanations for the abuse, and therefore the factors relevant to risk, may vary accordingly. The U.K. prevalence study¹² distinguished between forms of abuse that are interpersonal and of an intimate nature, financial forms, and neglect. Whether a common label and tendency to a common response are useful or not requires further research. The U.K. study gives a series of behavioral definitions of abuse that take frequency and severity into account that may be of greater use to professionals than ones intended for policy development.

Vulnerability of older people

In the context of elder abuse, vulnerability may be related to conditions of physical and mental frailty, and disability. Socioeconomic factors, such as low income, minority ethnic background, and bad housing, have been associated with enhanced risks.¹³ The majority of prevalence studies has looked at older people living in community settings. Evidence for institutional forms of abuse tends to arise from public inquiries, inspection reports, and case studies. A study from the Czech Republic¹⁴ suggests that 6% of care home residents suffer mistreatment either from staff or other residents. Residents of nursing homes, or of any institution providing social and health care, may be deemed vulnerable

by virtue of their increased disability or their living situation. Professionals are likely to have contact with older people, who, because of their physical and/or mental impairments, are least able to protect themselves. However, while there are various discussions about individual risks, it may also be

worth thinking about vulnerable situations. This means that we should be looking more at the context of the individual rather than about personal vulnerability. For example, not all people with dementia are at risk and those who are vulnerable are likely to be those who have few people to safeguard their best interests.

Table 113-1. Definitions of Types of Abuse, With Examples of Behavior and Effects³²

Physical abuse: Nonaccidental infliction of physical force that results in bodily injury, pain, or impairment
<ul style="list-style-type: none"> • <i>Examples of behavior:</i> hitting, slapping, pushing, burning, physical restraint • <i>Examples of effects:</i> bruises, fractures, burns, broken teeth, sprains, cuts, hair loss, bleeding from scalp, fear, anxiety, depression
Psychological abuse: The persistent use of threats, humiliation, bullying, swearing, and other verbal conduct, and/or of any other form of mental cruelty, that results in mental or physical distress
<ul style="list-style-type: none"> • <i>Examples of behavior:</i> treating an older person as a child, blaming, swearing, intimidating, name-calling, threatening violence, isolating older person • <i>Examples of effects:</i> fear, depression, confusion, loss of sleep, loss of appetite
Financial abuse: Unauthorized and improper use of funds, property, or any resources of an older person
<ul style="list-style-type: none"> • <i>Examples of behavior:</i> misappropriating money, valuables, or property; forcing changes to will; denying access to personal funds • <i>Examples of effects:</i> loss of money, etc., inability to pay bills, deterioration in health or standard of living, lack of amenities, unusual activity in bank accounts, signatures on documents uncertain, lack of solid arrangements for financial management, eviction or house sale notices
Sexual abuse: Direct or indirect involvement in sexual activity without consent
<ul style="list-style-type: none"> • <i>Examples of behavior</i> • <i>Noncontact:</i> looking, photography, indecent exposure, harassment, serious teasing or innuendo, pornography • <i>Contact:</i> touching breast, genitals, anus, mouth; masturbation of either or both persons; penetration or attempted penetration of vagina, anus, mouth, with or by penis, fingers, other objects • <i>Examples of effects:</i> difficulty in walking or sitting, bruises, bleeding, venereal disease, psychological trauma
Neglect: Repeated deprivation of assistance needed by the older person for important activities of daily living
<ul style="list-style-type: none"> • <i>Examples of behavior:</i> failure to provide food, shelter, clothing, medical care, hygiene, personal care; inappropriate use of medication or overmedication • <i>Examples of effects:</i> malnutrition, pressure ulcers, oversedation; untreated medical problems, depression, confusion

PREVALENCE AND INCIDENCE

Table 113-2 shows prevalence (in percentages) of elder mistreatment in North America, Canada, the United Kingdom, Amsterdam (in The Netherlands), and Spain. Studies have also taken place in Spain, the Czech Republic, Finland, Sweden, and Germany.¹⁵ The Spanish study¹⁶ is one of national community prevalence, indicating a figure of 0.8% reported by older people, but 4.5% by caregivers. The two major studies of community prevalence in North America^{4,17} were based on telephone interviews. The U.K. survey was based on individual interviews with people aged 66 and over.¹² This found that overall 2.6% of people aged 66 and over living in private households reported that they had experienced mistreatment involving a family member, close friend, or care worker (i.e., those in a traditional expectation of trust or trust relationship) during the past year. When this 1-year prevalence of mistreatment is widened to include incidents involving neighbors and acquaintances, the overall prevalence increases to 4.0%.

One particular difficulty for studies using the general population is that people who are highly dependent on another person, and particularly people who have significant mental impairment, are unable to participate, except by proxy. In the United Kingdom and Spanish studies people with severe dementia or otherwise unable to take part were excluded from the research. In the Dutch study, nonresponse was relatively high for those with mental and physical incapacity.¹⁸ Yet it is precisely these people whom practitioners would identify as most vulnerable. Clinical and forensic markers indicating abuse and neglect point to the importance of dementia, depression, psychosis, and alcohol abuse.¹⁹ Declining health, loneliness, and depression have been associated with enhanced risk factors.¹² A key finding from the U.K. prevalence study was that types of mistreatment vary by gender and age, such that neglect increases with age for women, but other forms of mistreatment

Table 113-2. Prevalence of Elder Abuse in Boston, USA, 1986,⁴ Canada, 1990,¹⁷ United Kingdom,^{12,33} Amsterdam (The Netherlands) 1994,¹⁸ and Spain¹⁶

*Persistent verbal abuse.

decline. For men, however, abuse, especially financial abuse, increases with age.

RISK FACTORS

Physical abuse

The most thoroughly researched area of physical abuse is that taking place in domestic settings:

1. Risk is higher for older people who live with someone.^{4,10,12,17} Older people may be abused by their partners, and by other relations including their adult children.
2. There is emerging research linking abuse with sociodemographic variables, such as marital status, occupation, and housing tenure.¹² Ethnic background has been the subject of more debate.^{10,13} However, it is possible that these factors are overemphasized by both reporting bias and the confounding of race and poverty.
3. Some abuse is longstanding—Homer and Gillear²⁰ refer to the “elderly graduates of domestic violence.” The predominance of women as victims of domestic violence at younger age groups is not so marked in the case of elder abuse.^{4,17} Lachs et al²¹ conclude: “Clinicians should be particularly aware of high-risk situations in which functional and/or cognitive impairment are present, especially in circumstances where violent behavior has been known to exist previously.”
4. Lachs et al²¹ found that the number of activities of daily living (ADL) impairments approximately doubled the chance of reported abuse or neglect, and did not consider that reporting bias substantially influenced this finding.
5. There is little evidence that the stress of caring for an older person is on its own a cause of abuse. Large numbers of caregivers are under stress, but do not abuse their relative. How caregivers react to the stresses associated with caring may, however, be important.
6. Risk appears to depend more on problematic characteristics associated with the abuser—particularly their physical and mental health and notably, in many studies, their heavy consumption of alcohol or drug substances.^{12,17,20,22} Research with general practitioners (GPs) (family physicians) linked identification of abuse with knowledge of these kinds of factor in patients’ households. Those GPs who identified five or more of 15 risk situations were seven times more likely (all other variables held constant) to have identified a case of abuse.²³
7. The role of dementia as a risk factor is controversial. Lachs et al²¹ observed that cognitive impairment, particularly if it was new, was highly significant. Research specifically with people with dementia and their caregivers found that the factors distinguishing the abusive situations related to caregivers.²⁰ Behavioral and psychological problems among people with dementia, such as aggression, may be associated with aggression on the part of the person caring for them.²⁰

Institutional settings

There is growing research about abuse in institutions.²⁴ Methods of caring assume significance, particularly as the prevalence of physical and mental disability is generally high among older people in institutions. Numerous inquiries in Britain into grave deficiencies in various areas of institutional care for all age groups have shown that abuse flourishes within a culture that allows it to be acceptable.²⁵ The leadership role of clinicians in such settings should include attention to complaints, staff turnover, risk management, and direct patient care. It is the worst of all possible worlds, as older people themselves are only too aware, to move an older person to an institution for safety’s sake only for them to be abused there.

Sexual abuse

This type of abuse has been little researched. Those affected are overwhelmingly female and rely on others for their care but others may be at risk. Abusers may have problems themselves and need help. Attention should be paid to the potential for sexual abuse in residential and nursing home settings and to the risk of sexual abuse by other residents or visitors to the facility. Physical examinations should be alert to possible indicators of abuse, such as unexplained trauma in the genital area.

Financial abuse

Nearly all definitions of elder abuse include financial abuse. The U.K. prevalence study showed that this was the most common form of abuse (after neglect) with a rate of 0.7%.¹² It has been suggested that the boundaries are unclear between the financial mismanagement of people’s affairs when they grow older and actual abuse. The financial affairs of older people with dementia appear often to be complex or confusing, thus increasing the risk of financial abuse. There is some evidence that financial abuse is more likely to be perpetrated by the extended family than by partners or paid care workers.^{12,17,26} When allied with physical and psychological abuse, the perpetrator may be a close adult relation (usually an adult child) with problems of their own, particularly relating to alcohol misuse.²² In England and Wales the Mental Capacity Act 2005 has strengthened the ability of people to make arrangements for their finances in the event of losing capacity to manage their money and set up a system of legal safeguards to reduce the likelihood of financial abuse. Other legal safeguards in England and Wales include systems to bar people from the paid and unpaid labor force if they are judged to have harmed or placed at risk of harm a vulnerable adult. This accepts a lower standard of proof than the criminal justice system. Financial abuse in the home has been discovered to be a major reason for banning staff working for older people.²⁷ The implications for medical professionals are that when an older person is in unexplained financial trouble, that where there seems to be a sudden drop in their living standards and if they seem unable to afford previously affordable items, then history taking may help to uncover matters of concern that should be reported to adult protective services.

Neglect

Neglect is generally interpreted as omission. However, opinion is divided about the appropriateness of classifying self-neglect as mistreatment in the context of adult protection

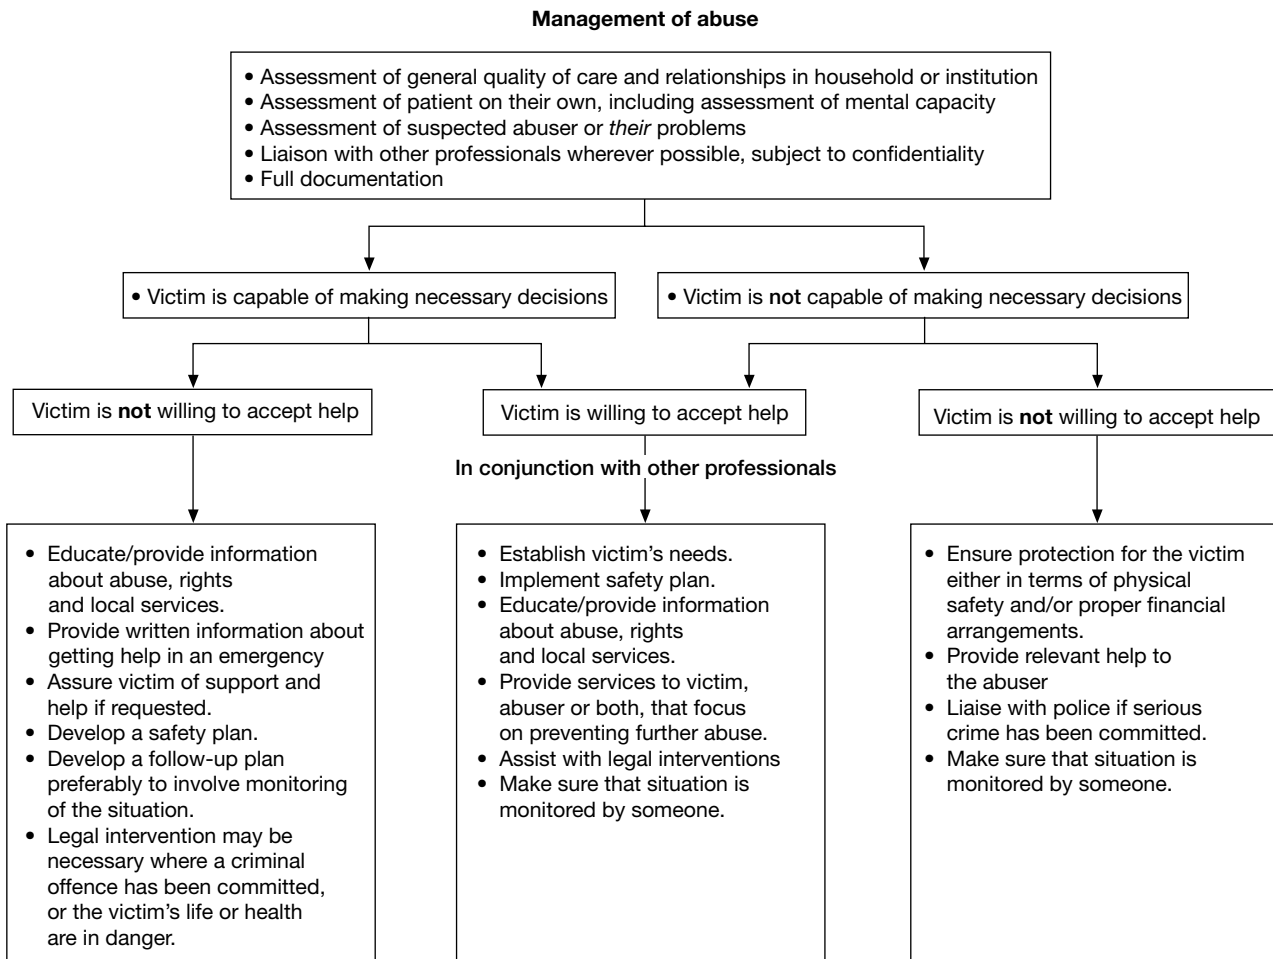

Figure 113-1. Management of abuse. (Data from Fisk J. Abuse of the elderly. In Jacoby R, Oppenheimer C (eds): *Psychiatry in the Elderly*, ed 2. Oxford, 1997, Oxford University Press, pp. 736–48; Lachs MS, Pillemer KA. Abuse and neglect of elderly persons. *N Engl J Med* 1995;332:437–43; Kurlle S. Elder abuse: A hidden problem. *Mod Med Aust* 1993;9:58–72; and American Medical Association.)

systems and local policies and procedures will assist in determining the clinical and care pathway. People whose needs are insufficiently met or ignored may be mentally frail, and unsurprisingly are in poor health.¹⁷ The partner, closely followed by other members of the family, is the most likely to be unable to provide necessary care, which may lead to a situation of neglect among community-dwelling older people.¹²

IDENTIFICATION

Elder abuse is often hidden. The U.K. prevalence study,¹² for example, indicated that only approximately 3% of mistreated older people were in touch with adult protection services. It estimated that approximately 1 in 40 older people visiting their family physician would, statistically speaking, be suffering some form of mistreatment but that contact with adult protection services was far less than might be expected. The majority of cases, whether in domestic or institutional settings, are likely to arise in either primary or secondary care as part of some other presenting problem. People who are abused are unlikely to volunteer information and may either fear retribution, not trust formal authorities, or not wish to criminalize significant others. Identification often depends on a high index of suspicion. Two surveys in England

showed that many family physicians might not recognize abuse and would welcome training in both identification and management.²³ Physical symptoms may be common to frail older people and be unreliable indicators alone.²⁰ As prevalence is relatively low, accurate diagnosis assumes great importance. Incorrect diagnosis followed by misplaced interventions may damage all those concerned. Apart from increased sensitivity and awareness of the possibility of abuse, the first general principle, common to all good practice in geriatric medicine and psychiatry, is that assessment must be holistic and interdisciplinary.²⁸ This may be time-consuming and some doctors may, under pressures of time and shortage of resources, be particularly unwilling to address issues of family violence. The logic of current research is that criminal justice and helping professionals should work together. Clinicians may be asked for opinions about possible abuse and their testimony may be vital in safeguarding an older person from further abuse but just as much in exonerating an innocent relative or care worker.

In the United States, where in some states the law requires mandatory reporting of alleged abuse cases, it is recommended that routine questioning should be built into daily practice and that in every clinical setting there should be a protocol for the detection and assessment of elder abuse. Knowing what to look for is key but so too is listening. There

are benefits of a protocol or framework for questioning^{11,29} and this can be useful in the context of possible financial abuse along with physical and psychological abuse.²⁶ Consultation with the older person on their own may be difficult but is advisable.²⁴

Financial abuse is an issue that doctors may encounter in various ways.¹¹ They may be approached to advise on financial decision making and the capacity of people to make decisions when this is in doubt. For example, they may be asked whether a person has the mental capacity to make an advance decision or to dispose of assets. They need to know to whom to refer people for appropriate guidance, to know the professional and legal guidance in their national context, to be aware of protocols around data sharing and evidence collection, and to ensure that the person understands what they are agreeing to. They may come across possible abuse in the course of patient contact and it is then necessary to know about local safeguarding systems. A small study of the views of geriatricians working in the United States found that the average number of cases of elder abuse diagnosed per year was about eight per geriatrician.³⁰ Their diagnostic work rested on a combination of history taking and physical examination.

PREVENTION, TREATMENT, AND MANAGEMENT

The key objectives are the prevention of abuse and the promotion of the older person's human rights.^{6,10} At the level of policy and guidance, it is essential that the medical profession is properly represented where any professional or local initiatives are taking place to develop a response to abuse. Experience from child protection suggests that this will not be easy to achieve. The issue of excessive or inappropriate medication being used as a form of abuse highlights the need for clinicians themselves to be careful of their own practices and those of their colleagues.

Two further general principles are meticulous documentation and liaison with other professionals, both within and outside medicine. The taking of photos or drawings, careful recording of suspected injuries, and conversations are important in collecting evidence. The difficulties of these and the time they take need to be taken into account when arranging consultations. The need to work interprofessionally raises difficult ethical questions in terms of confidentiality of the doctor-patient relationship, should the older person request the doctor to "do nothing." The older person's rights to autonomy have to be balanced with decisions that may need to be made in their best interests should they not have the capacity to consent or to refuse information sharing. The need for criminal justice intervention may arise if a crime is suspected to address possible dangers. The assessment of mental capacity, therefore, is of crucial importance and helps direct physicians to the options for intervention if the older person is unwilling to accept any help. Advocacy can be a particularly valuable service for the older person at the center of this concern, and in England and Wales this is now available for some people in situations of suspected abuse without mental capacity. [Figure 113-1](#) should be interpreted in relation to the type of abuse and to the legal and service provision

context in which medical practitioners are working. In most countries the number of laws that potentially bear on abuse are considerable, and advice may be needed from adult protection services. In the event of an emergency, the medical practitioner needs to make immediate contact with other responsible agencies and act to protect the older person from harm. Although safety of the alleged victim is the first priority, it is also essential to pay attention to the physical and psychological health of the other party, who themselves may be vulnerable.

SUMMARY AND CONCLUSION

Elder abuse can be divided into four distinct forms, including physical, psychological, sexual, and financial. Abuse is often associated with neglect, which together are often referred to as "elder mistreatment." The development of behavioral definitions, more precise targeting of risk factors, and the characteristics of the parties involved have led to a greater understanding of the risks associated with each form. Abuse and neglect can occur in community or institutional settings. In each case the principal aim should be to prevent abuse and neglect from occurring through building safe and responsive systems, regular monitoring, and interprofessional collaboration. Medical practitioners have key roles in ensuring that systems are safe and in responding to suspicions and allegations by providing expert medical intervention and testimony. Their responsibilities for the treatment of physical harm are evident but they also include offering support for

KEY POINTS

Elder Abuse

- Elder abuse refers to the mistreatment of an older person (usually defined as over age 65) by acts of commission or omission and key objectives are the prevention of abuse and the promotion of the older person's rights.
- It has been shown to affect between 2% and 6% of people aged over 65 depending upon definition and context and is generally understood to include physical, psychological, sexual, and financial forms.
- Risk of physical/verbal abuse appears to depend more on problematic characteristics associated with the abuser—particularly their physical and mental health and notably, alcohol and drug misuse. Those involved in suspected abuse may need support and may have health care needs of their own.
- Likelihood of having been mistreated may vary depending on gender, separation or divorce, socioeconomic position, declining health, and depression, and there is little evidence that the stress of caring for an older person is on its own a cause of such abuse.
- Identification may be enhanced by a high index of suspicion and is particularly important because of relatively low prevalence and physicians need to be aware of local protocols and their legal and professional responsibilities.
- Holistic assessment is necessary, through discussion with the older person and informants, physical examinations and history taking, including of mental capacity. The wider care team may be usefully involved.
- The severity of effect of the abuse, its frequency, how long it has been going on, and the intentions and capacity of those in the social network help practitioners judge the case for and type of intervention.

people in risky situations. That abuse takes place between adults, distinguishes it from child abuse. It has certain commonalities with domestic violence, but is wider in scope and form.

Abuse and neglect may best be currently understood within a human rights framework.

The primary aim should be to prevent abuse from occurring. There are at least four planks in prevention. The first is the provision of effective health and welfare services for older people, including income and medical provision.³¹ The second is awareness among professionals, among which the medical profession is crucial, that abuse exists and requires a response, which may be most effective when it is multidisciplinary.^{6,29} This may involve criminal justice interventions, skills development^{11,24} and agreement to

work within guidelines. It may also involve working with people who have mistreated older people or neglected them to prevent harm reoccurring. Third, in the context of a policy emphasis on care in people's own homes, is the need for recognition and action around caregivers, who may be both abuser and/or abused, older or younger themselves, and have physical and/or mental health problems. Finally, in the context of institutional care, monitoring or regulation of the quality of care is essential to respect the human rights of older people.

Despite its increased prevalence in older individuals, pain should not be considered a normal consequence of aging. Pain is always due to pathology, even if not easily identified or fully appreciated by the clinician. An understanding of the complex cellular, molecular, and genetic contributions to the experience of pain are beginning to emerge along with their relationship to physical, psychological, and environmental factors. Persistent pain interferes with enjoyment of life, and has deleterious effects on mood, social interaction, function, mobility, and independence. For many reasons, pain remains undertreated in this population. This chapter examines age-related changes in prevalence and perception of pain, and approaches to assessment and treatment. The focus is on pain and suffering, rather than the underlying causes of pain. The management of specific painful conditions is not discussed.

COMPONENTS OF PAIN

The pain experience is best understood by considering the influence of four determinants: nociception, pain perception, suffering, and pain behaviors.¹ *Nociception* is the detection of tissue damage by specialized transducers on primary afferent A delta and C nerve fibers in response to noxious stimuli. The subsequent *perception* of pain by the individual is affected by central processing of nociceptive input from the periphery, or from lesions in the peripheral and central nervous systems. Pain consequent upon nerve damage can occur with or without somatic nociceptive input. In the former case the perception of pain is altered from that which is usually reported following nociception. The intensity of pain under these circumstances bears little relationship to the extent and severity of observable pathology and tends to be less responsive to traditional analgesic medications. Adjuvant medications, or those formerly not used to treat pain, have demonstrated efficacy in treating pain that results from changes in the central and peripheral nervous system.

Suffering is a negative emotional response induced by pain, and also by fear, anxiety, loss, and other psychological states. Patients often use the language of pain to describe suffering, such as "heartache," although not all suffering is caused by pain. *Pain behaviors*, such as grimacing, lying down, limping, and avoidance of physical activity may result from pain perception and suffering. The clinician infers the existence of nociception, pain, and suffering from the patient's history, physical examination, and observation of pain behaviors.¹ Recognition of the multiple components of the pain experience will guide the clinician in assessing and planning age appropriate pain management.

TYPES OF PAIN

A simple classification differentiates pain as either acute or chronic. *Acute pain* can be of visceral or somatic origin. It usually has an identifiable temporal relationship with an injury or disease. Autonomic overactivity, such as diaphoresis and tachycardia, may be present. In this setting pain may be seen

to serve a useful role in drawing attention to injured tissues, altering behavior, and hence preventing further tissue damage. Acute pain often leads the individual to seek medical attention. Pain often resolves before healing is complete. As people age there may be a blunting of protective warning signals. Age related dysfunction along pain pathways may account for age-related differences in pain perception.²⁻⁴ Pain associated with visceral causes are prevalent and may present atypically in the older population. Visceral pain associated with cardiac, pulmonary, and abdominal disease is associated with morbidity and mortality, and can be difficult to diagnose in the elderly. Clinicians need to be especially vigilant in their pain assessment technique in this population.

Chronic pain persists beyond the normal duration of injury or tissue damage, or is associated with progressive disease. The time frame for the transition from acute to chronic pain is somewhat arbitrary, often determined by the underlying pathology, and not necessarily characterized by a change in quality or severity of symptoms. Chronic pain thus is often defined as pain persisting for longer than 3 to 6 months, or beyond the expected time of healing. There may be no identifiable pathology to account for the pain. Psychological and functional features are often associated with chronic pain and autonomic overactivity is not usually present. Chronic pain may be persistent (always present) or intermittent, such as migraine headache. Pain intensity may vary during the day or be related to activity level. Musculoskeletal disease, arthritis, orofacial, and neuropathic pain conditions are common in older persons. Once reversible factors have been excluded, the pain rather than the pathology is considered the major problem. At this stage, the goal of treatment shifts from a disease focus to reduction of pain, suffering, and disability.

Prevalence studies

Pain in older adults is common and has a tremendous impact on quality of life in this age group. There is great variability in the reported prevalence, likely due to differences in the reporting period for pain, the intensity of pain reported, and composition of the older population studies. Crook et al⁵ reported age-specific rates 29% for those aged between 71 and 80 years when asked "how often are you troubled by pain during the past 2 weeks..." Brattburg et al⁶ reported a 12-month prevalence of mild to severe pain in 75% in those over 75 years of age. Epidemiologic studies commonly show that pain affecting joints, feet, and legs is increased with age; that pain in the head, abdomen, and chest is reduced; but back pain frequency varies widely.^{7,8,9} The high prevalence of degenerative joint disease overwhelms any contribution from other causes in all surveys. Studies in residential care settings for the elderly have shown prevalence rates of chronic pain between 49% and 85%,^{10,11,12} with low back pain reported in 40%, arthritis of appendicular joints 24%, followed by old fracture site pain and painful neuropathies.¹³ Moss et al¹⁴ reported that during the last year of life 66% of individuals had frequent or continuous severe pain.

Among community-dwelling older adults, pain prevalence is reported between 25% to 83%,^{15,16,17,18} women have a higher prevalence compared with men at any given age.^{19–21} Lifestyle factors and preparedness to report pain may also be relevant.^{22,23} Measurement of pain in the community is difficult and most likely underestimated. This is due to a combination of constitutional, lifestyle, and psychosocial factors.

Age-related changes in pain perception

Pain may not be the cardinal symptom of disease in older people. Silent myocardial infarction is more common with age.²⁴ Similarly, in a retrospective study of elderly patients with peritonitis, abdominal pain was absent in nearly half of the cases.²⁵ The physiologic basis of these observations is uncertain. Clinicians should not underestimate the potential seriousness of underlying pathology in an older person because of the absence of severe pain.

There are widespread morphologic, electrophysiologic, neurochemical, and functional changes within the nociceptive pathways, and psychological factors that may alter pain experience in elderly people.²⁶ Most studies of experimental pain support the view that pain thresholds to short-duration noxious stimuli are increased in older people.^{27,28} Whether age also affects the level of discomfort and suffering associated with clinical pain is uncertain.²⁹ Controversy regarding the effect of age on pain thresholds exists, whereas pressure pain thresholds have been shown to both increase and decrease, with heat thresholds showing no changes with age.^{2,3} A decrease in the function of the descending inhibitory pain control pathway as a person ages³⁰ suggests greater sensitivity to noxious experimental pain. In other studies, reticence, self-doubt, and reluctance to label a stimulus as painful underlie the perception that stoicism to pain increases with age. However, when pain is perceived, the experience is the same, or under some circumstances, enhanced or prolonged.^{31,32} Tolerance to severe pain may even be reduced in older people.

Age-related loss of neurochemicals, such as serotonin,³³ glutamate, GABA,³⁴ and opioid receptors³⁵ implicated in pain modulation, may contribute to altered pain processing in older adults. Changes in the aging brain^{36,37} have been associated with older persons processing and response to pain. Taken together these studies suggest that pain is dependent on a complex neuroprocessing system that is affected by aging and has implications for the pain experience in older adults.

PATHOPHYSIOLOGIC PERSPECTIVE

Inferences about the underlying pathophysiology of a painful condition assist the clinician in the selection of therapy and determining prognosis. Pain may be subdivided into three pathophysiologic subtypes: nociceptive, neuropathic, and psychogenic. Pain that arises from noxious stimulation of specific peripheral or visceral nociceptors is termed *nociceptive pain*. Examples include pain arising from osteoarthritis, soft tissue injuries, and visceral pathology. Pain arising from pathology of the peripheral nerves or within the central nervous system leading to aberrant somatosensory processing is termed *neuropathic pain*. This term encompasses a diverse range of conditions including painful peripheral neuropathies, phantom limb pains, postherpetic neuralgia, trigeminal

neuralgia and central poststroke pain. Pain of neuropathic origin is often associated with abnormal and unpleasant sensations (dysesthesia) and may have a burning or shooting quality. Mild, normally nonnoxious stimuli in the affected region may cause pain (allodynia), and repetitive stimulation results in summation and pain persisting longer than the stimulus (hyperpathia). There may be a delay between the precipitating injury and the onset of pain. The onset of central poststroke pain syndrome occurs commonly between 1 and 3 months following the stroke, but may occur more than 1 year later.³⁸ Pain often persists in the absence of ongoing tissue damage.

The multidimensionality of chronic pain has long been recognized to include sensory-discriminative, affective-motivational, and cognitive-interpretative dimensions. These are influenced by biologic, psychological, and social factors. The ability of the individual to adapt to biopsychosocial changes in response to stress may be diminished with age. The term pain homeostenosis has been introduced to describe an organism's diminished ability to respond effectively to the stress of persistent pain.³⁷ Clinicians should be aware of factors that contribute to these phenomena, such as cognitive function, decreased density of opioid receptors, medical comorbidity, polypharmacy, and the effect of aging on pharmacokinetics and pharmacodynamics, social isolation, depression, and altered activities of daily living. There are specific assessment techniques and tools to assist in assessing these factors.

Depression is common in people with chronic pain. Patients who are depressed may exhibit decreased energy, decreased engagement in treatment modalities or avoidance of pleasant diversional activities. Anxiety has also been closely associated with pain^{39,40} and often coexists with depression in this population. Anxiety may play a part in fear-related behavior that might inhibit participation in physical rehabilitation efforts. Social networks and economic resources are important assessment parameters. Involvement with family and friends can provide pleasurable experiences and diversion away from a constant focus on pain. In addition to the availability of social support, the type of relationship should be assessed. Negative social reinforcement may present in the form of overly solicitous family members who encourage sedentary behavior. Other negative effects are likely if long-term caregivers become resentful of their support role. Economic resources have a great impact on access to potential treatment options and must to be identified.⁴¹ Finally, beliefs and attitudes about pain can impact on the overall pain management plan. Pain can signify loss of independence, debilitating illness, or be regarded as a general consequence of the aging process and therefore underreported. If older patients have a good understanding of the underlying cause of pain, what it means in terms of functions, and possible treatment options, it is likely that they will participate in the plan of care and obtain more satisfactory outcomes.

EVALUATION

Pain is inherently subjective; the individual's self-report is the gold standard for assessment. The history should focus on the onset and temporal pattern of the symptoms, site, and quality of the pain, the severity, aggravating and relieving factors, and the impact that pain is having on the patient's

lifestyle. The assessment of a patient with a complex pain problem may need to take place over several consultations. The reliability of the history can be affected by the chronicity of the pain, past interventions, and age-related conditions that affect cognition. A collaborative history from a family member is often helpful. Special emphasis should be placed on musculoskeletal and neurologic examinations because of their importance in the genesis of pain in elderly people. The assessment should include functional and psychological aspects and where possible the individual should be assessed within their own environment. The open-ended question, "What would you do if you no longer had pain?" often reveals valuable information regarding mood state, attitudes, and disability. Part of the assessment needs to focus on the patient's comorbidities, how these affect function, their contribution to altered mood state, and their propensity to affect management with medications, and physical or psychological interventions. One must be vigilant not to falsely attribute drug side effects to the underlying pathology.

Back pain is illustrative. An estimated two thirds of adults will experience back pain at some stage of their lives. Experimental studies reveal that pain may originate from any one of many structures. However, after clinical evaluation no precise pathoanatomic diagnosis can be established in 85% of cases.⁴² Investigations are used to confirm a diagnosis and exclude more serious pathology. The diagnostic probabilities change with increasing age; cancers, compression fractures, and spinal stenosis becoming more common. Plain radiology is not highly sensitive but findings on computerized tomography (CT) and magnetic resonance imaging (MRI) are nonspecific and thus may be misleading. CT and MRI studies of asymptomatic individuals over 60 years of age reveal about 80% have abnormal findings, such as disk prolapse and spinal canal stenosis. Therefore the identification of pathology on diagnostic investigations does not necessarily indicate causality. Deyo and Weinstein⁴² suggest that it is more helpful to address three questions during the assessment of a patient with low back pain: Is a systemic disease causing the pain? Secondly, is there social or psychological distress that may amplify or prolong pain? And thirdly, is there neurologic compromise that may require surgical evaluation? Under most circumstances, these questions can be answered from a careful history and physical examination without the need for further tests.

Several validated psychometric instruments can help to quantify and communicate the patient's pain experience. The widely used McGill Pain Questionnaire^{43,44} consists of 78 adjectives describing emotional, sensory, and evaluative dimensions of the pain experience. Words such as throbbing, sharp, cramping, burning, and aching describe a sensory dimension, whereas tiring, exhausting, cruel, punishing, fearful, and sickening describe an affective component. Although older adults vary greatly in their use and understanding of self-report pain instruments, numeric rating scales and verbal descriptor are generally preferable.^{45,46} Some visual analog scales have been found to be difficult to use among seniors.⁴⁷

Psychological assessment

A comprehensive psychological assessment is not usually required in the setting of acute pain. However, chronic pain may have profound effects on mood, interpersonal

relationships, and activity level, and it may be difficult to ascertain which is cause and which is effect. Psychological evaluation is indicated when medical evaluation fails to adequately explain the severity of pain behaviors. Psychological evaluation can also be valuable when the pain results in excessive health service use, or interference with normal activities or interpersonal relationships. Chronic pain patients are often resistant to psychological evaluation, considering this an inference that the pain is "in the head" rather than a physical problem. Patients often require careful explanation regarding the complex interaction between mind and body, which often influences pain, suffering, and disability.⁴⁸ Acknowledging that the pain is real preserves the patient's sense of legitimacy and allows for a more complete evaluation of the psychological factors contributing to the maintenance of pain.

It is important to evaluate how the patient and their relatives conceptualize the pain and goals of treatment. They may believe that the pain has persisted because the medical assessment has been inadequate or specific interventions denied. Each time a new intervention is tried and fails, the psychological distress is reinforced. Psychological strategies are not likely to be effective in teaching the patient how to manage with ongoing pain while the patient remains focused on seeking a cure. Pain behaviors such as limping, grimacing, inactivity, and verbalizing of pain complaints may be reinforced by social influences such as gaining attention, sympathy, or the ability to avoid unpleasant responsibilities. Fear of causing further pain or injury may lead to avoidance of activity. Attempts at management with medications and physical therapies, without addressing psychological factors, are often unsuccessful.

Assessment of pain in the presence of dementia

Dementia represents a major impediment to the evaluation and management of pain. Cognitive impairment may be aggravated by pain or medications used to treat the pain.⁴⁹ Bernabei et al reported that low cognitive performance and age greater than 85 years were independent risk factors for lack of appropriate treatment of pain in cancer patients.⁵⁰ The report of pain in demented individuals may be affected by memory impairment or limited communication skills. A corroborative history from relatives or previous therapists is often required. There is no convincing evidence of enhancement of pain by dementia. In fact, Parmelee et al¹² found a small negative relationship between pain intensity and cognitive impairment in a sample of 758 elderly institutionalized residents. Individuals with marked cognitive impairment were less likely to report pain in the back and joints. However, when pain was reported there was no difference in the presence or absence of a likely physical cause. Ferrell et al⁵¹ reported that elderly nursing home residents with mild to moderate cognitive impairment required more time to assimilate and respond to questions regarding pain, but of the 62% reporting pain complaints, 83% could complete a unidimensional pain-intensity scale, with the Present Pain Intensity Scale of the McGill Pain Questionnaire having the highest completion rate of 65%. A pain report should therefore not be disregarded because the individual has cognitive impairment.

When assessing pain in severely cognitively impaired patients, the clinician must rely on behavioral indicators.

These include nonverbal cues such as restlessness and guarding, verbal cues such as crying, moaning, and groaning, and facial expressions such as grimacing.^{52,53} Changes in usual activity may also indicate pain. There is tremendous variability in pain behavior and often certified nursing assistants will be the first to notice behavioral changes, including combativeness, resisting care, a decrease in social interactions, increased wandering, difficulty sleeping, and refusing to eat.^{54,55} Behavioral indicators for pain in this population and pain assessment tools are developed for cognitively impaired long-term care residents. The assessment instruments vary greatly on their reliability, validity, and applicability for easy clinical use.^{56,57} There are no shortage of geriatric assessment instruments available to clinicians. A recommendation from a comprehensive review of assessment of pain in older adults⁵⁸ suggests The Brief Pain Inventory⁵⁹ combined with the Short Form-McGill Pain Questionnaire⁴³ as an appropriate 10-minute battery for cognitively intact older adults.

Define the goals of therapy

Before embarking upon a treatment program, the patient and the clinician should agree on the goals of therapy, particularly when pain eradication is not feasible. Involvement of family members often assists with ensuring compliance and successful outcomes. A frank discussion about the prognosis and therapeutic options is often accepted with gratitude, particularly in individuals who have had unsatisfactory experiences in the past. Even if the sensory component of pain cannot be eliminated, improved outcomes can be achieved by addressing factors such as disability and mood disturbance. Management of severe pain often requires establishing a balance between the severity of sensory symptoms, the level of disability, and medication side effects. Disability may be more important to the patient than the pain. An improvement in the distance an individual is able to walk before being stopped by pain may be considered a positive outcome, although the intensity of maximum pain remains unaltered. Medication side effects may be more troublesome than the condition for which they were prescribed. Pain management programs combine cognitive and rehabilitative approaches to enhance coping strategies and minimize the impact that persistent pain has on the individual.

MANAGEMENT

Medications

Pharmacologic approaches with simple analgesics and nonsteroidal anti-inflammatory drugs (NSAIDs) are the mainstay, whether self-initiated or prescribed. This is often the most convenient and cost-effective approach. Selection of appropriate drug therapy for the older patient requires an understanding of age-related pharmacokinetic and pharmacodynamic changes, and needs to take into account any coexisting diseases and other medications, including those obtained without prescription. Selection of therapy needs to balance the potential efficacy with the potential for harm from the intervention. Timing is important. Analgesics may be prescribed on an "as required" basis for occasional pain or prophylactically for induced pain. However, for continuous pain, analgesics are best prescribed on a regular basis.

Additional doses may be required before activities known to exacerbate pain or for breakthrough pain. Medications with long half-lives may be used to reduce the frequency of dosing. In general, medications should be commenced at low doses, titrating upwards and stopping at the lowest dose that achieves the desired outcome. Concern regarding potential adverse effects should not result in suboptimal treatment of pain. Although generally less effective when used for neuropathic pain, all analgesics can be reasonably trialed in that situation.

Simple analgesics

Summary of Management Algorithm

Paracetamol:

- First-line analgesic for older patients with chronic pain
- Often as effective as NSAIDs
- Best given regularly for persistent pain, rather than as required

NSAIDs:

- Increased risk of GI and renal complications in elderly
- Avoid if possible

Selective COX-2 inhibitors:

- Preferable to nonselective NSAIDs
- Similar nongastrointestinal side effects to nonselective NSAIDs

Adjuvant analgesic (e.g., antidepressants and anticonvulsants):

- Proven role in neuropathic pain states
- Total pain eradication is unlikely
- Selection of medication is based on side effect profile rather than comparative efficacy
- Start at low dose, increase slowly

Opioid analgesics:

- Have a role in chronic nonmalignant pain
- Treat constipation preemptively
- Drug dependence is uncommon in elderly people

Nonpharmacologic approaches (e.g., physical and psychological therapies):

- Will reduce reliance on medications
- Failure to employ these strategies often accounts for treatment failure

Acetaminophen is the preferred analgesic for older adults.⁶⁰ A trial of paracetamol is warranted as initial therapy on the basis of cost, efficacy, and toxicity profile. For many patients, paracetamol affords similar efficacy to that achieved with NSAIDs.⁶¹ It is absorbed rapidly and metabolized by the liver. Because of the risk of hepatotoxicity, acetaminophen should be used with caution in patients with liver disease, chronic alcoholism, malnutrition, and dehydration. Dosages should be limited to 4000 mg per 24 hours, with lower doses used for persons with diminished renal or hepatic function or for those requiring chronic use.

As a class, NSAIDs have been among the most frequently prescribed medications, particularly for pain associated with osteoarthritis and inflammatory arthropathies. Although effective in reducing signs and symptoms, they have no

effect on the underlying musculoskeletal disease.⁶² The side effect and drug interaction profile of NSAIDs is of particular concern. At least 10% to 20% of patients taking NSAIDs will experience dyspepsia. Complications of ulcer disease, such as hemorrhage and perforation, occur far more often in patients taking NSAIDs.⁶³ An estimated 16,500 deaths occurred from NSAID gastrointestinal toxic effects in the United States in 1997.⁶⁴ Renal toxicity is another concern. Risk factors for renal failure in patients with intrinsic renal disease treated with NSAIDs include age over 65 years, a history of hypertension, congestive cardiac failure, and concomitant use of diuretics or angiotensin-converting enzyme inhibitors. Most NSAIDs have a dose-response relationship with a ceiling effect. Increasing the dose above the recommended level or adding a second NSAID does not impart any greater analgesia, but increases the likelihood of drug toxicity.

The rate of NSAID-related serious gastrointestinal complications requiring hospitalization has decreased in recent years, in part due to extensive medical education campaigns and a move away from NSAIDs as first-line management of osteoarthritis.⁶⁴ Patients with inflammatory arthritides should preferentially be treated with disease modifying drugs. The options for management of patients with NSAIDs who are at high risk of serious upper gastrointestinal events are the use of a nonselective NSAID with gastroprotective therapy, or the use of a cyclooxygenase-2 (COX-2) specific inhibitor. Co-administration of misoprostol has been demonstrated to reduce the upper gastrointestinal complication rate of nonselective NSAIDs but is not well tolerated. Proton pump inhibitors are an acceptable alternative. H₂ receptor antagonists have been shown to prevent duodenal ulceration only, and cannot be recommended.⁶³ Celecoxib is the only COX-2 selective NSAID currently available in the United States.⁴ The primary short-term advantage of this class of agents is the lack of effect on platelet function. As these drugs are frequently prescribed for pain control in rheumatoid arthritis and osteoarthritis, their usefulness for long-term therapy is limited. In addition, COX-2 inhibitors appear to affect renal function in a similar fashion to nonselective NSAIDs and particular care is required in patients with renal impairment, or those taking diuretics and angiotensin-converting enzyme inhibitors. COX-2 inhibitors may diminish the antihypertensive effects of ACE inhibitors and diuretic effects of furosemide and thiazides. Celecoxib inhibits CP450 (CYP2C9) enzyme and thus may cause elevation of plasma concentrations of drugs metabolized by this enzyme, such as some β -blockers, antidepressants, and antipsychotics.⁶⁵

Topical NSAIDs are an effective and safe alternative for some patients, especially in the management of acute musculoskeletal and soft tissue inflammatory pain.^{66,67} Diclofenac gel and patch formulations are currently available with several other NSAID formulations under development. Although GI side effects are less common than oral preparations, the risk exists especially in persons who have had previous side effects to NSAIDs.⁶⁸

Opioid analgesics

In the past, opioid analgesics have been divided into weak and strong categories according to their potency. This distinction has now become less useful. All opioid analgesics have the potential to cause nausea, constipation, sedation,

respiratory depression, and cognitive impairment. Increased cognitive impairment may itself lead to a diminished ability to cope with pain, thus leading to a paradoxical increase in pain with an increasing dose of opioid. Opioids are generally reserved for moderate or severe pain. Elderly patients tend to be more sensitive to equivalent doses and blood levels of opioids, receiving greater and more prolonged pain relief.⁴⁹ The analgesic effects of Codeine (methylnorphine) are mediated by its conversion to morphine via the cytochrome P450D6 (CYP2D6) system. About 8% of Caucasians and 2% of Asians are genetically deficient in CYP2D6 and obtain little pain relief with codeine. A number of medications frequently prescribed in elderly patients are capable of inhibiting CYP2D6, including cimetidine, quinidine, haloperidol, amitriptyline, and the selective serotonin reuptake inhibitors (SSRIs), including fluoxetine, paroxetine, and fluvoxamine. Side effects of codeine are common, particularly constipation, nausea, and confusion.

Other weak opioids include tramadol and propoxyphene. Tramadol is a centrally acting synthetic analgesic with opioid-like effects. Its mode of action is through binding to the μ -opioid receptor and inhibition of noradrenaline and serotonin reuptake. The efficacy of tramadol is comparable to ibuprofen in patients with hip and knee osteoarthritis. Dose reduction may be required in elderly patients. Propoxyphene should be used with caution or not at all in older adults because of the long half-life of its major metabolite and the potential for central nervous system side effects including hallucinations, seizures, and falls.^{69,70} It has no clinical advantage over nonopioids such as acetaminophen. Combinations of nonopioids with weak opioids, such as aspirin or paracetamol with codeine offer enhanced analgesia.⁷¹ The combined medications may result in a lower incidence of side effects as each analgesic can be used at a lower dose. The weak opioids have a ceiling effect for analgesia due to the combination and limits of acetaminophen. If adequate pain relief is not obtained at optimal doses, change to a strong opioid should be considered.

Morphine is the prototypic opioid. Its analgesic properties are not limited by a ceiling effect, but side effects are common. Tolerance to side effects develops more rapidly than tolerance to analgesic effects, although constipation tends to persist. Once the daily opioid requirements have been established through the administration of a short-acting opioid on a regular basis, then the use of delayed-release opioid agents should be considered. Delayed-release morphine and oxycodone preparations may be used in elderly patients but care must be taken to prevent drug accumulation. Other strong opioids include methadone, hydromorphone, (meperidine and fentanyl). Methadone must be used with caution because it has a long half-life of up to 2 or 3 days, resulting in accumulation in elderly patients.

Tolerance may develop with repeated administration of all opioids whereby higher doses are required to maintain equivalent analgesic effects. The rate of development of tolerance varies greatly, but is not as common as once believed. Before tolerance is suspected in a patient with a previously established opioid dose, evidence of advancing disease, new onset disease or injury, or psychosocial etiology should be investigated. If these are negative, the dose or frequency of dosing may be increased. Cross-tolerance with other opioids is not complete as they often act through

different combinations of receptors. The problem may be overcome by changing to another oral opioid, commencing at one half of the equianalgesic dose. When a patient is unable to tolerate oral opioids, or has refractory pain, parenteral analgesia by the transdermal, subcutaneous, venous, epidural, or intrathecal route should be considered. A transdermal fentanyl patch offers the advantage of one application every 72 hours. It has a similar side effect profile to other opioids, although some subjects report less constipation than with other preparations. Fentanyl accumulates in skeletal muscle and fat and then is slowly released into the blood. Minimum effective concentrations are reached approximately 6 hours after application. Serum fentanyl concentrations fall by 50% approximately 17 hours after removing the patch. The clearance of fentanyl is delayed in elderly, cachectic, and debilitated patients. The 25 µg/hr transdermal fentanyl patch is equivalent to about 90 mg of morphine per day. It is not recommended for opioid-naïve patients.

Adjuvant analgesics

Adjuvant analgesics are drugs that have a primary indication other than pain but are analgesic in neuropathic pain syndromes. They include medications from heterogeneous therapeutic classes, including tricyclic antidepressants, anticonvulsants, oral antiarrhythmics, and neuroleptics.

Antidepressants and anticonvulsants have a proven role in managing refractory neuropathic pain. Pain relief is usually only partial, with 30% reduction in pain scores usually being classified as success. For every three patients treated with either an antidepressant or anticonvulsant for postherpetic neuralgia or diabetic neuropathy, one patient experiences 50% pain relief that they would not have received with placebo.⁷² Empirically, antidepressants have been used for neuropathic pain with a burning quality and anticonvulsants for shooting pain, despite lack of evidence linking efficacy to the characteristics of pain. Tricyclic antidepressants also have a role in managing tension and migraine headache, atypical facial pain, rheumatoid arthritis, chronic low back pain, fibromyalgia, and cancer pain.⁷³ Tricyclic antidepressants have been widely used in older individuals despite their propensity for side effects such as dry mouth, postural hypotension, falls, constipation, sedation, and urinary retention. The sedating side effect may be used to advantage for some individuals with pain-related insomnia. The analgesic effects of tricyclic antidepressants are independent of antidepressant effects, occurring more rapidly and at a lower dose than used for depression. The median effective analgesic dose of agents such as amitriptyline or nortriptyline is in the order of 50 to 70 mg daily.⁷⁴ A low starting dose of around 10 mg is recommended. Newer antidepressant medications, such as selective serotonin reuptake inhibitors (SSRIs), have fewer side effects but have not been demonstrated to be more effective than a placebo in achieving analgesia, although there are insufficient data to draw a final conclusion.^{72,75} Newer selective SSRIs, venlafaxine⁷⁶ and duloxetine,⁷⁷ have been found effective for the treatment of peripheral diabetic neuropathy (PDN) and postherpetic neuralgia (PHN).

Anticonvulsants have been widely used for neuropathic pain despite surprisingly few trials of analgesic effectiveness.⁷⁸ Carbamazepine is the drug of choice for trigeminal

neuralgia, with pain control achieved in about 75% of patients.⁷⁹ Anticonvulsants are considered second-line therapy following antidepressants for other neuropathic pain states.⁷⁸ Anticonvulsants shown to be of benefit for diabetic neuropathy and postherpetic neuralgia are carbamazepine, phenytoin, and gabapentin.⁷⁸ Gabapentin has a lower incidence of side effects than carbamazepine or phenytoin, but has not been proven to be more effective than the older anticonvulsants.^{72,78} Other anticonvulsants that have been widely used to treat neuropathic pain without convincing evidence for benefit in clinical trials include valproate and lamotrigine.

The selection of an adjuvant analgesic agent for the management of neuropathic pain should be based on the side effect profile, and the potential for drug interaction, rather than relative efficacy of different agents. There is considerable individual variation in the response to these agents. Failure to respond to one agent is not predictive of the response to another agent within the same therapeutic class.

Topical lignocaine (lidocaine) patches have been licensed for use in postherpetic neuralgia in the United States. Extreme care must be used when using oral or parenteral local anesthetic agents, such as mexiletine and lignocaine to treat pain in older adults because of the potential for fatal arrhythmias. The use of neuroleptic medication for pain in older people is not indicated as side effects outweigh benefits. In addition herbal products and dietary supplements are used by many Americans. Marinac et al found that 21% of persons over 60 years old were using at least one herbal or dietary supplement with 19% at risk for a potential adverse drug reaction.⁸⁰

Nonpharmacologic therapies

Nonpharmacologic approaches, either alone or in combination with pharmacologic approaches, should be an integral part of the care plan for older individuals with chronic pain.⁶⁰ Nonpharmacologic approaches encompass a broad range of physical and other treatment modalities. They are widely used by patients, often without the knowledge of their health care provider. Few of these therapies have undergone formal evaluation.

Physical therapies

Simple adjustments in posture and daily routines, such as preparing meals in a seated position, breaking up the housework, or the provision of a walking aid can reduce the impact of pain on daily life. The use of a walking frame, which causes a mild degree of lumbar flexion, will often ease the pain of lumbar canal stenosis.

Exercise is a major component of most pain management programs, either alone or in conjunction with pharmacologic and other nonpharmacologic approaches. Even frail and institutionalized elderly people may benefit. Exercise can lead to decrease in pain, improvements in function, and elevation of mood.⁸¹ Hydrotherapy should be considered when weight-bearing exercises aggravate pain. The buoyancy effect of water reduces the weight of the body allowing joints to be moved with minimal friction through a full range of movements. The warmth of the water decreases pain and muscle spasm. Transcutaneous electrical nerve stimulation (TENS) is a popular method of symptom relief for a wide

range of painful conditions in elderly people, such as low back pain, osteoarthritis, and postherpetic neuralgia. Other physical therapies used for a wide range of painful conditions include massage, cold and heat treatments, acupuncture, and electrotherapies such as ultrasound, infrared lamps, microwave, and shortwave diathermy.

Joint replacement surgery has had a major impact in alleviating the suffering of older people with degenerative joint disease who have experienced inadequate symptom control with conservative management.

Psychological approaches

Psychological factors may contribute to the maintenance of pain or be causally related to the pain. Regardless of the pathophysiologic basis of chronic pain, psychological strategies have a role in management. The essence of management is to establish appropriate pain coping strategies and discourage behaviors that may perpetuate the pain syndrome. Usually a combination of behavioral and cognitive strategies is employed. Cognitive strategies are aimed at modifying belief structures, attitudes, and thoughts to modify the experience of pain and suffering. This approach also includes distraction therapy, relaxation, biofeedback, and hypnosis. The patient is encouraged to take an active role and accept responsibility for pain management, rather than being a passive victim. These strategies have been demonstrated to be effective managing pain in older adults.^{82,83}

Cognitive strategies are usually combined with a behavioral approach. Behavioral operant conditioning discourages pain behaviors, such as limping, grimacing, inactivity, and verbalizing of pain complaints. Usually, in conjunction with the patient's relatives, positive reinforcement is provided for behavior unrelated to pain and for successfully achieving preset goals. All other pain behaviors such as moaning are ignored. A number of studies have demonstrated increased activity, reduced analgesic consumption, and improved mood in middle-aged adults, with some reporting benefit for elderly patients with chronic pain.^{84,85}

Other self-management strategies such as yoga, Tai Chi, and music therapy, show promise in reducing pain and increasing function in older adults.^{86–88} The use on telephone and Internet delivered interventions may increase access to these therapies for older individuals.

Pain and cancer

Half of all cancers occur in the population over 65 years of age.⁸⁹ In the advanced stages of cancer, 70% experience pain, of which 80% is severe and persistent.⁹⁰ In up to 90% of cases, cancer pain can be managed by relatively simple means.⁹¹ The World Health Organization (WHO) has developed the Cancer Pain Relief Program to offer adequate pain relief to all cancer patients in the world through the existing health system.⁹⁰

The WHO method for relief of cancer pain is based on a three-step approach to the use of analgesia. The first step of the WHO analgesic ladder is the nonopioid analgesics, including paracetamol and NSAIDs. The second step is the weak opioids and the third step is the strong opioid group. Nonopioid analgesics are usually combined with an opioid in steps two and three to give additive analgesia. At each stage, adjuvant analgesic drugs, such as antidepressants and anticonvulsants, should be added when there is a specific

indication. Zech et al⁹² reported nearly 90% of 2118 palliative care patients were able to obtain satisfactory pain control on this regimen up to the time of death. Patients with residual pain were often content with the balance of analgesic efficacy and troublesome side effects. Emotional, spiritual, and functional aspects should not be neglected. Despite the widespread dissemination of the WHO ladder, most cancer pain patients around the world still appear to have inadequate analgesia.⁹³

The use of opioids in chronic noncancer pain

There is clear consensus about the use of opioids in severe acute and malignant pain; however, the role of opioid therapy in the management of chronic pain of noncancer origin remains controversial. Clinical experience demonstrates that selected patients obtain considerable benefit.⁹⁴ Exaggerated fear of adverse effects should not prevent a trial of opioid therapy in appropriately selected individuals who have not responded to other therapies. Maintenance opioid therapy for chronic pain of noncancer origin should only be considered after the patient has been thoroughly evaluated and has not responded to other conventional pharmacologic and nonpharmacologic therapies. There is an increased onus on the clinician to ensure the patient understands the risks and benefits of this therapy. The more serious the risk, the more important it is for the physician to outline such risk, even if the probability of it eventuating is small. To overcome anxiety about this form of therapy, the clinician may need to explain to the patient the distinction between addiction, dependence, and tolerance. Physical dependence occurs with the prolonged use of all opioids. It is manifested by unpleasant symptoms following abrupt withdrawal, such as diaphoresis, abdominal cramps, malaise, and fear. Although the symptoms are similar to those experienced by opioid addicts, the normal person does not experience opioid craving. When there is a possibility of dependence, opioids should not be abruptly withdrawn. Addiction following the therapeutic administration of opioids is very rare, especially in older individuals. Opioid tolerance is manifested by reduced analgesic effect at the same dose. Its cause is unknown. Increased opioid dose requirements are more likely to be due to the progression of the underlying disease than the development of tolerance. With the relatively low doses of opioids used for the management of chronic noncancer pain in this population, the older individual is less likely to be troubled by these problems.⁶⁰

The aims of treatment should be explicit, often aimed at easing the pain rather than total eradication. A technique such as Goal Attainment Scaling can be useful in this regard, identifying ranges of desired outcomes, and allowing for side effects to be considered ahead of time.⁹⁵ Total eradication of pain may occur at the expense of intolerable side effects. Four factors should be regularly monitored; pain relief, side effects, overall functional status, and evidence of aberrant behavior. The dose may be increased to obtain better pain control or functional status. If, however, the opioid dose is escalating at a time when pain control or functional status is declining, management should be reviewed. The physician must be familiar with and observe statutory requirements regarding the supply of opioids. Both parties must agree to close supervision for the duration of therapy.

CONCLUDING REMARKS

Advancing age is associated with an increased incidence of painful pathology. Anyone who has persistent pain despite what appears to be conventional treatment should be carefully reassessed to determine why there has been a failure of response to therapy. One should never conclude that it is the patient who has failed to respond to treatment; it is the treatment that has failed to achieve the desired result. Severe unrelieved pain has a profound impact on the individual. Various factors may preclude the older patient from the benefit of definitive therapy to eradicate pain and under these circumstances, symptom management is indicated. This must take into consideration the effect of comorbidities on the expression, assessment, diagnosis, and treatment of the painful condition. Overemphasis on pharmacologic approaches ignores the potential benefits of physical and cognitive-behavioral strategies. The persistence of pain despite apparently appropriate therapy raises the possibility of unrecognized mood disturbance, pain of neurogenic origin, or advancing pathology. Under these circumstances a multidisciplinary pain management approach involving medical, physical, and psychological therapeutic modalities is often more effective than a single disciplinary approach.⁹⁶ Multidisciplinary pain management clinics have emerged over the past 30 years, but are limited geographically and

by expertise in geriatric medicine. Age should not, however, be regarded as a barrier to successful outcomes from multidisciplinary management of pain problems. Even if pain cannot be eradicated, worthwhile improvements can often be achieved by addressing pain as a problem in a broader sense, not simply a sensory symptom.

KEY POINTS

Pain in the Older Adult

Assessments:

- Contribution of nociceptive and neuropathic factors
- Impact of pain on function and mood state
- Comorbidities affecting assessment, function, and treatment selection

Investigations:

- Presence of radiologic abnormalities does not prove causality
- Unexplained change in symptoms warrants reassessment to exclude serious pathology

Palliative Medicine for the Elderly Patient

Ilora Finlay
Margred Capel

This chapter will define palliative care and consider it in the context of the elderly patient. In addition it will consider briefly the impact age has on the illnesses encountered the social impact of this and the strategies available. The second part of this chapter will concentrate on symptom control.

INTRODUCTION

The hospice movement arose out of religious orders in the late nineteenth and early twentieth century, though arguably it has been practiced by medical practitioners in some form throughout history.^{1,2} However, it was Cicely Saunders pioneering work that brought the advances in pain and symptom control, leading to the special skills known as modern palliative care.

Death is an inevitable consequence of life; increasing life expectancy and altered disease trajectories means that death from disease occurs more commonly in the elderly population. In developed countries, elderly people may be affected by multiple coexisting acute and chronic illnesses. In the twenty-first century palliative medicine aims to ensure the dying process itself does not have to be the excruciating struggle that many of the older generation recollect observing when their grandparents died.

Palliative medicine can have an important role when patients are entering their last days of life, but also can contribute to ameliorating the quality of life of patients suffering from chronic or intractable diseases.^{1,2} Palliative care is defined by the World Health Organization (WHO) as "Palliative care is an approach that improves the quality of life of patients and their families facing the problems associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial, and spiritual."³

The aging process

Illnesses and coexisting morbidities encountered in the elderly population differ from those encountered in the young. The consequence of the aging process can mean patients have coexisting cardiac, metabolic, and rheumatologic disorders, such as ischemic heart disease, diabetes, and arthritis in addition to developing illnesses associated with age itself, such as neurodegenerative disorders (dementia, Parkinson disease), stroke, and cancer. The prevalence of failing organ function, such as heart failure and renal failure, can impose significant physical and psychological distress upon the individual, restricting activities and quality of life of the patient and the caregiver.

Providing palliative care to elderly patients with chronic illness may mean that at different stages of the illness the patient may require preventative or life-prolonging

intervention, rehabilitation, or purely comfort measures depending on the needs of the individual that are identified and their place along the illness journey. Recognition and shifting emphasis of care may require sensitive communication with the patient and their care providers.

The aging process alters organ function, which impacts upon the pharmacokinetics of drug metabolism.⁴ Pharmacodynamic processes are also affected by age with some receptors (including benzodiazepine and opiates) demonstrating greater sensitivity and others (including insulin) comparative insensitivity. The presence of coexisting disease risks compounding this through the consequences of polypharmacy.

Pressure ulcers

Immobility, incontinence, cachexia, malnutrition, and comorbidity contribute to the formation of decubitus pressure ulcers, which should be managed according to standard wound care guidelines.⁵ The presence of a wound is an indicator of advanced disease and poor prognosis, but is not in itself an independent risk factor for death.^{6,7}

Depending upon local access and availability, it may be appropriate to refer patients incapacitated from lymphedema to local lymphedema services to reduce size and restore function to limbs. General management of lymphedema includes careful skin hygiene and preventing acute inflammatory episodes.

Those at risk of pressure sores require an appropriate level of nursing intervention to turn and adjust the position of the patient regularly and systematically, when the patient is at home or in a long-stay accommodation family, and informal caregivers need instructions on how to protect vulnerable pressure points.

In the context of end of life care when a pressure sore is present it may be more appropriate to focus on comfort, including relief of pain and control of odor, bleeding, or discharge since healing may be an unrealistic goal. Pressure relieving equipment is still essential and dressings have a role in the relief of pain. Short-acting analgesia can be administered to the patient before painful dressing changes. There is some evidence that the application of topical analgesia in the form of diamorphine or morphine sulphate mixed in a medium such as Instillagel or lubricant jelly to painful wounds can cause local relief without the disadvantage of incurring systemic side effects.⁸ Odor can be limited through use of adequate cleaning, frequent dressing changes, and use of topical metronidazole or silver sulfadiazine. Appropriate topical dressings such as charcoal dressings can contain odors. If the patient is not suffering from nausea, lemon or vanilla oils, or filtering/air purifiers can be used to mask smells in the immediate environment. A short prognosis should not preclude a patient from referral to local wound care services if their input could ameliorate suffering from a wound.

Care providers

Cultural and social differences exist within communities, affecting the availability of support and expectations of care for the patient. The burden of home care falls mainly on female members of the family with more women in developed countries now at home providing care for elderly people, rather than for children.^{2,9} A minority of care of the elderly people is from paid caregivers. In addition to spouses providing care for their partners, in the absence of spouses or in the event of their ill health, children often provide care for their elderly parents. This role reversal impacts upon relationships, caregiver's physical and psychological health, and has economic consequences.^{9,10} Care providers are at increased risk factor of death, major physical ill health, and depression.

Care providers of the elderly patient need increased support from the medical team during episodes of acute illness of the patient, and ongoing support during chronic stages, which may require them to provide care over many years. Caregivers need full explanations of the disease processes to help manage their expectations and help them cope with the uncertainty that disease brings.

The umbrella of palliative care may entitle patients and care provider's access to financial and social resources, to help alleviate the economic and social burdens of care provision. Access to a day center or sitting services may provide some respite to the care provider and respite care should be considered both if the caregiver has acute health needs and also at planned regular intervals to provide a break from the work of caring. Unrelieved stress and the burden of care can otherwise result in a breakdown in the relationship between the care provider and the patient, potentially spiraling down into situations of neglect, abuse, and worsening health in both parties.

Care providers frequently have concerns and feeling of guilt when the patient is being cared for in a nursing or residential home environment, so they need to be listened to and when necessary reassured of the reasons for the appropriateness of place of care. Often those who have cared for a long time want to continue to provide some care when the patient is transferred to a nursing home or hospice facilities; helping them do so can relieve the burden of guilt and worry they feel from relinquishing care in the home environment.

Following the death of the patient, the care provider may experience severe grief both for the profound loss they have experienced and for their loss of role in addition to readjusting to life, and organizing funeral arrangements and financial affairs. Such individuals are at risk of prolonged or complicated bereavement and referral to bereavement support groups and counselors may be beneficial.

Future planning

The importance of forward planning with elderly patients and their families or care providers cannot be underestimated. This can prevent considerable distress and disagreement, if family members and care providers have to make decisions concerning health and social care when the patient is unable to do so. The Mental Capacity Act 2005 directs medical teams to consider the information provided by those individuals who are familiar with the patient in the event that the patient is unable to communicate their wishes. The

responsibility for medical decisions that have to be taken on behalf of a patient who has lost capacity still ultimately rests with the medical team and not the family. In the absence of family or friends, there is provision under the act for a court-appointed patient advocate who may input upon aspects of social and medical care.¹¹

Use of advanced decisions, which are now legally binding, can enable the patient to consider the recognized complications of their illness or dying process, explore treatment options, and communicate their future preferred medical management in specific circumstances. An advanced decision can be useful as a preemptive tool when the patient has been diagnosed with neurodegenerative illnesses, such as dementia or motor neurone disease, so that the clinical team is fully aware of the patient's wishes. The advance decision to refuse treatment can set limits upon the interventions a patient would want to refuse in the future, for example, with respect to artificial feeding and nutrition, use of antibiotics, repeated venipuncture, resuscitation, and respiratory support. But an advance decision cannot direct the clinical team to undertake an intervention if it is not clinically indicated in the patient's best interest.

The four ethical principles of autonomy, beneficence, non-maleficence, and justice create a framework within which all clinical decisions should be considered. Autonomy or self-governance requires respect for the individual's right to determine their own well-being; however, to do this patients require information in a comprehensible format to make informed choices concerning their future. Patient wishes for future care, values, and concerns can be recorded and some information can be used to form an advanced statement of wishes, bearing in mind that, anyway, the principle of non-maleficence means patients should not be burdened with futile investigations, treatments, or useless information that does not enhance their life. Attempts at cardiopulmonary resuscitation may fall into this category in certain circumstances. Beneficence dictates that the anticipated benefits must outweigh the anticipated risks and burdens. Justice implies that all patients may have similar access to investigations and treatments without prejudice. It also implies that they may have the best possible care within the resources available but these have to be fairly allocated and divided among their community.

The use of ethical frameworks can be applied to decisions regarding withdrawal of active treatment to achieve the appropriate choice for the individual and prevent unethical blanket policies.

Oral intake

Dysphagia and disordered swallowing may occur as part of end-stage dementia, other neurodegenerative diseases, stroke, and some malignancies, predisposing the individual to malnutrition and to aspiration pneumonia. Changing the texture of food and fluid, use of thickeners, and careful positioning of the individual when eating, supports safe swallowing. Patients should be reassessed by speech and language therapists as their disease progresses and swallowing changes so that appropriate advice can guide care.

Eating is a social activity; altered diets or exclusion of the individual from family meals can lead to social isolation and diminish quality of life.¹² Providing food and drinks can be a source of stress between patients and their caregivers, with

patients turning their heads away or clenching their teeth refusing to eat carefully prepared meals, so caregivers need support and explanation. Anorexia can be part of the natural dying process; in this situation artificial nutrition will not prolong life and indeed may be burdensome and distort the focus of care. But this matter must be communicated to and understood by any care providers via sensitive explanation to avoid the perception that the patient is being “starved to death” and food or fluid being forced into the mouth of an individual unable to swallow. Symptoms of thirst can be relieved with good oral hygiene, artificial saliva, and sips of water or ice cubes. These are practical interventions easily undertaken by the nurse or caregivers, if this does not appear adequate, subcutaneous fluids can be considered in the community or inpatient environment.

Artificial and supplemental feeding may need to be considered, depending upon the stage of the illness or acute intercurrent illness, with the patient’s consent, particularly in the preterminal stages. However, subcutaneous fluid rehydration may provide comfort even in the last days of life to some patients. Nasogastric feeding should not be considered a long-term option as it is uncomfortable, may require frequent replacement with risk of pulmonary placement, nasal irritation, and aspiration pneumonia. For long-term nutrition gastrostomy and jejunostomy tubes should be considered. These confer their own risks related to the procedure and infection, and do not prevent the risk of aspiration if they are fed to the patient in a supine position; diarrhea is a potential complication. Parenteral feeding predisposes to infection and loss of integrity of the intestinal lumen. Patients should be considered as individuals and options tailored accordingly to the circumstance rather than adhering to a single policy.

Anosmia is a frequent concomitant of advancing years, particular in those who have smoked; lack of smell aggravates lack of appetite as taste is impaired. Good dentition is essential to eating, so oral hygiene is key. The loss of dentures should be considered an emergency because it immediately restricts the individual’s diet, oral intake, communication, and socialization. Good dental care is increasingly important in those on bisphosphonates for osteoporosis because osteonecrosis of the jaw is a devastating potential complication.

Medication commonly causes dry mouth. In addition to discontinuing medication where possible, symptomatic relief can be achieved by sucking crushed ice, sips of fluid, artificial saliva, or sucking fresh or frozen pineapple pieces.^{1,2} Oral candida infection is a relatively frequent finding, as the fungi adhere to denture plastic, but oral candida does not necessarily correlate with oral symptoms.¹³ Dysphagia is an indication for systemic antifungals. However, radiologic imaging is indicated if the dysphagia does not resolve rapidly as other pathology may be concurrent. Oral ulcers can be systematically managed with a coating gel or mouthwash with topical lidocaine, topical steroid based cream, or topical coating agents, but the underlying cause, often ill-fitting dentures or poor nutrition must be sought.^{1,2}

Place of care

Preferred place of care through life and when dying should be explored sensitively and honestly, making the elderly patient aware of the feasible options and their limitations. Inequalities of access to home care nursing exists throughout the United Kingdom and can preclude care at home. Primary

care teams who keep palliative care registers can use the trigger for completing DS1500 and/or the question: “would you be surprised if the patient died within the next six months?” to identify patients for such a register. A register can be used to inform out of hours services of the patient’s condition and tailor provision of health care to prevent unwanted or unnecessary admissions to the hospital via the emergency or out-of-hours services. Use of the Gold Standards Framework in Care Homes can reduce crisis hospital admissions and reduce the percentage of residents dying in the hospital and facilitate patient-centered care.¹⁵

Many hospices offer short-term admissions but cannot accommodate people for a prolonged period of terminal illness, which may mean the individual receives several admissions throughout the course of the terminal part of their illness. The introduction of the Integrated Care Pathway for the last days of life and application in the community and secondary care may improve the standard of care for patients in their terminal phase.¹⁴ Approximately one fifth of the population die in care homes within the United Kingdom.

Patients can be considered terminally ill when they are likely to die within the foreseeable future from a specific progressing disease. Elderly patients often suffer from one or more chronic illnesses in addition to experiencing progressive or terminal diagnosis and can benefit from care with a palliative approach, quite apart from those who are actively dying and within their last days of life. Whenever symptoms occur, the potential cause of the symptom should be identified to guide treatment. Appropriate treatment of the cause may resolve the symptom and improve quality of life even in the face of concurrent terminal illness—such as treatment of hypothyroidism, Parkinson’s disease, or intercurrent infection. Problem-orientated clinical notes prove particularly useful in patients with multiple comorbidities.

SYMPTOM CONTROL

Pain

Pain is what the patient says it is and the same principles apply to treating pain in elderly people as apply in younger patients. Each pain should be identified, characterized (including site, duration intensity) and separately recorded, and precipitating and relieving factors identified. Application of the simplistic mnemonic PQRST¹⁶ may aid this process.

Eliciting the Cause of Each Pain Using “PQRST”

For each pain identify:

Precipitating or relieving factors

Quality of the pain (e.g., burning/in an area of altered sensation may point to neuropathic pain)

Radiation of the pain (e.g., radicular pain)

Severity (often rated using visual analogue or numeric on 0–10 scale)

Temporal factors (how long it has been present/how long it lasts if intermittent; whether worse at particular times of day)

Table 115-1. Causes of Pain Reported By 500 Patients on Admission to a Marie Curie Hospice Unit

Tumor bulk
Visceral, caused by compression of adjacent structures
Bone, metastases, and pathologic fractures
Intrinsic and extrinsic esophageal tumor mass
Organ capsule stretching, including liver capsule pain
Pleuritic pain from tumor nodules
Diaphragmatic pain, varying with respiration, from liver and diaphragmatic metastases
Nerve compression
Radicular pain from spinal cord compression
Headache from raised intracranial compression
Rectal tenesmus
Skin metastases
Pain not directly attributable to malignancy:
Concomitant infection: pleuritic chest pain, mouth discomfort, bladder spasm
Cystitis
Infected pressure sores
Herpes zoster (shingles)
Oral herpes simplex
Aches associated with debility, (but not attributable to malignancy)
Increased tone in paralyzed limb
Arthritis
Neuropathic pain
Skin burning following radiotherapy
Angina
Reflux esophagitis or dyspepsia
Peptic ulcer pain manifested as abdominal pain, referred pain to shoulder tip from perforation

The differential diagnosis of the pain should be recorded; this may determine pain treatments and possible disease modifying interventions. Meticulous physical examination is essential; for example, abdominal pain from urinary retention compared with pain from acute abdomen or tumor mass may give a similar history but have very different signs. The pain should be considered in holistic terms, including considering the impact this has upon the individual because effective control of the physical aspect of symptom control requires consideration and intervention to the social, emotional, and spiritual dimensions of the individual. Pain assessment should include mood, emotional functional, and cognitive assessment as these are recognized to impact upon pain perception and, unless addressed, may continue to be manifested as physical pain unresponsive to analgesia. Elderly patients in comparison to their younger counterparts are more likely to experience musculoskeletal, leg, and foot pain and less likely to experience headache and visceral pain (Table 115-1).¹⁷

After a baseline assessment of the pain, the situation should be evaluated every 24 hours until pain is controlled. A variety of tools can be used to assess pain including the Simple Descriptive Pain Intensity Scale, Numeric Pain Intensity Scale, and Visual Analogue Scale. The Functional Pain Scale has been validated for use in the elderly.² Altered behavior or agitation may be a manifestation of pain in patients with impaired communication.

Analgesia can be titrated in accordance with the WHO analgesic ladder, and depending upon the characteristics of the pain, appropriate adjuvants can be included in the regime. Consideration of tablet burden, medication compliance, and comorbidity may indicate the most simplistic regimen is appropriate, or alternatively a blister pack or dosset box may

Table 115-2. The Steps of the WHO Classification for Analgesic Use

Step 1	Step 2	Step 3
Nonopioid ± adjuvant	Weak opioids ± adjuvant ± nonopioid	Strong opioids ± adjuvant ± nonopioid
Paracetamol NSAIDS	Codeine Dihydrocodeine Tramadol [Buprenorphine is a mixed agonist/ antagonist]	Morphine Diamorphine Oxycodone Hydromorphone Fentanyl Alfentanil Methadone

need to be considered for a patient at home with support from the appropriate community services.

Paracetamol is appropriate for osteoarthritis or musculoskeletal pains; the dose should be reduced in patients with liver impairment or probable malnutrition. Codeine is a prodrug of morphine. Co-codamol 30/500 is an effective analgesic administered 6 hourly; however, variations in metabolism through cytochrome P450 2D6 may significantly impair the analgesia available for use. Analgesia should be titrated upwards rather than adding additional drugs of the same class or step.

Morphine is a recommended first-line step 3 analgesic (Table 115-2); the dose can be titrated in increments of 30% to 50% until analgesia is achieved.¹⁸ There is no ceiling dose for step 3 analgesics, rather these should be titrated stepwise if the pain responds (i.e., can be demonstrated on assessment to diminish or disappear with analgesia use). Presence of side effects or incomplete resolution of the pain despite opioid use should prompt addition of adjuvant, if not already commenced. In frail elderly people whose pain severity indicates they should go straight to step 3, oral morph 2.5 mg may be an appropriate starting dose of step 3 opioids given on a regular 4-hour basis reflecting the half-life of the drug.

Patients and care providers should be warned about potential side effects of medication used and where possible these should be minimized. For example a regular stimulant or mixed stimulant/softener laxative is almost always indicated when commencing step 3 strong opioids and about a third of patients will experience opioid induced nausea, so an antiemetic such as haloperidol may be indicated for the first 7 to 10 days on the drug. Reassurance and explanation is often needed for those patients and caregivers who feel the use of opioids risks could lead to the patient "becoming a drug addict" or becoming tolerant to the analgesic effect. Dosing interval or choice of opioids is influenced by coexisting organ failure. Persistence of side effects including drowsiness may be an indication for opioid rotation. Opioids that are extensively metabolized in the liver and do not accumulate in renal failure, such as fentanyl and alfentanil, would be of choice in patients with analgesic requirements and renal impairment. Fentanyl is poorly orally absorbed and subject to extensive first pass metabolism but is well absorbed from buccal, transdermal, and subcutaneous routes. However, the patch or transdermal route is a comparatively inflexible route of drug delivery and not suitable for a patient with unstable pain or rapidly escalating

requirements; in such situations, subcutaneous administration may be needed.

The signs of fentanyl excess in the elderly can initially be more subtle than those classically associated with morphine excess. In fentanyl toxicity care providers may report that the patient is quieter and more sedentary than usual, where morphine toxicity usually causes drowsiness, confusion, hallucinations, grimacing, pinpoint pupils, slowed respiratory rate (respiratory depression), twitching, and myoclonus. Allodynia, hyperalgesia, are occasionally seen as a paradoxical hyperalgesia, but usually their presence indicates a neuropathic pain that is only partly opioid sensitive.

Tables exist comparing equivalent doses of step 2 and 3 opioids, and they should be applied when switching opioids.

The route of drug delivery depends on the patient's condition and ability to ingest, retain, and absorb oral medication. Potential routes of drug delivery in frail palliative care patients include oral, rectal, buccal, transdermal, and subcutaneous routes. Subcutaneous routes (including infusions and injections) are less painful than intramuscular injections and attenuate the rapid tolerance that may develop with repeated use of the intravenous route, making subcutaneous routes the parenteral route of choice. In cachectic patients several drugs can be combined with use of a syringe driver and compatibility tables exist demonstrating which medication and concentrations can be combined safely.¹⁹

Diamorphine is preferred in the United Kingdom for subcutaneous administration because it is highly soluble and so high concentrations can be given in small volumes. However, in many countries it is not available and morphine is the drug of choice. When analgesia is obtained that controls ongoing or background pain, provision must still be made for short-acting analgesia to be available to ameliorate any breakthrough pain.

Breakthrough pain is any pain which occurs over and above a background of well controlled pain. This is a different entity from patients who have increasing analgesic requirement which increases over time because of underlying disease progression rather than tolerance.²⁰ Oral transmucosal fentanyl citrate (OTFC) "lozenges" or dispersible tablets can be applied to the patients moist oral mucosa to provide rescue analgesia for breakthrough pain as the drug is absorbed transmucosally. Fentanyl or alfentanil preparations are also available by inhaler or nasal delivery systems, but specialist supervision is suggested for the initial test dose as drug delivery is rapid but comparatively short lived, making this of use for pain associated with movement or dressing changes. Theoretically any short lived opioids may be given in advance if the pain is predictable in nature. Pains which occur unpredictably require accurate diagnosis of the cause of the pain and interrupting the pathologic process where possible or if not possible, adding adjuvant medication or increasing the background dose of opioids.

BONE PAIN

Bone and joint pain may respond to adjuvant analgesia including nonsteroidal anti-inflammatory drugs which have a synergistic effect with paracetamol. NSAIDs should be prescribed with caution for patients already taking aspirin or steroids (increased risk of gastrointestinal bleeding), diuretics or ACE inhibitors amongst others as these increase the risk of renal failure due to altered renal blood flow and increased sodium reabsorption in the loop of Henle, aggravating any edema.

In malignant disease bone metastases can erode the bone cortex; this can be identified on plain radiographs. Prophylactic surgical intervention may prevent subsequent pathologic fracture. Radiotherapy provides analgesia in 80% of patients with pain from bone metastases and can be considered in frail individuals.²¹ Patients with multiple bone metastases, in the absence of spinal cord compression and with a prognosis of greater than 6 weeks, may benefit from radioactive strontium injection. Bone pain, particularly from breast myeloma, or prostate primary may respond to infusions of intravenous bisphosphonates despite normal calcium, and there is some evidence that bisphosphonates protect against bone metastases in carcinoma of the breast.^{22,23} Fractured bones should always be immobilized if possible. If immobilization is not possible, local injection into the fracture site with Depo-Medrone (methylprednisolone acetate) 80 mg and bupivacaine hydrochloride 0.5% may provide sufficient relief to allow the patient to be turned in the last days of life. An alternative would be an interventional anesthetic procedure and nerve block to the area.

MUSCULOSKELETAL PAIN

Topical capsaicin cream has been advocated for mild musculoskeletal and neuropathic pain. However repeated applications are required to prevent substance P reaccumulating and pain recurring. As the capsaicin is very irritant, it can cause a burning sensation on initial application and care must be taken to prevent any contamination of eyes and mucous membranes. Topical analgesic preparations or lignocaine patches may be useful alternatives in select circumstances.²⁴ Massage and heat therapy (if sensation is intact) may ameliorate musculoskeletal pain. Physiotherapy may prevent contractures developing in paralyzed limbs and the patient and care providers should also be taught maintenance therapy exercises. Skeletal muscle relaxants such as baclofen may relieve discomfort caused by stiffness under these circumstances, but the dose has to be titrated against the sedative side effects.²⁵

NEUROPATHIC PAIN

Neuropathic pain is characterized by pain with a burning or electric shock quality or pain in an area of altered sensation and may occur as a result of nerve compression, destruction or infiltration. Patients may describe this pain in limbs affected by cerebrovascular events in particular if the thalamus is involved. The pain can be severe and associated with altered sensation including allodynia. Relief of nerve compression may be attempted through radiotherapy to diminish tumor size and high dose steroids (up to 16mg dexamethasone in divided dose to be reduced over time) to reduce any peritumor edema. In certain circumstances surgical intervention may be appropriate.

Tricyclic antidepressants in low doses such as amitriptyline 10–25 mg at night, are useful adjuvant medication in neuropathic pain; the mode of action occurs through potentiation of opioids, serotonin reuptake inhibition and reduction in pain perception.²⁵ In the elderly use of tricyclic antidepressants, even in low dose, may be limited by anticholinergic side effects which include constipation, dry mouth, urinary retention, confusion, and tachycardia. The use of membrane-stabilizing anticonvulsants such as carbamazepine and valproate are also limited by side effects, the most significant of which in the elderly is drowsiness; their use in neuropathic

pain has been largely overtaken by gabapentin. Gabapentin is licensed for use in neuropathic pain but the dose must be tapered against side effects of drowsiness and renal function; its precursor pregabalin is also marketed for neuropathic pain but its advantage seems relatively small and the cost is generally higher.

Ketamine, an anesthetic agent, has role in control of difficult neuropathic pain under specialist supervision in the inpatient environment. It is effective in low dose subcutaneous infusions 100–200mg/24 hours combined with low dose midazolam or antipsychotic medication to combat the side effects of dysphoria and hallucinations.²⁶ It is a cardiovascular stimulant so may be of use in combination with opioids as it counteracts their hypotensive effects and can be used in patients with renal failure.²⁷ Methadone can provide useful analgesia but its unpredictable half-life makes it difficult to use routinely because it tends to accumulate in the elderly and has been associated with prolonged QT interval on electrocardiograms (ECGs).

Nerve blocks

Nerve blocks have a role in the management of pain. Celiac plexus blocks in particular are useful for pain associated with pancreatic cancer, liver capsule stretch, and intraperitoneal and retroperitoneal structures. The block can be repeated after several months as required. Psoas compartment blocks can provide relief from hip pain. Epidural injections or indwelling catheters can provide relief from spinal nerve infiltration or compression. The medication used depends upon local policy and preference but tends to involve opioids and local anesthetic; steroids may also have a place. Complex pain with sympathetic involvement may also respond to sympathetic nerve blockade.

Nausea and vomiting

To treat nausea and vomiting effectively, it is essential to identify the underlying cause and then target the intervention accordingly; for example, vomiting can be an indication of hypercalcemia, renal failure, or bowel obstruction, which each require specific interventions in addition to tailored antiemetic therapy.

In the elderly patient causes related to comorbidity should always be considered such as benign positional vertigo, gastroparesis related to diabetes, and constipation. Nausea and vomiting can be an unwanted side effect of opioids and many other drugs, the opportunity to review an individual's medication with their general practitioner and discontinue any inappropriate medication to prevent polypharmacy should always be taken.

Vomiting is initiated by stimulus of different receptors on brain stem nuclei. Antiemetics can be selected to target different receptors depending upon the cause of the stimulus identified.²⁸ The specific neurotransmitters involved include dopamine, acetylcholine, histamine, and serotonin. Attention should be paid to comorbidities, such as Parkinson's disease, when selecting specific antiemetics to prevent exacerbating these conditions. Toxins, drugs, and metabolic abnormalities stimulate the chemoreceptor trigger zone lying next to the vomiting center on the floor of the fourth ventricle. Central dopamine antagonists including low dose haloperidol 1.5 mg to 5 mg or metoclopramide 10 to 80 mg orally or subcutaneously are effective.

Buccal or rectal prochlorperazine has limited use because it can cause confusion in the elderly as a side effect.

Cyclizine is an antihistamine anticholinergic drug, which may be used in combination with drugs acting at the central dopamine receptors to increase receptor blockade. It can be given orally; subcutaneous injections can be painful and associated with inflammation at sites. It may precipitate with certain drugs at high concentration in syringe drivers.

Prokinetics, such as metoclopramide or domperidone (available as suppositories or tablets), are of use if the individual has delayed gastric emptying as a consequence of extrinsic pressure from liver metastases, duodenal, mesenteric, or pancreatic tumor or ascites.

Patients with ascites caused by malignant pathology can receive symptomatic relief from nausea, vomiting, dyspnea, and discomfort from paracentesis. This can be performed in established inpatient centers as a day case. It is not always appropriate or necessary to perform paracentesis against intravenous administration of fluids.²⁹ Thought should be given to the pathologic and physiologic process contributing to the formation of ascites in the individual and to avoiding dehydrating the individual by removing excessive amounts of ascites while continuing diuretics or angiotensin-converting enzyme inhibitor medication. Patients on a therapeutic trial of diuretics aimed at reducing accumulation of ascites should be monitored for hypotension and the drugs discontinued if no discernable benefit is observed.

Nausea from liver metastases may respond to low-dose dexamethasone 2 to 4 mg daily. Serotonin receptor antagonists, such as ondansetron or granisetron, have a role in the short-term management of vomiting related to chemotherapy, radiotherapy, or nausea related to bleeding within the gastrointestinal tract. Constipation, headache, and expense limits prolonged use.

Hiccup can be distressing. Again, drug management must be tailored to the identified cause; for example, gastric distention through stasis may respond to prokinetic agents. Tumors involving the diaphragm or brain stem can respond to centrally acting drugs, including nifedipine,²⁸ baclofen,²⁹ and low-dose chlorpromazine.

Constipation

Constipation is a very common problem among the elderly community. Chronic conditions that predispose to constipation include Parkinson's disease, hypothyroidism, diabetes mellitus, depression, diverticular disease, and hemorrhoids.² Immobility and medication also significantly contribute to constipation. Constipation is a common side effect of opioids medication and all patients commenced upon opioids should be coprescribed laxatives. Nonopioid medications that predispose to constipation include iron and calcium supplements, calcium channel blockers, antihistamines, tricyclic antidepressants, and diuretics.

Assessment of constipation should include frequency, normal habit, consistency, pain, and diet. A rectal examination is useful to exclude impaction. High fiber preparations should be avoided because they may exacerbate constipation if used without adequate fluid intake. It may be prudent to avoid, or use with caution, stimulant medication in patients with known colonic lesions. Lactulose is an effective stool softener in large doses (60 to 90 mL daily) but can produce a lot of flatus.³²

Unless contraindicated a stimulant (such as senna) and softener sodium docusate or magnesium hydroxide are appropriate combinations to use. Codanthramer has a mixed action and can be used if the patient dislikes liquid medication; it is licensed for use in terminally ill patients only, and can discolor urine and feces. It can cause severe skin irritation in patients with fecal incontinence. In severe constipation, high-dose polyethylene glycol 3350 (e.g., Movicol up to 8 sachets daily for 3 days) or sodium picosulfate (5 mg tds) may be needed. Fecal impaction can be treated with high-dose Movicol, enemas, or manual disimpaction with suitable analgesia cover. Arachis oil retention enemas (in patients who are not allergic to peanuts) followed by phosphate enemas the subsequent morning can be successful. Constipation should be actively prevented in breathless individuals because the effort of defecating can exacerbate dyspnea.

Bowel obstruction

Surgery is often not indicated in patients with bowel obstruction at multiple sites. This situation arises more commonly in ovarian and colon cancer. Patients who are identified to be at risk of this benefit from preventative management with stool softeners. Bowel obstruction is associated with vomiting, which can become feculent; additional late signs include pain and distention. The diagnosis can be made on clinical grounds; plain abdominal films may be surprisingly unremarkable early on.

Medical management of acute obstructive episodes requires antispasmodics such as hyoscine butylbromide for colic with an opioid to relieve abdominal pain. An antiemetic acting at the vomiting center, such as cyclizine, should be considered. In obstruction the oral route is unreliable, so medication is often best delivered in a syringe driver but cyclizine cannot be mixed in the same syringe with hyoscine butylbromide.

Corticosteroids sometimes are of benefit in obstruction, but unfortunately the characteristics that determine those patients who will benefit have not been elucidated.³³ It may be appropriate to try high-dose dexamethasone for a few days and discontinue this if there is no discernable improvement. Octreotide may reduce the volume of intestinal secretions, but should be used under specialist supervision.³⁴ There is no evidence to support drip and suck regimes in most patients with intestinal obstruction. Patients can usually take oral fluids and even light meals, but may have to contend with one or two vomits per day.

Diarrhea

Diarrhea can result in dehydration, electrolyte imbalance, exhaustion, and a loss of dignity. It can be exhausting and distressing for care providers who have to assist patients to the bathroom, or change pads, clothing, and bed clothes for the bed bound individuals.

Identifying the cause is essential. Radiotherapy, antibiotics, malabsorption, stress, and gastrointestinal bleeding are recognized precipitants. Rectal examination can exclude fecal impaction and overflow leakage, which are all too common; management of this is referred to under constipation. A stool specimen will exclude *Clostridium difficile* infection. Once reversible causes have been excluded, patients can be managed with rehydration, bulking agents, loperamide, or

codeine-based products. Patients with fistulae, high output stomas, or secretory diarrhea as a consequence of underlying pathology can benefit from octreotide.³⁵

Dyspnea

Shortness of breath is a subjective sensation, which can be experienced despite normal pulse oximetry and respiratory rate. It is a common symptom in both malignant and nonmalignant disease, which increases in prevalence in the last weeks of life.^{2,36} Patients with nonmalignant disease but clear deteriorating health and recurrent hospital admissions should be encouraged to discuss their perceptions and fears and they may want to regain control of their condition through advanced care planning or an advance decision to refuse treatments should they suddenly deteriorate again.

Elucidating the cause of breathlessness requires a detailed history and examination; often modification of the disease process concurrently with palliation of the symptoms. Steroids, bronchodilators, diuretics, beta blockers, and angiotensin-converting enzyme inhibitors have a place in the management of chronic obstructive pulmonary disease (COPD) and cardiac failure, respectively. Acute cardiac failure may need intravenous frusemide, nitrates, and parenteral diamorphine. Uncontrolled arrhythmias should be identified and appropriately managed. Antibiotics have a place in symptom management even in the terminally ill to resolve pleuritic pain and the sensation of systemic ill health associated with pneumonia and infection. Draining of pleural effusions can provide prompt symptom relief. In selected individuals, endobronchial stents may relieve the dyspnea resulting from airways collapse and tumor occlusion.^{1,2}

Patients with anemia rarely benefit from iron supplementation. Transfusion of packed cells may achieve the most rapid improvement, particularly when the hemoglobin is below 10 g/L.

Long-term oxygen therapy may improve exercise tolerance and longevity in patients with COPD but unless humidifiers are used can produce nasal irritation and dryness. The mask and tubing are cumbersome. Relief from dyspnea can often be achieved quite simply through use of a fan or open window to cool the face.³⁷

Opioids reduce the symptoms of dyspnea.^{37–39} Case reports and studies on small series of patients involving administration of various opioids via different routes exist, but the most robust evidence exists for the use of morphine. Research has demonstrated that in the doses used for symptom control there is no significant adverse effect on respiratory rate, oxygen, or carbon dioxide concentration.³⁹ In the opioid naïve patient 2.5 to 5 mg of oral morphine 4 hourly may suffice. In patients already receiving regular opioids, an increase in the background dose of 25% to 30% may give similar relief.³⁸ In patients unable to swallow, subcutaneous administration of diamorphine can be used to achieve the same effect. Patients in whom anxiety and fear are prominent may benefit from administration of benzodiazepine, either low-dose oral diazepam or subcutaneous midazolam.

Breathlessness clinics incorporating the principles of activity pacing, relaxation, breathing control, and efficient mobilization can improve symptoms⁴⁰ for those patients able to attend them.

Cough

Persistent cough can be an irritating and tiring symptom in both malignant and nonmalignant diseases. Common nonmalignant causes include esophageal reflux, postnasal drip, COPD, cardiac failure, pneumonia, and side effects of medication. The treatment should target the underlying pathology. Treatment of cough resulting from malignant pathology may include steroids and radiotherapy. Oxygen should be humidified if the cough results from dry airways or regular saline nebulizers can be used. Mucolytics, expectorants, bronchodilators, and chest physiotherapy may be useful in the management of productive coughs. Cough linctus containing preparations of codeine or regular low-dose opioids, including morphine, can have an antitussive effective.

Patients entering their last days of life with weak or absent cough reflex are unable to clear their airways and may develop "death rattle" the sound of air passing over fluid in the trachea. The sound can be distressing to families who need reassurance and explanation from staff. Anticholinergics, including hyoscine hydrobromide, hyoscine butylbromide, atropine, and glycopyrronium, can reduce secretions and can administered subcutaneously.^{1,2,41} If it is important to prevent the sedative side effects and propensity to cause confusion or delirium then glycopyrronium or hyoscine butylbromide should be used because they do not cross the blood-brain barrier.

Dizziness

Dizziness is a commonly reported by older patients and is recognized as a syndrome in its own right. Unfortunately there is rarely a single etiologic cause for this distressing symptom, which may result in falls, syncope, functional disability, residential or nursing home placement, or death.⁴² Cardiac arrhythmias, vascular disease, vestibular disorders, diabetic neuropathy, and altered proprioception may all contribute. In the absence of reversible causes, management involves educating the patient and care providers to prevent triggers and creating a safe home environment.

Fatigue

Fatigue is a common and distressing symptom experienced as a consequence of many diseases, including malignancy, and end-stage cardiac and respiratory failure. This symptom results in a loss of independence of the patient; the dependence on care providers can have a profound psychological impact on the patient who may perceive he or she is becoming a burden. Reversible causes are worth excluding and include anemia, depression, thyroid disease, hypokalemia, hypocalcaemia, and magnesium deficiency. Drugs which cause daytime somnolence such as anxiolytics, antipsychotics, and β -blockers should be rationalized. Antihypertensives should be reviewed with respect to the patient's current cardiovascular and fluid status.

Optimizing physical fitness, pacing activities, and sleeping routine, and working with the patient and care providers to set realistic and achievable goals, can help the patient to maximize his or her quality of life.

Anorexia-cachexia syndrome commonly occurs in patients with end-stage illness, often leading to protein undernutrition. The syndrome is caused by altered equilibrium and disrupted metabolism of inflammatory cytokines.⁴³

Communicating this information to the patient and care provider may help both understanding and acceptance of this. Treatment of nausea, altered taste, maximizing oral hygiene, and ensuring dentures fit adequately is essential. Various protein and calorie supplements exist but should not be forced on the patient if they are found to be unpalatable. Frequent small meals of favorite foods may be an acceptable alternative. Steroids are often used to augment appetite, but the effect is short lived; long-term steroid therapy may exacerbate myopathy and fatigue.^{1,2}

Depression and adjustment disorder

Patients may undergo a bereavement process themselves as they become aware of their terminal illness, their loss of independence, and future. Patients may experience and express a range of emotions. The feelings experienced can be exacerbated by either unresolved bereavements or losses. Allowing time to explore the patients past may reveal these losses and provide support to enable patients to reconcile themselves to events.

Estimates vary about the number of terminally ill patients with depression (7% to 30%). Antidepressants may be appropriate for patients with early morning waking, anxiety states, lack of reactivity, feelings of pessimism toward others, anhedonia, or who are socially withdrawn. Symptoms including weakness, tiredness, loss of appetite, or pessimism concerning oneself are recognized manifestations of the terminal illness process and not necessarily pointers to depression.⁴⁴⁻⁴⁶

Confusion

Cognitive impairment unfortunately can accompany some chronic diseases and as eluded to earlier the patient should be encouraged to participate in advance preparation and sharing their wishes and preferences for future care. Elderly patients are particularly at risk of acute confusional states. The risk of delirium has been demonstrated to increase with age, cognitive impairment, infection, organ failure, and fracture.⁴⁷ Common causes of confusion are listed in Table 115-3.^{1,2}

Management of acute confusion involves treating reversible causes and minimizing sensory impairment by restoring

Table 115-3. Common Causes of Confusion

Comorbidity	Cognitive impairment Neurodegenerative conditions Dementia Cerebrovascular disease Poor vision Hearing loss
Drugs	Anticholinergics Benzodiazepines Withdrawal from medication Opioids
Systemic	Infection Urinary retention Constipation
Metabolic	Hypoxia Uremia Organ failure Hypercalcemia
Malignancy related	Cerebral metastases Paraneoplastic syndromes

hearing aids and glasses. The individual should be cared for in a well lit room with minimal background noise and spoken to calmly and reassuringly. Low-dose antipsychotic medication may be helpful in treating the agitated confused individual expressing paranoid thoughts or experiencing hallucinations. Benzodiazepines can exacerbate the symptoms. Care providers require explanation and reassurance for a symptom that can be distressing to observe in a loved one.

The causes of confusion specifically related to malignancy include cerebral metastases and hypercalcemia. Paraneoplastic syndromes are uncommonly encountered and respond to modification of the disease process where this is possible.⁴⁶ Cerebral metastases may respond to high-dose dexamethasone (16 mg).⁴⁸ If there is no response after 5 days, the steroid can be stopped abruptly.

Hypercalcemia is a reversible cause of confusion. In the context of malignancy it usually confers a poor prognosis. It can occur in patients with bone metastases or those with tumors secreting a parathyroid-like hormone. Rehydration with intravenous fluid 0.9% sodium chloride should be commenced, followed by intravenous bisphosphonate. Pamidronate can be effective or zoledronic acid a more effective but expensive alternative may be considered.^{1,2} Treatment for hypercalcemia may need to be repeated periodically, and the calcium monitored on discharge into the community.

Advanced illness can often be complicated by infection. Reduction of risk factors through maintenance of good skin care, individual nursing care to ensure appropriate toileting, repositioning of the immobile patient and careful feeding to minimize aspiration are necessary. Symptom relief measures including antipyretics and analgesics should be commenced if infection is identified. Antibiotics can be prescribed for symptom relief but may not be appropriate or confer any benefit in certain circumstances and advance planning with the patient and care providers is essential to identify the goals of care in the face of the changing needs of the patient. For example, antibiotics in advanced dementia do not improve survival benefit.^{49,50} Disadvantages of antibiotic therapy include allergic reactions, developing resistant infections, *C. difficile* infection, diarrhea, bone marrow impairment, seizures, renal failure, and vomiting. Patients with severe cognitive impairment may not be able to rationalize the administration of intravenous antibiotics or accept painful intramuscular antibiotics.

Spiritual suffering

The religious or spiritual beliefs of elderly patients are important; or faced with debilitating illness with terminal illness patients may question self identity, the meaning and purpose of their life, and prior decisions or actions undertaken during their lives.⁵¹ Faith leaders or religious customs may support both the individual patient and care providers, particularly during stressful periods and enable them to reconcile events.

Specific requests for euthanasia should be dealt with sympathetically and the request considered an opportunity to explore the deep distress the patient may be experiencing. The request may be associated with untreated physical or psychological symptoms; fear of the future, including fear of becoming a burden; anger and guilt concerning the effect the disease has had upon their life; and lack of an appropriate environment or dignity in their care delivery.^{44,45,51,52}

Terminal stage

Accurately predicting an individual's prognosis is difficult, and fraught with misinterpretation by the patient and care providers.^{1,2} Dying can be difficult to diagnose in patients who have been significantly unwell for a period of time through chronic ill health. The reflective question "Would you be surprised if your patient died within the next 6 months?"¹⁵ is useful to trigger entering the patient on the palliative primary care palliative register and ensuring access to financial support, and guiding decision making and information giving.

In general the prognosis is likely to be measured in days when the patient's condition is deteriorating on a daily basis, if they are unable to take oral medication or tolerate more than sips of water, and are bedbound or semicomatose.^{1,14} Sensitive communication of this information enables the patient and care providers to prepare for death but it can provoke various emotional responses in the face of a situation where care providers have looked after patients through various stages of health over a period of time.^{52,53} This may be an opportunity for resolution of any outstanding family or interpersonal conflict, apologies, and reconciliations, or to express feelings and love. Poor communication surrounding dying underpins over half of the complaints received in the National Health Service.^{54,55} Missed opportunities can result in bitterness, anger, and unresolved grief in care providers following the bereavement.

Realistic goals can then be set for care, which encompass the maintenance of dignity and comfort rather than prolonging the dying phase; this should be discussed with the care providers and where appropriate with the individual. Care providers may find that "death will be allowed to occur naturally" is far more acceptable than being told their loved one "will not be resuscitated." Explanation should include what to expect during the dying process (including the potential for "death rattle" and Cheyne-Stokes breathing pattern) and what to do after death occurs if the patient is dying at home.

Medication can be rationalized and many drugs omitted without detriment to the individual. Regular or routine monitoring of blood tests and many observations (for example blood pressure) can be discontinued although it can be useful sometimes to monitor respiratory rate to reassure relatives that the patient is not oversedated. Medications essential for symptom control can be given as subcutaneous injections or via infusion using a syringe driver.^{2,14} If repeated subcutaneous injections are needed, a small subcutaneous butterfly cannula can be sited for administration. Fluid intake can be poor but careful oral care alluded to earlier may relieve the sensation of thirst. Occasionally patients will benefit from subcutaneous hydration to maintain comfort when dying and preventing dehydration; subcutaneous fluids can be given at home.

Preemptive planning allows medication to be prescribed and obtained in patients homes to be administered if needed to maintain a symptom control.¹⁴ Medication should include opioids for administration for pain and dyspnea, antiemetic, anticholinergic for "death rattle," and sedative medication (such as midazolam) for use if the individual becomes agitated. Restlessness may have several potential causes, including urinary retention, constipation, metabolic abnormalities, pain, fear, and unresolved spiritual distress. Once reversible

causes have been addressed the patient may benefit from sedative medication administered subcutaneously via a syringe driver.

Care providers should be encouraged to talk to the patient and each other. They should also be shown how to participate in care giving if they wish to, including mouth care and physical turning if the patient is dying at home in particular. Any religious ceremony or customs surrounding death should be undertaken. A care pathway outlining these measures for the last days of life has been developed to improve the standard of care for the dying.¹⁴

Many deaths in patients with chronic disease follow recognized patterns or illness trajectories.⁵⁶ Occasionally a sudden catastrophic event, such as a massive hemorrhage, stridor, or pulmonary embolism, occurs and death takes place within moments.^{2,5} Staff are encouraged to maintain a calm and reassuring manner for the patient and any care providers present. If this situation has been foreseen and time permits the patients can be rendered unconscious and unaware through use of anxiolytic medication which has an amnesic effect. Care providers will require reassurance and explanation after the event to understand why the event occurred and that their loved one did not experience any distress.

Conclusion

Palliative care for elderly patients focuses on preserving function, dignity, and quality of life to enable the individuals to actively live their life. Attention should be paid

to identifying and relieving caregiver stress. Preparation and open discussion around the future including end of life care and death enable the individual to regain control over their lives and relieve the stress caregivers experience from decision making.

KEY POINTS

Palliative Medicine for the Elderly Patient

- The definition of palliative medicine and its application along with the different stages of the illness journey of the elderly population
- Supporting decision making and future planning, a place for the Mental Capacity Act and ethical frameworks
- The origin of pain and the therapeutic management options
- Palliation of gastrointestinal and respiratory symptoms
- Confusion, depression, and spiritual suffering
- Identifying the terminal phase in patients with chronic illness and end of life care for common symptoms

Ethical Issues in Geriatric Medicine

Søren Holm

In one sense there are no ethical issues or principles that are specific to geriatric medicine. Our moral status as persons do not change when we grow old and the old are due the same measure of respect and attention as the young.¹ The clinical situations in which ethical issues arise are also in most cases very similar to clinical situations that may arise in other areas of medical practice.

In another sense there are specific ethical issues in geriatric medicine caused by (1) a stereotypic social image in many Western societies of the elderly and old as less competent and less worthy of attention than the young, (2) the tendency in many health care systems to underfund geriatric medicine in comparison to other specialties, and (3) the complex interface between health care and social services for the old.

This chapter will briefly review some core general elements of medical ethics as they relate to geriatric medicine before considering some of the ethical problems that occur frequently in geriatric medicine, including decision making for incompetent patients, advanced decision making and the use of health care proxies, research involving the incompetent, and end of life issues. The final section will be concerned with resource allocation and the health care claims of the elderly and old.

Respect for autonomy

The cornerstone of clinical medical ethics is respect for autonomy or self-determination.² Competent patients who are informed about the available treatment options can decide which of the treatment options they prefer and can also decide not to have any treatment at all. It is generally accepted both in ethics and in law that competent patients can refuse treatment even if that treatment is simple and life saving.

The main reason that we ought to respect autonomy in health care is that the life the decisions are about is the life of the patient and he or she has a right to be able to shape that life according to his or her own values and ideas about the good life.

In most health care systems, respect for autonomy is institutionalized in clinical practice through a requirement for valid, informed consent for diagnostic and therapeutic procedures. And in research ethics, there is even stronger protection of autonomy through much more explicit informed consent requirements.

But respect for autonomy entails more than just respecting the decisions people make, it also entails respecting them as the primary decision makers in relation to their own life. This means first that patients have to be involved in decision-making processes at a point where there is real choice and before a default decision has been established by *fait à accompli*; second that they should not be forced to make decisions before they are ready to make them; and third that patients have to be given the information that they require to make

a decision, not only the information that I as a health care professional think is relevant.

Taking patients seriously as decision makers may therefore have implications for the way decision-making processes are designed and structured at the ward or department level to ensure that patients are involved at the right time and that there is time enough for them to be properly informed.

In a broader perspective, respect for self-determination also creates an obligation to promote people's abilities to make decisions by promoting their autonomy. If there is something we can do which will enable a person to make autonomous decisions we should do it. This may include clinically relatively trivial interventions (e.g., rehydrating a dehydrated and confused patient), but may also include patient education or the use of modern patient decision support programs.

Two common misunderstandings of what respect for self-determination means need to be mentioned. The first misunderstanding is that respect for autonomy entails that patients have to make all decisions themselves and that they cannot delegate decision making to other people. But delegating decision making is a perfectly autonomous thing to do! We all do it on a regular basis. And there is nothing ethically problematic in a patient asking a doctor to make the decision if that patient trusts that the doctor is able to make a better decision. Forcing patients to make decisions they do not want to make is not respecting the patient's self-determination.

The other common misconception is that you respect people's autonomy by giving them what they want and that this means that if you want something, for instance a specific treatment, I have a moral obligation to help you get it. But respect for autonomy only, strictly speaking, implies a negative duty of noninterference. Any positive duty to help cannot be derived from respect for self-determination, it has to be justified differently, for instance through some account of the professional obligations that flow from an established doctor-patient relationship.

Paternalism

Paternalism is the term used for actions we take or decisions we make for another person with the intention of benefiting that person. The word is derived from the Latin word for father and the idea is that a paternalist decision is like the decision a good father makes for his child. It is important to note that an action can only count as paternalist if it is done to benefit the other person. Actions chosen and performed to benefit the doctor, the health care system, or with mixed intentions are not paternalistic, but simply coercive.

Paternalistic decision making is not problematic if the person in question is incompetent (see latter discussion). This situation is sometimes referred to as genuine paternalism.

Paternalistic decision making is, however, problematic if the person is competent and wants to make his or her own

decisions. In that case the paternalistic action overrides the autonomy of the person. Paternalistic decision making can be justified in emergency situations where there is no time to consult the patient and it can sometimes be justified in a public health context, but it is rarely, if ever justified in non-emergency interactions with individual patients.

An increasingly common form of paternalism is what can be called informational paternalism. Informational paternalism occurs when patient have clearly signaled that they do not want some piece of information about their condition (e.g., do not want to know the precise prognosis) but where they are given information nevertheless because the health care team thinks that it is... "best for them to know..." This is sometimes supported by the claim that health care professionals have a duty to tell the truth to their patients. But it does not follow from that duty, which is essentially a duty not to lie or to tell the truth if asked, that there is a duty to impress the truth on people who do not want to hear it. This is easily seen if we consider a parallel example: Every one of us have a duty to tell the truth to our friends but this does not generate an obligation to provide unsolicited evaluations of their dress sense or latest hair cut, even if those evaluations are the gospel truth!

Dignity

In the context of geriatric medicine, respecting and preserving the dignity of patients is the second ethical consideration that takes center stage. Respect for autonomy and for the decisions of a person can be seen as part of preserving and respecting the dignity of that person, but dignity is a complex concept that is not exhausted by respect for self-determination.³

To treat someone in a dignified manner is to treat them in a way that recognizes that they are a complete person with personal integrity and worth and a protected zone of privacy. Exactly what this means will vary from culture to culture and from time period to time period. But everyone within a culture will be able to identify a core set of behaviors that count as undignified and disrespectful behavior. This is also an area where research focusing on the experiences of patients can play a role in making it clearer when they experience care as impinging on their dignity. It should come as no surprise that many old people think it is undignified if they are shabbily dressed or if they are exposed naked or half naked to the gaze of others.³

In this context it is important to remember that some of the largest problems in relation to the protection of dignity are brought about by the numerous small routine violations of dignity that may erode both a person's sense of personal worth and the staff's sense of what is right and proper. Although the actions are done by individual health care professionals, the solution to this kind of problem is often organizational.

The incompetent patient

Not all patients are competent to make decisions about health care matters. Patients may become temporarily incompetent during an acute illness episode or they may become permanently incompetent (e.g., in the later stages of dementia). But health care and other decisions still have to be made even when the patient cannot make them himself.

The concept of incompetence initially seems to be straightforward. The normal adult is the paradigm case of an individual who is competent to make decisions, and that competence is lost if the person becomes unconscious, is very inebriated, or develops late stage Alzheimer's disease where almost all memory and most reasoning capacities are gone. Between the extremes of full competence and complete incompetence there is, however, a very wide range of situations where a person is either partially competent (i.e., competent to make certain decisions but not others), or where a person's competence is questionable. This grey area is created by two complicating factors (1) competence is always competence to make a specific decision and (2) we do not have a good account of exactly what it takes to be competent and how far you can deviate from the norm before you become incompetent.

That competence is always the competence to make a specific decision is very obvious in the case of children. It is not the case that one day they are completely incompetent to make decisions, and the next day they become fully competent. Even a 3-year-old is competent to decide which ice cream he or she wants when given the choice on a warm day at the beach. In the same way, someone with dementia may be incompetent to make decisions about his or her treatment, without being incompetent to make decisions about what to eat for dinner, or when to get up in the morning.

The second complicating factor in decisions about competence is that it is unclear how rational and how informed a decision has to be to count as competent. Most of the decisions the people make do not conform to strict rules of rationality and are performed in a situation of at least partial ignorance. Just think of the ways most of us decide on quite important things such as applying to medical school, buying a house, marrying, or starting to save for a pension. We do not seek all the information that we could have sought and we do not always think carefully through all the options. This means that unless we want to rule most decision making to be incompetent, and therefore possibly open to being overruled by others, we have to have a less stringent standard of competent decision making than full rationality and complete information.

We could try to say that what matters is not how the decision was made, but its content (i.e., what decision that was made). But this is a problematic argument since we generally allow people to make foolish choices, even about very important things. That a decision is not one that I would have made does not *eo ipse* make it an incompetent decision.

Here it is important to note that questions about incompetence are often only raised when our patients make decisions that we do not agree with. This is in itself problematic. There are probably as many patients who make decisions that we do agree with, but where we could have challenged their competence to make these decisions.

Decision making for the incompetent

In a situation where one person has to make important decisions for another, often called proxy decision making, there are in principle two different ways in which such a decision can be made. These are commonly referred to as the "substituted judgment standard" and the "best interest standard."⁴

According to the substituted judgment standard, the task of the decision maker is to try to make the decision the incompetent person would have made, if competent. This might involve empathic identification with the patient to discern what the patient would have decided. The problem with this standard for proxy decision making is that it is not obvious which of the incompetent person's characteristics that should play a role. Should I for instance make rash decisions for a patient who all his life was a rash decision maker or should I take account of a patient's needle phobia? Because of these problems the substituted judgment standard has fallen out of favor.

The best interest standard specifies the task of the proxy decision maker as making the decision that is in the patient's best interest (i.e., the decision that is most likely to benefit the patient). This is the standard that is accepted in most jurisdictions for legal decision making for the incompetent. The conception of best interest that is at play here is quite wide. A patient's best interest is not confined to his "medical best interest" (e.g., which treatment that is medically optimal), it also encompasses social issues, etc. It is furthermore generally accepted that what is in a patient's best interest is at least partly determined by the patient's prior values and life goals. If understood in this broad way and drawing on knowledge about the patient's values decision making guided by best interest will often come close to decision making guided by substituted judgment.

The term "best interest" seems to imply that there is one and only one decision and course of action that will promote the patient's best interest and that our task is to find that course of action. But this view rests on a mistake. There are many situations where we will be unable to decide which course of action will benefit the patient most because of uncertainties about the clinical situation and/or uncertainties about the patient's values.⁵ We are often able to identify some decisions that are clearly not in the patient's best interest without being able to specify one of the remaining options as the one that clearly serves his or her interest the most.

Advanced decision making

Many jurisdictions now allow people to make legally valid advance decisions about health care that come into force if and when the person becomes incompetent. This can either be in the form of advance directives or in the form of the appointment of a designated proxy decision maker or a combination of the two.

Advance directives allow a person to specify what treatment he or she wants or does not want in specific future circumstances and are most useful for persons who suffer from a disease process with at least a somewhat predictable future course. In that situation it is also possible to help patients to clarify their wishes for future treatment by outlining the range of likely scenarios.

Advance directives formulated in more general terms such as "If I become unable to take care of myself, I do not want..." will always require a considerable amount of interpretation to decide whether they apply to the situation at hand and whether they should still be considered valid.

The problems in writing sufficiently specific advance directives have led to a move toward combining advance

directives with the appointment of a designated proxy decision maker.

The task of the designated proxy is to make decisions on behalf of the patient when the patient is no longer competent to make those decisions. These decisions have to be made in the best interest of the patient (see previous discussion concerning "best interest"), just as decisions for patients who do not have a designated proxy. But the advantage of having a proxy is that patients can appoint someone who knows them and their values and preferences well and who is therefore more likely to evaluate best interest in the same way as the patient.

In jurisdictions where it is possible to designate a proxy it is usually the case that health care professionals can only override the proxy's decisions if they can show that they are clearly not in the patient's best interest.

The role of the family in decision making

In most Western countries family members have no formal role in decision making *qua* family members. There may be a requirement to consult them before decisions are made concerning an incompetent patient but there is usually no legal requirement to follow their advice unless they are the patient's legally designated proxy decision maker.

In reality families do justifiably play a larger role in decision making in many circumstances. Many competent patients want to involve their family members in the decisions and some may want to leave decisions to the family or some specific relative.

In relation to incompetent patient families often have a better understanding of the patient's value system than the health care team has and it is furthermore often the family that has to care for the patient outside of the health care context. This means that it will almost always be appropriate to consult the family before important decisions are made about incompetent patients. But it is also important to realize the interests of the patient and the family can be entangled in complicated ways that may make it difficult for family members to see clearly what is best for the patient. There may also be conflicting views among family members as to what should be done.

Research and incompetent persons

The traditional research ethics problem discussed in connection with dementia research is the problem of research involving persons who are incapable of giving valid informed consent. This problem has been extensively analyzed and at the regulatory level of research ethics a consensus has developed on the requirements that have to be fulfilled for such research to be deemed ethically acceptable. These requirements are: (1) consent must be sought from the person's representative (proxy); (2) if the person is able to assent or dissent, although unable to consent, the person's assent must be obtained; (3) the research must either be directly beneficial to the person, or it must be beneficial to the patient group to which the person belongs, and it must be impossible to perform the research in a group of patients who can consent; and (4) the risk to the person must be minimal in those circumstances where there is no direct benefit.

This consensus is, for instance expressed in paragraphs 27 to 29 of the most recent revision of the Helsinki Declaration from the World Medical Association.⁶

The restriction on types of research that an incompetent person can be included in can be justified in three different ways:

The first line of argument is based on the historical fact that vulnerable groups have often been used in ethically problematic research and that if the incompetent could be used as research participants in ordinary projects there is a risk that they would become an easy source of research material.

The second focuses on the intersection of interests between the person with a specific condition and the group of sufferers with that condition. The argument is that even if a person does not realize a personal benefit from the research, he is benefited indirectly through the benefits accruing to the group.

The third possible justification is the pragmatic one that unless we allow some kinds of research without consent into conditions where all sufferers are incompetent, very little progress will be made in the treatment of such conditions (the "golden ghetto" argument), but such research should be limited to those projects that cannot be performed in any other way to minimize the infringements caused by research without consent.

End of life issues

Three types of end of life issues are currently under discussion in medical ethics: (1) withdrawing and withholding treatment, (2) physician assisted suicide, and (3) active euthanasia.

There is no doubt that a doctor can withdraw or withhold any treatment if either (1) a competent patient refuses the treatment or (2) the treatment is futile (i.e., cannot benefit the patient). But there are still three open questions in relation to withdrawing and withholding:

- Is there a moral difference between withdrawing and withholding?
- What about treatments that are not completely futile, or not futile from all points of view?
- Is the provision of nutrition and hydration treatment?

Doctors often feel that there is a difference between withdrawing and withholding a given treatment. It feels more difficult to stop a treatment that is going on than it feels not to start a treatment. But it is very difficult to find any good justification for this feeling. The consequences of stopping and not starting are often the same (e.g., think of stopping and not starting respiratory support in a patient who needs it). And the reasons for the decision are almost always also very similar (e.g., it is not in the patient's best interest to continue/initiate this treatment). This has meant that there is a growing consensus that despite the phenomenological difference (i.e., the difference in how it feels), there is no real ethical difference between decisions to withdraw and decisions to withhold.

When thinking of withdrawing or withholding a treatment from a patient it is not difficult to reach a decision if the treatment in question is completely futile, if it has no

chance of benefiting the patient in any way. But there are many situations where the treatment is not completely futile. It may have some small chance of being successful, or it may be likely to prolong the patient's life but raise the subsequent question of whether this longer life is worth having seen from the point of view of the patient. A typical situation where these issues arise is when contemplating cardiopulmonary resuscitation and the appropriateness of a do not resuscitate decision. If the patient is competent, all of this can be discussed with the patient and the patient can decide. But in the case of the noncompetent patient, others must decide what is in the best interest of the patient. It is not possible to give a percentage figure for when a treatment can be regarded as futile but it is generally agreed that a mere theoretical chance that something will work does not make it a worthwhile treatment.

The final controversial issue in relation to withdrawing and withholding is whether nutrition and hydration or "food and water" should be defined as treatment or as basic humane care that can never be withdrawn or withheld? Part of this controversy has been a discussion of whether withdrawal of nutrition and hydration leads to suffering and whether such suffering (e.g., thirst) can be relieved, but this discussion is in some sense a red herring. The real core issue in the controversy is not suffering but whether it can ever be justified not to provide this basic level of care. Legally the position is now settled in many jurisdictions by explicit legal judgments that it is acceptable to withdraw nutrition and hydration, but the ethical discussion is still not over, partly because it involves the thorny question of whether it is ever better for a person to be dead than alive. This links the withdrawing/withholding issue to the discussion of physician-assisted suicide and euthanasia.

Physician-assisted suicide and euthanasia

Physician-assisted suicide (PAS) is the situation where a doctor provides a patient with the means to commit suicide (e.g., by issuing a prescription for a lethal combination of drugs), but the patient performs the physical act of actually taking the drugs.

Active euthanasia is the situation where a doctor actively ends the life of a patient (e.g., by injecting a lethal combination of drugs). In relation to active euthanasia, it is possible to distinguish between voluntary euthanasia where the patient has requested euthanasia, nonvoluntary euthanasia where the patient is incompetent and nothing is known about his or her wishes, and involuntary euthanasia where a patient is killed against his or her will. Involuntary euthanasia is murder and nonvoluntary euthanasia raises a host of complex ethical and legal problems so the discussion about euthanasia is usually focused on whether or not voluntary active euthanasia should be legalized.

Physician-assisted suicide and/or voluntary active euthanasia has been legalized in a few countries. PAS is legal in Switzerland, the Netherlands, and the U.S. state of Oregon and active euthanasia is legal in the Netherlands and Belgium. In all cases, except in Switzerland, there are extensive procedural safeguards in place to try to ensure that the decision to ask for PAS or euthanasia is well considered and fully voluntary.

The ethical justification of PAS and/or euthanasia proceeds along two dimensions. The first line of justification

relies on respect for autonomy. If people have a strong interest in leading their life according to their own values, then it is plausible that they also have a strong interest in how that life ends and that their choices should be respected. A hypothetical example which is often discussed in this line of argument is the successful academic with the first symptoms of Alzheimer disease who does not want his life to end in severe dementia and who claims that such an end would make a mockery of his life's achievements and would furthermore be undignified. Proponents of this line of argument often claim that it is the individual person who has to decide whether he would be better off dead and that only he can make that evaluation.

The second line of justification focuses on suffering and is based on the claim that if a person is in great pain, has breathing difficulties, or severe psychological suffering and there is no way to relieve the suffering then PAS or euthanasia may be justified to end the suffering.

The two lines of justification come together in the core cases of severe irremediable suffering in a person with terminal illness who wants the suffering to end.

The opposition towards legalizing PAS and/or euthanasia may either be opposition to the two practices as such, for instance based on the view that suicide or killing is never right, or it may be opposition to the legalization of the practices. It is quite common for people to agree that there are specific cases where active voluntary euthanasia is justified, but still argue that it should not be legalized.

The arguments against legalization are primarily of two kinds. One line of argument claims that it is important that the law symbolically upholds the view that taking the life of another human being is always wrong. The second line of argument is worried about slippery slopes and a gradual expansion from core cases to less core cases. Here the argument is that even if we write a law that only allows PAS or euthanasia for people with terminal illness and irremediable suffering who wish to die, then we will over time also allow euthanasia in cases where the voluntary element is less clear or in cases where the suffering is not present but merely predicted for the future. Some also worry that we will allow euthanasia in situations where the decision is formally voluntary but based on motivations that are perceived as problematic (e.g., if a patient wants euthanasia not to be a burden to family or an economic drain on the health care system). Would it not be better if these problems were solved in another way for instance by appropriate allocation of resources to health and social care for the elderly?

Priority setting and the elderly

Until this point the chapter has mainly been concerned with decision making in relation to specific identifiable patients but resource allocation decisions between groups of patients also raise ethical issues. No health care system has the resources to provide the medically optimal treatment to everyone who is ill. There is always a mismatch between the available resources and the claims on the health care system. This means that priority setting between patients and patient

groups is a reality in all health care systems. Politicians may want to deny this, but it is nevertheless a fact.

This raises the question how the health care claims of the old should be prioritized? Should the claims of the old be given the same, greater, or lesser weight than the claims of the young? It is obvious that people's unreflective opinion on this issue vary according to how it is framed. We generally, and rightly agree that old people have the same worth and importance as young people and that, for instance there should be no difference in how we treat severe pain in the old and the young. But many people will express the opposite opinion if the issue is, for instance who should receive a kidney transplant and the hypothetical choice is between someone who is young and someone who is very old. People's views are often further complicated by considerations of merit and past contribution to the development of the welfare state. Those who are old now did not have access to the kind of health care we have today when they were young and may therefore have a stronger claim now.

It is difficult to devise a resource allocation system that takes into account of all these views concerning the relevance of age to priority setting and far beyond the scope of this chapter to try to settle which, if any is correct.

It is, however, important to note that some views on this issue raise considerable ethical worries. Some of the major tools of health economics directly institutionalize discrimination of the old. A range of these tools calculate the benefit of an intervention in terms of the increase in welfare/health or decrease in suffering/illness it produces and the time the patient experiences this benefit. But because the old have shorter life expectancy than the young, this has the consequence that a given curative treatment counts for less if given to an old person than to a young person, simply because the older person is likely to have less life left in which to benefit.¹ This is clearly unjust and against all principles of respecting every human being equally. The same is true of any kind of resource allocation that primarily bases itself on future contribution to society because that will also systematically discriminate against the elderly and old.

KEY POINTS

- The elderly and old have the same moral status and importance as anyone else.
- The health care claims of the elderly and old should be treated with the same attention as the health care claims of everyone else.
- Decision making for persons who are incompetent to make their own decisions have to be guided by what is in those persons' "best interest."
- The concept of "best interest" covers a wider range of considerations than merely "medical best interest."
- Advanced decision making is most useful for patients with a predictable clinical course.

The Elderly in Society: An International Perspective

Robert N. Butler

Oleg Volkov

INTRODUCTION

The extraordinary growth in life expectancy at birth in nearly all countries of the world constitutes a revolution in longevity that is still going on. This revolution encompasses both survival of individuals to older ages and changing age profiles of entire populations.

The impact of the longevity revolution has been pervasive and profound, and perhaps will prove to be as important as the industrial revolution was in the 1800s. In the earlier years of the last century, public health programs, better nutrition, and improved living standards worked to increase life expectancy; in the later years of the century, achievements in medical science applied to personal medical care decreased dramatically the death rates from heart disease, stroke, and some types of cancer after 65 and significantly increased the number and proportion of persons aged 65+, 75+, and even 90+ years. In many countries men aged 65 can expect to live 13 to 16 more years, and women, 14 to 20 years. Today, however, demographic predictions are not secure because the spread of infectious diseases – notably AIDS – threatens the lives of younger populations in vulnerable countries: it can wipe out gains in longevity and hinder further advances.¹

Women tend to live longer than men and several explanations have been offered aside from possible gender differences in biological endowment and development. Women's life style may be more healthful, with less smoking and alcohol use, and superior hygiene, while men, especially at younger ages, are more likely to pursue risky sports, to drive "under the influence," and to be in environments that promote violence. Women, as family health care representatives and users of reproductive health care, have tended to be more receptive to preventive services and more willing to accept help, which encourages early diagnosis. Yet in resource-scarce areas, tradition may favor allocation of household resources to the health of boys. Moreover, as women are more continuously exposed to workplace-related risks to health, the difference between the sexes may narrow. The strength of these diverse factors in different countries is likely to depend on cultural and economic patterns, including the degree of emancipation of women and the availability of modern health services.

Public concern with health and social services to maximize the personal and social benefits of increased longevity has spread. Furthermore, economic issues raised by such a rapid growth of older populations are now at the center of political debates in many developed and developing countries and on the agenda of international organizations. Much of the debate relates to the rising costs of pension and health programs.

Attention is also being directed to strengthening the quality of life of older persons, expanding their economic

opportunities, and acknowledging their contributions to family and society. A major challenge has been meeting the needs of older men and women who can no longer manage daily functions because of physical or cognitive disabilities. Long-term care is beyond the financial and organizational capacities of most individual households, and countries with large older populations, such as Japan, Germany, and Sweden, have accepted public responsibility. This chapter reviews selected demographic aspects of the worldwide phenomenon of increased longevity and discusses the approaches used in different nations to provide economic security to their older residents.

Inequality of longevity: longevity in developed world and shortevity in developing world

Not all nations are in a position to benefit from longevity, and in fact, a significant number suffer from its opposite—*shortevity*. In the developed world average life expectancy is 75, while the developing world has an average life expectancy of 50. Thirty-two nations (31 countries in the African continent and Afghanistan) have a life expectancy of less than 50 years and a disability-free life expectancy of less than 40.

Shortevity also occurs in countries that once achieved longevity but have subsequently lost years. This was dramatically illustrated when the Soviet Union was dissolved and the Russian Federation and separate states came into being. Female life expectancy in the Russian Federation is 58.5 years—the lowest in the developed world. Productive years of life were lost as a result of an increase in AIDS, and a spike in the incidence of alcoholism that occurred when people lost their sense of purpose and gave in to despair.

Most poor nations suffer from shortevity, and indeed, poverty and shortevity move in the same direction. It has been estimated that at the turn of the twenty-first century 200 million years of life were lost as a result of childhood and maternal malnutrition. Sierra Leone, for example, has an average life expectancy of 38 years and a disability-free life expectancy of only 26 years.

As long as there is shortevity and nations have huge populations with 35% to 40% under 15 years of age, there will be too few healthy, productive citizens to buy, sell, and exchange the goods and services with the developed world.

Demographic trends

As early as 1960, at least 10% of the total population for each gender was aged 65+ in Europe, North America, and Oceania. By 2000, females aged 70+ had become a substantial

proportion of all females in Europe and North America and the trend toward a high age profile will continue in these continents.

Table 117-1 shows changes in the size of the older population between 1960 and (projected) 2025, for individual

countries, the world as a whole, and separately, for developed and developing countries. Worldwide, people aged 65 and older as a percent of the total population will have doubled, the same rate of change will apply to developing countries, and the increase will be even greater in developed

Table 117-1. Aging Countries: % of Men and Woman in Age Groups 65+, 65–79, and 80+, in 1960 and 2025

Country	65+ (% of Total)				65–79 (% of Total)				80+ (% of Total)

countries. Both male and female populations will show these increases. The table presents countries in rank order by share of the female population in 2025; countries with less than 5.5 million persons aged 65 and older are shown in a lighter font. By 2025, females aged 80+ in developed countries will be 7% of the population in developed countries.

Countries with many older persons will need service development and implementation of social adjustments required to support health, living standards, and social integration. By 2010 there will be 21 countries having more than 3.5 million older men and women. These countries contain three quarters of the world population aged 65 and over.

Over the past century, very large gains in life expectancy both at birth and at age 65 have occurred and are evident in Table 117-2. This table contains statistics for 30 countries on six continents for which comparisons could be made. The greatest gain in life expectancy of males at birth was recorded for Spain—43.6 years; for females, Puerto Rico had the greatest gain—49.1 years.

Additional years of life gained during the past century did not result in larger labor force participation of older persons. Reports from the International Labour Office on about 200 countries for decades from 1950 to 2010 show that although the number of economically active older adults nearly doubled between 1960 and 2000 and will increase by

about 15% in the next decade, their proportion of the labor force falls after 1960.

Overall, the number of males aged 60+ who are economically active grew from 65 million (1960) to 113.6 million (2000) and by 2010 will be 130.6. But their proportion of the total male labor force fell from 7.4% (1960) to 6.5% (2000) and will be about the same in 2010. Contrary to the general trend, Europe shows a decline in both numbers and proportions.

Overall, while the number of males aged 60 to 64 in the labor force almost doubled between 1960 and 2000 and is expected to reach 68.3 million in 2010, their share in the male labor force has stayed between 3% and 4%.

The trend for females aged 60 to 64 in the world labor force is similar to that of males. By 2010 one can expect 34.0 million such women. But their share in the total female labor force hovers at a little over 2%.

In Japan, where the standard retirement age was raised from 60 to 65 in 1996,² male workers aged 60+ more than doubled in number from 1960 to 2000 from 2.5 million (9.1% of all males in the labor force) to 5.6 million (14.1%), and an increase to 6.4 million (16.8%) is predicted by 2010 by the ILO experts. Their percentage of the entire male workforce is, and will continue to be the highest among all nations. In absolute numbers, however, the greatest growth took place in India, which added 12.3 million active males, 5.0 million

of them 60 to 64 and 7.3 million 65+, over the course of 40 years, and in China, which added 10.6 million economically active males, 6.9 million aged 60 to 64 and 3.6 million 65+. However, these older males are not as large a proportion of the entire male labor force as in Jamaica and the Dominican Republic—9.4% and 8.6%, respectively.

In contrast, significant declines in the number of economically active older males were reported by Hungary and the United Kingdom. The rates of change in both numbers and older workers' share in the total working population of each sex vary from country to country. In 1960 males aged 60+ accounted for 10% or more of the male labor force in 11 countries. But in the 4 ensuing decades, these rates declined in 42 countries, while a drop in the numbers but not the rates occurred in 26 countries. Five countries, however, reported a substantial increase in the numbers of older males in the workforce, between 3.5 and 4.5 times their 1960 levels (China-Hong Kong, Nigeria, the Dominican Republic, Costa Rica, and Singapore).

There was a striking trend toward early retirement, shown by declines in the labor force participation rate of males aged 60 to 64 and 65+ in 52 countries with two other countries showing the decrease for 60 to 64+ only and one other for 65+ only.

Seven countries in Latin America and Asia reported steady growth in the numbers of older women in the labor force, and the proportion of older women in the total female labor force also grew. This trend is seen for 60+, 60 to 64, and 65+. In contrast, six European countries show a decrease in economically active older women. In Japan, where there will be 3.9 million women aged 60+ in the labor force in 2010, the proportion they represent of all women in the labor force is, and will continue to be the highest among all nations. The greatest growth in numbers has occurred in China (5.4 million added in 40 years; 2.0 million of them 65+) and India (4.2 million added; 2.0 million of them 65+).

Table 117-3 compares current (2010 projected) labor force involvement of males by age group with 1960 and shows significant declines at both 60 and 65. A major factor in this pattern of change has been the spread of pension systems enabling retirement (Africa being the continent least affected). Data for females (Table 117-4) show increased economic activity for all ages (chiefly due to growth in the age group 15–59) and relatively little activity after 60 in both 1960 and 2010. Change can be expected as costs of long retirement become personally and socially burdensome, and as productive capacity of older people is recognized as an asset.

With increased life expectancy at age 65 including more disability-free years ahead, the labor supply has the potential to increase. This will help keep the annual consumption expenditure (including health services) required to maintain daily living during the additional years of life in balance with annual incomes.

Paradoxically, recent history has shown a decline in the economic activity rate of men from age 60 onward in all continents, which is expected to continue in the years between 2000 to 2010. In 1960 work at older ages was relatively common in the world as a whole; of people aged 50 to 59, 92.8% were in the workforce, and the decline to 79.8% at ages 60 to 64 was relatively modest. Even at 65+, 48.3% of men were in the workforce. By 2000, there was a drop of about

7 percentage points at 50 to 59, but the economic activity rate for males aged 60 to 64 dropped by 12.9 percentage points, and at 65+, by 18.9 percentage points.

The economic activity rates are quite different for women. Globally, women's rate of economic activity for all ages has edged upward since 1960 to about half of the adult female population, but this has not yet made itself felt in older age groups, and for older women an increase in the next decade is not expected.

The interpretation of the rates of economic activity for women is complex. Their retirement age may be adapted to that of a spouse who is retiring early. Women's activity in the informal sector usually is not reflected in official data, in the same way that nonmarket work of males is poorly represented by official data, and household work and family caregiving generally are not part of labor force statistics. In fact, statistics on women are more likely to be substantially affected by these practices because they are more often working in the informal sector. Furthermore, cultural attitudes toward women working outside the home often limit their participation in the labor market of developing countries. Women's productive activities, whatever their form, generally support their consumption in old age. However, the scope of their activities is more limited and opportunities for mental stimulation would not be as extensive.

For men, the rate of labor force participation at age 60 and over declined between 1960 to 2000 in more than 40 of the 56 countries represented. Although low rates are more typical in industrialized countries that have well-established retirement systems and greater longevity, declines are also occurring in less developed countries as urbanization increases and job structures change. Some of the decline in economic activity of men after 65 is attributable to the emergence of disabling conditions with greater age, and to the higher age profile that appears within the 65+ population as longevity increases.

Gender differences in economic activity of older people are common. Labor force activity rates of women aged 60+ are above 20% in only 12 countries. After 65, only 7 countries reported labor force participation of more than 20%, and in 40 countries under 10% of women 65+ were economically active, including 10 countries where fewer than 2% were active.

In view of population aging, these statistics suggest major policy questions. Given the older populations' low labor force activity, how can individuals and societies finance additional anticipated years of life? Nations are in the early stages of gearing retirement programs, employment practices, workplace culture, and other institutional features to the new age profiles. How can older women, now the majority, be relieved of fear of poverty and isolation, provided with more avenues of activity, and be equipped financially to attain a good quality of life? Health care professions and industries are involved as well in maintaining work-readiness, reducing the burden of chronic illnesses, protecting populations against threats to longevity, and promoting attitudes that will assist in personal and social adjustment to the new opportunities and responsibilities.

Social protection for old age

NATIONAL RESOURCES

The standard of living of a country's older residents and the ability of the country to adjust smoothly to increased longevity are dependent on its overall resources and the

commitment of the public sector to social expenditures. Important indicators of these factors include production per capita, government spending on consumption, and unemployment. In OECD countries, where population aging has been the most advanced, wide variation in these indicators can be observed.

Gross domestic product (GDP) per capita measures the annual total of national production available for all purposes, adjusted for population size. Government final consumption expenditure shows the extent to which household consumption of goods and services depends on public programs rather than private incomes. Sweden, with its tradition as a welfare state, leads with 26.2% of GDP. Social security and welfare programs account for as much as 6.7% of GDP in Denmark but less than 1% in several countries. These categories are important for older populations because they are likely to contain the programs intended to benefit older age groups.

The last of the selected indicators is unemployment. If the rate is high, the drain on unemployment insurance funds and social programs for supplementary income payments and job creation is likely to be substantial. Funds available for various services to older age groups will be more limited, and, furthermore, policymakers are less likely to be interested in expanding economic opportunities for older persons as an alternative to retirement.

Overview of pension systems

Income maintenance programs for old age were adopted throughout the world as market economies and industrialization spread along with institutions of political democracy. These programs varied widely in their coverage and specifications. The totality of the features vitally influences the standard of living of older populations, including ability to sustain healthful diets and living environments. Although the systems came earlier and were generally more extensive in the developed countries, even developing countries tended to cover public employees and special groups and branched out in time to broader coverage.

The income programs for old age have been referred to by several different names, each with its own shade of meaning. The term "social insurance" stresses the concept of pooling of risk through either a nationwide governmental fund, or funds under national supervision maintained by industry, occupation groups, or geographical divisions. "Insurance" implies adherence to actuarial requirements, that is, expected probabilities regarding length of life and other contingencies, although important modifications of actuarial control have been numerous (such as a floor under benefits for low-wage workers). "Social security" has a rather similar meaning since it embraces statutory programs that insure against loss of earning power "as a result of old age" (which is not actually a determinant of lost earning power but represents the risks of unemployment and disability, when applied to an older population). Both social security and social insurance have been associated with a goal of averting destitution and deprivation caused by various occurrences throughout the life course, such as death of a parent or minor children. This inclusive approach most likely helps adults to prepare financially for old age. Risk pooling and a benefit structure that allows for alleviation of poverty distinguish social security from individual investment programs.

The term "social protection" has come into use to express a broader ambition—the use of public, private, and combined initiatives to mitigate income problems, aid the vulnerable, and secure minimum standards of well-being for all. At the same time, social protection as an umbrella concept acknowledges that priorities will vary with each country's circumstances. It also features a proactive dimension—averting risk through the delivery of targeted or populationwide services and providing programs to help people move out of poverty.

Old age benefit programs in the developing world tend to have narrow coverage and modest benefits. Owing to difficulties in compliance with respect to mandated contributions and in asset management, the ability to deliver benefits has not always been maintained. These problems have also afflicted countries which, despite universal pension systems, are in transition from state to private enterprise. Additionally, at least one international agency (the World Bank) and others interested in developing capital markets have favored privatized programs as a stimulus and an infrastructure for economic growth.³

Social security systems use a variety of arrangements to deliver income in old age. Employment-related programs are mostly compulsory for defined categories of employees and employers, and sometimes permit self-employed persons to participate voluntarily. Length of employment and earning level determine benefit size. The government may contribute by subsidizing benefits for low-paid workers or meeting a fund deficit.

Universal or demogrant programs give a flat rate cash benefit upon retirement and are financed from general revenues. Some length of residency is required, and they are often combined with an earnings-related tier. Contributions by employers and employees may be used even though major support comes from income taxes.

The publicly operated provident funds that are sometimes used in developing countries (such as Singapore) are based on employer and employee contributions but the distribution at retirement is received as a lump sum (one time) rather than income over a period of years. Although the lump sum, which reflects the accumulated amounts credited to each worker's account plus accrued interest, may help a retiree to start a small business or to acquire additional training, in this method retirement assets may be depleted by emergency use or the risks endemic to small enterprises.

Supplementing or replacing these program types, mandatory private insurance requires that either the employee alone or the employee and employer contribute to an employee's individual retirement account. Survivor benefits are not included and must be acquired by private purchase. Other countries require employers to provide a lump sum refund of employer and employee contributions plus interest to an aged employee who leaves the firm. There is no pooling for risk across employers, although presumably in a large firm there is an implicit pool.

Complete or substantial retirement from the workforce is required for benefits in some countries (e.g., France, Finland, Egypt), but others start payments to all covered persons when they reach the specified retirement age. Some systems allow the individual to be credited for years out of the labor force for the purpose of child rearing. In some countries workers are allowed to accumulate wage credits after the

normal retirement age, so as to entitle them to an adequate pension. Means-tested retirement pensions (as in Australia) may discourage labor force activity in the years preceding retirement by those who wish to reduce their earning record in order to qualify. This is a disincentive poorly adapted to the increased need for retirement savings created by greater life expectancy and a divergence from the objective of relieving poverty in old age.

The usual age of retirement ranges between 60 and 65 but sometimes it is length of service that establishes eligibility. Lowering of the qualifying age in response to public pressure was sometimes reversed to cut costs. Usually the age for women is 5 years less than for men but the trend is toward equalization.

Many pension laws include an early retirement option when special conditions are met, such as an unhealthy occupation, unemployment near the normal retirement age, and many years in covered employment. The wage base used in calculating benefits is critical in determining retirement income. Depending on individual work history, it makes a difference whether the last years of coverage or the highest-earning years are used. Indexing benefits for price changes protects against inflation and indexing for wage trends enables retirees to maintain the standard of living prevailing in the community. Such adjustments are subject to political trends and fiscal exigencies.²

Industrialized countries with extensive public pension systems have been facing fiscal and political problems as increasing longevity produces a growing number of pensioners. In some cases shifting older unemployed workers to pensioner status has alleviated general unemployment and drains on unemployment insurance funds. More generally, as macroeconomies grew workers became able to satisfy their desire to leave their long-term career jobs, especially physically demanding and psychologically stressful ones, for leisure or other uses of time, by early retirement.

This was made possible by provisions in social security laws that allowed benefits to start up to 5 years before the normal qualifying age when there were special circumstances, and also, without special circumstances but with actuarially reduced monthly pensions. The pronounced drop in labor force participation of older men that occurred after 1960 increased the annual obligations of public pension funds, while exits from the paid labor force reduced the productive resources of industrialized countries, in turn affecting (inter alia) the tax base supporting the pension system.

The trend of increased longevity and lower prevalence of disability in older age groups have led observers to question policies that tend to truncate the potentially active life years of aging persons. Specifically, provisions in pension laws that encourage early retirement are being scrutinized. If the normal retirement age is raised, economic support must be planned for those who can no longer work owing to impaired health; but disability insurance provides the community with the framework to handle this possibility.

A study of 11 industrialized countries measures the amount of wasted productive capacity implied by lowered economic activity rates. Although at age 50 about 90% of men are in the labor force, by age 69 this rate has dropped, but the decline varies among countries. In Belgium, virtually

no male aged 69 works and in fact most have left by age 65; in Japan, almost 50% still work at age 69. In the examples given, unused capacity is 61% of potential capacity of older workers in Belgium but much less (22%) in Japan. These measures are crude in that hours of work may vary among those who remain in the paid labor force, and much of their work may be at less productive tasks, while for many of those who leave, nonmarket activities, including caregiving, may contribute to society.⁴

Privatization experiences of three countries

Individual retirement accounts with tax deferment privileges as a vehicle for household saving for old age have now appeared in countries on several continents, sparking extensive debate as to the relative merits, risks, and costs involved. Proponents have stressed the opportunity to accumulate returns from investment in financial markets that funnel capital to corporate economies and thus participate in the gains from growth, and the wider range of options at the disposal of each active employee (compared, for example, with national funds restricted to buying government bonds). At the same time, the need for regulation of the investment and management companies that handle the placement of retirement savings into investment outlets and the administration of benefits is acknowledged. Regulations plus fees charged by the companies plus costs of competing for enrollees narrow the difference in returns to retirees compared with conventional social security. Since a long horizon for saving is necessary for sufficient accruals to occur, averaging good and bad periods, privatization programs would be more appropriate for younger workers than those nearing retirement.

The circumstances that led to privatization varied by country. For example, in Chile, there was dissatisfaction with the public program owing to mismanagement and political corruption, failure to keep up with inflation, and uneven coverage across occupations. Policy makers supported the opportunity to promote investment in the economy.^{5,6} In March of 2008, Chile reported adding public payouts for low-income elderly, granting public pensions to about a quarter of the nation's workforce by 2012. Nearly two thirds of elderly urban poor will benefit.

In China, pension cost allocation practices under the state system were obstructive to the transition to private enterprise, in which flexibility was important, and compliance with the state system was deficient. A potential problem is that low retirement ages were incorporated in the new legislation, limiting the amount that would be accrued in individual accounts, while the program was not fully geared to provide benefits for extended survival.⁷

The United Kingdom's privatized component was an outgrowth of an earnings-related tier that was added to the basic public pension system, and of allowing employers to offer their own plan as an alternative to the state system. Eventually, individuals were permitted to opt out of their employer's plan. When the economy declined, severe cuts in public pensions weakened support for the traditional system. The United Kingdom, like Chile, experienced problems under its new program, based on overselling, high charges, and limited utility of individual accounts to older workers that reduced overall net gains to participating workers.⁸

The privatization movement depends for success on a commitment of younger workers to save despite the stimulus of a consumerist economy, and has not had much to offer to those who could not afford to save much. Nor does "private security" provide accommodation, as can a state plan, for those whose work record is discontinuous because of child care, illness, or unemployment. Further experience will no doubt produce a more settled appraisal of the value of a substantial private investment component in the social planning for retirement security.⁹

Early retirement

Social security laws have the potential to influence both retirement before, and continued work after the statutory pensionable age. In OECD countries, provisions for receipt of pension benefits vary considerably from country to country. Twenty have early retirement options in their public pension programs, and among them 13 specify conditions under which early retirement is allowed. These provisions result in a difference between the standard retirement age stated in the law and the actual age at which pension benefits are awarded. The option allows older workers with sufficient credited years to change their time-use pattern. This could include self-employment and leisure pursuits and nonmarket services such as care of family members. Some countries, however, promoted early retirement as a response to high levels of unemployment, encouraging older workers receiving unemployment insurance benefits to leave the labor force. However, such a shift results in an increased social expenditure for pensions and loss of a productive resource to the labor market.

As pensions systems mature over time, more workers have sufficient earnings to become eligible for benefit payments before reaching the statutory qualifying age. Provisions for early retirement generally allow such workers to start drawing their pension. Pensionable age is also reduced for women with dependent children or children with disabilities and for men and women employed in difficult or unhealthy work.

Partial retirement, legally available in some countries, has become an attractive option for many persons, but its utility to older workers depends on whether part-time jobs are available.

Labor force participation in OECD countries declines as people approach pensionable age under prevailing programs, but the trend differs by gender. The rate for men aged 60+ is much greater than that for women, but the decreases in labor force participation among men age 65 and over is quite dramatic, dropping from 3 to 12 percentage points in several countries.

In contrast, economic activity rates among older women in these OECD countries vary enormously. Rates are high in developing countries, where pension and retirement support systems are relatively infrequent, and are very low in the developed countries.

CONCLUSION: THE GERIATRICIAN'S ROLE

The demographic trend of an increased life expectancy has already changed the age profile of many countries and is continuing to be felt throughout the world, resulting in significant changes, both in private lives and public discourse.

Older persons will be affected by national economic resources, systems that are set in place to protect them from destitution, and their involvement in the paid labor force. These in turn will have an impact on the agendas and goals of health care professionals. The long-term variations in economic growth rates, pension policies, anticipated shortage of workers that will necessitate that older persons remain in the labor force longer, among other considerations, constrain long-range predictions and create difficulties in planning for the well-being of the aging population. For example, since nations are likely to raise the normal age of retirement in response to longevity changes, the interests of older persons whose disabilities preclude full-time work will need to be safeguarded.

The ongoing demographic changes increase the numbers of individuals who will be strongly affected by the availability, perspective, and content of geriatric services. The health professions must be prepared for this growing number of older persons (projecting from numbers of persons already born) and for a variety of life alterations. The changing social and economic environment in which the health and

KEY POINTS

The Elderly in Society

- The extraordinary growth in life expectancy at birth in nearly all countries of the world has changed both survival rates of individuals and age profiles of whole populations. Since 1950, scientific achievements applied to personal medical care decreased death rates from heart disease, stroke, and some types of cancer after age 65.
- Women's survival advantage may be due to a healthier lifestyle, more risk avoidance, and receptivity to prevention and early care of illness. The gender difference in longevity may vary between countries, depending on whether tradition favors allocation of household resources to boys' health, whether women are increasingly exposed to workplace risks, and whether modern health services are available.
- Longevity creates economic problems because of the costs of retirement to individuals and society. Pension systems often contain counter-incentives to working, although use of the productive potential of older workers would help meet the costs of longevity to society and contribute to their morale and life quality.
- The labor force participation of older persons has not kept pace with the increase in their numbers and the control of late-life disability. Reports on about 200 countries show that although almost twice as many older adults were economically active in 2000 as in 1960, their proportion of the labor force had fallen.
- The spread of social security programs across the world means that both their built-in incentives to productive activity and their protective power against poverty are of wide interest at all levels of development. Indexing in benefit calculation, gender differences in the legal age of retirement, and incentives and disincentives relating to early retirement are among the features affecting whether the programs are compatible with the increased life expectancy and social goals of contemporary societies.
- Privatization of retirement programs has spread on several continents but is faced with many challenges. The problems include, among others, the level of fees charged by private companies administering the deposits, placement of investments, and payouts; the adequacy of retirement income afforded to older workers and low-wage workers, and the market risks encountered.

social care of older persons will be carried out will have an impact on important health service issues.

Geriatricians combine the application of medical science with a concern for the whole individual in responding to the challenge posed by demographic change. They must be prepared to make comprehensive assessments oriented (1) to preventive maintenance and restoration of function, and (2) not only to the seriously disabled but also to the mostly well. Doctors who care for older patients should be cognizant of their economic and social resources, and of the setting in which they live, not only their biologic parameters and organ integrity. The nature and stability of social support networks need to be understood, since changes in household composition, depletion of financial assets, and suitability of the housing environment can affect compliance with treatment, adherence to healthy regimens, and sources of morale and well-being. The death or disability of a spouse, migration of children, market fluctuations, and failures that affect the value of retirement savings are examples of risks embedded within the context of the individual's state of health. Thus, a patient's "fallback" options and the means of accessing them are important in effective care management.

Since most older persons are being treated for more than one ailment, the adoption of an integrated approach to care management can help doctors coordinate the stream of services that may be required. Geriatricians and other health care professionals, who have an understanding of the resilience and determination of many older persons, can be effective advocates and facilitators for preventive behaviors and the delay of functional loss. This advocacy should extend to the specifics of long-term care, including its coordination with acute-care services that chronically ill persons may require and the particular needs associated with hospice care.

It is anticipated that the activity level of the aging population will continue to increase, along with their access to information as the Internet becomes more accessible worldwide. As the strengths and options of older persons increase and more and more of them remain highly functional for long periods of time, the outlook of doctors who treat them will change.

AGING IN EUROPE

In common with more developed countries throughout the world, the next 50 years will see a dramatic change in population demographics in Western Europe (Figure 118-1).

The EU-27 countries show a predicted increase for those aged 65 or more from 16.6 % of the total population in 2005 to 29.9 % by 2050,¹ although these increases are not uniform across the member countries. A greater, almost triple, increase for those aged 80 years or more is projected by 2050 to more than 50 million people.¹ These changes are due to reduced fertility and increasing life expectancy; however, there remain major differences in the latter between European countries. For example, for males in Estonia it is 67.3 and in Spain 77.0.¹ The differences for women are not as great but still substantial at 78.2 and 83.7, respectively.¹

The rationale for public policies to adapt to meet this population change are similar in all European countries. The need for specialized services for older people has also been recognized. Geriatric medicine as a distinct specialty has developed at different rates in different countries despite the needs of older people being relatively similar. This chapter summarizes the state of geriatric medicine in Europe and the work of organizations whose work is focused on improving the health of frail older Europeans.

Health care in Europe

The requirement that in a civilized society all citizens should have access to good quality health care has been one of the principal features of European public policy. Different models have emerged based on state-funded systems, work-based or independent compulsory health insurance, or various combinations of the two. Some countries require co-payments, others do not. There has also been recognition that older people are disadvantaged in terms of their burden of illness, disability, and poverty in relation to the rest of community. Special arrangements have been introduced in most countries to try and reduce these disadvantages. For example, in England all those over 60 years do not pay for prescription medication. European Union citizens are also entitled to health care in every other EU country as if they were a citizen of that country. However, the specific way health care is funded and what services are provided and by whom is a matter for national and in some countries, regional determination.

THE DEVELOPMENT OF GERIATRIC MEDICINE

It is generally recognized that the identification of geriatric medicine as a distinct specialty resulted from the publications of Nascher in the United States.^{2,3} However, the development of a national geriatric medicine service has been credited to the United Kingdom and the pioneering work of Marjorie Warren who implemented her service at the West Middlesex Hospital.^{4,5} Fortuitously, this interest coincided

with the introduction of a new universal National Health Service in 1948, which incorporated from its foundation a network of hospitals that provided care for the chronically disabled, most of whom were older people.

The history of the development of the specialty has been described in a previous edition of this textbook⁶ and further information can be found in the excellent articles of Barton and Mulley⁷ and of Morley.⁸ Therefore only an abbreviated account will be given here. Until the reformation care for older disabled and sick people was provided under the auspices of the monasteries. These were closed during the reign of Henry VIII (1509–1547) and responsibility for this group of people passed to the civil authorities, who as time went on, built institutions for their incarceration in what were called workhouses. The basic principle was that of “less eligibility” with life being worse than that of the poorest laborer. The scandal of the workhouse, drawn to public attention through the work of Charles Dickens’ *Oliver Twist* for example led toward the end of the nineteenth century into the establishment of Poor Law Infirmaries, which in turn were transferred to the management of county and city municipalities in the 1920s. These hospitals became the first geriatric medicine hospitals in 1948. The arrangements of the NHS allowed for services to develop in accordance with local needs and the existing hospital structures. Three different types of geriatric medicine services were developed. The integrated model had geriatricians working alongside general physicians, often sharing wards and support medical staff.⁹ The age-related model saw medical emergency patients admitted to geriatric medicine or general medicine services according to age, most frequently 75.¹⁰ The third model, the “needs-related” service, saw geriatric medicine services taking responsibility for older people with complex needs but often not until their acute needs had been treated first. In practice many services were not so rigidly demarcated.

Figure 118-1. Western European countries population change. (Data extracted from *World Population Prospects: The 2006 Revision Population Database*, <http://esa.un.org/unpp>)

GERIATRIC MEDICINE IN SELECTED COUNTRIES TODAY

United Kingdom

The National Health Service came into being in July 1948 based on the principles of universality and provision on the basis of need rather than the ability to pay. Devolution of political power to the Nations of the United Kingdom (England, Scotland, Wales, and Northern Ireland) has produced differences in organizational structures, financial arrangements for medical staff, and patient co-payments but the underlying premise of "free at the point of use" remains. Private sector medicine is essentially geared to provide services for simple one-off conditions, whereas the management of chronic disease remains within the National Health Service.

All people are eligible to register with a general practitioner who now usually works in small groups or practices although so called "single-handed" practitioners remain. There is a right to register with a general practitioner of one's choice but in practice this may be difficult for those in rural areas and those who live in underdoctored areas and with those doctors whose list might be "full." The range of services provided by the primary care team varies but might include therapy, minor surgery, and specialist outpatient clinics. In rural areas they might dispense drugs.

General practitioners presently undergo a 5-year training program, a 2-year foundation program common to all physicians, followed by 3 years as a general practitioner registrar, which comprises 2 years in a hospital post and 1 year in a general practice. There is no obligatory requirement to have a placement in geriatric medicine or old age psychiatry.

Most general practitioners are so-called "independent contractors" who are paid by a combination of basic allowances, capitation fees, meeting specific service targets (e.g., identifying patients with hypertension) and fees per item of service. Others are salaried employed by the practice partners or by the local health service. Medical consultations involve no direct payment by patients and medications for older people are free.

General practitioners may have their competence in geriatric medicine recognized by undertaking a diploma examination organized by the Royal College of Physicians of London and of Glasgow. A few general practitioners who undertake some degree of specialist work (e.g., falls investigation, care home medicine) may be employed as general practitioners with a special interest (GPwSI). They have to undergo specific training supervised by the local geriatrician.

SPECIALISTS

The training program for geriatricians lasts 9 years and has three components: the 2-year common foundation program, 2 years of core medical training followed by 5 years of training in geriatric medicine and general medicine. Entry into training is competitive and there are a range of assessment methods that are used to monitor and confirm progress. Successful completion of training renders a physician eligible to apply for a consultant post. In addition many hospitals will employ a number of physicians who have not completed the full training program and who work as assistants to consultants. Training takes place in the main teaching hospitals associated with medical schools, smaller district general hospitals, and in the community. Responsibility for the

Acute and general medicine	141		

Source: The Federation of the Royal Colleges of Physicians of the UK, 2007.

organization and delivery of postgraduate training rests with the National Health Service rather than the university, which is only responsible for the first year of the foundation program. Full details of training can be obtained from the Joint Royal Colleges Training Board Web site (www.jrcptb.org.uk). The present training system is in a state of transition and is not yet fully implemented (for details see www.mmc.nhs.uk).

CONSULTANT NUMBERS

The Federation of the Royal Colleges of Physicians of the United Kingdom undertake an annual census of the numbers and work practices of consultants in the medical specialties in the United Kingdom.¹¹ Geriatric medicine is the largest of the medical specialties with 1092 consultants in post in 2006. The comparison with the other larger specialties is shown in Table 118-1. It should be noted that only a minority of physicians practice general or acute medicine as a standalone specialty, although it is expected that this will rise in the next few years. In contrast in 1993 there were only 658 consultant geriatricians and the growth has been steady over the last 15 years. Approximately 25% of the consultant workforce is female, but it is expected that this proportion will increase. Forty five percent of trainees in geriatric medicine are now women and women form the majority of new entrants into the profession.

THE WORK OF A GERIATRICIAN

The overwhelming number of geriatricians work as part of a multidisciplinary team based within an acute hospital. Geriatric medicine (often called care of the elderly or similar) is in turn usually placed within a medical division alongside specialties, such as diabetes and respiratory medicine. A few geriatricians work in smaller community hospitals as community geriatricians. Referral to geriatricians is via the patient's general practitioner, from other consultants or via emergency admissions. Typically there will be four or more consultant geriatricians in each acute hospital with support provided by doctors at different stages of training. The standard care pathway is for emergency admissions to be transferred either directly to the most appropriate inpatient service or to an acute all-specialty assessment unit. Patients no longer needing the services of an acute hospital may be transferred to a range of step-down (now often called intermediate care) facilities in community hospitals and care homes. A range of enhanced home care services are also usually available for the first month or so after discharge from the hospital. A list of U.K. government documents on health policy is contained in Table 118-2.

Most geriatricians have a subspecialty interest, such as orthogeriatrics, stroke, continence care, falls investigation,

and a few may practice exclusively or almost exclusively in this subspecialty. The training of geriatricians in acute care and in rehabilitation has made them ideally suited to lead the development of stroke care in separate acute stroke units and the majority of patients admitted to the hospital with stroke are now treated by geriatricians. Stroke has become a recognized subspecialty of geriatrics, neurology, general medicine, clinical pharmacology, and cardiovascular disease, although the number of physicians who have undergone the required extra training in stroke care is small.

Eighty per cent of geriatricians take part in unselected medical emergency work and geriatricians are the largest specialty providing this work (22.6%).¹²

GERIATRIC MEDICINE IN OTHER EUROPEAN COUNTRIES

There has not been a comprehensive review of the state of geriatric medicine in each of the countries of Europe. However, national societies have produced summaries of their own activities, key features of training, and the current state of development of the specialty for the Web sites of the EUGMS (www.eugms.org) and UEMS (<http://www.uemsgeriaticmedicine.org>). Principal features have been listed below.

Austria. The Austrian Society of Geriatrics and Gerontology is involved in research on the aging process and diseases in old age, the production of guidelines, and the organization of scientific meetings alone and in collaboration with other German speaking countries. Geriatric medicine is not recognized as a specialty, although attempts to create a subspecialty have been made. Similarly geriatric medicine is yet to establish itself in the undergraduate curriculum and in academia. The process of developing specialist services in acute hospitals is progressing slowly. The society publishes

two journals: *geriatrie praxis Österreich* and *Journal für Geriatrie*. (www.geriatrie-online.at).

Belgium. The Belgian Society of Gerontology and Geriatrics organizes two conferences a year. Geriatric medicine has been recognized as a full specialty since 2006 and a geriatric medicine department (acute and rehabilitation is present in each of the over 100 general hospitals in the country).

Bulgaria. The Bulgarian Association on Aging was founded in 1997 although there had been other societies previously. The specialty is only starting its development and an optional training program for undergraduates has been instituted in the Sofia Medical School. The association holds regular meetings for its multidisciplinary membership.

Czech Republic. The Czech Society of Gerontology and Geriatrics engages in the development of clinical practice, education, research, and national and regional government policies. It organizes scientific conferences and publishes the *Ceska geriatrická revue* and together with the Slovak Society of Gerontology and Geriatrics *Geriatría*. Although comprehensive services for older people exist in many places they are not yet universal. Academic units have been established in three of the country's seven medical schools.

Denmark. In Denmark geriatric medicine developed as part of the assessment for care home admission. Today, however, geriatricians are involved in all aspects of the care of older people including the emergency department. Geriatric medicine is one of nine internal medicine specialties.

Estonia. The Estonian Association of Gerontology and Geriatrics was founded in 1997 and has a multidisciplinary membership. Its mission includes raising the profile of older people and training and organizing scientific conferences.

Finland. Finland has one of the oldest geriatrics societies (founded in 1948) and organizes an annual conference and other symposia. Geriatric medicine is a recognized independent specialty previously having been a subspecialty of internal medicine, neurology, and psychiatry. There are professors of geriatric medicine in all Finnish medical schools and geriatrics is a compulsory part of the undergraduate medical curriculum.

Germany. The first German Gerontology Society was founded in 1938, reconstituted after both World War II and the reunification of Germany. A separate medical geriatric society was founded in 1995. Geriatric medicine is recognized as a subspecialty of internal medicine, family medicine, and neurology and psychiatry although there are variations in each of the Länder. The German Geriatrics Society favors a training program that graduates joint internal medicine/geriatrics specialists. Although geriatric medicine is a compulsory part of the curriculum, academic departments have only been established in a minority of medical schools. The German Geriatrics Society organizes scientific meetings and publishes the *European Journal of Geriatrics*.

Hungary. The first Hungarian congress on gerontology as held in 1937 and the XV World Congress of Gerontology was held in Budapest in 1993. Recognition of the specialty occurred only in 2000.

Iceland. Geriatrics is recognized as a subspecialty of internal medicine and is being considered as a subspecialty of family medicine. Although it is possible to train in geriatric medicine entirely in Iceland, trainees are encouraged to train overseas. Geriatrics is taught in the medical school and the Icelandic Geriatrics Society was founded in 1989.

Ireland. Ireland has traditionally spent less on health than other Western European countries and this is reflected in generally lower numbers of specialists than in comparable countries. The development of geriatric medicine in Ireland has in many ways paralleled that in the United Kingdom, although the first geriatrician was not appointed until 1969. These similarities include: the presence of geriatricians in all general hospitals, the involvement of geriatricians in acute medicine on-call duties, and dual training in geriatric and general medicine. The review of O'Neil and O'Keefe in 2003¹³ reported that there were at that time 41 geriatricians in the country, the largest specialty with internal medicine. Two models of care existed; an age-related service in the major teaching hospitals and an integrated approach in smaller hospitals where there may be a solo geriatrician working alongside four or five other medical specialists. The pattern of postgraduate training is very similar to the United Kingdom and there is cross-representation on many postgraduate training bodies. The Membership of the Royal College of Physicians (MRCP) in Ireland examination is recognized as equivalent to that of the MRCP UK. Most Irish geriatricians will have undertaken part of their postgraduate training in the United Kingdom or other countries. The Irish Society of Physicians in Geriatric Medicine was founded in 1979 but geriatricians are also active in the Irish Gerontological Society whose membership extends into Northern Ireland, part of the United Kingdom.

Italy. The Italian Society of Gerontology and Geriatrics was founded in 1950 and has a biogerontology, nursing, and sociobehavioral sections in addition to its large clinical section. It has conducted large scale national studies and publishes a number of journals including *Ageing Clinical and Experimental Research* and *Giornale di Gerontologia*. It organizes an annual scientific meeting and a summer school for fellows.

Luxembourg. Luxembourg Society of Gerontology and Geriatrics was founded in 1985. It holds an annual conference.

Malta. There are five geriatricians working in this small island country. They work mainly outside the country's main acute hospital.

Norway. In Norway geriatrics is a subspecialty of internal medicine. The Norwegian Geriatrics Society holds a scientific meeting every other year but also takes part in Nordic congresses. Geriatrics is part of the undergraduate curriculum and there are professors in Oslo, Bergen, Trondheim, and Tromsø.

Spain. The Spanish Society of Geriatrics and Gerontology was founded in 1948 and has clinical, biologic, and behavioral-social sections. There are 2500 members, the majority of whom are physicians. In addition to a national conference, the Society publishes *Revista Española de Geriatría y Gerontología*. A second society, the Spanish Society of Geriatrics and Gerontology, was founded in 2000 and holds biennial scientific meetings and has published a number of books. A survey conducted in 2003 revealed that there were no acute geriatric care units in seven of the country's regions amounting to two thirds of the country's acute hospitals.

Slovakia. Slovakia recognizes geriatric medicine as a specialty with training following European guidelines. The Slovakian Society of Geriatrics and Gerontology includes among its roles the dissemination of knowledge about older people to physicians and other health care workers, policy

development, activities aimed at ending age discrimination, and organizing scientific meetings. Its journal *Geriatrics* is published four times a year.

Sweden. Geriatrics is recognized as a full specialty. Most geriatricians work in specialist services for older people with a minority working in primary care or internal medicine. The Swedish Society for Geriatrics and Gerontology organizes a scientific conference each year.

Switzerland. Geriatric medicine was recognized as a specialty in 2000 and the Swiss Geriatrics Society was founded shortly after that in 2002. Before that geriatricians formed a section of the Swiss Gerontological Society. The two Societies share the same administrative office. Most geriatricians initially trained in internal medicine before undertaking geriatric medicine training but a small number first became family physicians. Specialist training comprises 2 years in geriatric medicine and 1 year in old age psychiatry after the 5 years in either internal medicine or family medicine. A recent review of the health care of older people in Switzerland, while recognizing that per capita spending on health was one of the highest in the world, highlighted a number of areas of concern.¹⁴ There was a tenfold variation in the number of geriatricians between urban and rural areas. The Swiss National Science Foundation had no specific program on aging research. Only three of the five medical schools have academic departments and there were insufficient opportunities to train academic geriatricians.

The Swiss Geriatrics Society participates in meetings of the Swiss Internal medicine and Gerontology Societies and Congresses in French and German-speaking neighboring countries.

Turkey. The Geriatric Society-Turkey was founded in 2003 and publishes the *Turkish Journal of Geriatrics*. Its aims include the promotion of health of older people, teaching about their health care needs, public education, and organizing scientific meetings.

GERIATRIC MEDICINE ORGANIZATIONS IN EUROPE

There are three major European organizations whose principal *raison d'être* is the advancement of specialty of geriatric medicine and the improvement of health care for older people. These are:

- The International Association of Geriatrics and (IAGG) (www.iagg.com.br)
- The European Union Geriatric Medicine Society (EUGMS) (www.eugms.org)
- Union of Medical Specialists – Geriatric Medicine Section (EUMS-GM). (<http://www.uemsgeriatricmedicine.org/>)

Although three of these bodies are autonomous, they share common goals and cooperate in a number of ways by, for example, offering board membership to the other organizations and by organizing joint sessions at congresses. Their structure, functions, and successes are described below.

IAGG

The IAGG is a worldwide learned society for all those interested in the health and welfare of older people. Its member organizations come from more than 60 countries with a

combined total membership of over 45,000. It has consultative status with the United Nations and its subsidiary bodies. Founded in 1950 it has held 18 World Congresses and plans to hold the nineteenth in Paris in 2009. Its official journal is *Gerontology – International Journal of Experimental, Clinical and Behavioral Gerontology*.

The IAGG is organized into five regions: Africa, Asia/Oceania, North America, Latin America and the Caribbean, and Europe (ER). The latter region, IAGG-ER, (<http://www.iagg-er.org>) is itself organized into three sections: clinical, biologic, and behavioral social science. Its affairs are coordinated by an executive board elected every 4 years by delegates from European societies affiliated with IAGG. Some countries have more than one member organization (Table 118-3). For example, the United Kingdom has three societies affiliated to IAGG: The British Geriatrics Society (clinical), the British Society of Gerontology (social science), and the British Society of Research on Ageing (biologic).

The principal activity of the IAGG-ER is to organize scientific conferences, which are presently held every 4 years. The next one will be held in Bologna in 2011. The conferences comprise plenary sessions, symposia, and free communications organized by the three sections together with some cross-sectional events. The clinical section has held eight separate congresses, the first being in Berlin in 1992 and latest in Ostend in 2006 in association with the annual meeting of the Belgian Society of Geriatrics and Gerontology. A joint symposium with the British Geriatrics Society will be held in April 2009. The clinical section has their own president and secretary-general but only the president is a member of the board of IAGG-ER. Membership of the IAGG-ER includes countries outside the European Union and some outside the traditional boundary between Europe and Asia (e.g., Georgia, Israel). Ribera Casado¹⁵ has reviewed the history of the clinical section.

EUGMS

The EUGMS is a relatively new organization founded in 2000. It held its first congress in Paris in 2001. Individuals are members of the EUGMS on the basis that their national society is a member. As the European Union has enlarged to encompass countries from Middle and Eastern Europe, the number of affiliated societies and members has steadily increased. It is possible that all national geriatric medicine societies in Europe will eventually affiliate. Current affiliation is shown in Table 118-3. Its affairs are coordinated by a full board consisting of representatives of all member organizations and others. This meets once a year and elects an executive board. The secretariat is based in the British Geriatrics Society headquarters in London.

The goals of EUGMS include continuing professional development, representation of the specialty to the European Union, guideline development, and the promotion of research and education. However, its most obvious visible activity has been the organization of major international conferences every 2 years with smaller subject specific symposia in the intervening years. The next conferences are scheduled to take place in Copenhagen in 2008 and Dublin in 2010.

Other activities have included the publication of guidelines on type 2 diabetes mellitus (<http://www.eugms.org/index.php?show=search&query=diabetes>) and syncope

(<http://www.eugms.org/index.php?show=search&query=syncope>). On the political front, EUGMS interacts with both the European Commission and the European Parliament. EUGMS also has an official scientific journal *The Journal of Nutrition Health and Aging*. A position paper setting out EUGMS' priorities is abridged in Table 118-4.

The desirability of having two separate clinical societies in Europe has been questioned,¹⁵ particularly as many organizations are members of both and several geriatricians hold or have held office in both organizations.

EUMS - Geriatric Medicine Section

One of the basic tenets of the European Union is the free movement of workers between its countries with each nation's qualifications being recognized in all members of the European Union. As far as physicians are concerned, this means that undergraduate and postgraduate diplomas and certificates are acceptable in each country without the need for further examinations. The EUMS, now in its fiftieth year, is the body charged with coordinating specialist education within the European Union.

Responsibilities for specialist training are divided between national authorities and EUMS. National bodies are responsible for the duration and contents of training, quality control, determining entry procedures, assessment, and control of numbers. EUMS is allowed to set minimum standards, which have to be met in each country.

EUMS is organized into numerous specialist sections, including one for geriatric medicine—European Union of Medical Specialists (EUMS) – Geriatric Medicine (EUMS-GM). The activities of the section are coordinated through a board, the current president of which is Ian Hastie of the United Kingdom. Countries represented on the board are shown in Table 118-3. National representation is via the recognized national medical body in each country. In the case of the United Kingdom, this is the British Medical Association although this is then delegated to each specialty society.

Geriatric medicine is recognized as a specialty in Belgium, Denmark, Finland, France, Germany, Ireland, Italy, The Netherlands, Spain, Sweden, and the United Kingdom. However, it is not recognized in Austria, Greece, Luxembourg, and Portugal. The situation in the "new" European countries in central and eastern Europe is in transition, with the specialty being recognized in the Czech Republic, Hungary, and Slovakia although these countries are not yet integrated into EUMS-GM.

The goals of the section are to promote the recognition of geriatric medicine in all countries of the European Union, to standardize training standards and requirements, and as a consequence to ensure that all older people in Europe have access to adequately trained geriatric medicine specialists. It is tackling these issues through a wide range of activities (Table 118-5).

Training and the Curriculum

The EUMS-GM has produced a curriculum (http://www.uemgeriatricmedicine.org/important_documents/geriatric_training_-_condensed_version.pdf), which should serve as a basis for those produced by national bodies. In summary, specialist training should take place over a 4-year period preceded by 2 years in general internal medicine. One of the 4 years may be in research. Training should

take place predominately in hospitals. Training institutions should be capable of delivering training and have a broad range of high-quality services. Research ethics and therapeutics committees should be in place. The director of training should be a specialist of at least 5 years standing, although it is recognized that exceptions may be needed. Training should comply with all national and international requirements and each trainee should have a named educational supervisor. Trainees should keep a personal logbook or other record of training. Emphasis is stressed on following both national and EU regulations.

The duration of training varies slightly from country to country. In the United Kingdom those wishing to become a geriatrician undertake the 2 years foundation program that all doctors have to complete. This is followed by 2 years of

core medical training and then 5 years further training in both geriatric medicine and acute medicine. This qualifies the doctor to work in both geriatric medicine and in acute medicine. This pattern is similar to other medical specialists (e.g., respiratory medicine, diabetes) who also undertake acute medicine. In other countries, different routes exist. For example, for those just wishing to practice as geriatricians in the Netherlands, there is a common trunk in general medicine of 2 years and 2 years in geriatrics and 1 year in old age psychiatry. Consultants in general medicine with a special interest in geriatric medicine have to undertake 4 years in general medicine and 2 years in geriatrics, of which 6 months has to be in old age psychiatry. In Belgium trainees have to complete 3 years in general medicine and 3 years in geriatric medicine.

Table 118-4. Key Points from a Position Paper on the State of Geriatric Medicine in Europe*

- Geriatric medicine is involved in the medical care of older people with acute, rehabilitation, and long-term health conditions in the community, care homes, and hospitals.
- There is a need to harmonize geriatric medicine throughout Europe.
- Geriatricians are able to undertake a comprehensive assessment of the patient with cognizance of atypical presentation, comorbidity, and functional state.
- Undergraduate medical students and postgraduate physicians need training in geriatric medicine from suitably qualified teachers.
- There is a need to develop an objective-based curriculum for specialists.
- There is a need to increase research capacity in aging research.
- Guidelines on ethical issues in old age should be developed.
- There is a need for geriatricians to collaborate with other medical specialties and with allied health professionals to improve the health of older people.

*Adapted from Duursma S, Castleden M, Cerubini A, et al. European Union Geriatric Medicine Society. Position statement on geriatric medicine and the provision of healthcare services to older people. *J Nutr Health Aging* 2004;8(3):190–5.

The EUMS-GM has also produced a summary curriculum that considers learning objectives under the following headings:

- Basis of care and provision of appropriate services
- Assessment and treatment
- Rehabilitation
- Discharge planning
- Assessment for long-term care
- Research
- Medical education
- Development of geriatric services
- Administration
- Contribution to the nation's health service
- Clinical audit
- Professional development

There are considerable differences in the state of development and the role of the specialty within the health service in each European country. However, EUMS-GM has been able to produce a consensus statement defining the purpose of the specialty (Table 118-6).

European Academy for Medicine for Ageing (EAMA)

The need for a concerted effort to increase academic capacity in geriatric medicine in Europe has long been recognized. The linking of the development of the specialty to the state of academic geriatrics was identified by the Group of European Professors in Medical Gerontology (GEPMG).¹⁶ This group suggested a number of concerted activities, including training junior faculty, the development of a core curriculum at both the undergraduate and the postgraduate levels, and the establishment of a professorship in what they called medical gerontology in every medical school. One of the outputs from this report was the establishment of the European Academy for Medicine of Ageing, which graduated its first cohort of potential geriatric medicine leaders in 1996.¹⁷ The format of teaching comprised four 1-week sessions held in Switzerland, which covered a broad range biologic and clinical topics. A subsequent evaluation reporting on the

Table 118-5. Achievements and Activities of the EUMS - GM

- The production of standards and curricula for specialist training in geriatric medicine
- The production of guidelines for the training of medical undergraduates in geriatric medicine and gerontology
- The production of a system of inspection of training posts and their accreditation for equivalent training
- Contributing to the development of a Master's in Gerontology diploma
- Contributing to the EU Manual of Internal Medicine
- Developing a database of information about the training opportunities and organization in the individual member states
- Disseminating information about the organization and practice of geriatric medicine and other issues including revalidation and continuing professional development
- Establishing a Web site of the geriatric medicine section, with links to national associations of geriatrics and gerontology
- Encouraging participation by all members and their trainees in the International Meetings of the European Union Geriatric Medicine Society

Adapted from <http://www.uemsgeriatricmedicine.org/>

Table 118-6. Definition of the Specialty of Geriatric Medicine

- Geriatric medicine is a specialty of medicine concerned with physical, mental, functional, and social conditions occurring in acute care, chronic disease, rehabilitation, prevention, social, and end of life situations in older patients.
- This group of patients are considered to have a high degree of frailty and active multiple pathology, requiring a holistic approach. Diseases may present differently in old age, are often very difficult to diagnose, the response to treatment is often delayed and there is frequently a need for social support.
- Geriatric medicine therefore exceeds organ-orientated medicine offering additional therapy in a multidisciplinary team setting, the main aim of which is to optimize the functional status of the older person and improve the quality of life and autonomy.
- Geriatric medicine is not specifically age defined, but will deal with the typical morbidity found in older patients. Most patients will be over 65 years of age but the problems best dealt with by the specialty of geriatric medicine become much more common in the 80 and over age group.
- It is recognized that for historic and structural reasons the organization of geriatric medicine may vary between European Member Countries.

Adapted by EUMS-GM on May 3, 2008.

first 10 years of the program¹⁸ identified a number of factors, which the authors thought were important. These included the involvement of international leaders, the intense interactive nature of the course, and the international nature of the student body, which now includes younger geriatricians from outside Europe. A large proportion of the students were able to advance their careers but whether they would have done so without their involvement in this course is not clear. Further information about EAMA is available from its Web site (<http://www.healthandage.com/html/min/eama/>).

The European Masters Program in Gerontology (EuMaG)

This program is coordinated by the Free University of Amsterdam and is designed for professionals from both health and social science backgrounds to study in an

interdisciplinary-fashion. Modules are offered in different countries and students can study individual modules or undertake the whole course. At the present time modules are offered in the Netherlands (Introduction to Gerontology), Germany (Psychogerontology), United Kingdom (Social gerontology, and France (Health Gerontology and Summer School). Modules are often integrated with local teaching programs thus enhancing the mix of students. Further details are available on <http://www.eumag.org/>

COLLABORATIVE RESEARCH IN EUROPE

The European Union fosters collaborative international projects through its Framework programs, which have been in existence since 1984. The current program (framework 7) includes a number of projects relevant to the needs of older people. These include: PREDICT: Increasing the participation of the elderly in clinical trials; SMILING: Self mobility improvement in the elderly by counteracting falls; RESOLVE: Resolve chronic inflammation and achieve healthy aging by understanding non-regenerative repair; CAPSIL: International support of a common awareness and knowledge platform for studying and enabling independent living; and HERMES: Cognitive care and guidance for active aging. More information is available at <http://cordis.europa.eu/en/home.html>.

Links between nongovernmental organizations

Nongovernmental organizations have also formed European collaborations aimed at influencing European policy and for mutual support. The European Older People's Platform AGE has as its aim "to voice and promote the interests of older people in the European Union and to raise awareness of the issues that concern them most." (<http://www.age-platform.org/EN/>). The European Healthy Ageing Advocacy

Forum has been set up with the main aim of sharing best practices among advocacy groups and charitable organizations. The forum is a network of independent organizations from eight countries.

CONCLUSIONS

As has been described, the development of the specialty of geriatric medicine has progressed at varying paces in different European countries despite the demographic needs being relatively similar. A number of organizations have been established whose aim has been to advance the health care of older people by professional development within the specialty of geriatric medicine and related disciplines. Several geriatricians hold office in more than one of these organizations and it is therefore not surprising that calls for closer working have been made.^{15,19}

The demographic and technological changes that are taking place are having similar effects on the development of policy regarding health care of older people with the move to the provision of more care in the home and with ever shorter hospital stays. This will impact on the role of the geriatrician, which is likely to see a greater presence outside the hospital than is currently seen and a continued role in the general hospital. It is of interest that a majority of leading European geriatricians opted for a division of geriatrics into a community and a hospital branch.²⁰ However, there is consensus that older people, particularly those with physical and mental health comorbidity, in whatever setting they are, need to be treated by trained doctors and allied health care practitioners.

INTRODUCTION

In this chapter we will examine the history and current state of geriatrics in Canada (2008 estimated population 33.4 million; per capita gross domestic product \$42,738) and the United States (2008 estimated population 304.9 million; per capita gross domestic product \$43,594), two countries with strong historical and economic ties. Although geriatrics developed in response to similar demographic pressures in both countries, it has evolved in a different manner. In this chapter we will not be covering developments in the Caribbean or Latin America, where demographic aging is less advanced and the challenges differ from those encountered in more developed countries.¹ Nor will we be dealing with antiaging medicine and the effort to decelerate, if not fully arrest, aging.²

As with other parts of the more developed world, the absolute number and the relative proportion of older individuals (or seniors) in Canada and the United States are increasing. Defining what we mean by senior, though, is not straightforward. The use of the chronologic age of 65 to sharply demarcate the start of old age reflects an arbitrary choice made by our society. It is not driven by a strong biologic or clinical rationale. If the term senior is used in a relative sense to describe the oldest segment of the age pyramid in our countries, we should have continuously revised our age cut-off over the last half century. In 1971, 8% of the Canadian population was 65 years of age or older. Today, the 8% who make up the top of the age pyramid are 81 years of age or older.³ In this chapter we will stick with the "usual" definition of a senior as an adult who is 65 years of age or older.

Both countries had large post-World War II baby booms from 1946 until 1964 in the United States and 1966 in Canada. Currently (2008) there are 37.3 million Americans 65 years of age or older (12% of the population).⁴ Over the next 2 decades there will be on average 1.6 million seniors added to the United States population every year. It is expected that there will be more than 70 million seniors in America by 2030^{5,6} and 86.7 million (21% of the population) in 2050.⁴ Similar changes will be taking place in Canada. Between 2006 and 2026 the number of seniors is projected to grow from 4.3 to 8.0 million, with their share of the population increasing from 13.2% to 21.2%.⁷ Both countries will have to meet the challenge of dealing with this unprecedented growth in the number of seniors.

There has been a degree of angst among at least some about the potential cost implications of these increases in the senior population.⁸ As an extreme example of this, in 1984 the then Governor of Colorado, Richard D. Lamm, was inaccurately but widely reported as saying that older Americans "got a duty to die and get out of the way."⁹ Although a Chicken Little, alarmist reaction is clearly inappropriate, there are legitimate concerns about issues such as how aging Americans and Canadians are planning (or more accurately not planning) for their later years. Rather than putting sufficient money aside to deal with retirements that might last for 30 years or longer, in the United States people are saving less for old age now than they have in any decade since

the Great Depression.¹⁰ The growth in the senior population will lead to increases in health care use and costs if their health status remains the same and we carry on with our current practices. Although the majority of American seniors are in good health, per capita health spending averages three to five times higher than for younger adults.¹¹ Seniors currently make up 12% of the American population, but they account for a quarter of physician office visits, a third of all hospitalizations, and a third of all prescriptions.¹² Those with complex, chronic health problems in particular use the health and social care system more. It is important, though, to take a balanced view on the impact of population aging on the health care system. Although it will add to costs in acute care, population aging does not rank with the pressures arising from other drivers such as increases in per capita use or the implementation of new technologies.¹¹ It is anticipated that the health care impact of population aging will be primarily on the home and residential care sector.³

Geriatrics is the branch of medicine that focuses on health promotion and the study, understanding, prevention, and treatment of disease and disability in later life. The rise in the number of older people during the twentieth and twenty-first century has led to an increase in interest about this field of practice. The history of geriatrics in North America goes further back than most realize. The word itself was coined nearly 100 years ago in 1909 by a New York physician, Ignatz Leo Nascher. He stated that old age was as "distinct [a] period of life... as... childhood" and deserved "a special branch of medicine."¹³ He later authored the lengthy textbook *Geriatrics: The Diseases of Old Age and Their Treatment* that was published in 1914, but he failed in making it an inviting field of medical practice.¹⁴

During the first half of the twentieth century medical care in Canada and the United States was organized and financed in a similar manner. It was only in the 1950s that we began diverging in a significant manner. A number of Canadian physicians and researchers who emigrated to the United States, such as Sir William Osler, infamous for *The Fixed Period* controversy,¹⁵ played important roles in shaping American attitudes and approaches toward the aged during the first half of the last century.¹⁴ The birth of scientific gerontology can be said to have occurred in 1939 with the publication of *The Problems of Ageing*. This was edited by the noted anatomist Edmund Vincent Cowdry who was born and educated in Canada but spent most of his professional career in the United States, principally at Washington University in St. Louis.^{14,16} The American Geriatrics Society was founded in 1942, before the Medical Society for the Care of the Elderly (in 1959 renamed the British Geriatrics Society) in the United Kingdom.¹⁶ Five Canadians have served as its president. One of them, Willard O. Thompson, was the founding editor of the *Journal of the American Geriatrics Society*.^{14,16}

Most North American physicians working in the field during the middle part of the last century had "day jobs" that consumed most of their time. With few exceptions they did not work full-time as geriatricians. Their clinical focus was on preventing problems. Healthy old age was felt

to be dependent on the involvement of a physician in the care of the older person. Health maintenance activities were emphasized.¹⁷ The development of geriatrics as a full-time specialty area lagged behind the United Kingdom. As noted by John Grimley Evans, while "Ignatz Nascher invented the word, Marjory Warren created the specialty."¹⁸ Both formal recognition of the field and the creation of training programs in geriatrics were slow to occur. It was not until 1977 that the Council of the Royal College of Physicians and Surgeons of Canada (RCPSC) recognized of geriatric medicine as a subspecialty of internal medicine.¹⁴ That year the Institute of Medicine of the National Academy of Sciences in the United States concluded that a formal practice specialty in geriatrics should not be established. It was only in 1988 that the first American certifying examination in geriatric medicine were held (the first Canadian examinations took place in 1981).^{14,16} The first American fellowship in geriatric medicine was established in the late 1960s by Leslie Libow,¹⁶ whereas Canadian residency training programs were in place by 1980.¹⁴

A particular strength of geriatrics in the United States has been the breadth and depth of its research enterprise, which has come to dwarf activities elsewhere in the world. More than half (53.9%) of the articles published in gerontology and/or geriatric journals during 2002 were authored or co-authored by Americans.¹⁹ This compares with 9.7% for contributors from the United Kingdom and 6.7% for Canadians, who ranked second and third, respectively.¹⁹ The establishment of the National Institute on Aging (<http://www.nia.nih.gov/>) in 1974 was an important milestone in the United States. It helped legitimize research into aging, while support from the institute was important in establishing geriatric programs within American medical schools.¹⁶ In 2000 the Canadian Institutes of Health Research (CIHR) was established. One of the 13 Institutes making up the CIHR is an Institute on Aging (<http://www.cihr-irsc.gc.ca/e/8671.html>).

Care of older patients

There are important differences between older and younger adults that should affect the care provided. Seniors typically have diminished physiologic reserves. Chronic conditions such as cardiovascular disease, stroke, diabetes, cancer, chronic obstructive airway disease, musculoskeletal conditions, and dementia are more common and when present often more severe. Of even greater importance is the frequent presence within an aging patient of multiple morbidities occurring in many different combinations. The vast majority (82%) of seniors have at least one chronic condition with 24% having four or more.⁶ Geriatric syndromes (e.g., delirium, falls, incontinence, frailty), malnutrition, sensory impairments, and disability including impaired mobility are also common among seniors. With both the physical and social environment of the patient, they are all important considerations in the provision of care. Polypharmacy (the consumption of many drugs together) to deal with the symptoms, diseases, and risk states (e.g., hypertension, hypercholesterolemia, osteoporosis) frequently encountered by older patients has become the rule rather than the exception. This in turn can lead to problems with adverse drug effects, prescribing cascades, disease-drug interactions, drug-drug interactions, inappropriate prescribing, and nonadherence. The inherent complexity of older patients unfortunately leads all

too often to fragmented, uncoordinated care provided by an array of specialists and subspecialists.

Most older patients are (and will be) looked after by physicians without advanced training in geriatrics. These physicians will require sound knowledge about health and illness in older patients, and how to mobilize available resources to meet their needs.²⁰ "Gerontologize" is the awkward verb used to describe both the dissemination by education of the principles of effective care of older patients within the various fields of medical practice and the integration of these principles within clinical practice guidelines. Although progress has been made,^{6,20,21} further work is required. As with other sociodemographic subgroups,²² there is room for improvement in the quality of care provided to seniors. The Assessing Care of Vulnerable Elders (ACOVE) study found that the care provided to community-dwelling seniors fell short of acceptable levels for a wide variety of conditions. The care for geriatric conditions (e.g., falls, incontinence) was generally worse than that for general medical ones (e.g., diabetes, heart failure).²³ Within the acute care sector, the overall incidence of adverse events (unintended injuries or complications resulting in death, disability, or prolonged hospitalization that arise from health care management) during hospitalization of adult patients in Canada is in the order of 7.5 per 100 hospital admissions with increasing age a statistically significant risk factor for their occurrence.²³

Dealing with the unique needs of seniors must be integrated within the broader context of health care planning, policy development, and service delivery for the entire population. An example of this would be in emergency care. Both the 2003 heat wave in France and Hurricane Katrina demonstrated how they are at particular risk during disasters. Emergency planning has to take this into account.^{25,26} It is furthermore predicted that emergency departments will be strained by the pending influx of aged baby boomers.²⁷ How emergency care is provided, especially to frail seniors, will have to be modified to deal effectively with them.²⁸

Although improving the care of *all* older patients must be a goal of our respective health care systems, how do geriatricians (i.e., those with advanced training in the care of older patients) fit within this overarching aspiration? In the next section I will address this question.

Specialty practice in geriatrics

In the United States geriatric medicine is recognized as a subspecialty of internal medicine by the American Board of Internal Medicine and a Certificate of Added Qualification by the American Board of Family Medicine. A certifying examination is jointly offered by the two boards on a yearly basis. After completion of a residency in either family medicine or internal medicine, trainees are required to take at least a year of additional training in geriatrics to be eligible for the certifying examination. Very few trainees take more than 1 year of training.⁶ There are now 145 training programs in geriatric medicine with 514 residency positions, but only 62% were filled.²⁹ The decision to lower the duration of training from 2 to 1 year in 1998 was controversial.^{6,16} It was recently suggested that training programs be strengthened so that geriatricians would be better able to fulfill leadership roles.³⁰ About half of all physicians certified in geriatric medicine before 1994 have pursued recertification.⁶ This rate is substantially lower than that seen for other subspecialties of

internal medicine, and raises concerns about retention. Currently (2008) there are approximately 7100 American physicians certified in geriatric medicine.⁶

There are two recognized training options available for Canadian physicians interested in geriatrics.³¹ Physicians who have completed their training in family medicine can enroll in a 6- to 12-month residency in Care of the Elderly accredited by the College of Family Physicians of Canada. Graduates of these programs do not have to take a certifying examination. Their training is intended to equip them to provide primary medical care to older individuals, work within specialized geriatric programs, and/ or function as a medical resource in the care of older patients for their community. Since it was first offered in the early 1990s, there have been about 140 graduates of Care of the Elderly programs. The second option is for those trained in internal medicine. They can take a 2-year residency in geriatric medicine.³⁰ These programs are accredited by the RCPSC, which also administers a qualifying examination for those who have successfully completed their residency. Residents are trained to provide clinical consultations on older patients with complex health problems in a variety of settings, including hospitals. Currently (2008) there are about 220 Canadian specialists in geriatric medicine. Although both training streams are separate, graduates from either can be involved in medical education, program development, research, and medical leadership. To date internist geriatricians have been those principally engaged in these activities.

Geriatric psychiatry is the subspecialty of psychiatry that deals with the assessment and management of mental disorders in later life.³¹ Notwithstanding its long history in Canada,¹⁴ the RCPSC has just recognized it as a subspecialty of psychiatry. Currently there are about 200 geriatric psychiatrists in Canada.³¹ The American Board of Psychiatry and Neurology recognized the subspecialty in 1989. The postgraduate training requirement is 1 year.⁶ There are approximately 1600 certified geriatric psychiatrists in the United States.⁶ In 2008–2009 there were 57 American trainees in geriatric psychiatry compared with 743 enrolled in a child and adolescent psychiatry training program.²⁹

There is general agreement that American physicians with additional training in the care of older patients should have major roles in meeting academic requirements in education and research, and providing medical leadership. There is greater debate in the delineation of their clinical role. Indecision and inconsistency about what geriatricians should do has hampered the growth of the field.³² In the United States it was initially thought that these physicians would be principally concerned with the medical care of the residents of long-term care facilities. Then it was thought that they would be consultants equipped to manage complex cases on referral. Next there was an effort to redefine geriatrics as a primary care field, but current and projected future numbers have made it clear that American geriatricians cannot have a major role in providing primary medical care to unselected older individuals. In the United States (and Canada) linkages frequently exist between geriatrics and palliative care. Although the two areas are complementary, they do have distinct roles.³³

Compared to the American situation, geriatric medicine in Canada has been more consistently seen as a consulting field. A disconcerting finding of a recent survey of Care of the Elderly graduates was that less than half were restricting

or focusing their practice to seniors.³⁴ The rest appeared to be working as a “typical” family physician, which raises questions about the utility (to themselves and society) of their additional training in geriatrics.

A critical issue on both sides of our border is recruiting sufficient numbers of physicians into the field. See Table 119-1 for an overview of the training situation in Canada. The 38 Care of the Elderly and geriatric medicine trainees in 2008–2009 represented less than 0.8% of all Canadian trainees in family medicine and internal medicine that year.³⁵ This compares to the 546 trainees in pediatrics excluding subspecialties. That year 10 Care of the Elderly and 6 geriatric medicine trainees, a total of 16, entered practice—well less than what is needed to correct the current physician resource deficit, deal with population growth, and replace retirees. Table 119-2 provides similar data for the United States. The 320 trainees in 2008–2009 represented about 0.3% of all residents in training.²⁹ That year there were 8089 trainees (7.5% of all residents) in pediatrics.²⁹ Assuming current rates of training and expected attrition rates, the Association of Directors of Geriatric Academic Programs has projected a daunting deficit of approximately 28,000 geriatricians in the United States by 2030.⁶ In neither country is there evidence of significant increases in the number of trainees entering the field.

Table 119-1. Number of Trainees Enrolled in Postgraduate Training Programs in Care of the Elderly (6–12 Month Program) and Geriatric Medicine (2-Year Program) in Canada (1998–2008)—Data From Annual Reports of the Canadian Post-M.D. Education Registry

	Care of the Elderly	Geriatric Medicine	Total
1998–99	8	28	36
1999–00	14	29	43
2000–01	13	25	38
2001–02	14	23	37
2002–03	16	24	40
2003–04	13	15	28
2004–05	10	15	25
2005–06	12	15	27
2006–07	10	19	29
2007–08	14	24	38
2008–09	13	25	38

Table 119-2. Number of Trainees from Family Medicine and Internal Medicine Enrolled in Postgraduate Training (1 Year Program for Most) in Geriatrics in the United States (1998–2007)—Data from Annual JAMA Issue on Medical Education

	Family Medicine	Internal Medicine	Total
1998–99	37	298	335
1999–00	42	326	368
2000–01	28	293	321
2001–02	36	302	338
2002–03	41	327	368
2003–04	47	305	352
2004–05	46	288	334

2006–07	44	243	287
2007–08	46	246	292
2008–09	64	256	320

Barriers to recruitment include the poor pay compared with other fields of medical practice and its perceived lack of glamour. In the United States the financial return on obtaining additional training in geriatrics is negative—internists who take this additional training end up making *less* money on average than those who do not.³⁶ As noted by Robert L. Kane the “prospect of working hard for less money is not a strong recruitment device.”³² An example of the perceived lack of “sparkle” compared with other fields is the exchange between two characters in the then hit television medical drama *Grey’s Anatomy*:

George: “Maybe I should have gone into geriatrics. No one minds when you kill an old person.”

Cristina: “Surgery’s hot. It’s the marines. It’s macho. It’s hostile. It’s hardcore. Geriatrics is for freaks who live with their mothers and never have sex.” (Episode - A Hard Day’s Night; first aired March 27, 2005.)

Geriatrics has faced persistent opposition from within the medical profession. This might be due to factors such as the misconception that geriatrics just means taking care of an older patient, the perceived threat of the field to the identity and finances of existing practitioners and/or the subconscious fear of physicians to their own aging.³³ All of these misperceptions plus others were present within the RCPSC Specialty Committee for Internal Medicine in the late 1970s. It had not been consulted before the Council of the RCPSC recognized geriatric medicine as a specialty in 1977. Once informed they expressed strong disapproval and on two separate occasions (1978 and 1979) passed motions “deploring” the recognition. Comments from the minutes of their meetings included: “Geriatrics is the business of internists... [and] segregation [of older patients]... [is] not in their best interests”; British geriatricians were described as “curators of parking lots”; and, geriatrics in England was called “the refuge for failed internists, and the elderly receive very indifferent care in settings apart from other medical patients.” Members of the committee declared that geriatrics had no specific knowledge base and that advances were not being made by geriatricians but by clinicians and scientists in other fields. One member stated that “geriatric practice can be very depressing, and that physicians are more likely to perform well with a broad spectrum of patients.”¹⁴ Their protests were to no avail as the decision by the Council of the RCPSC was not rescinded, but the inescapable conclusion is that within at least some corners of organized medicine, geriatrics “like its patients, is disrespected and marginalized⁵ with little recognition of our knowledge base and the clinical skills of geriatricians.¹⁰

Although recommendations have been made to improve recruitment, it is uncertain how effective they would be even if implemented.^{6,30,31,34,37} Because of the shortage in the number of geriatricians there appears to be no option other than restricting practice to the subpopulation of seniors with the most complicated needs. This underscores as well the importance for geriatricians to focus on teaching the core

principles of good elder care to medical students, post-graduate trainees in various fields, and practicing physicians. Another option would be to look outside the confines of medical practice and consider building up a cadre of nurses with additional training in the care of older patients who could assume a greater role in the primary care of seniors and/or the provision of health services within long-term care facilities.¹⁰

We are gradually acquiring the knowledge needed to improve the care we offer our older patients. Early North American contributions in the clinical care of older patients have included supporting the widespread use of standardized assessment instruments, emphasizing the importance of function in addition to traditional disease categories when assessing an older patient, and in developing the concept of comprehensive geriatric assessment.¹⁶ Innovative models of care ranging from comprehensive community-based services (e.g., Program for the All-Inclusive Care of the Elderly, *Système de services intégrés pour personnes âgées en perte d'autonomie*) to those based in hospitals (e.g., geriatric evaluation and management programs, Acute Care of the Elderly units, approaches to the prevention of delirium such as the Hospital Elder Life Program) have been developed in North America.^{6,38–40} Particularly exciting research is taking place with regard to dementia and frailty.⁴⁰ Advances have also been made in other areas such as safe drug prescribing and advance directives/bioethics.^{41,42} The conceptual work being done on geriatric syndromes such as delirium, falls, and incontinence is already influencing clinical practice and will pay further dividends in the future.⁴³ Exercise is showing promise as an intervention for challenges as diverse as preventing cognitive impairment/dementia,⁴⁴ improving outcomes in hospitalized older patients,⁴⁵ managing various chronic diseases,⁴⁶ and improving balance/preventing falls.^{47,48} On the other hand, efforts to slow the aging process with hormone replacement therapy have yielded disappointing results.⁴⁹ Although much has been learned, even more remains to be discovered. Research on interventions and novel models of care must receive ongoing support.

Future directions

WHERE SHOULD WE GO FROM HERE? ADVICE IS NOT LACKING

Robert Kane offered a choice of six nonmutually exclusive alternatives for American geriatrics: carry on as a marginal activity primarily based in academic medical centers; become the dominant model for the primary medical care of complex older patients combined with a hospital practice to address their special needs; see geriatric primary care becoming the purview of geriatric nurse practitioners with geriatricians functioning as consultants for particularly complex cases; work primarily in long-term care facilities with geriatric nurse practitioners; palliative care; or, become role models for chronic disease care (his preferred option).³² The responses to Kane’s paper were generally negative. Some felt that no change was needed as our time would come,⁵⁰ while others expressed concern about prematurely restricting potential future roles for the specialty.⁵¹ Leslie Libow called on American geriatricians to clarify their identity. Although he felt that there was a place for geriatrics in acute care, he feared the field would lose its way if it became too committed to that setting. Others disagree, feeling that hospital

care should be emphasized.^{52,53} He felt that American society should “nurture the growth of geriatrics... (as) to create and sustain a health care system for the elderly... we must first attend to the health of geriatrics.”⁵³ The Canadian geriatrician Colin Powell advised us to work within multidisciplinary teams, focus our attention on frail older patients, develop alliances with older adults, and become accountable to them and society.⁵⁴ In response to a news item about the critical shortage of geriatricians in the United States, a *Lancet* editorial challenged geriatricians to take on “the opportunities of education, research, advocacy, and collaboration presented by an aging population” and called on all other health disciplines to cooperate with geriatricians in improving the care provided to seniors.⁵ Some believe it is already too late to train an adequate number of geriatricians to deal with the clinical needs of the coming tsunami of the aged and that we should focus our limited resources on training both other physicians and nonmedical health care providers.¹⁰

According to the American Geriatrics Society future geriatricians will be engaged in the design and implementation of systems of care for older persons while maintaining key clinical (both primary medical care for some seniors and leading teams caring for frail seniors and those with complex medical conditions), teaching, research, administrative, and consultant roles. Frequently they will be leading these activities but often they will be partnering with other physicians and health care providers.³⁰

At the 2007 Banff Conference on the future of geriatrics in Canada there was discussion among attendees about what should be the principal responsibilities of geriatricians.³⁴ Advocacy for older persons and their care was considered important. The primary clinical role identified was to provide consultations on older patients with complex health needs (e.g., multiple chronic medical conditions, those requiring interdisciplinary/multidisciplinary care, frailty). A majority, albeit slim (57%), of attendees did not believe that geriatricians should provide primary medical care to even

this subgroup of seniors. From an academic standpoint, it was felt that teaching should be primarily directed to those in medicine and other health care providers while clinical and health service research relevant to aging were highlighted as investigative areas requiring emphasis. It was felt that those trained in geriatrics had much to offer in policy and system development and program leadership/administration.

The challenges facing geriatrics in North America include more clearly defining the field of practice and marketing it to various stakeholders, in particular physicians in training. The path we should take is not clear and the direction followed might well differ in our two countries. The only given is that we must not fail in crafting the future of geriatrics to best meet the needs of our grandparents now, our parents shortly, and ourselves before long.

KEY POINTS

Geriatrics in North America

- Physicians without advanced training in geriatrics will provide most of the medical care received by seniors. Geriatricians have an important role to play in ensuring that these physicians receive appropriate training in the principles of effective care of older patients.
- In both Canada and the United States, the recruitment and retention of geriatricians has been poor. With the anticipated growth in the number of seniors, the short-fall in physician resources will reach a crisis level.
- In each country, steps must be taken now to clarify the desired roles and responsibilities of geriatricians within the health care system, the number required to fulfill these obligations, and to put into place a comprehensive strategy for the recruitment and retention of these physicians.

Geriatrics in the Rest of the World

Jean Woo

There is variable information on elderly populations in countries other than Europe and North America. In general, characteristics of elderly populations in economically developed countries are similar to Europe and North America. This chapter describes the impact of demographic and economic changes on life expectancy, morbidity, and disability and responses of health and social systems to these changes, using countries representing different stages of economic development in the Western Pacific and Southeast Asian regions.

Life Expectancy, Morbidity, and Disability

In 2007 the percentage of population aged 65 years and above ranged from 3% to 4% in Laos and Cambodia, to 12% to 13% in New Zealand, Hong Kong, and Australia, to 21% in Japan (Figure 120-1). In general, with economic development, life expectancy increases and morbidity changes from higher prevalence of communicable to noncommunicable diseases. The causes of death from chronic noncommunicable diseases ranged from approximately 90% in New Zealand and Australia, 80% in Singapore, South Korea, Japan, and China, 50% in India and Myanmar, to 35% in Cambodia and Laos.¹ Life expectancy at birth is highest in Japan and the Hong Kong Special Administrative Region (SAR) of China (80%), and lowest in Laos (56%) (Figure 120-2). Ideally increasing life expectancy should be accompanied by compression of morbidity and disability. There is little available data to determine whether there is compression of morbidity and disability in Asia, nor what chronic diseases make the largest contribution to disability. In Hong Kong SAR, China, active life expectancy at age 70 years is approximately 10 years for both men and women; however, total life expectancy and the life expectancy lived with disability (DLE) are longer in women compared with men, DLE being 4.4 years in women and 2.2 years in men. Diseases making the largest contribution to disability are stroke, dementia, fractures, Parkinson's disease, and diabetes mellitus.

Chronic diseases of major impact in the elderly population

The prevalence of cognitive impairment among elderly Hong Kong Chinese aged 70 years and over is approximately 15% in two community surveys carried out in 1990–91 and 2001–02. Age, female gender, history of Parkinson's disease and stroke, functional disability, low education level and low social class and income, were predisposing factors. A review of epidemiologic studies on dementia in China showed rates at the lower end of the rates in Caucasians, with regional variation in the ratio of vascular dementia to Alzheimer's diseases.² The prevalence of dementia ranged from 0.46% to 7.0%, whereas the annual incidence ranged from 0.81% to 2.02%, being slightly higher in women and those with lower education. Alzheimer's disease was the predominant type of dementia, followed by vascular dementia. In contrast to western studies, the prevalence of Lewy body dementia

was lower in Hong Kong Chinese, with a prevalence rate of 2.9% over a 2-year period.³ Similar to Caucasian populations, presence of the apolipoprotein epsilon-4 allele is associated with more rapid deterioration in cognitive function,⁴ and an association has also been observed between promoter polymorphism of the interleukin-10 gene and Alzheimer's disease.⁵

Osteoporotic fracture is another common problem with major impact in terms of disability and mortality. It has been projected that 50% of all hip fractures in the world will occur in Asia by 2050. Increasing incidences have been documented for many regions, in Hong Kong, Japan, and Singapore, the rates being higher in urban compared with rural areas.^{6,7} Risk factors were similar to those in Caucasian populations: lack of load bearing activity, smoking, alcohol consumption, past-history of stroke, fractures, greater height, use of sedatives and thyroid drugs, and low calcium intake.⁸

Chronic respiratory disease also causes considerable disability and mortality, being among the top causes of hospital admission and mortality for the elderly. Unfortunately the trend in respiratory symptoms appear to be increasing among the elderly, likely a result of environmental factors such as increasing air pollution, since smoking prevalence decreased at the same time.⁹ Unfortunately governments in Asia tend to lag behind the West in acknowledging the health impacts of air pollution, and to take definitive action.

Frailty

The transition state from a fully functional state, with gradual decline and development of dependence toward death, may be viewed as a state of frailty. Geriatric medicine is largely care for frail elderly persons. The concept of frailty as an accumulation of deficits covering physical, functional, psychological, nutritional, and social domains, with the balance tipped toward deficits rather than assets, had been developed initially in a Canadian elderly population, and an index consisting of summation of deficits in many domains used as a quantitative indicator of frailty,¹⁰ and shown to predict mortality, and may be used as a measure of biologic age. This concept of a frailty index had been tested in a Hong Kong Chinese elderly population aged 70 years and over, and shown to be equally applicable in a different ethnic and cultural setting irrespective of which particular variables were measured.¹¹ It was able to predict mortality, functional, and cognitive decline,¹² and was influenced by social and environmental factors in keeping with the concept of frailty being multidimensional.¹³

A characteristic feature of frailty is sarcopenia, which describes the age-associated loss of skeletal muscle mass and loss of strength even in the absence of disease. The underlying cause is thought to be a consequence of a decrease in androgens, growth hormone, and IGF-1 that occurs with aging, accompanied by an increase in inflammatory cytokines. This is an important concept in geriatric medicine

Figure 120-1. Percentage of population aged 65 and above, 2007. (Sources: Sources: CIA World Factbook; Department of Statistics of Malaysia; China Population Information & Research Centre; Department of Statistics of Singapore; Statistics New Zealand; Census and Statistics Department of Hong Kong; Australian Bureau of Statistics; and Statistics Bureau & Statistical Research and Training Institute of Japan.)

Figure 120-2. Life expectancy at birth (both sexes), 2007. (Source: CIA World Factbook.)

because it affects function and hence independence, and predisposes to falls. It was initially defined as a mean value of appendicular skeletal muscle mass divided by [height]² less than 2SD below mean values for young adults, analogous to the definition of osteoporosis. Using this definition, sarcopenia exists in elderly Hong Kong Chinese aged 70 years and over, but apparently at a lower prevalence (12.3% in men and 7.6% in women) compared with Caucasians (between 16% and 57.6% in men and 11% and 60% in women).¹⁴ However, the Asian young adult mean value was about 15% lower compared with published Caucasian figures, so that the actual prevalence may be similar between Chinese and Caucasians. Older age, cigarette smoking, chronic lung disease, atherosclerosis, underweight and physical inactivity were associated risk factors, while the consequences include

poorer physical well-being, slower walking speed and chair stand, and reduced grip strength.

Communicable diseases

Elderly people are particularly susceptible to pneumonia, with common infection agents being tuberculosis, *Streptococcus pneumoniae*, *Haemophilus influenzae*, and a virus affecting the respiratory tract.

TUBERCULOSIS

Many of the current generation of people aged 70 years and above would have been exposed to *Mycobacterium tuberculosis* before chemotherapy and vaccination became available, particularly during periods of deprivation such as during the World Wars. Therefore tuberculosis in the elderly is largely

due to reactivation of the disease. Furthermore declining immunocompetence with age and many diseases or conditions commonly encountered in this age group predispose to tuberculosis, such as diabetes mellitus, chronic renal failure, malignancies, or malnutrition. For example, in Hong Kong in 2007, the tuberculosis notification rate per 100,000 population rose steeply with age, being 55.2, 156.5, 464.5 in the 20 to 24, 65 to 69, and 85+ age groups, respectively. Similarly the mortality rate was 0, 9.4, and 63.9 per 100,000, respectively, in these age groups. As a result of population aging and increased prevalence of tuberculosis with age, the falling incidence of tuberculosis has leveled out in countries, with significant tuberculosis burden in Hong Kong, Japan, Singapore, and Malaysia.

Certain clinical features of tuberculosis are distinctive for elderly patients. Diagnosis is often delayed in the elderly.¹⁵ A study of patients with tuberculosis in Hong Kong showed that elderly patients had more frequent nonspecific complaints and less frequent hemoptysis, more extensive lung infiltration on chest x-ray, and lower serum albumin concentrations.¹⁶ Mortality from tuberculosis is higher in the elderly, likely due to delayed diagnosis, more extensive disease, and presence of multiple morbidity. The elderly are also more susceptible to adverse effects from antituberculous drugs as a result of pharmacokinetic changes with age,¹⁷ hepatic involvement in military tuberculosis, and undernutrition, as in some parts of India. Reduced protein binding of antituberculous drugs with age and slower metabolism of toxic metabolites such as hydrazine, may contribute to the increased incidence of side effects.

Residents of old age homes are particularly at risk from tuberculosis, as a result of factors predisposing to reactivation of latent tuberculosis and also cross infection. For example, a survey in Hong Kong SAR China in 1993 showed a rate of between 1200/100,000 and 2600/100,000 compared with a rate of between 100/100,000 and 400/100,000 in the general population.¹⁸ A larger study 10 years later gave a prevalence of between 530 to 1101 per 100,000 population,¹⁹ indicating perhaps improvement in the old age home environments. In an environment where TB prevalence is high in the general population, the Mantoux test is not a useful method for screening or surveillance, and chest x-ray and sputum examination would be more useful. For the same reason, isoniazid prophylaxis for those who have a positive Mantoux test is not adopted, more attention being paid toward infection control, such as optimal nutrition, adequate ventilation, and avoidance of overcrowding.

INFLUENZA-LIKE ILLNESS (ILI)

ILI is of particular concern among elderly people living in old age homes, as a potential cause of epidemic outbreaks, and a common cause for hospitalization. A prospective clinical and microbiologic survey of ILI in a cohort of people living in old age homes in Hong Kong SAR China over a 1-year period recorded 259 episodes in 194 out of a total of 771 subjects, with mild peaks in winter and summer, over a sustained level throughout the year.²⁰ An infection agent was identified in 61.4% of episodes, 58.3% of which were bacterial and 46.7% were viral. Organisms encountered in order of frequency were *S. pneumoniae*, respiratory syncytial virus, *Pseudomonas aeruginosa*, metapneumovirus, and parainfluenza viruses types 1 and 3. Presenting clinical features commonly

include "decrease in general condition," cognitive and functional deterioration, irrespective of the underlying cause. Distinction from aspiration pneumonia was difficult and an unknown proportion could have this as the underlying cause. Mortality was high, being 10% for the episode, predisposing factors being MRSA infection, low body mass index, and poor premorbid function. Eighty-seven percent of episodes resulted in hospital admissions. There may be a role for vaccination programs to include organisms other than influenza A alone, as is the current prevention policy.

SEVERE ACUTE RESPIRATORY SYNDROME (SARS)

The occurrence of the SARS outbreak in Hong Kong in 2003 was a very good example of failure to recognize atypical presentation of disease in the elderly resulting in outbreaks in old age homes caused by elderly people contracting the disease from hospital admissions during the epidemic and then spreading to other residents on discharge, as the diagnosis was missed. In an effort to curb the spread in old age homes, the Hong Kong Geriatric Society issued a position statement pointing out the limitations of the World Health Organization criteria for SARS, stating some elderly people may have geriatric syndromes only, such as falls, confusion, incontinence, and poor feeding.^{21,22} Furthermore, diarrhea may be mistaken for fecal incontinence. Multiple morbidity such as aspiration pneumonia further confuse the picture. Therefore a contact history was a key factor in consideration of the diagnosis. Other points to note are a lengthened incubation period from 14 to 21 days, higher incidence of side effects to ribavirin and corticosteroids, and a higher mortality rate. The latter could be a result of delayed diagnosis or reduced likelihood of ventilator support for those with multimorbidity. Failure to recognize the diagnosis constituted a risk of infection for all caregivers, and this pathway was repeatedly demonstrated during the months of the epidemic from March to June in 2003.

Geriatric medicine development

Apart from Australia and New Zealand, where geriatric medicine is well developed, care of elderly people tends to follow an organ-based approach, with the focus on individual diseases rather than on geriatric syndromes and frailty. The spectrum of geriatric medicine from the biomedical model to functional capacity, the immediate surroundings of an elderly person, ethical issues, and quality of life requiring interdisciplinary continuity of care, is not widely recognized. Countries that have been under British rule or influence, and that are economically developed, tend to adopt a perspective following that in the United Kingdom and North America. To address this issue, ideally undergraduate curricula should contain mandatory geriatric medicine teaching, with structured postgraduate training. Provision of undergraduate and postgraduate training is highly variable, being well-developed in some countries such as Australia, New Zealand, and Hong Kong. In mainland China, although large cities have developed geriatric clinical services and research centers, most of the physicians are from system-based specialties, so that training in geriatric syndromes and a holistic approach is lacking. However, there are developments in this area in collaboration with countries where geriatric medicine training is well developed. For example, the China Medical Board of New York funded a 4-year project between John Hopkins

University School of Medicine and Peking Union Medical College Hospital in Beijing, where Chinese staff were initially trained in the United States and then established demonstration services in Beijing using the train the trainer concept.²³ The geriatric units in Hong Kong have also participated in training staff from the mainland.

Comprehensive geriatric assessment

A key feature of geriatric medicine is comprehensive assessment. Some of the tools used in comprehensive geriatric assessment developed in Western populations may not be applied to other populations with different ethnicity, language, and culture. Translation and validation are required before tools can be incorporated into part of the assessment procedure. This process has been carried out among Chinese for the Mini Mental State Examination,²⁴ where a cover cut-off point of 18 was used as a large majority of the current elderly population received no or little education; the Geriatric Depression Scale (cut-off point of 8)²⁵; the London Handicap Scale (LHS)²⁶; and the Philadelphia Geriatric Morale Scale (PGMS).²⁷ The LHS appears to be applicable across cultures, with subjects from mainland China, Hong Kong, and the United Kingdom sharing similar perceptions on selected handicap scenarios.²⁶ The factor structure of the PGMS has also been confirmed in Hong Kong Chinese.²⁷

Scales are particularly useful in assessment of dementia. The Alzheimer's disease assessment scale cognitive subscale (ADAS-log) has been validated in elderly Chinese in Hong Kong, and discriminant function analysis between demented and nondemented subjects yielded a canonical discriminant function with three question items, word recall test, orientation, and comprehension of speech.²⁸ The short version had a sensitivity of 90%, specificity of 94.6%, and overall accuracy of 92.5%. The clock drawing test as a quick screening assessment of dementia has also been validated, a cut-off score of 3/4 having a positive predictive value of 98%.²⁹ Likewise, the Chinese version of the Community Screening Instrument for Dementia (CSI-D) has been validated as an educationally independent instrument sensitive enough to detect early stages of the disease.³⁰ A short memory questionnaire has also been developed for screening of mild cognitive impairment, which also correlated with subjective memory complaints.³¹

Another important domain for assessment, particularly among elderly living in institutional settings, is the detection of undernutrition or malnutrition. The latter is a recognized risk factor for adverse health outcomes and mortality. One of the widely used nutrition screening tools is the Mini Nutritional Assessment (MNA) originally developed in Europe. It consists of questions regarding intake of particular food items and anthropometric measures, with classification into three categories of nutritional status. However, it may not be easily translated into populations with different body size and dietary habits. Furthermore, in some settings it may not be possible to measure body weight due to absence of suitable scales for dependent subjects and lack of manpower, as in many old age homes in China and Hong Kong. A screening tool that does not depend on weighing is all the more important in such settings. The MNA was adapted for use in the Chinese population in such settings and validated in institutional settings in Hong Kong and Shanghai (The Chinese Nutrition Screen: CNS).³² A cut-off value of ≥ 21 was

found to be useful in screening out those at risk or had malnutrition, correctly identifying 90% of those with normal nutritional status.

Health and social services

To complement the development of comprehensive geriatric assessment, appropriate health and social services meeting the needs of the elderly in the acute, convalescent, rehabilitative settings, along with long-term care in the community or residential care setting are required.

PRIMARY AND SECONDARY HEALTH CARE

Accessibility to good primary health care partly depends on provision of health care professionals and the health care financing system. A wide spectrum of health care systems exists in Asia, Australia, and New Zealand. At one extreme there is the predominantly government subsidized low cost system in Hong Kong SAR, China, to the other extreme of largely user pays private system dictated by market forces in mainland China. In between are systems sustained by insurance, government contributors, and part self-payment, as in Singapore, Japan, Australia, and New Zealand. The system of one primary care doctor as the first contact point, as in the British National Health Service, is particularly suited for care of the elderly. The development of health care centers, with the primary care doctor coordinating all health social needs using the case management model, would have provided a more flexible response to the needs of people with increasing frailty. Variations of such systems exist in Australia and New Zealand, but are poorly developed particularly where primary care largely relies on a user-pays system.

For example, the change from a government-funded to a market-orientated health care system in mainland China in the 1980s has resulted in the system serving a small proportion of the population who can afford to buy insurance, mainly in urban areas, where employers may make a contribution to a medical savings account. However, in rural areas, health care expenditure is largely out of pocket.^{33,34} In one recent survey, 87% of rural and 37% of urban residents were uninsured, and seniors, ethnic minorities, and residents in less-developed regions (where there are few doctors and geographic barriers exist) visited physicians less than those who were insured. Urban residents also used hospitals more compared with rural residents. Therefore it is likely that both financial barriers and adequacy of provision of health care will affect health of the elderly in mainland China.

In contrast, the health and social care system in Hong Kong SAR China represents the other extreme, where the government largely subsidizes the health care system, with the user paying a small fee. For those who cannot afford the fee, after means testing, the same level of care is provided entirely free. Although more than 85% of primary care is provided by private doctors, those who cannot afford it are cared for by government outpatient clinics, or users may make use of 24-hour access of the accident and emergency departments. The standards of care supplied by government hospitals are as high, if not higher than private hospitals, patients having access to the latest drugs and technology. The comprehensive range of medical and social services have developed over the years based on the U.K. model. There are well-developed acute and nonacute geriatric and psychogeriatric services that extend to the community and

old age homes, palliative care for both cancer and noncancer patients, day hospitals, various types of social welfare allowances and community support home care services. Currently models for chronic disease management and transitional care in the community are being developed.³⁵ However, the current health care financing system is considered unsustainable and insurance and user pays models are being developed.

There is little data reporting on the health profile of elderly people cared for under different health and social care systems. The question of whether there is one particular model that would result in better health outcomes, while of key importance, is difficult to address as a result of many confounding factors. A comparison of health profile of three elderly Chinese cohorts carried out at approximately the same (1990–1991) under opposite extremes of the spectrum of health care systems (predominantly government subsidized or predominantly self-paying), showed that the Beijing rural cohort had the best health profile while the Hong Kong cohort had the worst profile, despite better lifestyle practices and higher socioeconomic status in the Hong Kong and Beijing urban cohort. However, the Beijing rural cohort also had the highest prevalence of functional limitations.³⁶ The findings suggest that while the relationship between health care systems and life expectancy may be more direct, the influence on health profile elderly people may be more complex, as lifestyle, socioeconomic, and psychosocial factors are likely to play important roles.

LONG-TERM CARE

The number of frail elderly people with multiple morbidities, functional, and psychological impairments requiring care by others, will increase with aging populations. Although development in community support services is important in enabling elderly people to remain at home, development in the residential care sector both in terms of number of places and quality of care will be equally important. The anticipated shift from community to residential care is partly the result of changing social patterns from large extended families living together, to smaller units or to living alone. For example although the percentage of elderly people in Japan living with adult children is higher than Western populations, it fell from 50% in 2000 to 45.5% in 2004.³⁷ This is in contrast to 30% of men and 38% women aged 80 years and older living alone in Australia. In both Japan and Australia, the number of residential care places is increasing rapidly, while at the same time the provision of community care services also increased, although the provision ratio per 1000 persons aged 70 years and over is actually decreasing in Australia. In Hong Kong, the percentage of elderly people living in residential care institutions has also risen rapidly from about 5% to 9% over a 12-year period. Therefore it would be unrealistic to expect that improvement and increased provision of community service alone would be sufficient to meet the needs of increasingly frail aging populations.

An essential feature of community care is a seamless interface between health and social services, and between care by different disciplines of health care professionals and volunteers. Coordination is required to provide care plans specific to individual needs. The actual models vary depending on health care financing systems. For example in Hong Kong, various types of community care centers run by nongovernment organizations have evolved, covering a wide spectrum

of support from social centers; day care centers, which provide personal and rehabilitative care during daytime; and enhanced home care (visits by allied health staff, nurses, or doctors).

There is a role for information technology support for those living in the community. In Hong Kong, for those living alone, they can subscribe to an alarm system where an alarm bell can be worn as a necklace and connected via the telephone system to community centers. In an emergency such as a fall, the center can arrange ambulance transport to the nearest hospital. Home rehabilitation via teleconferencing with a rehabilitation center has also been pioneered; a group therapy in community centers conducted by staff from a partner hospital via teleconference has also been developed and evaluated for older persons with memory problems,³⁸ knee pain,³⁹ diabetes,⁴⁰ urinary incontinence,⁴¹ and stroke.⁴² Evaluation showed that this mode of service delivery is feasible and resulted in beneficial objective outcomes.

As in many parts of the world, the quality of care in residential care homes is variable and there is much room for improvement. The change in philosophy in residential care from an institutional environment to a home environment with dedicated trained care workers pioneered by the Green House Project homes in the United States, while producing impressive results,⁴³ have yet to be replicated in Asia. In this region, quality of care is largely governed by fiscal concerns and the rising demand despite questionable quality. Regulating standards of care effectively determines the number and the care staff needed, with resulting increases in fees that adversely influence affordability. In many regions, a pragmatic balance exists between total lack of care, and residential care of variable quality that is affordable to individuals and governments. Poor quality has repeatedly been documented in the past 20 years among residential care homes in Hong Kong, for example in the area of undernutrition⁴⁴ and restraint use.⁴⁵ Twenty-five percent of residents have a body mass index of less than 18.5 kg/m², while use of restraints is among the highest in the world. Nevertheless efforts have been made in providing health care support by geriatric and psychogeriatric outreach teams supplemented with teleconference consultation.

The future of long-term care of acceptable quality likely depends on a health care financing system consisting of a mixture of government subsidy, insurance, and self-payment. Geriatricians will have a vital role in developing systems appropriate to the culture and region, with a key element of comprehensive assessment to tailor made services in response to individual needs.

END OF LIFE CARE

There is a general consensus that end of life care could be improved, and palliative services should also cover those who are dying of chronic diseases such as heart failure, chronic lung disease, or end-stage neurodegenerative diseases, in addition to those dying of cancer, even though the trajectories toward death may be different. The core components of symptom control and attention to psychospiritual needs remain the same. However, there may be cultural differences in management of patients and their families in these settings. For example, many elderly people defer to their families, who sometimes adopt an approach that is futile against the recommendation of the physician, out of

a wish of “doing their best” for their relative. Improved public education would be desirable to discuss these issues. In Western cultures, spending the last few days in privacy with relatives in a side room in the hospital may be considered desirable, but among Chinese people in Hong Kong, it may be reviewed as neglect by staff and relatives have sometimes complained about such management that was assumed by health care workers as desirable.

Prevention of chronic diseases and functional decline

Health promotion efforts have been made by many countries in an attempt to lessen the morbidity and disability burden of aging populations by advocating healthy lifestyles. A key to effectiveness of dietary and physical activity counseling is the strategy for achieving behavioral change, since simple impartment of knowledge is unlikely to be effective. An interesting cultural addition to these efforts is the role of traditional Chinese Medicine (TCM) in healthy aging.⁴⁶ The philosophy of TCM is to treat diseases before they appear, thus fulfilling the role of prevention very well. Theoretically and at cellular level or in animal studies, TCMs have been shown to inhibit uptake of neurotransmitters, to have anabolic effects, immunoenhancing effects, and antiproliferative effects on tumor cells, antioxidant properties, stimulate nitric oxide production in endothelial cells and erectile tissues, inhibit platelet aggregation, improve glucose tolerance, and have estrogen-like properties. However, few have been subjected to randomized controlled trials to document benefits in humans. Nevertheless, TCM is widely used in prevention of various conditions associated with aging, which may or may not be effective. However, adverse side effects have also been documented.

CONCLUSION

The importance of geriatric medicine appears to be proportional to demographic changes with increasing life expectancy and the shift from communicable to noncommunicable

disease, and it is in variable stages of development in parts of the world other than Europe and North America. Training systems and models of care in the latter would be relevant, with adaptation to local needs. The principles of care of the elderly remain unchanged, and could form the basis of training irrespective of geographic or political regions. Development in previous British colonies or commonwealth countries show how this diffusion of knowledge has occurred and is ongoing, through formation of the Asian Pacific Geriatrics Network. The latter has annual meetings where geriatric problems from different countries in the region are discussed and provides a forum for continual sharing of knowledge.

KEY POINTS

Geriatrics in the Rest of the World

- Life expectancy and the proportion of population aged 65 years and over increase in parallel with economic development of countries
- Patterns of diseases change from dominantly communicable to noncommunicable, in parallel with this transition
- Chronic diseases of major impact include dementia and other neurodegenerative diseases. Communicable diseases of impact are tuberculosis, and bacterial and viral causes of pneumonia
- Frailty is a key component in geriatric medicine, and measurements are applicable across ethnic and cultural groups
- Scales used for comprehensive geriatric assessment may need to be adapted and validated for local use
- Health and social care systems vary across countries, and the impact on health of the elderly is uncertain
- Geriatric training and service development follow the principles developed in Europe and North America, with adaptation to local systems and needs

INTRODUCTION

From Mexico in the north to Chile and Argentina in the south, there are 20 countries in Latin America (LA) and some other greater economies in the Caribbean. Notwithstanding the cultural interface, countries are not uniform in showing great diversity in demography, economy, and political organization. From the 561 million people living in this region, about 5.7% are 65 years and over.¹ From the middle twentieth century to the present, the region has shown an accelerated aging of its population. The rate of this demographic change has been so fast that the state, society, and families have been unable to develop adequate mechanisms to confront the health, cultural, and economic demands of the aged.^{2,3,4,5} In the region, the process of population aging is very different from that experienced by the developed countries; in the latter, the process took place at a rather slow pace (over a period of 2 or more centuries) and was preceded by improvements in social and sanitary conditions. The dependency ratio (people 65 and over / people 15 to 64 years old) reflects the economic impact of aging. It will increase from 9% in 2000 to 13.4% by the year 2020 (Table 121-1). This makes clear the economy in the region will have to grow vigorously to be able to support pension schemes and other social needs of old people.

Life expectancy at birth for the quinquennium 2005 to 2010 in LA is expected to reach 73.3 years for both sexes, 70.1 years for men and 76.6 for women, lower than in the United States where it is expected to be 79.4 years (75.5 for men and 83.3 years for women). Table 121-2 shows life expectancy at birth in selected countries. It is noteworthy that countries such as Costa Rica and Chile have reached life expectancy near to that of United States, with differences smaller than a year for both men and women. However, life expectancy at birth in less developed countries may be misleading because it includes deaths at early ages and does not reflect that millions are living longer. Life expectancy at age 65 shows little difference in relation to the United States where it is 18.4 years compared with 17.5 years in LA.⁶ Thus Latin Americans who achieve the age of 65 may remain alive for as many years as old people living in more developed countries.

The socioeconomic situation in LA is far from ideal.^{7,8} The unemployment rate in the region is 8%, reaching 15% in the Dominican Republic, in Haiti more than two thirds of the labor force does not have a formal job. The illiteracy rate among people 15 years and older is 9.5% for LA as a whole, with Uruguay having the lowest rate (2%), and Haiti the highest (45%). Furthermore, poverty indices are very high; it is estimated that about 31% of the total population is poor and 8.6% are indigent. In countries such as Bolivia and Honduras more than half of the population live under the poverty line.¹ Some examples are shown in Table 121-3.

Demographic transition

The demographic transition model of a population begins with a sustained decline in mortality, followed by a decline in fertility. The early stage of this model is characterized by high rates of fertility and mortality contrasting with the very

advanced stage, which has low mortality and fertility, added to population growth near zero or even negative.⁵

In the middle of the twentieth century, the majority of countries in LA were in the early stage of demographic transition with Uruguay being the only country in the full stage, with low mortality, stable fertility, and limited population growth. At present no country is in the early stage, even in Guatemala and Haiti mortality is decreasing. Most countries are in the full demographic transition stage. Argentina, Brazil, Costa Rica, and Chile are in the advanced stage, with a population annual growth rate that fluctuates between 1% and 1.4%, whereas Uruguay and Cuba are in the very advanced stage, with annual population growth rates of 0.6% and 0.3%, respectively.³ By 2030, Brazil will rank sixth in the world in absolute number of old people with 30 million being 60 years and over.⁹ It is of concern that the majority of the older population, a group that poses great demands on health care, will live in less developed countries, where little resources are available to attend to those demands.¹⁰ At the beginning of the demographic transition, the rate of dependency is high as a result of high fertility, followed by certain relief as fertility declines. In LA this situation is only temporal, as the rapid aging population will increase the demographic dependence, something expected to occur around 2020.³ Inequality in LA is very wide and grows deeper with advanced age.¹¹ Aging and its health and social consequences may act like an amplifier of inequality. It is difficult to be young and poor; however, it is worse to incorporate the burden of some condition that may be present in old age to an already poor person.

Epidemiologic transition

In 1971, Omran¹² formulated his epidemiologic transition theory, proposing that mortality is a fundamental factor in population dynamics; that a long-term shift in mortality and disease patterns occur during the transition; that the deepest changes in the models of health and disease appear in children and women in fertile age, and changes in health and disease are associated to the demographic and socioeconomic transition. A model characteristic of less developed countries proposed by Omran describes the changes over time in three major stages: (1) pestilence and famine, (2) receding pandemic, and (3) the triple health burden. Most of the countries of LA are in the third stage of the epidemiologic change.^{13,14,15} The triple burden of health refers, in the first place, to the persistence of some old diseases, especially infections. In LA for example, many countries still have higher rates of infection such as tuberculosis, malaria, or dengue, among others.¹⁶ A second aspect of the triple load refers to the increase in the rate of prevalent pathologies, especially chronic diseases such as obesity, blood hypertension, and diabetes mellitus.¹⁷ An ill-prepared health care system characterizes the third stage, emphasizing that a particular country is not in a good position to cope with the new challenges.^{9,10,18}

In Peru, for example, the mortality rate declined from 21 per 1000 in 1950 to 6 per 1000 in 1995, period infant

mortality declined from 159 per 1000 to 42 per 1000. The reduction in the mortality rate in LA has been very fast when compared with the developed Western countries, where the rate of mortality dropped from 25 per 1000 inhabitants in 1860 to near 10 per 1000 in 1930; it means this phenomenon lasted almost the double when compared to what happened in several LA countries.¹⁶ Nevertheless, the epidemiologic transition process in some countries of the region did not follow the same course of the developed ones because there is an overlap in stages. There is an increase in the prevalence of chronic noncommunicable diseases coexisting with a resurgence of certain infectious diseases, such as malaria and leishmaniasis, a phenomenon that has received the name countertransition.¹⁹ Cardiac diseases in countries such as Cuba, Costa Rica, and Chile represent approximately 30% of the deaths, whereas in El Salvador, Guatemala, and Ecuador they represent less than 5%.²⁰ For instance, about 1955 in Mexico transmissible diseases accounted for 70% of all deaths, but now are 12%; on the other hand, in the same time period the ratio of deaths due to noncommunicable diseases increased from 23% to 75% of all deaths.²¹

It is then evident that the LA epidemiologic transition model varies between certain countries, and there are even variations within different regions of a same country, given the great social and economic gaps existing among them.^{16,20,22} Three major groups of epidemiologic transition can be distinguished in the region: (1) countries that are in the advanced stage, (2) countries that are in the initial stage, and (3) an intermediate group of countries in an epidemiologic transition known as a prolonged polarized model, with

The answer of Latin America to the new demands

RETIREMENT POLICIES

In the countries of the world with highest incomes per capita, people retire younger, so that the participation of elders in the workforce is lower, and only 13% of men older than 65 years are economically active. In contrast, in the less favored countries, 39% of men older than 65 years are still economically active,⁶ with percentages in LA ranging between 18% in Uruguay and up to 47% in Bolivia.³ This is due to a limited coverage by the pension programs and to pensions being insufficient to cover the basic needs. In most of the social security systems of the region, pensions values are defined in accordance with the person's income at the age of retirement, and by the time the employee contributed to social security. In many countries the social security system coexists with social care systems based on pensions, subsidies, or bonuses to poor elderly and handicapped people who did not have any formal work and were unable to make contributions to social security.^{5,23} Half of the people 65 years and over in LA do not have any pension system or savings that allows them to cover their needs, and they depend to a great extent on the support of their families or charitable organizations. The proportion of old people that receive some type of pension or retirement varies between the countries, Nicaragua being lowest with a coverage of only 6.3% and Brazil the highest with 81.5%.⁵ Table 121-4 shows the percentage of people older than 65 years with pension in some LA countries.

As a consequence of the demographic changes there have been substantial reforms in the social security pension systems in the majority of the LA countries in recent years. These reforms are of such magnitude that experts consider this to be the biggest change in just so short a time ever to happen in the history of social security so far.²⁴ Chile has made a deeper reform and the World Bank considers it an example for the world. The type of reform preferred by the governors of the region was one directed toward the privatization of the pension system, moving from a collective system to an individual one. The argument, not yet validated, was that this system would grant the financial viability of pensions, making them more efficient, by increased savings and investment.²⁵ Another challenge identified with pension reform is the accentuation of gender inequality. In several countries of the region, it has become evident that women are less covered by social insurance than men, and that the amount of their pensions is inferior.²⁵ The average amount of annual pension received by the beneficiaries varies from approximately \$960 per year in Peru and Venezuela, up to \$6000 a year in Chile and Costa Rica.⁵

HEALTH

The theory of compression of morbidity proposes that health prevention and assistance could delay the expression of morbidity allowing people to age with less morbidity and disability.²⁶ Nevertheless an analysis of old people health in developing countries suggests expansion more than compression of morbidity.^{27,28} This can be explained by the concept of health capital and aging proposed by Guimarães.²⁹ It posits that health status in old age reflects life time events, including genetics, social economic factors, formal education, and health support. Thus the health condition of elderly people who survive in adverse conditions in many Latin American underdeveloped countries reveals a low health capital, with a low functional reserve and high prevalence of disability, as consequence of a lifetime of deprivation.

In Latin American countries the share of the gross domestic product (GDP) destined to health fluctuates between 1.6% (Venezuela) to 6.9% (Cuba), with the vast majority being below the 5%.³ At times of economic crises the mortality among the elderly can increase. This was the case in Cuba at the time of embargo, when an increase of 15% in the mortality of people 65 years and older was observed. A similar increase was observed in Mexico in 1995 due to the economic crisis.³⁰ Notwithstanding, health goes beyond the viability of doctors. It can be appreciated how some countries such as Nicaragua have a limited health human resource with a doctor for every 2568 inhabitants, whereas in Uruguay there is a doctor for every 248 persons. (Table 121-5).³

Like in most of the world, women in LA live longer, but they also live more years with disability.³¹ A study in Brazil found that although men at the age of 60 years have a life expectancy of 17.6 years, from which 14.6 (83%) are free from functional disability. At the same age women can hope to live 22.2 years, 16.4 years (74%) without disability.³² Studies on the health of the elderly in Mexico have found that approximately 40% of those over 80 years old, and 66% of those over 90 years old are unable to perform lighter domestic tasks and, likewise, this functional limitation is greater among women.³⁰ The major study on health

of the old people in LA is the SABE study (Salud, Bienestar y Envejecimiento: Health, Well-being, and Aging), a multicentric project conducted by the Pan-American Health Organization (PAHO). It included 10,891 people 60 years and older, living in seven big cities of the region (Bridgetown; Buenos Aires; Havana; Mexico City; Montevideo, Uruguay; Santiago, Chile; and Sao Paulo). Data from that study show that a high percentage of old people have a poor self-perception of their health. For example, 49.1% in Bridgetown, 53.4% in Sao Paulo, 62.6% in Havana, 63.2% in Santiago, and 69.4% in Mexico DF, perceived their health as being either fair or poor. This study also documented that the prevalence of basic daily life activities fluctuated between 13.8% in Bridgetown to 23.7% in Sao Paulo, where 40.3% also referred to difficulties with instrumental activities.³³ The SABE study also focused on basic problems, such as falls and dementia. The prevalence of falls varied from 21.6% in Bridgetown to 34.0% in Santiago.³⁴ The prevalence of cognitive decline evaluated by the Mini Mental State Examination (MMSE) was 1.1% in Montevideo and 12% in Sao Paulo.³³ The wide difference may reflect problems in methodology because it also contrasts with the result of a survey that of 2,000 old people living in the community in Brazil using the DSM IV criteria (Diagnostic and Statistical Manual of Mental Disorders), where a 2% prevalence of dementia was found.³⁵

There is a cultural tradition in Latin America of families given support for their older relatives. The Latin caregiver (usually a daughter) tends to spend more time with their old or ill relative,³⁶ a fact that can cross the borders. A study done in San Francisco, for example, found that female Latin caregivers delayed the institutionalization of their old relatives with dementia when compared with female caregivers with Caucasian origin. In addition, when comparing both groups using Kaplan-Meier curves, a higher life expectancy was found among the Latin elderly with dementia compared with Caucasians.³⁷

HEALTH OF THE ELDERLY IN RURAL AREAS

Twenty three percent of the total population in Latin America lives in rural areas.³ In contrast to what happens in developed countries,³⁸ these areas usually have precarious sanitary and health services, which render the old particularly vulnerable and prone to suffer serious health situations. It has been seen that, even when sick, elders living in rural areas look less for health services than those living in urban areas.²² In Costa Rica, a country with a high percentage of rural

population (37%),³ it has been demonstrated that old people living in the countryside are at a high risk of not being seen by specialists or not being hospitalized when they merit it because of their health conditions.³⁹

Several studies have analyzed other health topics of the elderly in LA rural areas. In Mexico, for instance, it was found that the chronic diseases most frequently reported by old people in rural areas were blood hypertension, diabetes mellitus, and cardiopathies,⁴⁰ that is to say, pathologies similar to those found in urban zones. In the countryside of the Colombian coffee region, 1668 people with an age average of 71 years were studied; 83% of them reported a fear of falling, and half of them restricted their activities as a result of this fear.⁴¹ Nevertheless a study in Brazil found that women who live in the countryside have a significantly smaller risk of having walking limitations than the women from urban areas.⁴²

Development of geriatric medicine in Latin America

In LA the increase of the old population has not been matched by a parallel increase of professionals and services in gerontology and geriatrics. Doctors specialized in geriatrics are few, a characteristic also shared by developed countries. In the United States, there are about 7000 geriatricians to take care of 38 million old people, which is equivalent to one geriatrician for each 5500 people 65 years and older,⁴³ a number similar to that in Uruguay with 5000, and Costa Rica with 5300 (see Table 121-6). The development of geriatrics in Latin America is quite heterogeneous, with countries that have already gone a long way on the matter such as Brazil, Mexico, and Argentina, passing by other countries where the specialty is relatively young, such as Colombia and Peru. In many countries such as Paraguay, Panama, and Bolivia, geriatrics do not exist or is rather scarce. Apart from a few exceptions, geriatric medicine is not integrated into hospitals and it is practiced more as an outpatient service. A progressive inclusion of geriatric medicine in the national health system can be observed in Chile and Brazil.

The Argentinean Society of Gerontology and Geriatrics (Sociedad Argentina de Gerontología y Geriátría) was created in 1951 and the specialty approved in 1977.⁴⁴ Brazil was also one of the first LA countries in developing a Society of Geriatrics, which is already older than 45 years, and has training programs in geriatrics for doctors since the late 70s. However, there is only one specialized doctor in geriatrics

Table 121-6. People 65 Years and Over Per Geriatrician in Some Latin American Countries

for every 37,000 old people.⁴⁵ Table 121-6 shows the number of people 65 and over per geriatrician in some LA countries.

Geriatrics and geriatric research in Latin America

One of the main recommendations expressed in the Madrid International Plan of Action on Aging is to stimulate research on aging, mainly in less developed countries.⁴⁶ This makes sense considering the enormous demographic, social, economic, and health burden that these countries will face in coming years, added to the little amount of research originated in these countries. An investigation done in 2002 to analyze the origin (by countries) of the investigation in gerontology and geriatrics supports this appreciation: 95% of the research in aging came from the wealthiest countries. More than half (54%) of the research was done in the United States, followed by the United Kingdom (10%), and Canada (7%). Only 1.4% of the published works come from Latin America, with 85% of the scientific publications in this region coming from only three countries: Argentina (37%), Brazil (31%), and Mexico (17%).⁴⁷ Only 122 scientific articles on geriatrics and gerontology were found in LA between 1980 and 2000, most of them indexed in the LILACS database (Literatura Latinoamericana y del Caribe en Ciencias de la Salud or Latin American and Caribbean Health Sciences Literature), 32 of them published between 1980 and 1989, and 90 published between 1990 and 2000. This demonstrates an increasing interest on the subject, although research clearly continues to be scarce. However, it should be noted that the best researchers tend to publish their papers in international journals. The majority of papers published in Latin America were qualitative (approximately 60%), whereas the rest (approximately 40%) were quantitative. In 54% of them the main subject was geriatrics, whereas in the remaining 46% the main subject was gerontology.⁴⁸ Added to the fact that research on the subject is scarce, it is also noteworthy to point out that, in some cases, the publication of scientific research is very little, as it was demonstrated by an investigation in Peru, where it was found that only 19% of the research work was published, with 86% of it being a descriptive investigation.⁴⁹

The scarcity of research in LA is also demonstrated when the clinical trials database from the United States National Institutes of Health is reviewed: from approximately 60,000 trials registered, little more than 3000, or only about 5%, are being carried out in the region. Table 121-7 shows some examples in LA and Table 121-8 shows them broken down by regions.⁵⁰

Perspectives of geriatric medicine in Latin America

As in the rest of the world, the fast population aging in LA contrasts with the slow development of economic, social, and health policies necessary to deal with the huge challenges that this great and unprecedented change demands. It is widely documented that there are not enough highly qualified human resources necessary to take care of the older population. This situation is evident not only in health sciences but also, and perhaps in a more marked way, in other areas of knowledge on aging, and, in the short term, there seems not to be strategies designed to attend to this need.

Table 121-7. Top 10 Latin America and Caribbean Countries, According to Number of Trials Registered in the US NIH Clinical Trial Database

Although the great majority of countries in LA signed the Madrid International Plan of Action on Ageing, 2002,⁴⁶ very few governments can show concrete results after 6 years. In most medical schools students are trained in the care of children, pregnant women, and adults, but training in care for the elderly is little, especially from a bio-psycho-social perspective. Teaching geriatrics is in its first steps. It is also necessary to qualify nonmedical health personnel such as nurses, physical therapists, dentists, psychologists, and social workers with the purpose of integrating interdisciplinary teams able to attend the old.⁵¹

At the postgraduate level in medicine, besides to prepare geriatricians, it is also important to train specialists from other clinical and surgical areas in the care of the old. It is widely known that, among others, urologists, ophthalmologists, orthopedists, and anesthesiologist, attend to a high volume of geriatric patients, although they have received

very little or no formal training at all in how to attend to the elderly.^{52,53}

ACKNOWLEDGMENTS

Thanks to Dr. Diana Palacios for revising and correcting part of the manuscript, and to Dr. Carlos Gonzalez' helpful aid in translating part of the paper. The following doctors also gave invaluable help to the authors: Luis M. Gutierrez-Robledo (Mexico), Laura Bazaldua (Mexico), Jose Gonzalez (U.S.), Daniel Valerio (Costa Rica) Patricio Buendía (Ecuador), Pedro P. Marin (Chile), Luis Varela (Peru), Ricardo Jaúregui (Argentina), Clever Nieto (Uruguay), and Fernando Gómez (Colombia).

KEY POINTS

Geriatrics in Latin America

- From the 561 million people living in Latin America, about 5.7% are 65 years and over and life expectancy at birth for the quinquennium 2005 to 2010 is expected to reach 73.3 years for both sexes.
- In this region, it is estimated that about 31% of the total population is poor and 8.6% are indigent.
- In the countries of the world with the highest incomes per capita, only 13% of men older than 65 years are economically active; in contrast, in the less favored countries, 39% of men older than 65 years are still economically active.
- Half of the people 65 years and over in Latin America do not have any pension system. They depend to a great extent on the support of their families or charitable organizations.
- The major study on the health of old people in Latin America is the SABE study (Salud, Bienestar y Envejecimiento: Health, Well-being, and Aging); data from that study show that more than half of old people perceived their health as being either fair or poor.
- Twenty three percent of the total population in Latin America live in rural areas, which usually have precarious sanitary and health services and render the old particularly vulnerable and prone to suffer serious health situations.
- As in the rest of the world, the fast population aging in Latin America contrasts with the slow development of economic, social, and health policies necessary to deal with the huge challenges that this change demands.

Long-Term Care in the United Kingdom

Clive Bowman

LONG-TERM CARE IN THE UNITED KINGDOM

The history of long-term care in the United Kingdom is curious mix of benevolence, denial, and pragmatism driven more by social conscience and political pressure than intelligent epidemiologic understanding of needs and planned services. The key issue of quality of life rather than its length being a guiding principle is widely accepted, in stating "I would want to live as long as my quality of life is good and I can look forward to each new day."¹ Kirkwood succinctly represents a widely held view. It is a curious phenomenon that while strenuous medical endeavors to prolong life continue, the nature of life in long-term care remains inadequately described and understood.²

Poor law policies of the nineteenth century sought to provide refuge for the destitute, the unemployed, the sick, the blind, people with epilepsy and the elderly. The principle was to offer a standard of life below the lowest achievable by anyone in employment with the intention of deterring idleness. The advent of the National Health Service (NHS) in 1948 incorporated beds providing long-term care for elderly and disabled people into the service. The NHS inherited a motley collection of chronic sick wards in municipal hospitals, workhouse infirmaries, former infectious diseases hospitals, and sanatoria. From this unpromising estate geriatric medicine (GM) emerged. The main purpose of GM was the supervision of patients in these beds (and the many hundreds on lists waiting to occupy them). The reports by Warren and other pioneers highlighting the potential for rehabilitation and restoration to independence through accurate diagnosis, effective treatment, and the provision of rehabilitation³ kick-started more positive attitudes. Through the 1950s and 1960s the management of long-term care remained the core of geriatric practice, but this concerned primarily the activity of managing a scarce resource, avoiding long-term care through comprehensive clinical and social assessment, treatment and rehabilitation together with increasing support at home. Although there were individual initiatives and innovation, the profile and the clinical and social aspects of the care of people in long-term care did not receive such attention or investment.

In 1962 Townsend published "The Last Refuge," a study of residential institutions and homes for the aged in England.⁴ The study concluded that communal homes were "not adequately meeting the physical, psychological, and social needs of the elderly people living in them, and that alternative services and living arrangements should quickly take their place." The number of geriatric beds in the NHS remained virtually unchanged from 1959 to 1985, with improved and new treatments, rehabilitation, and community care counterbalancing increasing numbers of older people. From 1986 to 1994, the number of these beds declined with beds in private and voluntary nursing homes increasing dramatically (see [Table 122-1](#)). Similar trends were apparent in the local authority residential home sector with an increase of 136% in private and voluntary homes. Hospitals

for patients with mental illness also provided a good deal of long-term care for elderly people but the psychogeriatric beds were separately counted and distinguished in official statistics from 1988.⁵

Cochrane's monograph of 1971,⁶ "Effectiveness and Efficiency," predicted the inflation of acute health care and a widening gap in the standards between curative endeavor and caring. Isaacs et al⁷ described in 1972, "The Hard Core" of patients that a geriatric service traditionally looked after and emphasized that only well coordinated health and care services could respond effectively to the needs of this group. In the early 1970s, these people were still largely the result of neglect, poverty, and despondency of the frail, isolated, sick, and dispossessed old. Improvements in both living standards and aspects of health and care have considerably addressed the issues of, "filth, hunger, cold, and danger" confronting the frailest. However, Cochrane's prescient concerns regarding the organization of care have largely been unheeded.

In the early 1980s, a crisis in housing and health care resources led to social security payments being made available on demand, without assessment of needs, for residential and nursing home care. This resulted in a rapid development of an independent sector eager to satisfy a seemingly unending demand. The total scale of this expenditure escalated from \$14.5 million (£10 million) in England and Wales in 1979 to \$275.5 million (£190 million) in 1983, \$636.5 million (£439 million) in 1986, and \$3.62 billion (£2.5 billion) in 1992.⁸ The rapid, uncontrolled expenditure favored institutional care and prompted a review from which the report "Caring for People" in 1989⁹ emerged. This resulted in renewed promotion of domiciliary services to enable people to live in their own homes whenever feasible and sensible, with an emphasis on proper assessment of need and case management, in essence these introduced needed hurdles to access care. The role of the independent sector was affirmed along with good quality public services. Social service departments became responsible for the assessment of need, offering various choices, including wherever possible, domiciliary support as an alternative to residential care. These recommendations were enshrined in the National Health Service Community Care Act, 1990.¹⁰ Means testing, a longstanding feature of social services support, was effectively extended to frail older people who previously could have anticipated free NHS care, albeit typically in outdated Victorian wards. The architects of the welfare state did not include a commitment to fully state-funded care and support for older people. With greater personal wealth, care has increasingly become dependent on "self-funding" until personal resources are diminished to a proscribed level. Concurrently an increasing reliance on top up payments has emerged to be paid from remaining savings, family, friends, or charity to supplement fees from local authorities. Although testing has hall-marked social care there remains a provision for fully NHS funded or "free" care either in hospitals or more recently in

Table 122-1. Provision of Residential Care Places, United Kingdom 1980–1994/5

	1980	1985	1991–92	1994–95
LA residential homes	134,500	137,100	117,400	86,400
Independent residential homes	80,000	130,400	203,100	218,200
Independent nursing homes	26,900	38,000	147,300	194,800
NHS geriatric/long stay	46,100	46,300	44,300	34,700

Source: Department of Health, UK.

the community at large and in care homes for people with a poorly defined level of complexity and frequency of care.

The anomaly of access to free NHS care for some and means tested care for others based perhaps as much by chance as assessed need has proved particularly unpopular especially among middle-class families, many of whom saw their inheritance threatened, often successfully challenging flawed decision making. Difficulties in eligibility assessment have continued with complaints for fully funded care dwarfing all others to the health service ombudsman and repeated revisions to policy reflecting more a need to control resource allocation than understand the health care needs of the aging population. Present policies for funding care are widely considered to be unfit for the purpose and at the time of writing (June 2008) there is intense consultation and a hope that a green paper will pave the way to a sustainable political solution to the issue of overall care funding and its financing for the individual.

The cost of long-term care has dominated debate and with some 80% of government funding committed to care home fees together and the desire to maintain people in their own homes unsurprisingly has meant continued pressure to keep people out of care homes. On occasion extraordinary packages of domiciliary care have been provided to maintain people often socially isolated in their own home, while the limited supply of community workers has meant that people with lower levels of support have found access to care much more difficult. At the same time pressure on funding in social care has led to people being placed in residential care rather than professionally led care in nursing homes. Financial settlements of local authorities have competing statutory demands such as child protection services placing further pressure on funding. One of the many frustrations is that policies that attempt to modernize or change the place of care tend to be substitutional rather than encouraging a spectrum of solutions to provide for a range of needs.

Rigorous eligibility assessment, and improved availability of housing options led to a reduction in the number of care home beds, in 2000, 9700 beds were reported to have closed, 7267 from the private and voluntary sector, and 2481 places from local authority homes.¹¹ The number of care home places have fallen steadily for more than a decade, from 511,000 at a peak in 1993 to 420,000 in 2007.¹² More recently a point of inflection has been reached with the reduction of beds seems to have slowing.

The dissolution of medical leadership in long-term care

The medical supervision, leadership, and multidisciplinary care that had been a feature of traditional geriatric care in the United Kingdom since the inception of the NHS has not followed patients to community care whether it be in the individual's own home or in care homes, and the established professional time and clinical teams have been redirected largely to support acute hospital medicine. Increasingly, general practitioners have had the responsibilities thrust upon them, generally without contractual incentives or training to develop appropriate patterns of care often in the absence of input from specialists.¹³ Discontinuities and inconsistencies in health care rapidly have become evident.¹⁴ Two surveys of consultant involvement in long-term care,^{15,16} produced similar findings with between 60% and 66% carrying out ward rounds once weekly or more often, although 15% visited the wards only monthly or less frequently. The day-to-day care of patients was generally by doctors in training or contracted general practitioners, these arrangements provided a continuity of the skills and craft of the medicine of long-term care and a defined responsibility to a consultant.

The demands on general practitioners to support patients housed in care homes have generally have been incorporated into existing work routines rather than attributed defined time. As there are some three care home beds for every NHS hospital bed, it is unsurprising that care has been reactive rather than planned, proactive, or anticipatory. The consequence has been that an inadequate model of care¹⁷ has evolved. The tradition of geriatric care has been compromised¹⁸ with both primary and secondary health care now offering little more than a fire-fighting service to the most vulnerable. Local innovation and adaptations have occurred but their effectiveness is largely unknown; moreover, the clinical oversight of long-term care has become largely unregulated and beyond scrutiny.

Despite emphasizing on the need for preadmission assessment to avert inappropriate institutionalization, evidence continues to indicate shortcomings. A multi-center audit in the late 1990s of nursing home admissions revealed that only 40% of admissions had undergone specialist geriatric or psychogeriatric preadmission assessment.¹⁹ A small single center prospective study accepted older people referred by their general practitioners for long-term care for whom the responsible social workers had misgivings of the need, remarkably 8 out of 33 were admitted to Nursing Home Care with 13 being able to return home.²⁰ Attempts in the National Service Framework²¹ of 2001 to embed a single assessment process, failed through a combination of a lack of proportionality in assessment tools and commitment. Although it remains difficult to determine the reason for people to be in long-term care, a census in 2003 of more than 15,000 care home residents described the drivers for care home admission and the dependencies of residents (Tables 122-2 and 122-3). Although this data was limited to a national provider (Bupa)²² of care, the findings were validated in a larger survey of homes in 2006.²³

Within the case mix and dependencies recorded, there is a further complication in that the discharge and transfer rate

from care homes means that much temporary care is being provided and so actually understanding the actual numbers of long-term care residents remains difficult.

Extrapolation using population projections and present patterns of care home use suggests that between 2003 and 2051²⁴ that the number of care home places will need to rise by 150% in the United Kingdom. This projection is reflected in a review by the King's Fund's Wanless,²⁵ which estimated that the costs of social care could increase in England from \$17.4 billion (£12 billion) in 2002 to \$43.5 billion (£30 billion) in 2026. The single greatest driver for care home admission is and increasingly will be dementia.

DEVELOPING QUALITY IN CARE

For a long time, no statutory mechanism for the routine inspection of the long-term care within the NHS existed. A government agency—the Hospital Advisory Service, later renamed The Health Advisory Service (HAS)—was established in 1969 in response to a series of reports of patients mistreated in psychiatric hospitals. The HAS was charged with visiting geriatric and psychiatric departments of hospitals in rotation, the intention being to advise and encourage good practice rather than to admonish. A visiting team consisting of a consultant geriatrician, manager, nurse, and therapist would spend 1 to 2 weeks in a hospital and present a detailed report and recommendations to the Health Authority and would follow with the director reporting to Parliament annually. The final report of the outgoing director

Table 122-3. Patterns of Mobility, Mental State and Continence in Care Homes

	Residential	Nursing	Overall
1. Mobility	n=3894	n=11,335	n=15,287
Ambulant	40% (1566)	18% (2059)	24% (3642)
Ambulant with assistance	43% (1687)	28% (3228)	32% (4933)
Entirely dependent	16% (641)	53% (6048)	44% (6712)
2. Mental State	n=3849	n=11,104	n=15,015
Normal	31% (1175)	19% (2110)	22% (3295)
Confused or forgetful	60% (2319)	65% (7231)	64% (9591)
Challenging behavior	11% (423)	23% (2549)	20% (2989)
Depressed or agitated	12% (479)	21% (2352)	19% (2840)
3. Continence	n=3832	n=11,278	n=15,166

of the HAS in 1987 stated, "The quality of long-term care offered to elderly people in hospital is still generally very poor. There is a growing contrast with the individual personal care offered in many local authority homes to elderly people with degrees of disability not significantly different from those seen in hospital.²¹" The scope of the HAS inspections did not fully extend to the care in the community provided by independent nursing and residential care homes. Care homes have been subject to regulation primarily by a variety of bodies using largely social and personal care derived standards, most recently administered by the Commission for Social Care Inspection, generally separate from the regulation of health care.

The personalization and empowerment of care home residents has been encouraged through many reports, notably "Home Life" and its successor "A Better Home Life," which provided a code of good practice for residential and nursing home care.²² This latter report espoused principles to guide daily life in a continuing care setting (see Table 122-4).

Currently a project promoting personalization through "My Home Life"²⁸ aims to improve the quality of life of

those who are living, dying, visiting, and working in care homes for older people has championed good practice and engagement in quality of care.

Although the enthusiasm to support improving the experiences of people in care remains important, it contrasts with the wider understanding of the needs of people in care, their clinical dependencies, and reliance on structured health care support. In 1998 The Royal College of Physicians, British Geriatrics Society, and Royal Surgical Aid Society drew up clinical guidelines to enhance the health of older people in long-term care.²⁹ This report gave guidance on the management of dementia, depression, disability, autonomy, continence, medication, falls, and pressure care. The media and public more generally have a poor regard for care and although awareness of dignity issues is a theme, the greatest sense of outrage surrounds clinical issues, in particular the management of medication and specifically the use of neuroleptic drugs. Medication, particularly sedation, has and remains poorly managed despite many reports that have criticized care homes in their use of drugs. Slowly, but inevitably, understanding that there is a medical responsibility in prescribing drugs is gaining understanding³⁰ and at some point it will become apparent that inadequate commissioning of services with limited staff resources can only be squared through poor practices.

The present and future of long-term care in the United Kingdom

As levels of clinical complexity and dependency in long-term care has evolved, patients have become paradoxically redesignated "residents and clients" with greater emphasis on the social aspects of care. Often the potential for fulfilling personal autonomy and ability to choose are undermined by great physical and mental impairment. In reality the outcome of care is dependent, as never before, on clinical care and well-being. As hospitals become more focused on procedural investigation and treatment with increasingly short lengths of stay and rapid discharge, the level of advocacy, navigation, and support for older people can confidently be predicted to increasingly be found in postacute care settings, particularly care home facilities. Not only will care homes have more complex long-stay care case mix, but also patients without clear anticipated outcomes. For instance, consider a patient with a devastating stroke for whom enteral feeding is necessary to maintain hydration and nutrition. Such patients have traditionally remained in the hospital with continuity of specialist care being a positive contribution to difficult decision making. Now an increasingly initial investigation, assessment, and insertion of feeding tube will signal the end of the hospital episode with discharge before an agreed long-term care plan and realistic set of objectives can be established, placing a significant responsibility on a system of care not equipped to provide such decision making. The implication is that geriatric medicine will have to rapidly develop or be reinvented!

The political problem of long-term care prompted the establishment of a Royal Commission on long-term care.³¹ The commission examined various funding options for the future provision of housing and personal care. In an authoritative review, the commission described the epidemiologic uncertainties regarding future needs as a "funnel of doubt"; however, the failure by the commissioners to agree a single

solution dissipated their impact. The government's response to the Royal Commission on long-term care was to determine that from October 2001 the separation of personal care and health care be clarified through an eligibility assessment with the funding of the professional nursing component of care being provided by the state and the remaining costs of care being met through a means-tested process. Real difficulties pervade the definition of "nursing care" as opposed to "personal care." Subsequently, the subject has continued to be contentious with a number of "sticking plaster" solutions to what are increasingly viewed as system failures.

Most recently the increasing volume of critical reports from a wide range of respected foundations and think tanks has led to a renewed commitment to change. A continuing difficult problem with long-term care has been its resources, especially beds to be used to meet a range of needs just as many of the original geriatric NHS beds were used for "slow stream" rehabilitation, "respite care" or "end of life care" so it is been with care homes and community care more widely. Inevitably, this lack of precision in definition of long term care adds difficulties to the understanding of funding requirements with means-tested social care, free at the point of delivery health care, and determining budgetary allocations.

Table 122-5. Recommendations for a Comprehensive Interdisciplinary Approach to the Health and Care of Older People in Care Homes

1. An agreed comprehensive assessment tool should be adopted that records diagnoses along with disabilities to enable commissioning, inform care planning, and governance.
2. Individual care planning should address clearly assessed needs and wishes of the individual. It should also identify expectations, responsibilities, and limitations of health and care. The care plan provides an individual benchmark from which an individual's care may be monitored.
3. A population-based approach should be used for the planning and provision of services to residents in care homes. Integrating all the professions into an organization sized to address the care home population needs is most likely to produce effective and efficient care.
4. A specialist gerontological nurse should be the lead clinical practitioner for the identification and integration of health care support to the home in the care of its residents. Recognition, definition, development, and training within interdisciplinary care are required.
5. General practitioners need their roles and responsibilities to be defined and supported in care homes. New ways of working should greatly improve patterns of care; training and qualifications should be encouraged and recognized.
6. There is an urgent need to reengage specialist geriatric medicine and old age psychiatry in a structured manner to the care home population.
7. The management of medication and the role of the pharmacist may be enhanced through an institutional approach.
8. The organization, application, and governance of all the professions allied to medicine may be enhanced through integration with other professionals and through core institutional-based care rather than individual contracting.
9. A major investment in training, learning, and development is required for medical, nursing, social work, and paramedical professions. The concept of a "teaching nursing home" as a learning organization should be developed.
10. Research is needed to inform further developments that aim to improve health and care outcomes through evidenced-based practice for care home residents through evidence-based practice.

If the purpose of care is poorly understood, there has been no shortage of commitment to regulation of care. The Care Standards Act³² presented national standards for residential and nursing homes for older people from April 2002. These were initially administered by The National Care Standards Commission (NCSC), supplanted after several years by the Commission for Social Care Inspection (CSCI), and in the near future to be replaced by a new commission that will integrate health care regulation with social care regulation.

It should be clear that what is missing in the United Kingdom is a comprehensive strategy of need, funding financing, and perhaps most relevant to readers, the organization of health care. A proposal formulated by a working party of the Royal College of Physicians in partnership with the Royal College of Nursing and the British Geriatrics Society in 2000³³ features 10 recommendations that could collectively provide a comprehensive interdisciplinary approach to care (Table 122-5), this report, like so many others remains a testament to the authors commitment rather than a landmark of progress!

Finally, the availability and organization of the staffing of care remains fragile. Low fee levels have meant poor levels of remuneration, dissuading some potential care staff and undermining staff retention particularly in the prevailing economic climate of near full employment. Care workers from around the globe have sustained the United Kingdom

care needs, whether changing economics will make this sustainable remains uncertain.

KEY POINTS

Long-Term Care in the United Kingdom

- Long-term care remains underdeveloped in the United Kingdom, with attention principally being focused on avoiding care rather than on the care itself.
- Inadequate epidemiologic information regarding the population in long-term care has seriously undermined policy planning.
- Diminishing use of care as a substitute for inadequate housing provision for older people has been "offset" by the epidemiologic impact of dementia and other neurodegenerative diseases.
- Policy concerns have addressed the cost of care rather than determining the funding necessary to deliver care of an acceptable standard and then determining financing mechanisms for individuals confronting the need for care.
- A whole system formulation for long-term remains elusive and is required to determine the needs to be met and the means by which they are provided.

Institutional Long-Term Care in the United States

Luis F. Samos
Enrique Aguilar
Joseph G. Ouslander

HISTORY OF INSTITUTIONAL LONG-TERM CARE

This chapter will provide an overview of institutional long-term care (LTC) in the United States. Long-term care is the broad range of medical and nonmedical services that are designed to meet the needs of people with chronic illnesses and variable degrees of disability. These services may be needed on a temporary basis going from weeks to months or may be needed permanently. The need for long-term care may also be due to terminal illness. There are two basic types of LTC institutions in the United States: nursing homes (NH) and assisted living facilities (ALFs).

In the early 1900s, there was no federal program to support health care for the elderly, so that impoverished seniors were sent to “poor farms” or almshouses. In the 1920s, a U.S. Department of Labor report increased the awareness of the problem and the public began demanding reform. In 1935 the Social Security Act was signed by President Franklin D. Roosevelt, which created the “Old Age Assistance Program.” This provided financial support for older people, but discouraged almshouse living, paving the way for the creation of private old-age homes.^{1,2}

In 1954 a change in federal law provided grants for the construction of nursing homes, which were modeled after hospitals. In 1965 President Lyndon Johnson declared: “thirty years ago, the American people made a basic decision that the later years of life should not be the years of despondency and drift.”² Soon after Medicare and Medicaid were passed into law and these programs provided additional support for LTC. There was an enthusiastic response to Medicare but also overwhelming costs, so that in 1969 the government restricted much of the coverage for NH care. In the 1970s a new policy authorized Medicaid to pay for NH care on a reasonable cost and needs related basis.

In the 1970s and 80s significant concern about the quality of care in NHs began to be voiced.^{1,2,3} In 1986 a study conducted by the Institute of Medicine at the request of Congress found that many residents of NHs were receiving substandard care. This led to the passage of the Nursing Home Reform act as a part of the Omnibus Budget Reconciliation Act (OBRA) in 1987. The purpose of this legislation was to ensure that residents in NHs would receive quality physical and mental care. This act included guidelines for the use of antipsychotics and physical restraints, and created the NH Resident Bill of Rights (Table 123-1).^{2,4}

OBRA 1987 also mandated the creation of a resident assessment system, which led to the development of the minimum data set (MDS). The MDS is a structured tool designed to comprehensively assess NH residents from a general clinical and functional point of view. Screening with the MDS may trigger the use of one or more resident assessment protocols (RAPs), which address 18 common conditions. The RAPs in turn are used for care planning for individual residents. In addition, data from the MDS is submitted to state

governments electronically and used to calculate reimbursement for Medicare-reimbursed skilled nursing stays, and to examine quality of care (see later discussion).^{1,2}

DEMOGRAPHICS AND ECONOMIC CONSIDERATIONS

Demographics

With current trends towards a rapidly aging population in the United States, the health care system and its LTC services will face many challenges. According to the U.S. Census Bureau, 37 million people age 65 and over lived in the United States in 2006, accounting for more than 12% of the population. Over the twentieth century this population grew from 3 million and is projected to be 86.7 million in 2050, comprising 21% of the population. The estimated percentage increase of this age group between 2000 to 2050 is projected to be 147%.^{5,6} By comparison, the population as a whole will have increased only 49% over the same period. The older (65 and over) population is expected to more than double between 2000 and 2030 going from 35 million to 71.5 million,⁷ but this growth rate will slow after 2030, when the “Baby Boomers” enter the group of the oldest-old population (those 85 and older). The oldest-old population is projected to grow rapidly after 2030. For example, the population 85 and over grew from just over 100,000 in 1900 to 5.3 million in 2006.^{8,9}

Life expectancies at both age 65 and age 85 have increased. Current mortality trends suggest that people who survive to age 65 can expect to live an average of 18.7 more years, almost 7 years longer than people age 65 in 1900. The life expectancy of people who survive to age 85 today is 7.2 years for women and 6.1 years for men.⁹

From the above numbers, the growing importance of LTC services is not surprising. Estimates indicate that approximately 35% of Americans age 65 will receive some NH care in their lifetime, 18% will live in a NH at least a year, and 5% for at least 5 years.

Approximately 2% of Americans age 65 to 84 and 14% age 85 and older live in NHs. There are currently close to 1.8 million residents in NHs in the United States, which represents an increase from 1.6 in 2004, although the percentage of elderly living in NHs has declined in recent years from 8.1% of those 75 and older in 2000, to 7.4% in 2006. This is likely due in part to improved short-term rehabilitation and an increasing number of residents returning home, along with the increasing number of ALFs.

Almost half of all individuals living in NHs are 85 years or older and about 70% are women. Residents with dementia account for more than half of the population, more than half are confined to a bed or wheelchair, and 80% need help with four or five activities of daily living. NH residents can be divided into two basic groups: one that stays a short period of time because they are undergoing rehabilitation or because they are medically ill and are hospitalized or die, and a second group of long-stayers (Figure 123-1).^{10,11,12}

Economics

Economic considerations in LTC are of paramount importance in an era of ever increasing health care costs. The average cost of residing in a NH in 2008 is \$187 per day for a semiprivate room and \$209 per day for a private room. An ALF costs about \$3,000 per month for a one-bedroom unit, and the cost for a home health aide is \$29 per hour. The federal government does not provide for ALF care; some states provide limited support through Medicaid or other programs.

The total amount spent on LTC in the United States in 2005 was \$207 billion, excluding informal care (provided by family or friends). There are only two basic ways to pay for NH care in the United States—out-of-pocket from savings (or private LTC insurance which generally has limited coverage), or Medicaid, which essentially requires impoverishment to qualify. About half of NH and other LTC services are in fact covered by Medicaid, which is a federal and state program for low income individuals (not just the elderly). Medicaid expenditures on NH and other LTC services now amount to more than \$100 billion.^{13,14}

Medicare, which is federal health insurance for the elderly and disabled, has two parts: Medicare Part A, which pays for hospital and related care, and Medicare Part B which pays for outpatient services including physician fees. Medicare

Part A will only pay for a skilled nursing facility stay after a 3-day qualifying stay in an acute hospital. Thus, in the United States, Medicare does not pay for direct admission to a NH or for long-stay NH care. This is because Medicare was originally designed to protect older people from the costs of catastrophic acute illnesses—thus Medicare Part A benefits are linked to the care of acute conditions. Medicare will pay for short-term NH care if the resident needs frequent medical and/or nursing services, or rehabilitation with goal of returning home. Although Medicare will theoretically pay for 100 days, most stays are in the 30 to 40 day range, after which long-stay NH care is paid for privately or by Medicaid (see later discussion).¹⁶

For skilled NH care (short-stay), Medicare uses a Prospective Payment System (PPS) that makes payments based on predetermined amounts. As opposed to the diagnosis-related groups (DRGs) used in inpatient hospital settings, a system that is based on the expected amount of resources needed according to the resident's physical functioning, diagnoses, health conditions, and treatments as documented in the MDS. This system is called the Resource Utilization Groups (RUG), and currently includes 53 groups. RUG payments cover all services except physician fees (which are paid for by Medicare Part B). Since the RUG system was implemented, it has changed the relationship between physicians and NH administrators because the costs of services ordered by the physician are now bundled into the RUG payment. Previously, Medicare paid for medications, diagnostic tests, and rehabilitation therapy separately, so the NH administrators were not as concerned about what physicians ordered.¹⁷

A relatively small proportion of older people are in Medicare managed (or capitated) care plans (the proportion varies considerably across the United States). In these programs, the 3-day acute hospital requirement can be waived for skilled care. Thus the Medicare managed care plan enables these individuals to be directly admitted to a NH for short-term care for conditions such as deep vein thrombosis, pneumonia, congestive heart failure, pelvic fracture, etc.^{16,17}

Types of services

Most NH residents require mainly nonskilled or maintenance care such as help with activities of daily living like bathing, dressing, eating, getting in or out of a bed or chair,

Table 123-1. The Nursing Home Residents' Bill of Rights

The Nursing Home Reform Act of 1987 established the following rights for nursing home residents:

- Freedom from abuse, mistreatment, and neglect
- Freedom from physical restraints
- Privacy
- Accommodation of medical, physical, psychological, and social needs
- Participation in resident and family groups
- Treatment with dignity
- Exercise of self-determination
- Free communication
- Participation in the review of one's care plan, and to be fully informed in advance about any changes in care, treatment, or change of status in the facility
- The right to voice grievances without discrimination or reprisal

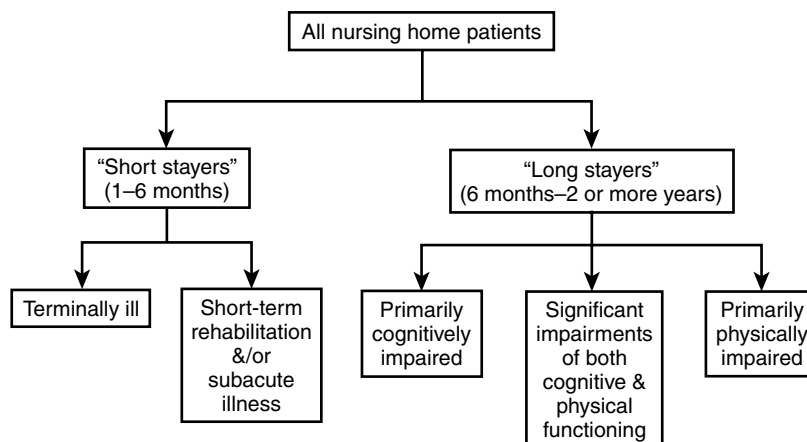

Figure 123-1. Types of patients in U.S. long-term care facilities. From Kane RA, Ouslander JG, Abrass IB. *Essentials of clinical geriatrics*. ed 4, New York, 1999, McGraw-Hill.

and using the bathroom. These individuals have generally already maximized their rehabilitation potential. This care does not require skilled health care personnel and Medicare does not pay for this level of care, but Medicaid does if the individual qualifies financially. Skilled care requires the intervention of medical, nursing, and rehabilitation personnel. Examples of skilled NH care include intravenous injections, wound care, and physical, occupational, and speech therapy (including cardiac, neurologic, pulmonary, or orthopedic rehabilitation).

Hospice care is also provided in both NHs and ALFs. Hospice programs provide medical, psychological, and spiritual support to terminally ill patients and their loved ones. The emphasis of hospice is quality of life, comfort, and dignity. A major point of hospice is to control pain and other symptoms so the patient can remain as alert and comfortable as possible. Hospice services are available through Medicare to persons who can no longer benefit from curative treatment and are estimated to have a limited life expectancy. Enrollment in a Medicare hospice program enables additional support to be brought into the NH or ALF through private hospice providers.

Settings

In the United States, institutional long-term care takes place either in NHs or ALFs. ALFs offer a housing alternative for older adults who are relatively independent. The services generally provided or arranged for in ALFs are listed in Table 123-2. ALF residents generally do not require the intensive medical and nursing care provided in NHs, and usually perform their basic activities of daily living themselves or with little help. The philosophy of ALF care is to allow older people to enjoy freedom and independence.

According to the National Center for Assisted Living, there are more than 36,000 ALFs in the United States, housing more than 1 million people. Since there is no strict definition of what constitutes an ALF, it is difficult to indicate the exact number of facilities. The average age of ALF residents is 83. About 74% of the residents are women and about half need assistance with dressing or bathing. According to NCAL, the average size of an assisted living residence

is 43 units and ranges from 3 to 200 units. The average number of residents in a facility is 40, with a range up to 175. Residents are assessed on admission and periodically thereafter, and monthly fees are often based on the number of services provided.¹⁹⁻²²

ALFs encourage their residents to “age in place.” This has resulted in a substantial number of ALF residents being functionally disabled, and a blurring in the distinction between ALFs and long-stay NHs. Moreover, with relatively few exceptions, physicians and nurse practitioners do not visit ALFs, and many geriatric conditions, such as dementia, fall risk, incontinence, and others are inadequately recognized and managed in the ALF setting.

NHs provide assistance with activities of daily living but also offer an array of medical and nursing care within a 24-hour per day supervised environment. There are approximately 17,000 NHs in the United States. Most of them are free-standing facilities, but some are a part of a retirement community that usually includes independent living, an ALF, and other elderly services (Continuing Care Retirement Communities). Approximately half of U.S. NHs are owned by multifacility chains. Table 123-3 shows selected characteristics of NHs in the United States.^{11-13,23}

Individuals admitted to a NH are usually more dependent than ALF residents on admission, especially those admitted for long stay, which can extend to years of institutional living. About half of residents spend at least a year in the NH and 21% of them live there for almost 5 years. Among residents admitted for short stay, which could last from days up to 3 months, many are admitted for rehabilitation, usually after a qualifying stay in the hospital (as described previously). Other individuals admitted for short stay are admitted for respite care. Respite programs involve a temporary admission, so that the family member or caregiver can take some time off. Respite care is not supported by Medicare, but may be by Medicaid in some states. The Veterans Health Administration, which has over 100 NH care units and state Veteran’s Homes, offers respite free of charge for up to 30 days a year to qualifying veterans.

Table 123-2. Services Generally Provided in an Assisted Living Facility*

- 24-hour supervision
- Three meals a day in a group dining room
- A range of services that promote the quality of life and independence of the individual, such as:
 - Personal care services (help with bathing, dressing, toileting, etc.)
 - Assistance with medication management, or with self-administration of medicine
 - Social services
 - Supervision and assistance for persons with Alzheimer’s or other dementias and disabilities
 - Recreational and spiritual activities
 - Exercise and wellness programs
 - Laundry and linen service
 - Housekeeping and maintenance
 - Arrangements for transportation

*Residents are assessed on admission and periodically, and monthly fees are often based on the number of services provided.

Provision of care

Key leadership in a U.S. NH includes the administrator (who may or may not have had training as a nurse or other direct care health professional), the director of nursing, and the medical director. All licensed NHs are required to have a physician medical director. The medical director performs several functions and must integrate clinical best practices with regulatory issues. The medical director can be extremely important in establishing a professional and caring culture in the organization. In most facilities the medical director also has direct patient care responsibility; in some cases they care for the majority of residents. The medical director is also instrumental in ensuring that the NH meets state and federal regulations. He or she must ensure medical coverage and quality care, participate in policy and procedure development and implementation, infection control, and other quality improvement initiatives. The American Medical Directors Association (AMDA) has professionalized the role of the U.S. NH medical director over the last several years, and offers advanced training and certification for this role.^{11,24}

In the majority of U.S. NHs, there is infrequent presence of physicians, nurse practitioners, or physician assistants, though some NHs, especially the larger ones, have on-site medical staff most days of the week. Nurses, both registered nurses (RNs) and licensed practical nurses (LPNs) are the key members of the clinical staff in NHs. Certified nurse assistants (CNAs) provide 90% of the hands on care, and support the services of RNs and LPNs. NHs also have either on a part of full-time basis physical, occupational, and speech therapists, social workers, psychologists, dietitians, pharmacists, and one or more chaplains. All of these professionals form part of the interdisciplinary team.^{11,25,26}

Optimally care is delivered to NH residents by an interdisciplinary team that specializes in geriatric care. Interdisciplinary team care can be complex and time-consuming, but it is essential for the delivery of high quality care in the NH setting.

The basic paradigm for clinical care in the NH is theoretically guided by the resident assessment instrument, which is composed of the MDS and 18 RAPs (Table 123-4). Completion of the MDS is mandated within 14 days of admission and whenever there is a major change in status (such as a hospitalization), and specific sections are updated quarterly. When a condition is identified, the interdisciplinary team must document whether further assessment is indicated, and use one or more of the RAPs as appropriate to the clinical situation to generate an individualized care plan. MDS data must be entered into a computer data base, which is downloaded to the state government. These data are then used to calculate RUG rates (for residents on the Medicare Part A benefit) and to generate a series of quality indicators (see later discussion). In actual practice in the majority of U.S. NHs, an MDS coordinator (usually a nurse) completes the MDS with variable input from team members, and medical evaluations are done separately with little coordination with the MDS and care planning process.^{27,28,29}

Quality of care

Quality of care in U.S. NHs is highly variable. Some facilities provide outstanding care. However, despite intensive efforts by federal and state governments and professional

TABLE 123-4. Conditions Addressed by Resident Assessment Protocols

- Dehydration/fluid maintenance
- Dental care
- Pressure ulcers
- Psychotropic drug use
- Physical restraints

and advocacy organizations, the quality of care in many NHs remains suboptimal.

NH care delivery in the United States is highly regulated. NHs are subject to regular (at least annual) surveys by state and/or federal surveyors, and can be fined, lose the ability to admit new residents, or closed depending on the scope and severity of violations of regulations cited by the surveyors. Extensive reforms and regulatory changes were enacted as part of Omnibus Reconciliation Act in 1987 and they have continued to evolve. These regulations establish quality standards and related guidance to surveyors, minimum staffing and training requirements, reinforce residents' rights and quality of life, and limit restraints and the use of psychoactive medications as a mean to control resident behavior.

The major focus of quality improvement efforts in NHs is based on a series of quality indicators (QIs) that are derived from the MDS. QIs now address both short-stay and long-stay residents, and are publicly reported on the "Nursing Home Compare" section of the Medicare Web site (www.Medicare.gov/nhcompare) so that consumers can view QIs of NHs they are considering. Table 123-5 lists the quality measures monitored by the federal and state governments. At the level of the individual NH, these measures can be benchmarked against other NHs in the same multifacility chain, in the state, or nationally. These analyses can be used to target specific quality improvement initiatives. State and federal surveyors also use the QIs to target areas of concern for their surveys.

The Center for Medicare and Medicaid Services supports Quality Improvement Organizations (QIOs) in each state in the United States that are contracted to assist NHs (as well as other health care providers) with quality improvement efforts. The effects of the QIO programs are difficult to prove, but there is evidence that NH care quality has improved in association with QIO efforts. The focus of the QIO NH initiatives over the last several years have been on reduction of the use of physical restraints, pressure ulcers, pain, and depression, and on culture change in NHs (see later discussion) with a specific focus on resident and staff satisfaction, "person-centered care," and staff turnover (which averages 50% to 100% among certified nursing assistants in many U.S. NHs).^{30,31,32} A wide variety of quality

Table 123-5. Quality Measures for Nursing Home Care in the United States

Quality Measures	MDS Observation Time Frame
Long Term Measures	
Percent of long-stay residents given influenza vaccination during the flu season	October 1 thru March 31
Percent of long-stay residents who were assessed and given pneumococcal vaccination	Looks back 5 years
Percent of residents whose need for help with daily activities has increased	Looks back 7 days
Percent of residents who have moderate to severe pain	Looks back 7 days
Percent of high-risk residents who have pressure sores	Looks back 7 days
Percent of low-risk residents who have pressure sores	Looks back 7 days
Percent of residents who were physically restrained	Looks back 7 days
Percent of residents who are more depressed or anxious	Looks back 30 days
Percent of low-risk residents who lose control of their bowels or bladder	Looks back 14 days
Percent of residents who have/had a catheter inserted and left in their bladder	Looks back 14 days
Percent of residents who spent most of their time in bed or in a chair	Looks back 7 days
Percent of residents whose ability to move about in and around their room got worse	Looks back 7 days
Percent of residents with a urinary tract infection	Looks back 30 days
Percent of residents who lose too much weight	Looks back 30 days
Short-Stay Measures	
Percent of short-stay residents given influenza vaccination during the flu season	October 1 thru March 31
Percent of short-stay residents who were assessed and given pneumococcal vaccination	Looks back 5 years
Percent of short-stay residents with delirium	Looks back 7 days
Percent of short-stay residents who had moderate to severe pain	Looks back 7 days
Percent of short-stay residents with pressure sores	Looks back 7 days

CULTURE CHANGE IN U.S. NURSING HOMES

“Culture change” is a current buzzword in the U.S. NH industry. Numerous professional and advocacy organizations are focused on changing the culture of NHs to one that focuses on quality first. A multiorganization initiative, “Advancing Excellence in America’s Nursing Homes” (<http://www.nhqualitycampaign.org/>) is focused on culture change and other aspects of quality improvement in U.S. NHs. The culture-change movement grew slowly at first and since 2005 has now begun to spread rapidly. It focuses on empowering staff to deliver person-centered care and improve quality of life for residents, and advocates changing the environment from an institutional or hospital model to a more homelike

or social model, considering the facility as the residents own home. Table 123-6 illustrates some of the differences between these two models. Table 123-7 lists some of the other key components of culture change.³³

FUTURE PERSPECTIVES

Many challenges lie ahead for institutional LTC in the United States. Growing need and complexity of chronic illnesses and their treatment will stress the system. ALFs will continue to care for an increasingly complex population, with little medical and nursing input. This will place them at risk for poor quality of care, regulatory sanctions, and legal liability, unless good geriatric care is incorporated into this setting. NHs will continue to serve an increasingly frail resident population with high medical and nursing needs, especially as the reimbursement system begins to provide financial disincentives to hospitalize NH residents. These changes will come at a time when there is a crisis in terms of shortage of trained nurses, nurse practitioners, and physicians who specialize in geriatrics and long-term care. Blending the medical needs with the person-centered culture described above will be extremely challenging. Fiscal constraints in the Medicare and Medicaid programs will serve to exacerbate these challenges.

At the same time, there are opportunities. Opportunities to build upon the early successes of the culture change movement and quality improvement initiatives that have begun to permeate some U.S. NHs.³⁴ There are strategies that can be employed to improve care quality and reduce avoidable expenditures. Examples include preventing complications of chronic illnesses and avoiding iatrogenic problems, reducing polypharmacy, using care protocols and improved communication tools to reduce avoidable hospitalizations, and

Table 123-6. Institutional vs. Homelike Model of Nursing Home Care

Institutional (Hospital) Model	Homelike (Social) Model
Residents follow facility routine	Facility follows residents’ routine
Staff float	Permanent assignments
Staff make decision for patients	Residents make their own decisions
Facility belongs to staff	Facility is residents’ home
Staff know residents’ diagnosis	Staff knows residents as individuals
	Nurture the human spirit in addition to providing treatments

Table 123-7. Key Components of Nursing Home Culture Change

Control of equipment	Group bonding
Natural smells	Celebrations
New technologies	Contact with other generations
Home like artificial lighting	Home like meals

more proactive use of advance directives to avoid unnecessary and expensive care at the end of life. Some of the cost savings might be reinvested in pay-for-performance initiatives that incentivize quality and culture change. NHs and ALFs also have the opportunity to partner with hospitals and home health care programs to improve transitions in care, a major quality and patient safety issue in the United States. This is a major focus of the current Medicare QIO program. Finally, and very importantly, there are opportunities to use

health information technology—electronic medical records, remote monitoring devices, and others—to improve care quality, make care more efficient, and focus efforts on person-centered care that improves the quality of life of elderly people in need of institutional LTC.

INTRODUCTION

Education in geriatric medicine is currently failing to meet its objectives. Although geriatricians report the highest satisfaction with their specialty,¹ few medical students opt to join our ranks, particularly in the USA² and Canada.³ Worldwide, populations are aging with the oldest old the most rapidly growing segment of society.⁴ Yet many physicians and family doctors remain unfamiliar with key principles and practices of geriatric medicine.⁵

In this chapter, motivators for improvements in geriatric medicine education are contrasted with barriers to change. Newer educational theories have generally placed greater emphasis on processes of learning and the personal development of students. A working summary of these learning theories is provided, with examples of innovative educational programs linked to each approach. This education evidence base is intended to inform clinical geriatricians, optimizing the effectiveness of both their teaching and their own learning.

Motivators for change

Several factors are motivating improvements to the education of geriatric medicine (Table 124-1). Improving the care of older people has been prioritized at a governmental level, particularly in Australia⁶ and the United Kingdom⁷ and the teaching of geriatric medicine in the undergraduate curriculum is advocated by the World Health Organization,⁸ General Medical Council⁹ and the Association of American Medical Colleges.¹⁰

In the United States, philanthropic institutions are driving improvements in health care for older people. Between 1997 and 2008, the Hartford Foundation (www.jhartfound.org) and the Reynolds Foundation (www.dwreynolds.org) committed \$118 million to U.S. medical schools to fund comprehensive programs to strengthen the geriatrics training of medical students, residents, and/or practicing physicians. The Reynolds Foundation has also provided support to the Association of Directors of Geriatric Academic Programs (ADGAP) to facilitate information exchange. This has included the development of an online system to share geriatric educational materials (www.pogoe.org).

Perhaps the most powerful motivator for change is the yawning gap that currently exists between service provision and care need. Two thirds of hospital inpatients in the United Kingdom are now aged over 65 years.¹¹ Older, dependent patients with rehabilitation need are not confined to Care of the Elderly units but are scattered throughout intensive care, medical, and surgical wards.¹² All doctors looking after adult patients therefore need the skills to work with older people. Yet the list of knowledge deficits in geriatric medicine identified by physicians^{13,14} encompasses many essential domains:

- Medication prescribing
- Neurologic and behavioral problems
- Urinary incontinence and falls
- Health screening

- Ethical issues such as capacity to make treatment decisions
- Multidisciplinary working
- Navigating transitions to or from the acute hospital

Knowledge deficits result in greater medical uncertainty and feelings of inadequacy and frustration for the physician.¹⁴ This frustration may manifest as negative stereotyping and suboptimal care. Ageist practices and undignified care of older people are all too apparent to geriatricians in our day to day practice¹⁵ and continue to make the headlines in the medical¹⁶ and lay press.¹⁷

Barriers to change

The barriers to improvements in geriatric medicine education include logistical and philosophical factors (Table 124-2). The medical school curriculum is already overcrowded, there may be difficulties coordinating teaching across nontraditional sites, such as nursing homes, and qualified teachers are a scarce resource.^{18,19} In the United Kingdom, for example, the infrastructure for teaching and promoting geriatric medicine is being eroded. Between 1986 and 2006 numbers of both medical schools and medical students increased but the number of academic departments of geriatric medicine declined.²⁰ Moreover, teaching is the dual casualty of the escalating pressures of clinicians' service commitments and academics' research output accountability.

Some physicians openly question the need for geriatric medicine. Increasing numbers of older complex inpatients and the positive results achieved by nongeriatricians supervising multidisciplinary teams have both been used as arguments to abolish the specialty.²¹ It is hard to imagine similar debates about the existence of cardiology ("we all manage patients with ischemic heart disease") or endocrinology ("we too use oral hypoglycemics to lower blood sugar") being countenanced by leading medical journals. These negative attitudes act as impediments to geriatric medicine education. Before attitudes can be changed, the reasons for them must be explored.²²

Medical attitudes

Most medical students do not consider pursuing a career in geriatric medicine.²³⁻²⁵ Students not interested in geriatrics rate performing procedures, technical skills, and not managing chronically ill patients as important practice characteristics.²³ Some students feel older people are "to blame" for their illnesses through life-style choices.²⁶ A more positive attitude to older people increases the likelihood of choosing a career in geriatric medicine.²⁴ Early exposure to geriatric medicine has been advocated²⁵ as students with more experience of older people, both positive and negative, are less likely to resort to stereotype and show more interest in geriatric medicine as a career.²⁶

The presentation of geriatric medicine as a specialty founded on utilitarian values ("our interventions work") may have compromised its appeal. Modern concepts of frailty have the potential to provide a scientific framework, helping

Table 124-1. Motivators for Improving Education in Geriatric Medicine

Motivators for Change
Increasing numbers of older people
Current lack of knowledge → frustration for the physician and suboptimal care for the older patient
Improving the care of older people prioritized at governmental level
Funding initiatives in United States
Wide support (e.g., WHO, GMC) for increased teaching of geriatric medicine in the undergraduate curriculum

Table 124-2. Barriers to Improving Education in Medical Education

Barriers to Change
Shortage of time in the curriculum
Lack of funding
Few qualified teaching staff
Negative attitudes of students
Problems integrating teaching in nontraditional sites such as nursing homes

us understand and explain why these interventions work, and for whom.²⁷ Fifty years ago, “senile dementia” was viewed as an inevitable consequence of aging but “Alzheimerization” has changed public perceptions and motivated enhanced research endowments.^{28,29} A clear description of clinical features, insights into pathogenesis, and development of modifying interventions have been essential components in this transformation. The “frailterization” of decrepitude and decline through comparable investigative steps is a tantalizing prospect.

Perceptions of prestige also contribute to negative attitudes. In one survey,³⁰ medical students, and junior and senior doctors consistently ranked neurosurgery and thoracic surgery as the highest prestige specialties. Only dermatovenerology rivaled geriatric medicine for the lowest prestige rating. Highest prestige conditions, such as myocardial infarction, leukemia, and brain tumor, seem to share an acute onset, definitive diagnostic strategies, high-tech interventions, and the possibility of complete cure. They reinforce the doctor’s role as healer (anticipated by medical students as “Your job is to make the person better and help them live”²⁶). Low prestige conditions, such as fibromyalgia and anxiety neurosis, often require a shift in philosophy from cure to care and demand communication skills rather than procedural finesse. Indeed, the knowledge and skills required to manage such conditions are the very ones that physicians report most difficulty in mastering.^{13,14}

Societal attitudes

Medical student beliefs are shaped not just by their own experiences but by the attitudes of wider society.³¹ The following opening gambits may stimulate discussion and act as a means to explore societal attitudes:

- In 2005, a U.K. survey of 2000 adults aged over 16 years reported that one third of people thought that the demographic shift toward an older society would make life worse in terms of standards of living, security, health, jobs, and education and one in three

respondents viewed the over 70s as incompetent and incapable.³²

- Charities that work with older people in the United Kingdom report difficulties generating financial support, with a quarter of the total income of charities that work with children and adolescents and half that of animal charities.³³
- Simone de Beauvoir described two stereotypes of older people³⁴: “The purified image of themselves that society offers the aged is that of the white haired and venerable sage, rich in experience, planing high above the common state of mankind; if they vary from this then they fall below it; the counterpart of the first image is that of the old fool in his dotage, a laughing stock for his children. In any case either by their virtue or by their degradation, they stand outside humanity.”
- Older people have not always been undervalued. Before advancement of the written word, “elders” acted as collective memories during long evenings and at legal proceedings.³⁵
- Societies that value physical beauty tend to depreciate old age whereas those that aim at a spiritual ideal entertain a more abstract aesthetic ideal.³⁶

Educational theory

BACKGROUND

Teaching methods within the medical profession have traditionally been hierarchical, both at undergraduate and postgraduate level.³⁷ Medical knowledge is seen as the possession of experts, Socratic figures who transmit this knowledge to passive learners,³⁸ conforming to objectivist philosophy that knowledge is an entity that “exists in the world” outside the minds of individuals.³⁹

Any teaching session may be seen by the well-intentioned traditional medical educator as an opportunity to “pass on” as much of this knowledge as possible, perhaps by recalling numerous “facts” for the students to transcribe. The learners are expected to commit the information to memory, becoming “little living libraries” capable of regurgitating the same information at a later date.⁴⁰ But increasing the density of information given to students has detrimental effects on the amount of information actually retained.⁴¹ The objectivist, pedagogic teaching model is being supplanted by teaching methods based on alternative educational theories.

Those theories stem from five main sources⁴²: behaviorism, adult learning (andragogy), constructivism, cognitivism, and social learning. Concern has been raised that these theories lack a solid evidence base and are founded on metaphor rather than science.⁴³ However, a familiarity with educational epistemology [coupled with an awareness that epistemology means “theory of knowledge”] can improve the effectiveness of teaching practice by providing a basis for the selection of instructional and evaluation strategies to match intended goals of learning.

Behaviorism

LEARNING THEORY

The behaviorist model involves a teacher-centered approach and has traditionally been used for the development of competencies and for demonstrating psychomotor skills. The focus of learning (as espoused by Skinner) is on observable

behavior: environment shapes behavior and reinforcement is central to the learning process.⁴⁴ A behavioral objective should include the performance (what behavior will be performed), conditions (under which the behavior must be performed), and criteria (the measure of acceptable performance).⁴⁵ Behaviorists deny the importance of consciousness and cognitive processes and define mental state solely in terms of environmental input and behavioral output.⁴⁶ Behaviorist-medical methodology is said to conform to a Western "dominator" paradigm reinforcing "masculine" values and traits.⁴⁷ Though educational programs are now more often based on andragogy and constructivism, behaviorism still has an important role in developing competency based curricula.⁴²

APPLICATION IN GERIATRIC MEDICINE EDUCATION

As already discussed, students not interested in geriatrics rate performing procedures and technical skills.²³ Geriatric medicine has been dismissed as "an approach centered on gentle symptom management."²¹ Behaviorist teaching may therefore be particularly useful to counteract the perception that geriatricians use no special skills. Behaviorist objectives (performance, conditions, criteria) improved the functional assessment of an older person at the University of Michigan Medical School.⁴⁸ Performance included history taking (e.g., asking about falls and memory impairment) noting visual and hearing impairments and gait assessment. This was evaluated at a Standardized Patient Instructor station of an Objective Structured Clinical Examination (OSCE). The measure of acceptable performance was a score of 50% on a 17-item check list. Student performance was initially poor (with a mean score of 43%) but improved significantly after the introduction of an integrated geriatric curriculum. The curriculum included more geriatric content in preclinical courses, experience in an outpatient clinic, and clearly stated learning objectives related to clinical skills in functional assessment.

Adult learning theory

LEARNING THEORY

The objective of education in adult learning (andragogy) is for the learner to become autonomous and self-directed.⁴⁹ The role of the teacher is to facilitate the growth and development of the overall person. Maslow's contention that self-actualization could only occur once when threats were minimized⁵⁰ challenged the teaching methods of Lancelot Spratt characters, whose gentle humiliation of students for comedic effect engendered fear as well as the desired respect. Key characteristics of adult learning described by Carl Rogers⁵¹ include personal involvement of the student such that learning is self-initiated and self-evaluated. Significant andragogical learning only occurs when the subject matter is perceived to be relevant.

APPLICATION IN GERIATRIC MEDICINE EDUCATION

The andragogical principle of self-directed learning was the driving force behind the General Medical Council guidance in the United Kingdom that student-selected components should comprise a quarter to a third of medical school curricula.⁹ Geriatric medicine may not benefit from such initiatives since students are unlikely to choose self-selected modules to address knowledge deficits. Self-ratings correlate

poorly with externally generated measures of ability⁵² and adult learners tend to gravitate to studying things they enjoy and are already good at.⁵³

Another tenet of andragogy is that significant learning is acquired through doing.⁴⁵ Experiential learning improves knowledge of and attitudes to the subject taught.⁵⁴ A randomized controlled trial of an experiential educational intervention in geriatric medicine was undertaken at the University of Western Ontario.⁵⁵ The experiential session included:

- A game-show style quiz on demographics
- Use of specialized goggles and footwear to simulate visual and physical impairments often felt by older people
- Group interview of an older lady in a wheelchair and hospital gown. She suddenly disrobed to reveal her exercise wear and led the class through the fitness exercises she taught at the local community center.

Assessment 1-year later showed no greater knowledge in the intervention group but student behavior and feedback suggested improved attitudes to older people and more chose geriatric medicine as a clinical elective.

Constructivism

LEARNING THEORY

Constructivists believe that learners build knowledge from their own perceptions and experiences. Learning is an active process, occurring within the minds of each individual.⁴⁰ The role of the constructivist teacher is therefore to support the learners' own construction of knowledge.³⁸ This differs fundamentally from the traditional role as conveyor of information. Learners are thought to possess a current field of knowledge, described by Vygotsky as the "zone of proximal development."⁵⁶ The role of subject experts as preferred teachers for medical students is questioned (since their knowledge may be beyond the zone of proximal development of the students) and peer teaching promoted. Constructivism has gained popularity as a framework for medical education. The emphasis on processes of learning and personal development of students is considered to be particularly effective in fostering professional attitudes and beliefs.⁵⁷

APPLICATION IN GERIATRIC MEDICINE EDUCATION

The principle of building on knowledge through the curriculum has been employed in the geriatric medicine program at the Southern Illinois School of Medicine.⁵⁸ Students encounter a simulated older couple through standardized couple patient experiences, small group sessions, and paper-based learning modules. The couple ages 10 years between each annual, 4-hour session. The woman represents healthy aging whereas her husband becomes frail, with multiple comorbidities, polypharmacy, and functional decline. Thus the students gain insights into health promotion/illness prevention and caregiver burden along with medical complexity and the impact of frailty. Discussions are guided by the SEMPACE model, which aims to address all areas affecting older people's health: Social, Environmental, Medical, Psychological, Activities of Daily Living, Caregiver, and Economic domains. Although Aging Couple Across the

Curriculum is currently in the development phase, and may require a more appealing acronym to have a truly pervasive impact, early student evaluations have been positive and an increased interest in geriatric medicine is suggested by more students choosing geriatric electives.

Cognitivism

LEARNING THEORY

The emergence of cognitive science precipitated a significant change, some would even say a Kuhnian revolution⁵⁹ in education and teaching methods. Although radical behaviorists minimize the importance of consciousness and mental processes, cognitive scientists focus on the learner's thought processes.⁴² The teacher's role is to develop the learner's capacity for effective self-directed learning.

Reflective practice, integral to cognitivism to develop critical thinking, is an increasingly advocated concept in the fields of medical and nursing education. Reflective practice was first described by Schon in the early 1980s⁶⁰: reflection *in* action occurs during the experience whereas reflection *on* action occurs, perhaps axiomatically, after the event. Reflection is more than simply replaying or thinking about practice.⁶¹ It is "not complete without action"⁶² and should lead to the development of new perspectives, behaviors, and practices.⁶³ Some argue that reflection may lead to anxiety⁶⁴ and psychological harm⁶⁵ and that discussion of case histories may compromise patient confidentiality.⁶⁶ Reflection has even been compared with Orwellian thought control since participants are encouraged to express their own feelings and amend them to harmonize with the majority view.⁶⁷ Despite these criticisms, reflection has been widely extolled as the pathway to medical professionalism.⁶⁸

APPLICATION IN GERIATRIC MEDICINE EDUCATION

A mandatory 4 week clerkship in geriatric medicine introduced at McGill University, Montreal involved elements of independent and self-directed study, learning in and on practice, and web-based teaching to reinforce learning.⁶⁹ An electronic evaluation portfolio seemed to motivate students' self-reflection⁷⁰ and induce a positive change in attitudes.⁷¹

Concept maps are a cognitivist technique in which students create a 2-dimensional diagram exploring their understanding of important topics.⁷² Concept maps reflect expected differences due to experience and training and can be scored reliably.⁷³ However, the absence of correlation between concept map assessment scores and conventional measures of learning such as final course grades suggests different knowledge characteristics are being tapped.⁷⁴ Geriatric medicine, replete with complexity, may be particularly suitable for concept mapping. Student understanding of the geriatric giants, for instance, could be explored. Examples of how a concept map may evolve as knowledge increases and complexity is appreciated are shown in Figures 124-1 and 124-2.

Social learning

LEARNING THEORY

Social learning is the result of a continuous interplay between three factors: the person, the learning environment, and the desired behavior.⁷⁴ Role modeling, bedside teaching, and

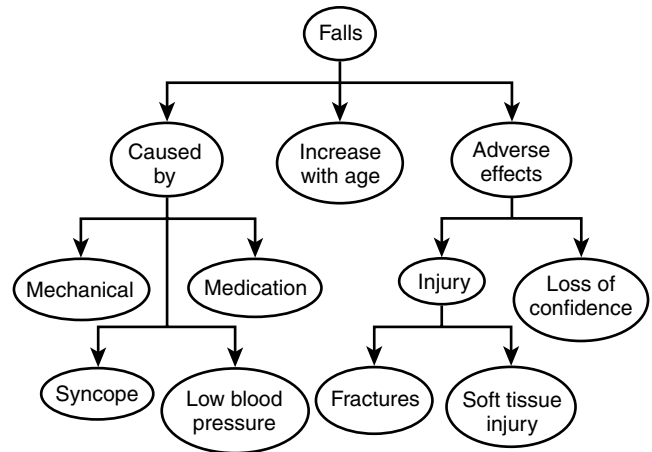

Figure 124-1. Concept map of falls. The absence of cross-links and the consistent use of 2 to 3 levels of hierarchy would result in a low score.

applications of social learning have long been the mainstay of teaching to students and junior doctors.⁴² The teacher is responsible for creating the desired model (e.g., history taking, cognitive assessment) and should then observe and correct the student's performance.

APPLICATION IN GERIATRIC MEDICINE EDUCATION

Clinical geriatricians may be unaware of the extent to which we impact students attending ward rounds or outpatient clinics. As role models, knowledge is essential but we also need to understand and articulate the reasons for actions.⁷⁵ The factors militating against referral for major surgery, for example, may be carefully weighed by an experienced geriatrician but without exploration and explanation, the observing student may interpret that the decision was based on chronological age alone.

Hafferty and Franks' seminal work⁷⁶ on the learning of ethics proposed that the "broader cultural milieu" or "hidden curriculum" of medical schools had a greater influence than the formal curriculum on physicians' personality and conduct. This hidden curriculum may be particularly disadvantageous to geriatric medicine. Positive forces such as governmental edicts to abolish ageist practices⁷ are undermined by what medical students hear and see on the wards.¹⁵ Qualitative studies of trainees have confirmed that "clinician-teachers sometimes make disparaging remarks about particular medical specialties which may act as a barrier to recruitment."⁷⁵ At a time when even the British Geriatrics Society debates changing its name since "geriatrics" has "acquired negative connotations,"⁷⁷ we should be careful about the message this sends to others about the patients we care for. Through explicit consideration of the hidden curriculum, students may learn to challenge rather than accept ageist practices and behaviors.

SUMMARY

Educational theories emerging since the 1960s have shifted the emphasis of teaching from transmission of medical knowledge to support of learners as they develop. There is considerable overlap between different constructs; reflective practice and self-directed learning, for example, are commonly occurring themes. This should not compromise

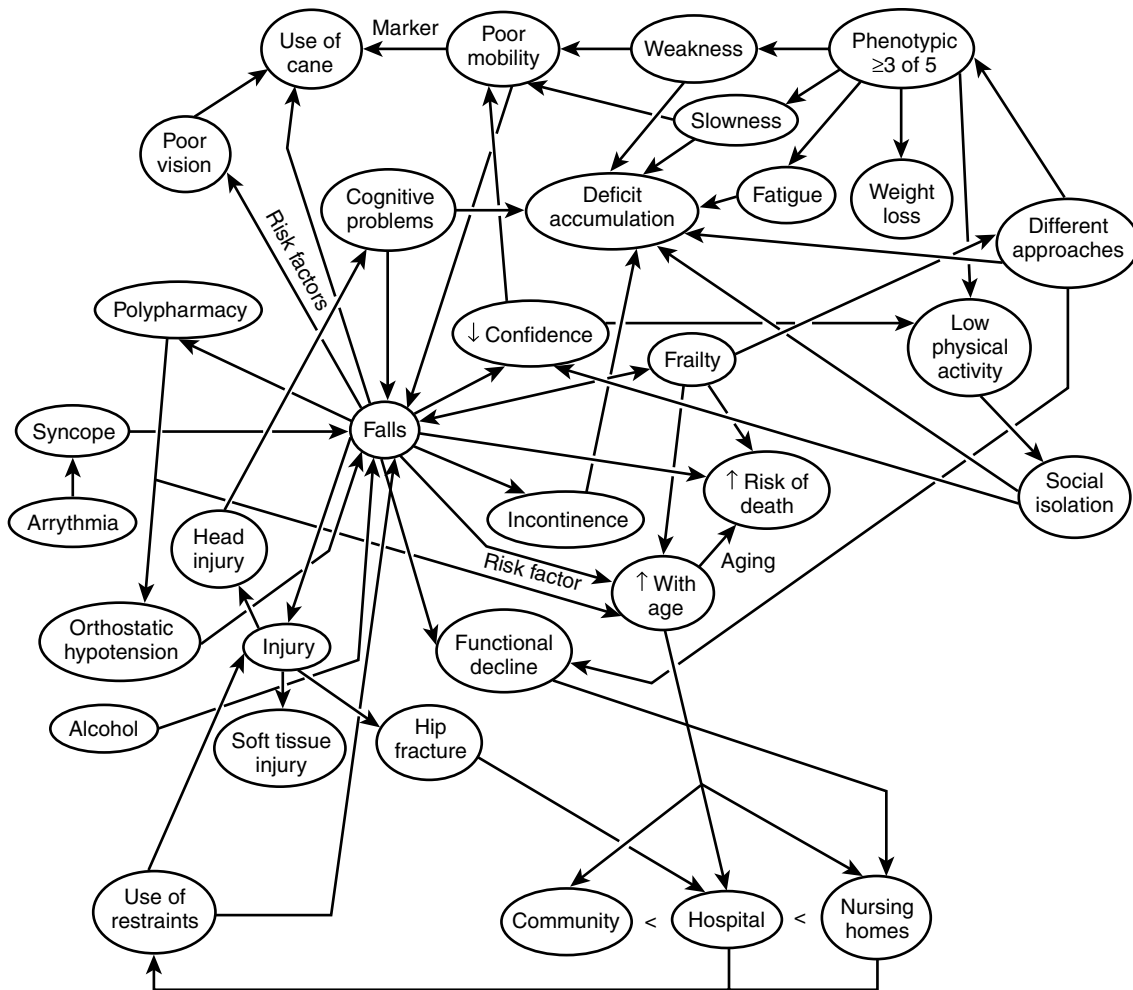

Figure 124-2. Higher scoring concept map of falls with frequent cross-links and consistent use of 5 or more levels of hierarchy.

curriculum design, the purpose of which is to optimize learning rather than exclusively apply a single educational theory.

The focus on learning processes and personal development of students is particularly relevant for the education of geriatricians. Younger patients having a single pathology such as chest pain, benefit from a rich evidence base and decision making can chiefly follow algorithm. Decision making for older, complex patients, on the other hand, is often guided by wisdom and prudence, described by Thomas Aquinas as “a keen understanding of the present that is informed by a memory of the past and modulated by current counsel.”⁷⁸ Geriatricians therefore need to be able to integrate knowledge gained through management of each patient (“memory of the past”) and keeping up to date with a rapidly evolving evidence base (“current counsel”). Newer learning strategies—reflection on experience, social collaboration, identification of own learning needs—may foster these skills.

CONCLUSION

Geriatricians understand that caring for older people is a dynamic, complex, and richly gratifying specialty but this has not always been appreciated by others. We need

charismatic and motivational teachers to raise the profile of geriatric medicine at medical schools and attract a higher number of trainees. To become an excellent clinical teacher, knowledge of our specialty is necessary but

KEY POINTS

Education in Geriatric Medicine

- Currently, few students consider becoming geriatricians and physicians and family doctors remain unfamiliar with key principles and practices of geriatric medicine.
- Barriers to change in medical schools include negative attitudes of students, an overcrowded curriculum and lack of motivated teachers.
- Educational theories emerging since the 1960s have shifted the emphasis of teaching from transmission of medical knowledge to support of learners as they develop.
- Geriatricians should be familiar with techniques to optimize the effectiveness of both their teaching and their own learning.
- Charismatic educators with geriatric knowledge and teaching skills have the potential to increase recruitment of geriatricians and improve standards of care by our colleagues in other specialties.

not sufficient. Enthusiasm, communication skills, and the ability to create a supportive learning environment are noncognitive attributes that may need to be cultivated.^{79,80}

Ultimately, though, education in geriatric medicine should not just be targeted at recruiting and training a workforce of talented geriatricians. Old, dependent patients with rehabilitation need comprise the majority of the inpatient population.¹² We cannot directly provide care for all these older patients but have a responsibility to ensure that effective practices and essential skills are shared. In so doing, our colleagues in other specialties would find geriatric medicine less frustrating and more

rewarding and, most importantly of all, the quality of care for all older people would be improved.

Improving Quality of Care in the United Kingdom

David A. Black

Improving quality of care is difficult and controversial. Over the last 20 years in the United Kingdom there have been growing pressures from an increasing number of stakeholders to demonstrate and deliver quality improvement. From the inception of the National Health Service (NHS), politicians have been seen to be held responsible for a state-funded health service; patients are becoming increasingly knowledgeable and empowered to act and insist on improvements; health care purchasers have a particular interest in risk management processes owing to the influence of litigation; and finally the professions themselves have a growing interest in evidence-based medicine and delivering the best possible care. Yet the problems of improving care have recently been summarized by Brook, who in a review states "in the last 30 years research has demonstrated that quality of care can be measured, the quality varies enormously, that where you go for care affects its quality far more than who you are, improving quality of care, while possible, is difficult, and in general has yet to be successfully accomplished."¹ Although this seems a pessimistic view, the gain from improving quality of care, when successful, can be spectacular. During the Crimea War, by enforcing improved standards of care and hygiene, Florence Nightingale reduced the mortality rates at the Scutari Military Hospital from 42.2% to 2% within 6 months.

Some may view the quality improvement movement as a management fashion. Yet the very success of geriatric medicine in the United Kingdom is a result of continuous improvements in the care of older people, starting in 1946 when Dr. Marjory Warren identified the large numbers of older people confined in atrocious workhouse settings who were denied effective health care. From those beginnings at the very onset of the NHS have evolved the comprehensive systems of assessment and care that are so different from the world of 1946. The development of geriatric medicine has been largely based on a persistent striving at the local level for more and better services in the face of policy weakness, professional neglect, and resource starvation, coupled with poor training and a neglected research base. The health care of older people remains one of the major challenges for quality improvement within the health service, particularly in the face of continual pressures to manage the growing number of the very old in the population.

The purpose of this chapter is to provide a theoretical understanding of the background to quality improvement by describing quality initiatives in the wider world of business and relating these to current health service policy with practical examples in geriatric medicine. A major problem for practitioners is the confusion of terminology and definitions. The experience of other areas, such as industry, has not been properly understood and the health service has been showered with initiatives, activities, jargon, and buzz words. The problems for clinicians have included failure to provide adequate commitment of time, significant problems with the

information gathered, and difficulties implementing change when the needs have been identified. This chapter attempts to explain how the history of quality initiatives in business and the health service have led to the current government's approach, in particular the concept of clinical governance.

WHAT IS QUALITY?

At its very simplest, a basic working definition of highest quality care is "doing the right things well." In business, quality can be seen to have a number of dimensions²:

1. *Performance* - the primary operating characteristics or the product of services.
2. *Features* - add-ons or supplements.
3. *Reliability*.
4. *Conformance* - the degree to which a product's design and operating characteristics meet established standards.
5. *Durability* - measures of a product's life.
6. *Serviceability* - the speed and ease of repair.
7. *Esthetic* - the product's look, feel, and taste.
8. *Perceived quality* - as viewed by a customer or client.

These dimensions do not map immediately to health care, and experts have struggled to find generally applicable definitions of the quality of health care.

The situation is especially complex as a service may have multiple customers, including the patient, the general practitioner (GP), and the local health authority. The World Health Organization divided quality into four aspects³:

- Professional performance (technical quality)
- Resource usage (efficiency)
- Risk management (the risk of injury or illness associated with the services provided)
- Patient satisfaction with the services provided

Whatever definition is used, it must capture the complexity and variability of health care. One of the most widely used definitions was published by the Institute of Medicine in 1990 and states that quality consists of: the degree to which health services for individual and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge.⁴

Blumenthal has noted that health care professionals tend to define quality in terms of the attributes and results of care provided by practitioners.⁵ This technical quality of care has two dimensions: the appropriateness of the services provided, and the skill with which appropriate care is performed. The biggest change for health care professionals has been to understand that care has also to be responsive to the preferences and values of consumers, particularly the individual patient.

A further view of quality, particularly in the United Kingdom, has been espoused by Maxwell.⁶ This takes into

account not just the individual patient but a wider population approach. Maxwell's six dimensions of quality are:

1. *Access* (issues such as physical accessibility and waiting times).
2. *Relevance to need* (appropriate to the assessed needs of the whole community).
3. *Effectiveness* (ability of the treatment or service to produce the desired result).
4. *Equity* (fair distribution of resources within the publicly funded system).
5. *Social acceptability* (including issues such as the environment and privacy).
6. *Efficiency and economy* (the best possible for the best possible price).

This model has been widely used for the purchasing or commissioning of services over the last decade in the United Kingdom.

MEASURING QUALITY OF CARE

Once the dimensions of quality have been identified, it should be possible to set standards and indicators of good practice (see later discussion). However, we cannot start to improve the quality of care unless we are able to measure it. The real challenge is to find measures that are effective, that can be obtained inexpensively, and ideally that are part of the care process itself.

Quality of care may be assessed using measures of structure, process, or outcome. These three attributes were originally described by Donabedian.⁷

1. *Structure* - includes the building blocks and characteristics of health care, including buildings, equipment, and staff.
2. *Processes* - refers to all the activities forming the encounter between the health care professional and the patient, including diagnosis, tests, treatments, and record-keeping.
3. *Outcomes* - refers to the patient's subsequent health status and other effects of care, including knowledge and satisfaction.

These three attributes are interlinked, with both structure and process contributing to the outcome of care. There are implications:

- If quality-of-care criteria based on structural and process data are to be believed, it must be possible to show that variation in either process or structure leads to a difference in outcome.
- If outcome criteria are to be believable, it must be shown that differences in outcome will result if the processes under the control of the health professionals are altered.

Brook et al⁸ argue that, in health care, process measures are the most valid. Outcome measures, which may seem at first to be the most obvious measure, have also been widely used to assess quality but there are problems. Outcomes may be due, at least in part, to factors not related to the quality of care (e.g., a patient's physiologic reserve or age). Also, some

outcomes of care may become obvious only many years later; this will seriously limit their use as a tool for quality improvement. An example is the long-term outcome of good diabetic care in preventing vascular disease.

Measures of process are currently thought to be the tool of choice. An example is the management of stroke disease. The Cochrane Collaboration review of stroke units demonstrated that bringing together multidisciplinary teams and changing the process of care brought major benefits: patients managed within specialist stroke units are much more likely to be alive and at home a year after stroke than those managed on general medical wards.⁹ Local measures of outcome would not have shown this as *individual* stroke units do not have enough patients to demonstrate improved survival. Process measures, however, are useful in enabling comparisons to be made with those processes shown in the Cochrane Collaboration.

Although there are exceptions to this rule (an example might be of the outcomes of carotid artery surgery in carotid artery stenosis), process measures then are most commonly used to assess quality. Several issues arise:

1. Which data should be used?
2. Are the data reliable? The problems of completeness and accuracy of data in the National Health Service are well described.
3. Are the data valid? Are we choosing the right measures to reflect changes in quality care?
4. Are the data sensitive enough?
5. Is the evidence generalizable? For example, are data about the management of incontinence applicable to both an acute hospital and a nursing home?
6. Does the importance of the quality data justify the cost of collecting them?
7. Are the measures understandable to all users, both professionals and patients? For example, are the patient surveys that are currently used as a measure of quality helpful and understandable by all parties?

RECENT QUALITY IMPROVEMENT INITIATIVES IN THE UNITED KINGDOM

Clinical audit

Audit was formally introduced into the NHS in 1989 and was the main quality improvement technique used by clinicians in the 1990s. Clinical audit can be described as "systematically looking at processes used for diagnosis, care and treatment, examining how associated resources are used, and investigating the effect that care has on the outcome of quality of life for the patient."¹⁰

Clinical audit is usually described in the form of a cycle in which teams are encouraged to move through a process of setting standards, collecting and analyzing data, comparing the data with the standards set in a peer-review environment, and finally planning changes to improve the quality of care to meet the original standards set. The cycle is then repeated. In an environment of elderly care, it is essential that audit is undertaken by multiprofessional teams and is focused on the needs of patients.

Clinical audit is not clinical research although, like research, it requires systematic collection of standardized data. Clinical audit is not simply counting but it is not necessarily complicated. It can be done just as effectively with

a pencil and paper as with a computerized system. Clinical audit produced a great deal of activity among health care professionals, and by 1996 it was estimated that 20,000 projects had taken place with the majority of consultants (83%) and general practitioners (86%) participating. Projects in geriatric medicine included the Royal College of Physicians' CARE scheme¹¹ and regional audits of hip fractures, for example in East Anglia.¹²

The criticism and challenges of clinical audit include:

- Failure to use nationally set standards, and the use of resources on many small local projects with ill-defined standards and aims
- Failure to complete the audit cycle—projects demonstrate problems but changes are not made and no further re-audits are carried out to demonstrate improvement (or otherwise) in quality
- A lack of patient-focused audits
- A lack of links between audit and management, and between audit and education
- Far too few audits being multidisciplinary or multisectoral
- Constraints of time, staff shortages, and limitations of information technology and the failure of some staff to participate at all

Recently the General Medical Council (GMC) has made it a requirement that all doctors in the United Kingdom take part in clinical audit, and it will be a requirement for revalidation.

The problems of single department or hospital audits being able to provide meaningful changes in quality have led to newer initiatives across networks of hospitals or even on a national basis. Examples include work of the clinical effectiveness and evaluation unit of the Royal College of Physicians (rounds 1-3), voluntary audit of stroke care involving more than 80% of hospitals nationally, allowing all hospitals to measure their own performance against the national picture.¹³ Current work includes Falls and Bone Health in Older People, and Continence Services as part of the assessment of progress with the National Service Framework.¹³

Standards, guidelines, and protocols

To support clinical audit it is necessary to be clear about the standards that are being measured. During the 1990s many national and local organizations started to produce standard guidelines and protocols to inform the audit process, and to encourage a "clinical effectiveness" approach. Clinical effectiveness is seen as the extent to which the health status of patients can be expected to be enhanced by clinical interventions. Specific examples include the British Geriatrics Society's compendium of guidelines,¹⁴ and the work of the Royal College of Physicians' Clinical Effectiveness and Evaluation Unit.

Another major stimulus for assembling the evidence of effectiveness of interventions has been the Cochrane Collaboration launched in 1993. Cochrane reviews are systematic reviews of randomized control trials of health care carried out in a very precise way using the techniques of meta-analysis to pool the results of trials.⁹ The six principles of the Cochrane Collaboration are: collaboration, building on people's enthusiasm and interest, minimizing duplication of effort, avoidance of bias, keeping up to date, and ensuring access.

NHS guideline production is now principally in the hands of the National Institute for Clinical Excellence ([NICE] see later discussion) and they have set out 10 key principles for NHS guideline production (Table 125-1). The Clinical Resource and Audit Group¹⁵ defined standards, guidelines, and protocols as follows:

- *Standards* - specific statements relevant to particular criteria of care against which practice can be assessed.
- *Guidelines* - a systematically developed set of statements that assist in decision making about appropriate health care for specific clinical conditions.
- *Protocols* - a fixed set of instructions to follow in the management of conditions, designed to reduce treatment variation and improve outcomes.

In practice, guidelines are seen as advisory and protocols as mandatory. The challenge for clinicians is to integrate guidelines or protocols into everyday care, usually in the form of integrated care pathways, which aim to both ensure best care and allow easy audit to determine variation from the best pathway of care. This seems to be effective for single diseases, but becomes much more complex in the elderly-care environment, even when there is a single primary defined problem such as stroke.¹⁶

THE AUDIT COMMISSION

The Audit Commission is an independent organization reporting to Parliament. It has a statutory role to report on value for money in both health services and local authorities. The auditors have a duty to examine the economy, efficiency, and effectiveness of use of public resources. Each year a small number of topics are chosen for detailed investigation, resulting in a report describing the issues and currently

Table 125-1. Principles for NHS Guideline Production

1. The objective of NHS clinical guidelines is to improve the quality of clinical care by making available to health professionals and patients well-founded advice on best practice.
2. Quality care is based on clinical effectiveness—the extent to which health status of patients can be expected to be enhanced by clinical interventions.
3. Quality of care in the NHS necessarily includes giving due attention to the cost-effectiveness of health care interventions.
4. NHS clinical guidelines are relevant to the care provided by the NHS throughout England and Wales.
5. NHS clinical guidelines are advisory.
6. NHS clinical guidelines are based on best possible research evidence, expert opinion, and professional consensus.
7. NHS clinical guidelines are developed using methods that command the respect of patients, the NHS, and NHS stakeholders.
8. Although NHS clinical guidelines are focused around clinical care provided by clinicians, patients are treated as full and equal partners along with relevant professional groups involved in a clinical guideline development.
9. All those who might be affected by NHS clinical guidelines deserve consideration within the clinical guideline development (usually including patients and their caregivers, service managers, the wider public, government, and health care industries).
10. NHS clinical guidelines should be both ambitious and realistic in nature. They should set out clinical care that might reasonably be expected throughout the NHS.

identified best practice. The following year all organizations in the NHS offering these features are reviewed by the commission. Those for whom indicators suggest problems have an in-depth review and detailed recommendations are produced for the board of the organization. Follow-up to review progress against the objectives set usually occurs a year later.

Reports relating to older people include¹⁷: *United They Stand* (update 1999)—reviewing the coordinated care of elderly people with hip fractures; *Fully Equipped* (2000)—the provision of equipment to older or disabled people by the NHS and social services in England and Wales; *The Way To Go Home* (2000)—rehabilitation and remedial services for older people; and *Forget Me Not: developing mental health services for older people* (2000).

ACCREDITATION

In the United Kingdom and elsewhere there are external inspection systems, which may lead to accreditation. For example, within industry, the British Standards Institution has accreditation standards BS5750 and ISO9000. These are voluntary schemes that identify organizations that have reached basic standard procedures to ensure that customer requirements are met. Accreditation depends upon documentation of procedures and policies, and assessment by an accrediting team visit. In the health services this has been used mostly in facilities departments, but clinical departments, including mental health services, have on occasion achieved these standards.

Currently accreditation is out of favor as a quality management tool in the National Health Service. The Healthcare Commission (see later discussion) do yearly assessment of performance of every NHS Trust in England, the "annual health check." The National Service Litigation Authority will charge differential fees to trusts based on an assessment of their risk management service, while postgraduate deaneries will approve the delivery of standards of training for junior doctors. Although these bodies have some inspecting function and in some cases can remove or close down services, they do not formally accredit services.

Complaints procedures

Complaints form another mechanism for monitoring the quality of health care delivery. In the United Kingdom, any complaint to a hospital must be acknowledged by the chief executive within 48 hours, and there is a national standard of the complainant receiving a reply following a completed investigation within 20 working days. It is expected local resolution should resolve the vast majority of complaints in the NHS organizations, and NHS organizations all have a Patient Advice and Liaison Service (PALS), which will support complainants.

However if complainants are not satisfied, they may ask the Health Care Commission for an independent review of their case. The Healthcare Commission will appoint a care manager, who can decide how far to investigate the case; to refer the case back for local resolution; or to provide a final report and recommendations for the NHS Trust. If a complainant is still dissatisfied, the complainant has a right to refer the matter to the National Health Service ombudsman, who may decide to investigate the complaint further. The ombudsman provides an annual report to Parliament, which may "name and shame" publicly.

Since most complaints against doctors relate to poor communication, there may be particular challenges in elderly medicine both in avoiding complaints and in learning from them.¹⁸ There are distinctive features that affect communication between older patients and physicians. For example, ageism can occur in medical encounters, with physicians trivializing older people's problems. Physicians may spend less time with older people and may consider older patients to be more difficult to deal with than younger patients. Clinical discussion with older people is sometimes unusual in that a third person is often present, which complicates the communication process. These problems are additional to the generic problems of communication between doctor and patient.

The rise in the number of complaints about hospital-based elderly care was one of the main drivers that led to the setting up of the National Service Framework for Older People, an initiative from the Department of Health.

LESSONS FROM INDUSTRY ON QUALITY MANAGEMENT

The main advances in the business world in the field of quality improvement came during the 1970s and early 1980s with the understanding that quality could not be improved simply by inspection, and problems corrected by removing those defective goods or poorly performing individuals found by the inspection. In health care this is called by Berwick "the bad-apple theory."¹⁹ The bad-apple theory of improving health care suggests that, as there are increasingly sensitive and specific tools for identifying poor outlier performance (for example this might be the bottom performing 5% in a population of doctors, services, or hospitals), then by removing these outliers it is possible to improve quality. This is still the theory behind accreditation, revalidation, and purchasing to set standards.

The radical conceptual change to this was introduced by the management theorists William Deming and Joseph Duran who brought back from Japan to America the theory of continuous improvement. They found that problems in business were usually implicit in the complex production processes, and that problems with quality could only rarely be attributed to the lack of ability, will, or intention of the people involved with the processes. Thus removing the "bad apples" rarely worked. The problems were not of motivation or effort but of poor job design, failure of leadership, or unclear purpose. From this basic concept a number of models of quality improvement evolved in the business world, which have subsequently been applied patchily to the health care environment. These include total quality management (TQM), re-engineering, and benchmarking. Continuous quality improvement in its widest sense remains the major influence on U.K. health care quality improvement.

Total quality management (TQM)

The most widely used quality intervention, certainly in business, is TQM. This has been defined as²⁰:

The management of activities involved in improving the quality of the organization's product or service. TQM is a philosophy and a set of guiding principles for continuous improvement. It applies human resources and analytical

tools focused on meeting the customer's current and future needs and tries to integrate these into management's efforts.

There are several widely recognized key characteristics of TQM systems that must always involve the whole organization and focus on the customer.²⁰

- TQM has to take into account all parts of the organization.
- The chief executive and all top managers must visibly support it.
- TQM is ingrained as a value in the organization and the culture. It is not an add-on, TQM is "how we do things around here."
- Partnerships with customers and suppliers are encouraged, and the aim is to exceed the customer's expectations.
- Everyone in an organization should be trying to exceed the expectations not just of external customers but of everyone with whom they interact within the organization who may equally be a customer.
 - Cycle times can be reduced by focusing on doing the job faster.
 - Statistical quality control and the use of self-managed work teams can improve processes.
 - Do it right first time. Do not rely on inspection to identify defects, but correct the process to ensure that defects do not occur.
 - There should be corporate citizenship. The organization values everyone, both those within it and those it serves—these are often called "stakeholders."
 - No single formula works for everyone. Each organization is unique and must find its own way rather than taking an "off the shelf" approach.

Business process reengineering (BPR)

Reengineering, such as TQM, is a systemwide change approach focusing on changing the basic processes of the organization.²¹ BPR can be defined as the fundamental rethinking and radical redesign of business processes to achieve dramatic improvements in performance. Reengineering seeks to make all processes more efficient by combining, eliminating, or restructuring tasks, and the idea is to achieve large improvements in performance. Claims from the original studies suggested 100% improvement or more. Whereas TQM often looks at small continuous changes or improvements, reengineering tries to take a radical approach to large-scale changes. Certainly in the business world, reengineering can be seen as a high-risk strategy. Its success rate is under 50% and perhaps much less.

Benchmarking

Benchmarking, developed in the early 1990s, is the detailed study of productivity, quality, and value in different departments and activities in relation to performance elsewhere. The idea is basically simple. Find an organization that is good (ideally the best) at the particular process that you also carry out. Study carefully how it does well what it does, and then incorporate its technique into your own organization. This might involve looking at an organization in a completely different sector of the economy. An example in health care might be a hospital that looked at how a hotel

managed its room booking processes to maximize the use of elective beds.

Outcomes in the health service

These three techniques for quality improvement and organizational development have been applied, sometimes indiscriminately, in the health care environment. Pollitt noted how difficult it has been to implement them within the health service.²²

Seventeen pilot total TQM projects were set up by the Department of Health in 1989, and the term "total quality management" has also been applied to other projects in the health service. A number of trusts also received considerable investment for pilot schemes of reengineering. Leicester Royal Infirmary made a considerable name for itself for its one-stop neurology clinic, but demonstrable quality gains across a whole organization have not been found, at least in the NHS projects. Benchmarking as a specific project does not appear to have had an independent systematic evaluation in the health service.

Pollitt points out that these quality initiatives were difficult to implement within the health service.²² In particular, they fail to take account of the professions and the complexity of standards and guidelines emanating from professional bodies. They all require considerable time and resources and yet specialist quality training is a resource that few health care organizations have been able to deliver. Moreover, a hospital environment is far more complex than the single-process environment of a manufacturing business. Hospitals fail to match many of the key elements that would be required to translate these business approaches into the NHS. Existing quality improvement activities reflect fragmented occupational structures and relationships within the organizations. In the NHS quality still remains, in large part, as a "bolt-on" extra.

Continuous improvement

Despite the problems set out above, it is widely accepted that a continuous improvement model is most likely to succeed in achieving quality improvement in health care. It is clear that quality improvement is a painstaking and time-consuming business and that team working, team building, and leadership skills are all required for quality improvement.

One goal that has been suggested for health care is that the medical profession should move to so-called "six sigma quality."²³ The sixth-sigma goal aims for a rate of errors that lies six standard deviations outside of the normal distribution (i.e., fewer than 3.4 errors per 1 million events). Currently in anesthesia, using many techniques of quality improvement, deaths have been reduced to 5.4 per million, very close to the sixth-sigma goal. Yet 79% of eligible survivors after myocardial infarction do not receive β -blockers, a rate equal to about one sigma.²³

Berwick uses the term "continuous improvement" to mean "continuously improving systems."²⁴ He suggests a very simple model of system improvement, described by Langley et al.²⁵ This comprises three basic questions and a cycle for testing innovations (Figure 125-1). The Plan-Do-Study-Act cycle describes the growth of knowledge through making changes and reflecting on the consequences. A simple model with clear leadership is often the best place to start quality improvement processes.

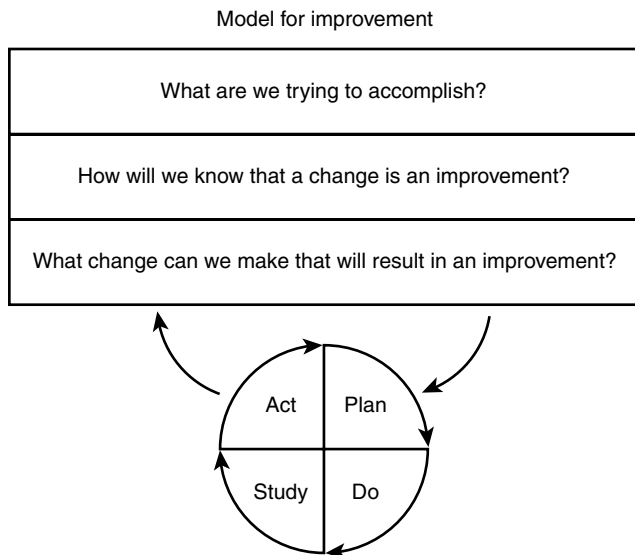

Figure 125-1. A model of improvement adapted by Berwick from Langley et al.²⁵ Reproduced from Berwick DM: *A primer on leading the improvement of systems*. *BMJ* 1996;312:619–22.

THE CURRENT NHS APPROACH

Service standards, delivery, and monitoring

Based on the 1997 NHS white paper²⁶ and the subsequent white paper, *A First Class Service*,²⁷ the government set out a new model for quality improvement within the health service. This has three main parts: clear standards of service; dependable local delivery; and monitored standards (Figure 125-2).

Clear standards of service and the national institute of clinical excellence (NICE)

Clear standards of service are being increasingly defined through two approaches. The first is the National Institute for Clinical Excellence (NICE). NICE is an independent organization responsible for providing national guidance on promoting good health and preventing and treating ill health.²⁸ It promotes clinical and cost effectiveness through guidance and audit. It advises on best practice in existing treatment options, appraises new health interventions, and advises the health service on how they can be implemented. Examples of importance for older people include: clinical guidelines on Parkinson's disease, technology appraisals of drugs in the treatment of Alzheimer's disease, guidelines on supporting people with dementia and their caregivers in Health and Social Care, and guidelines on the assessment and prevention of falls in older people. However, a major challenge for all organizations is the effective implementation and follow through of NICE guidance.

The second approach to setting standards is through the National Service Frameworks (NSFs). These set national standards and define care models for specific services or care groups, put in place programs to support implementation, and establish performance measures against which the progress and timetable can be measured. A National Service Framework should bring together the best evidence of clinical and cost effectiveness with the views of the service users to determine the best ways of providing particular services.

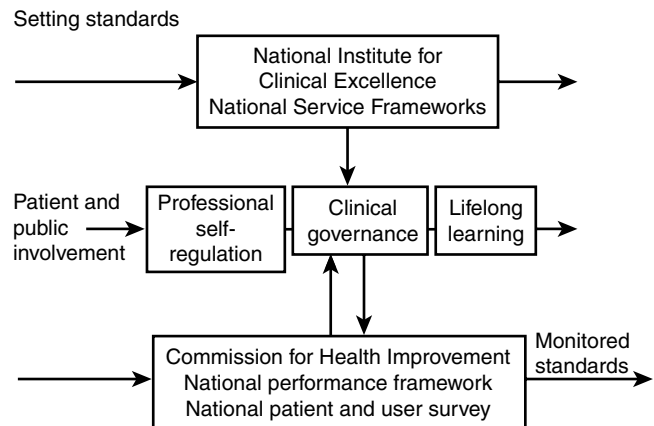

Figure 125-2. A model for quality improvement in the NHS.

The National Service Framework in Elderly Care was published in May 2001.²⁹ It contained guidelines on the management of specific conditions such as stroke and falls, on the organization of services with an emphasis on patient-centered care, and on the use of intermediate-care facilities. It has policy statements about rooting out ageism whereby older people are denied some treatments simply on account of their age. The National Service Framework has proved to be a focus for quality improvement, although the impact in geriatric medicine may not have been as dramatic as the National Service Frameworks in other areas, such as cancer and heart disease.³⁰

Dependable local delivery

The second strand of *A First Class Service* is ensuring that arrangements are in place to support dependable local delivery of good care. Professional self-regulation includes the introduction of appraisal for all doctors and revalidation through the General Medical Council. It encourages programs of lifelong learning based on effective appraisal, and the introduction of personal development plans for all staff.

For over 10 years the GMC and the government discussed concept and framework for licensing and revalidation of doctors. This will finally be introduced in 2009 in two parts. The first is relicensing for all doctors as demonstration of their fitness to practice and to continue with a license in medicine. The second aspect is recertification in the specialty that they are currently documented in the Medical Register. This recertification in specialty will occur on a 5-year rolling basis, but the detail of the standards—how they will be assessed for all clinicians—remains to be agreed on between the GMC and Royal Colleges.

It also involved the quality improvement tool of “clinical governance” (see later discussion).

Monitoring and publicizing standards

Thirdly, the government put in place systems to monitor and publicize standards. The Healthcare Commission is the independent inspection body for both the NHS and independent health care.³¹ It is responsible for assessing and reporting on the performance of health care organizations to ensure they are meeting expected standards of care while encouraging them to continually improve their

services and the way they work. The Healthcare Commission works by setting standards and requiring all organizations to undertake a self-assessment against those standards on an annual basis. They then use a risk-based approach to validate those assessments or to investigate where there have been allegations of serious service failings or concerns for patients' safety. A huge amount of data is published each year including the annual health check. The standards of care covered:

- Safety - is it safe for patients?
- Clinical and cost-effective - is it providing treatment in line with national guidelines in the most effective way.
- Governance - is it well run?
- Patient focused - does it organize its services around the needs and preferences of patients?
- Accessible and responsive care - is it easy to get the care you need without unreasonable delays?
- Environment and amenities - is the place where you are treated well designed and maintained?
- Public health - does it improve, promote, and protect the health of local people?

The Healthcare Commission reports annually to Parliament. If the Healthcare Commission has concerns that an organization is unsafe, it does have statutory powers of enforcement.

Clinical governance

Within the process of inspection, standard-setting, and attempts to measure quality, the main driver for clinical quality improvement at the local level is the concept of "clinical governance."³² Clinical governance is defined as: "a system through which NHS organizations are accountable for continuously improving the quality of their services and safeguarding high standards of care by creating an environment in which excellence in clinical care will flourish."

Clinical governance is seen as a process of continuous quality improvement in health care along the lines described by Berwick.²⁴ This aims to put quality at the heart of what health care organizations do in the United Kingdom as opposed to merely bolting it on or "inspecting it in." For the first time, the chief executives of trusts became personally responsible for the quality of health care provided in their organizations.

The seven pillars underpinning clinical governance include: clinical effectiveness, risk management effectiveness, patient experiences, communication effectiveness, resource effectiveness, strategic effectiveness, and learning effectiveness. At a local level this involves integrating a focus on safety and risk management with continuous professional development and lifelong learning. Also understanding an individual practitioner's performance with both patients and their colleagues while setting this in the wider context of organizational delivery and the expectations of the Healthcare Commission. Tools at a local level include patient surveys, appraisal systems including 360 degree feedback, audit data about comparative individual and team performance and outcomes, and a rigorous approach to clinical incidents and risk management. Patient safety issues, for example, reducing health care related infections, have

become a major focus of clinical governance activities over the last few years.

Clinical governance in geriatric medicine

The British Geriatrics Society and the Royal College of Physicians published a position paper in 1999 on interpreting clinical governance and its implications for geriatric medicine.³³ Along with recommending an integrated common scheme for clinical governance, the paper made specific recommendations for individual practitioners, and for services within an organization and the services crossing organizations. An integrated common scheme was based on the clinical governance cycle (Figure 125-3). This requires practitioners or services to consider each aspect of the cycle.

- *Standards* include those set by NICE and the National Service Framework, along with professional standards from the GMC and legal standards.
- *Professional qualities* are based around the individual or the service needs for differing knowledge and skills. These may vary over time and are not exclusively clinical.
- *Service delivery and organization* includes the use of guidelines and protocols, and analysis of whether the structures available within the organization can deliver the care that is required.
- *Monitoring* includes systematic evaluation of clinical audit, both local and national; complaints; risk assessment; national performance indicators; critical incident reviews; national patient surveys; and external body reviews such as the Healthcare Commission.
- *Change management* includes all those processes that can be used to improve the quality of care, such as the quality improvement tools discussed within this chapter.

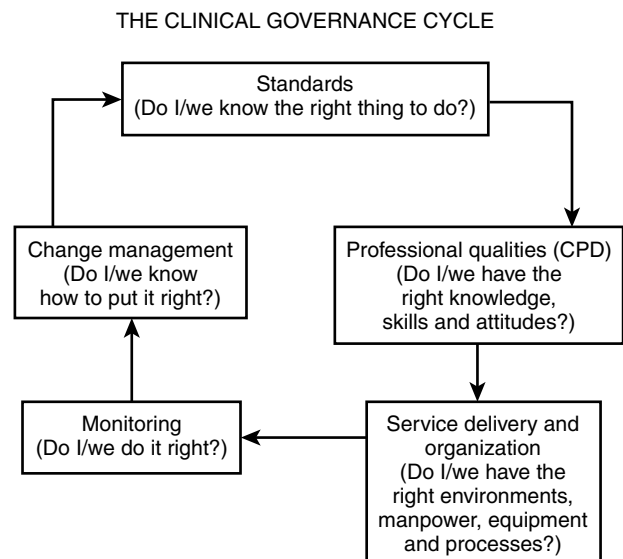

Figure 125-3. The clinical governance cycle. Reproduced from British Geriatrics Society and Royal College of Physicians of London: *Clinical Governance: A Position Paper*. London, 1999.

The British Geriatrics Society has further considered guidelines for implementing clinical governance at the departmental level.³⁴ Key areas of implementation are:

1. Each department of geriatric medicine should have a nominated lead consultant in organizational service quality.
2. The appropriate participation of consultants in geriatric medicine in processes covering each element of the clinical governance cycle should be clearly demonstrable.

If clinical governance is to be successful, it must have the same strengths as corporate governance: it must be rigorous in its application, have an organizationwide emphasis, and be accountable in its delivery, developmental in its thrust, and positive in its connotations. The drive to clinical governance is by far the most ambitious quality initiative that has ever been implemented in the NHS. It is too early to say whether clinical governance will bring about the revolution in quality improvement that was promised at its launch; however, it can be seen how the various quality initiatives of the previous 20 years have been drawn together into an integrated common scheme, which is more closely in touch with the reality of the National Health Service rather than the business world.

Long-term care

Geriatric medicine in the United Kingdom grew out of long-term care with attempts to improve the quality of care of older people in that environment.

Changes in social security funding led to massive expansion of private sector provision, in particular nursing-home care in the 1980s and 1990s. The vast majority of long-term nursing-home and residential-home care is now in the private and "not-for-profit" sector. The main driver for standards remains inspection. The Commission for Social Care Inspection is now the regulatory and inspecting body for all social care services in the private, public, and voluntary sectors including all care homes. Inspection processes in the past have been very much based on structure rather than process of outcome. There is an increasing move to try and produce more data regarding overall quality with a new star rating system being introduced in 2008.

In 1992, the Royal College of Physicians and the British Geriatrics Society produced the first document on guidelines and audit measures in long-term care followed by a clinical audit scheme called the CARE (Continuous Assessment Review and Evaluation) scheme.¹¹ This allowed users to

audit seven main domains (Table 125-2) and encouraged a process of continuous review and reassessment. Although not widely used, where it has been used there is some evidence of improvement.³⁵ Yet the problems of improving quality in long-term care, particularly the medical aspects, remain.³⁶ Among the recommendations are reengagement of physicians in geriatric medicine in long-term care within the community, a whole-system approach to planning care, and the development of a new nursing role for the gerontological specialist. The current drive in the NHS to move specialty care out into the community to support community activity is an opportunity to revitalize and improve medical care for older people in the community particularly in long-term care.

Aids and adaptations
The medical role in long-term care

KEY POINTS

Improving Quality of Care in the United Kingdom

- Quality in health care has a number of dimensions, which makes definitions, standard setting, and measurement complex.
- Until recently the main approaches to improving quality involved inspection of services and encouragement for clinical audit.
- During the 1990s, new approaches from business introduced the ideas of continuous quality improvement, although implementation, in large part, has been haphazard and inadequately understood and resourced.
- The U.K. government has introduced the concept of "clinical governance," which now places a responsibility on all professionals to be accountable for not only maintaining but also improving standards of care within the health service.
- There is still huge room for improvement in our approaches to improving the quality of care of older people in the United Kingdom.

Preserving Medicare Through a “Quality” Focus

Richard G. Stefanacci

MEDICARE’S NEW FOCUS ON QUALITY

Guardians of Medicare believe that the answer to preserving Medicare is to focus on quality improvement. The Institute of Medicine (IOM) describes quality health care as care that is, “safe, effective, patient-centered, timely, efficient, and equitable.” These six determinates were part of their watershed document, *Crossing the Quality Chasm: A New Health System for the 21st Century*.¹ The Agency for Healthcare Research and Quality (AHRQ), an arm of the federal government, defines health care quality as, “doing the right thing for the right patient, at the right time, in the right way to achieve the best possible results.”²

Both definitions provide a clear picture of quality health care based on scientific evidence. It is also clear that by focusing on quality, not only will Medicare beneficiaries benefit, but Medicare as a whole will through reduction in expenditures. These reductions in expenditures are the result of decreased waste and preventive measures resulting in a decrease in our current and future health expenditures. This is a shift from health care reform that has traditionally started with the presumption that the major problem is high costs.

In 1965 when Medicare was born the expenses were limited both because of the limited availability of services and the demand. The total number of Medicare beneficiaries was around 10 million while the average life expectancy for a Medicare senior at that time was about 4 years. Today with almost an unlimited availability of innovative expensive services in the face of exploding demand, Medicare is facing resource management challenges. This demand for services is driven by baby boomers now numbering over 40 million with life expectancy when they reach Medicare of an additional 20 years. Rather than restrict benefits, Medicare instead is looking toward quality improvement as a means to operate more efficiently and effectively.

The evidence of quality shortcomings is substantial and growing. The following are a few examples:

Researchers from the RAND Corp. have found that, on average, Americans receive the care indicated by medical evidence as necessary only 55% of the time. Most of these results reflect underuse of necessary care that can lead to needless complications, adding to health care costs and reducing productivity. Some results reflect overuse of unnecessary care that increases costs directly, and if complications occur, can further increase costs and threaten the health of patients.

A 1999 Institute of Medicine (IOM) report estimated that as many as 98,000 Americans die each year as a result of avoidable patient safety errors, while the Centers for Disease Control and Prevention has estimated that 90,000 Americans die each year due to hospital-based infections. These reflect misuse, another quality problem that leads to preventable deaths and injuries.

There also are examples of enormous variations in delivery of care nationally, regionally, and locally. A report to Congress by the Agency for Healthcare Research and Quality

(AHRQ) found that the proportion of elderly patients with pneumonia who received recommended pneumococcal screenings or vaccinations in the highest-performing state was 7.5 times higher than in the lowest-performing state. Researchers at Dartmouth University have shown that Medicare expenditures in Los Angeles were twice as high compared with Sacramento for care given to persons in the last 2 years of their lives. These results indicate that care for these Medicare beneficiaries was not based on standardized or evidence-based guidelines. Similarly, a recent analysis of data from the Hospital Quality Alliance (HQA), the first initiative to report routinely on hospital performance, showed that the quality of hospital care varies widely, not only by geographic region and hospital type, but also across conditions within individual hospitals.

This focus on quality has been demonstrated both behind and in front of the scenes. Perhaps the most expressive of which was the name change from the Health Care Finance Administration to the Centers for Medicare and Medicaid (CMS). As CMS, Medicare is now exerting a greater influence on quality rather than simply on finance, although Medicare’s focus on quality improvement is hoped to have a substantial effect on extending Medicare’s resources. They are dearly needed as the number of Medicare beneficiaries doubles over the next 2 decades.

Historically, Medicare reimbursement has been based on volume of acute care services provided. However, the current belief is that if we just keep paying the bills the same old way, we will not get higher quality, more efficient care. Medicare has long provided critical support for hospital and doctor care when beneficiaries have complications from their diseases. But Medicare’s benefits have not kept up with the shift toward preventing diseases and their complications that has been such an integral part of the progress in medical care in the past 35 years. Medicare has not paid for many preventive tests to detect diseases early or prevent them in the first place, or for programs that help our beneficiaries with chronic illnesses to take proven steps to prevent their complications, or for the prescription drugs that can head off the costly and often deadly consequences of chronic illnesses. Consequently, Medicare has seen rapid spending growth on the complications of diabetes, heart disease and failure, lung disease, advanced cancers, and many other illnesses. By closing the gap in prevention-oriented coverage, Medicare believes it can foster the health care system to deliver higher-quality care.

It is often stated that the three most important measures for a health care system are access, cost, and quality. Although much of the focus has been on the components of cost (price times use), perhaps the most difficult to define and measure is quality. In addition to being the most difficult to assess, quality is not necessarily directly effected by the cost of health care, making it even more difficult to improve since simply adding more dollars does not always improve quality. In fact several studies demonstrated that regions of

high Medicare spending did not enjoy better quality.³ Fisher found that higher spending was the result of a greater use of inpatient-based and specialist-oriented patterns of practice. So to achieve better health outcomes, it takes more than just added dollars but an approach focused on quality.

Of course the focus on quality is not entirely new. Since its beginning, Medicare has been keenly interested in ensuring quality care for its beneficiaries. This push for quality health care has evolved slowly over time; first, focusing primarily on a regulatory approach while at the same time building some assistive programs for providers to achieve quality care delivery standards. Most recently Medicare has moved to effecting the demand and supply for quality Medicare services by using market forces. Medicare has undertaken a strategy of measuring, reporting, and rewarding performance in health care through both the demand and supply side. On the demand side this is accomplished through the use of public reporting of quality data. The thought is that consumers will be driven toward higher quality providers and away from lower quality providers. On the supply side, the focus is pay-for-performance measures and a reimbursement system that rewards high-quality providers financially, providing them the resources to expand their services.

Starting with a regulatory approach

In the early days of Medicare the focus for achieving quality outcomes was strictly regulatory. This regulatory approach to assuring quality has existed since the beginning of the Medicare program. The focus here has primarily been on fraud and abuse prevention. Regulation against fraud and abuse is thought in many circles to be the best defense against this problem, which is currently estimated to cost Medicare and Medicaid about \$33 billion each year. Medicare fraud is defined as purposely billing Medicare for services that were never provided or received. This is of course not to say that CMS regulations all fall in the area of fraud and abuse. In the area of nursing home care, for example, state surveyors are armed with volumes of regulations to enforce such things as food temperature and the storage of medications.

In the move toward quality many have outlined plans for achieving better quality results that go beyond regulations; Steinberg published his four actions needed to produce the greatest effect.⁴ His actions included the following:

- Quality of care should be measured and reported routinely at both the national and provider-specific levels.
- We must make greater use of information technology.
- We should draw on the power of patients to improve the quality of care they receive and their health outcomes.
- Current financial incentives need to be redesigned so as to not discourage quality improvements.

Movement away from a pure regulatory focus is in part due to the fact that quality problems persist despite a decline in deficiencies. Also there is concern that over time effectiveness of regulations decline.⁵

Reporting quality to push demand

For Medicare's first 3 decades very little public reporting of data was available. Even the commercial world data was limited to information available in HEDIS (Health

Plan Employer Data and Information Set.) CMS began its move in the collection and use of data on a grassroots level through peer review organizations (PROs), now referred to as Quality Improvement Organizations. PROs systematically promoted improvements in quality measures tracked using voluntary, collaborative, and educational approaches.

Initial reporting of quality measures was viewed as a way to promote self-improvement as providers compared themselves to their competitors. This role of reported quality data has evolved. The first change was to use the data to promote movement of patients to higher quality providers.

This worked especially well as payers shifted more of the cost of insurance to patients and their families and asked them to take a greater role in decisions about their care. This model of "consumer-directed health care" aims to give patients incentives to make informed decisions and choose necessary, cost-effective care. However, this model assumes that patients will have sufficient information about the quality, performance, and costs of hospitals, doctors, health plans, and others that deliver care. Consumers report that they do not generally have this kind of information available to them.

To help patients gain access to this information companies such as HealthGrades have developed. HealthGrades is the leading health care ratings organization, providing ratings and profiles of hospitals, nursing homes, and physicians to consumers, corporations, health plans, and hospitals. Millions of consumers and hundreds of the nation's largest employers, health plans, and hospitals rely on HealthGrades' independent ratings to make health care decisions based on the quality of care. Visitors to HealthGrades.com find quality ratings of the nation's 5000 hospitals and 16,000 nursing homes along with in-depth profiles of the nation's 650,000 physicians. As a leader in the consumer revolution in health care, HealthGrades receives more than 2.5 million unique visitors to its consumer Web site each month. It is thought that this type of information is what is needed to move toward consumer driven health care. This is moving the medical market on the demand side through the use of public reporting of quality data. Again, the thought is that consumers will be driven toward higher quality providers and away from lower quality providers.

Quality measurement and reporting in health care are crucial for identifying areas in need of improvement, monitoring progress, and providing consumers and purchasers with comparative information about health system performance. Although several measurement systems are used routinely to assess ambulatory, hospital, and long-term care, a systematic assessment of quality across spectrums of care is lacking. Spurred by rising costs and lagging quality improvement, large purchasers, health plans, and others have developed and implemented a variety of approaches that seek to reward high performance and create incentives for quality improvement. Efforts to improve and increase care measurement and align the incentives of providers through pay-for-performance programs are important building blocks in developing a health care system that performs more effectively and efficiently. Federal leadership is important to provide consistency to measurement and incentive systems so that the nation can gain the full value of these tools.

The measuring and reporting of quality measures is a very active process as there continues to be many barriers.

Barriers that include: limited availability of data, the burden associated with collecting or obtaining data, and the generally poor quality of data, including insufficient level of detail and lack of timeliness.

Even with following guidelines consensus regarding appropriate quality measures is not always agreed upon. Many feel that quality cannot be reflected in a single, meaningful criterion because it involves many criteria emerging from preferences of multiple constituencies—policymakers, health care professionals, administrators, owners, investors, third-party insurers, and consumers. Such values and preferences may overlap, but they may conflict as well.⁶

In evaluating measures that are important to measure, the following criteria have been recommended to follow:

- The disease is prevalent and a major source of morbidity or mortality in the Medicare population
- There is strong scientific evidence and practitioner consensus that there are processes of care that can substantially improve outcomes
- Reliably measuring the delivery of these processes is feasible
- There is a substantial “performance gap” between current performance and desirable performance
- There is at least anecdotal evidence that QIOs can intervene effectively to improve these performance measures.

As a result the first series of measures focused on acute myocardial infarction, heart failure, stroke, treatment and prevention of pneumonia, breast cancer, and diabetes.

A change in direction: pay-for-performance (P4P)

In 2001, the Institute of Medicine (IOM) identified the flat-rate fee schedule as a barrier to quality improvement and recommended that CMS adopt reimbursement policies linked to quality improvement such as through a pay-for-performance system.⁷

Thus data can be used to drive demand for services but on the other side CMS is also using data to drive supply by increasing the resources given to high-quality providers through pay-for-performance initiatives. Here the focus is pay-for-performance measures and reimbursement systems that reward high-quality providers financially, providing them the resources to expand their services. Medicare is testing two quality-based bonus reimbursement models for hospitals and large physician groups. On the hospital side, Medicare is awarding bonus Medicare payments to hospitals based on their performance on evidence-based quality measures for inpatients with heart attack, heart failure, pneumonia, coronary artery bypass graft, and hip and knee replacements. Within these five clinical areas, CMS will evaluate hospital performance on 34 measures. The Physician Group Practice Demonstration tests a hybrid payment method for paying physicians by combining Medicare fee-for-service payments with a bonus pool derived from savings achieved through improved management of patient care and services.

The pay-for-quality concept is not new, as insurers such as Independence Blue Cross (IBC) and Highmark Blue Cross Blue Shield have for years offered reimbursement bonus

in addition to their capitation payments to primary care physicians who follow clinical guidelines such as Health Plan Employer Data and Information Set (HEDIS).

There is a growing belief that current payment systems not only fail to reward or encourage quality and quality improvement but sometimes actually penalize them. Many payment systems pay for each service rendered on a fee-for-service basis. As a result, if a hospital, physician, or other provider performs fewer or less intensive services by following evidence-based guidelines, the organization or provider receives less money. As the IOM stated in its Quality Chasm report, policymakers must align payment incentives with the drive to improve quality.

Today, the Medicare payment policy is structured so as to align payments with provider performance. The Medicare Payment Advisory Commission (MedPAC) is required to consider a variety of measures because the direct relevance, availability, and quality of information in each potential indicator varies among providers.⁸ In the development of measurements the focus has started in the areas of structural capacity and process standards before moving to outcome measures. The reason for these starting points before moving to outcome measures is the following:

- There is more consensus on appropriate processes.
- Measuring processes of care are generally easier, requiring no need for risk adjustment.
- It is easier for practitioners to identify and fix the reasons why critical processes of care are not being met.
- Many outcome measures take years to calculate their effect.⁹

The AMA House of Delegates amended and approved the AMA Principles and Guidelines for the formation and implementation of pay-for-performance programs.

As the pay-for-performance concept becomes more commonplace, the physician community will work to ensure pay-for-performance programs are positively structured and appropriately applied. The AMA believes pay-for-performance programs must be aligned with the following five principles:

- Ensure quality of care
- Foster the relationship between patient and physician
- Offer voluntary physician participation
- Use accurate data and fair reporting
- Provide fair and equitable program incentives

In the end CMS's movement toward quality measures as a means to push the demand and supply of provider systems will have profound effects on how physicians practice

MEASURING QUALITY

Physician

Medicare payments for physician services are made on the basis of a fee schedule, which has been in place since 1992. The Medicare fee schedule is intended to relate payments to the actual resources used in providing the health care services. The fee schedule assigns relative values to services that reflect physician work (i.e., time, skill, and intensity it takes to provide the service), practice expenses, and malpractice

costs. These relative values are adjusted for geographic variations in costs.

In addition to responding to external pressures to measure quality performance, some payers have taken the initiative to measure the quality performance of individual physicians or physician groups.^{6,7} Typically, physician or physician group performance is compared with peers, adjusting for differences in case mix. This profiling of physician performance relative to peers often includes comparisons on health care use and cost along with measures of quality. The objective of the payer is to compensate physicians on the basis of quality and use management.

In practice, producing credible physician profiles of quality are difficult for individual HMOs to do. The physician's contribution to health care usage and costs is known to the health plan from administrative records (claims paid for services provided under fee-for-service, and capitation payments made for services provided under capitation). The physician's quality performance is more difficult to measure with the claims data typically used by health plans for this purpose. In particular, primary care physicians under capitation will generate limited claims for services assessed in process measures of quality. An exception is the fee-for-service reimbursement of immunizations to remove any disincentive to provide the preventive measure and to provide data to the health plan. Furthermore, some services of quality performance such as whether a diabetic in the health plan received a hemoglobin A_{1c} are not available on many payers databases.

The 2006 Tax Relief and Health Care Act (TRHCA) (P.L. 109-432) required the establishment of a physician quality reporting system, including an incentive payment for eligible professionals who satisfactorily report data on quality measures for covered services furnished to Medicare beneficiaries during the second half of 2007. CMS named this program the Physician Quality Reporting Initiative (PQRI).

The Medicare, Medicaid, and SCHIP Extension Act of 2007 (MMSEA) was enacted on December 29, 2007 (Pub. Law 110-173). MMSEA authorizes CMS to make PQRI incentive payments for satisfactorily reporting quality measures data. Eligible professionals who meet the criteria for satisfactory submission of quality measures data for services furnished will earn an incentive payment of 2% of their total allowed charges for Physician Fee Schedule (PFS) covered professional services furnished during that same period. This incentive payment has been increased since the introduction of the program in 2007.

The 2008 PQRI consists of 119 quality measures, including two structural measures. One structural measure conveys whether a professional has and uses electronic health records (EHR) and the other electronic prescribing. Besides providing PQRI information during a patient encounter in the form of a completed billing/HCF 1500 form, CMS has also opened up submission through registries. In an era of EHR this is especially efficient. Providers can manage and submit data on the PQRIs of their choosing from their EHR database.

To test the effectiveness of the pay-for-performance system, CMS implemented a demonstration program. The Physician Group Practice demonstration provided rewards to large, multi-specialty group practices for improving the quality of care and reducing the cost increases for their

patients. Unfortunately in this first application of the pay-for-performance initiatives, the "Physician Group Practice Demonstration" found that a number of groups did not earn performance payments because they did not generate savings to the Medicare program despite incurring upfront costs to improve care management systems that totaled millions of dollars in some cases.¹⁰

Besides the effectiveness in providing a return back to physicians who participated in this pay-for-performance program, another barrier to their impact on quality is the fact that since many physicians contract with several payers in their market area, only a portion of the physician's patients will be a member of a given payer. A profile produced by any given payer may be based on a small sample of the physician's patients. Furthermore, performance measures may differ on the profiles produced by the different payers for which the physician contracts. Because physicians are more likely to dismiss as flawed the results of profiles produced under these circumstances, their effectiveness in improving performance may be limited. Furthermore, some performance measures monitored by the payer are population-based; however, a fraction of payer members do not see their physicians regularly. Physicians have no opportunity or infrequent opportunities to demonstrate that they have provided quality care for this fraction of the payer's members for which they are responsible. Again, physicians will not view such measures as credible gauges of performance. However, with Medicare as the major driving force in the development and implementation of physician quality measures, the thought is that other payers will follow making these quality measures universally accepted.

Hospital

CMS hospital quality measures come from information collected by hospitals that volunteer to provide data for public reporting. The information is intended to illustrate how quality of care can vary between hospitals. Currently, the quality information relates to the care given for patients with three serious medical conditions that are common in people with Medicare:

- Myocardial infarction (i.e., heart attacks)
- Congestive heart failure
- Pneumonia

CMS first attempted to collect this information on a purely voluntary basis, but could not garner sufficient interest from hospitals. When voluntary participation failed, CMS tied submission of quality data to payments for services administered to Medicare patients. Today, hospitals that fail to submit data are not eligible for the payment increase applied to the payment, which can translate to as much as a 0.4% reduction in revenue for some facilities. This increased financial support resulted in almost 99% of U.S. hospitals (over 4200 hospitals) providing data for comparative quality measures. It is now been proposed that the measures will be expanded to include outcomes such as patient satisfaction and surgical complications. Measures of hospital efficiency are also under consideration.

Measures of hospital quality have been developed through the Hospital Quality Alliance (HQA). The HQA consists of more than a dozen organizations including AARP, AFL-CIO,

AHRQ, AHA, AHIP, AMA, ANA, and JCAHO to facilitate nationwide public reporting of useful quality measures by hospitals. All of this activity was done in a transparent, collaborative fashion with the goal of providing more information to consumers and practitioners to lead to better performance.

The hospital data is reported online through Medicare's Hospital Compare site. In this tool information on how well hospitals care for patients with certain medical conditions or surgical procedures, and results from a survey of patients about the quality of care they received during a recent hospital stay is reported. This information is provided to help patients compare the quality of care hospitals provide, again as a means to drive demand to the higher quality providers.

Expansion of this program is being tested through CMS demonstration programs. One such program has CMS collaborating with Premier, Inc., a group of nonprofit hospitals, to operate a demonstration to improve their quality of care. This demonstration tracks and reports quality data for 34 measures at each of about 270 participating hospitals. Under the demonstration, top-performing hospitals will receive incentive payments for the care of inpatients with any of five conditions: acute myocardial infarction, heart failure, community acquired pneumonia, coronary artery bypass graft, and hip and knee replacement. Participating hospitals will get composite scores for each of the five clinical conditions, and the hospitals will be ranked in order of their scores. Hospitals with scores in the top 10% will get a 2% bonus of their payments for Medicare fee for service patients, whereas hospitals with scores in the second 10% will get a 1% bonus. Early results are promising, showing improvement in quality scores for the participating hospitals. It is expected that lessons learned from the Premier demonstration will shape our future hospital pay-for-performance initiatives.

Nursing home

With 3 million of the frailest Americans relying on services provided by a nursing home at some point during the year and of them 1.5 million staying long enough to consider the nursing home their main residences,¹¹ it should come as no surprise that nursing homes are heavily governed to assure appropriate care. But even with heavy oversight one in five nursing homes nationwide were cited for serious deficiencies, deficiencies that caused actual harm or placed residents in immediate jeopardy.¹²

Some major areas of focus identified by nursing home medical directors include the following¹³: telephone conversations, transitional care, falls and hip fracture, Coumadin use, pressure ulcers, inappropriate medications, pain control, urinary incontinence, weight loss, and exercise.

Under the Omnibus Budget Reconciliation Act (OBRA) of 1987, nursing homes participating in the Medicare and Medicaid programs are required to monitor nursing-home residents using the Resident Assessment Instrument (RAI). The RAI consists of the Minimum Data Set for nursing home resident assessment and care screening (MDS), which assesses functioning on activities of daily living (ADLs), cognition, continence, mood, behaviors, nutritional status, vision and communication, activities, and psychosocial well-being. Problems or risks for decline identified through the MDS assessment will trigger further assessment on one or more of the RAI's 18 resident assessment protocols, which are used

to identify treatable causes of problems common to nursing home residents.¹⁰ The OBRA 1987 requirements, which became federal law in 1990, were the result of widespread evidence of poor quality of care in nursing homes. Prior studies found prevalent use of physical restraints, inappropriate use of psychotropic medications, overuse of urinary catheters, and inadequate treatment of incontinence, pressure ulcers, nutritional problems, and behavioral problems.

Several studies compared process quality and patient outcomes before implementation of the RAI with the postimplementation period and found evidence of improvements. More specifically, in a study of 254 nursing homes in 10 states, accuracy of information in medical records, comprehensiveness of care plans, presence of advanced directives, participation in activities, and use of toileting programs for those with bowel incontinence improved after implementation of the RAI. Use of physical restraints declined by 25% and use of indwelling catheters declined by 29%. Another study of 267 nursing homes showed that the rate of decline in ADLs, social engagement, and cognitive function was reduced after the introduction of the RAI.

Nursing Home Compare includes information only on nursing homes that are Medicare or Medicaid certified. The data on this Web site refers to the regulatory requirements that the nursing home failed to meet but does not reflect the entire inspection report (which, in some cases, may be well over 100 pages in length). The detailed inspection report (the form HCFA-2567) contains the specific findings that support the state's determination that the requirement was not met. A complete inspection report and the nursing home's corresponding plan of correction to address the deficiencies found during the inspection are available from the state survey agency or from the nursing home itself.

The Department of Health and Human Services (DHHS) has a national Nursing Home Quality Initiative to improve the quality of nursing home (NH) care. A critical part of this initiative is CMS's posting of quality indicators for every NH on 10 quality indicators.¹⁴ These "report cards" are intended to be used by consumers to make informed decisions and motivate providers to improve their care. The CMS quality initiative is a major redirection to focus on clinical care needs of the frail elder instead of historically focusing on the process of care. This is the result of a shift toward the resident and away from the institution. Although fairly well received, these nursing home report cards have been said to have limited value because of their failure to adjust for differences in risk in different long-term care facilities.¹⁵

Measures of nursing home quality as part of the Nursing Home Quality Initiative, has already achieved important improvements in aspects of nursing home care such as use of restraints and controlling pain. This alliance recently expanded and refined its measures and is taking further steps to improve additional important outcomes and efficiency, such as to reduce pressure ulcers and avoid hospital admissions with preventable complications.

CMS under its 2007 Action Plan¹⁶ addresses nursing home quality through:

- Web-based report card "Nursing Home Compare"
- Expanding the certification and survey process
- Adding a pilot test pay-for-performance under the heading of "value-based purchasing"

In the Nursing Home Value-Based Purchasing Demonstration, the hypothetical savings for the incentive payments would come from reductions in hospitalizations and subsequent skilled nursing facility stays. The problem is that if no savings are generated, no performance payments will be made, regardless of the nursing homes' performance.¹⁷

Managed care plans

Medicare beneficiaries began enrolling in Medicare MCOs in 1985 under provisions of the Tax Equity and Fiscal Responsibility Act (TEFRA). However, it would be more than a decade later that the Medicare program would begin ongoing review of health care quality in Medicare MCOs. This was because PROs had access to Medicare fee-for-service claims for random case selection, but did not have access to Medicare MCO claims for the same purpose. In the interim, comprehensive evaluations of quality performance were conducted under contract with CMS by Mathematica Policy Research for both the Medicare HMO demonstrations and the Medicare MCOs contracting in the first 5 years of the TEFRA risk-contracting program.¹⁸ The evaluations, which compared measures of process and outcomes for beneficiaries receiving care in Medicare MCOs to Medicare fee-for-service, reported that quality performance under MCOs and fee-for-service were quite similar. Although comprehensive, these evaluations did not have the surveillance effect of the ongoing review of cases by the PROs. In addition, standards for quality performance and quality improvement measurement in commercial MCOs (i.e., MCOs other than Medicare and Medicaid), such as HEDIS and NCQA accreditation, were in notable contrast to the lack of comparable quality performance standards for Medicare HMOs.

The lack of ongoing quality performance measurement in Medicare managed care ended in 1998, when CMS first required HEDIS reporting by Medicare MCOs. In addition, CMS required Medicare MCOs to submit for audit the beneficiary-level data used in the computation of the HEDIS measures. As part of the current HEDIS reporting set, CMS requires Medicare MCOs to conduct a longitudinal survey of health status for a random sample of the MCO's Medicare beneficiaries. Using the SF-36, the Health Outcomes Study compares the health status of beneficiaries surveyed in a baseline year with their health status measured 2 years later.

Under the 1997 Balanced Budget Act, the Quality Improvement System for Managed Care (QISMC) was established and became operational in 1999. QISMC applied many of the same principles of CQI adopted by the PROs in the Health Care Quality Improvement Program. More specifically, Medicare MCOs were required to measure clinical performance in the prevention or treatment of acute and chronic conditions, high-volume services, high-risk services, and continuity and coordination of care. Similarly, QISMC requires measurement of performance in nonclinical areas such as availability of and accessibility to care, quality of provider encounters, and resolution of appeals, grievances, and other complaints. For clinical and nonclinical areas selected by HCFA and the MCO, QISMC requires Medicare MCOs to develop and implement interventions for improving performance, and remeasure performance over time to demonstrate quality improvements. QISMC also imposes standards on methods of performance measurement; for example, they must be unambiguous, based on current clinical knowledge

or health services research, and measure outcomes such as health status, functional status, beneficiary satisfaction, or valid proxies of the measures (ref. 4 QISMC standards). Performance must be measured over all relevant providers and beneficiaries at risk, and valid sampling methods must be used if performance is not measured for all beneficiaries at risk. A quality-improvement project under QISMC standards requires a minimum of 3 years: measurement of baseline performance in the first year, remeasurement of performance in the subsequent year when significant performance improvement is demonstrated, and continued measurement for a year beyond achieving significant improvement to demonstrate that a higher performance has been sustained over time.⁴

CMS is also paying organizations in Medicare to help chronically ill beneficiaries get better continuity, support, and treatment for their care. This includes Medicare Advantage health plans, including HMOs, PPOs, and fee for service plans that offer additional benefits. Medicare is moving to full "risk adjustment" of payments to these plans, so that to do well in Medicare, a health plan must pay particular attention to providing benefits that are attractive to beneficiaries who are chronically ill, frail, or dually eligible. This year, Medicare Advantage plans are more widely available than ever before in the history of the program, with well more than 90% of beneficiaries having access. And beneficiaries can save about \$100 a month on average compared with the traditional plan with or without a Medigap plan they purchase on their own, with beneficiaries in fair or poor health able to save even more. In fact, this year, there are over 50 plans specializing in coordinated care for dual-eligible and chronically ill beneficiaries around the country, and many more such plans are expected to be available next year although Medicare Advantage plans may be subject to substantial reductions in their revenue from CMS as a result of a political switch toward traditional Medicare.

Working beyond Medicare Advantage plans, CMS is also working to bring better continuity of care and support for chronically ill beneficiaries in the traditional Medicare plan, by creating financial incentives through our Medicare Chronic Care Improvement Program (CCIP). Medicare CCIP is designed to help beneficiaries who account for a majority of Medicare costs today - those with diseases including congestive heart failure, complex diabetes, and chronic lung diseases. The evidence shows that it is possible to improve outcomes and lower costs by avoiding disease complications, by helping beneficiaries understand their disease, their physician's treatment plan, how they can improve their outcomes through medication compliance and certain lifestyle steps, and what to do with early signs of poor disease control. Now, organizations participating in Medicare CCIP initiative will get paid by Medicare when they get improvements in valid clinical quality measures, patient and physician satisfaction measures, and total Medicare costs. Their payments will come from some of the savings they create, and successful programs will have an opportunity to expand.

Prescription drug plans

Quality measures and reporting is involving all areas of Medicare including its newest benefit, Medicare Part D, the prescription drug benefit. Medicare Part D plans since their beginning in 2006 have been responsible for providing medication therapy management (MTM). MTM is viewed by

CMS as an opportunity for prescription drug plans (PDPs) to improve the health outcomes of their patients. Although the structure of MTM has to date been left in the hands of the specific plans, CMS is establishing standards and will expect plans to adhere to them. Organizations such as the Pharmacy Quality Alliance are developing the frame work of measurable standards for MTM programs.

COST EFFECTIVE QUALITY

Although the historic focus of CMS has been on coverage for acute services, there is a growing realization that to preserve Medicare a focus on quality is required. This is based on the findings that a small portion of seniors with chronic comorbid conditions use a disproportionately large amount of resources. Focus on preventive care using primary care providers in community-based settings of care can improve quality and at a reduced cost (Table 126-1).

Primary care expansion

Our current reimbursement structure rewards procedures and the use of technology but not time spent with patients or coordinating care. There is little incentive for primary care although there are plans to revise this trend by providing loan repayment, training grants, and improved provider reimbursement as a means to increase the availability of primary care services.

When comparing the United States to other countries that enjoy better health at lower costs, one major contributing factor is their focus on convenient primary care services. The United States has slowly moved in that direction through the increased use of nurse practitioners (NPs), convenient care clinic, and the demonstration project operating under the heading of the medical home.

It should come as no surprise that NPs are increasingly providing primary care to our seniors. NPs are advanced practice nurses whose field was born in 1965 at the University of Colorado. Today there are over 115,000 NPs practicing with additional 6000 added annually as a result of programs at over 300 academic centers. NPs are able to reach patients in a unique manner by blending nursing and medical care.

This unique manner combined with the increased availability of NPs has not been lost on the Governor of Pennsylvania Ed Rendell who believes strongly in the value of NPs. The governor stated that "We should employ nurse practitioners in the delivery of health care services far more than we do." A major reason for this support is an estimate by academics that a nurse practitioner can perform about 70% of the things that a primary care physician can do, often at 50% or less of the costs. The Pennsylvania plan calls for

expanding the scope of nurse practitioners through unlocking of regulations that restrict their scope of practice.

Federal legislators are also attempting to expand the scope of NPs with an aim for long-term care involvement as current law requires that all care in a skilled nursing facility be provided under the direct supervision of a physician. The Long-term Care Quality and Modernization Act of 2006 would amend this to include that "at the option of a state, under the supervision of a nurse practitioner, clinical nurse specialist, or physician assistant who is working in collaboration with a physician." This would expand the role and responsibilities of NPs in skilled nursing facilities. In addition this legislation would amend current law that does not permit nonphysician practitioners to be employed by the skilled nursing facility. By removing this language, NPs could be employed by the facility and supervise resident care.

Besides a focus on primary care, a back to basics approach also calls for encouraging coordination of care. Under our current system care is often fragmented into silos. Medicare is engaging in reimbursement systems that promote greater coordination of care. One example is Medicare demonstration in bundling Medicare Part A and B payments.

Providers such as skilled nursing facilities and hospitals will have Medicare Part B payments included in their Medicare Part A reimbursement. Instead of physicians billing Medicare directly under Medicare Part B, they will instead be engaged by these Part A providers (hospitals and sub-acute nursing centers) who will be responsible for paying for their services. As such it is likely that these Part A providers will employ physicians directly, thus resulting in greater coordination of care.

Yet another example of the promotion of coordination of care is the Medical Home Demonstration. This demonstration mandates a trial in up to eight states to provide targeted, accessible, continuous, and coordinated family-centered care to Medicare beneficiaries who are deemed to be high need (that is, with multiple chronic or prolonged illnesses that require regular medical monitoring, advising, or treatment.) The objective is to bring greater coordination of care to the Medicare fee for services system.

Coordinated care models

Medicare has for some time been expanding programs that care for LTC residents in and outside of the traditional nursing home. In 1987, United Healthcare launched a program known as Evercare. Evercare uses NPs within nursing homes to increase onsite the primary care thereby reducing the need for emergency room evaluations and increasing preventive care and timely acute care assessment and treatment, all of which help reduce avoidable admissions. In addition the Evercare program is able to provide a skilled level of services without Medicare's requirement for a hospitalization of 3 days.

More recently the Medicare Modernization Act allowed for the development of these types of programs and a broader range of options under Medicare Advantage (MA) and specifically their Special Needs Plans (SNP). SNPs are permitted to focus solely on one of three distinct groups: residents of nursing homes, dual eligible seniors (those who are entitled to Medicare Part A and/or Part B and are eligible for some form of Medicaid benefit), or those suffering from multiple chronic illnesses. These are managed care programs

Table 126-1. Focus of Medicare

	Original Medicare	Future Medicare
Level of Care	Acute	Preventive
Providers	Specialist	Primary Care (PCP, NP, PA)
Facility	Hospital	Community
Integration	Silos	Coordinated Care
Technology	na	eRx, EHR, monitoring devices

to specific populations that have the same incentives as any Medicare managed care plan. The incentive is to provide care to improve health outcomes, thereby avoiding preventable hospitalizations.

A predecessor to the SNPs is PACE—the Program for All-inclusive Care for the Elderly. The PACE model began to evolve in the early 1970s in an effort to help the Asian American and other non-English speaking communities of San Francisco care for elders in their own homes. For these ethnicities, placing frail, elderly family members in a nursing home was not a culturally acceptable solution; therefore On Lok Senior Health Services created an innovative way to offer a comprehensive array of medical supervision, physical and occupational therapies, nutrition, transportation, respite care, socialization, and other needed services.

The benefits for these seniors living outside of the nursing home have been demonstrated in several studies. For instance, a 1996 study of Washington, Oregon, and Colorado seniors that were eligible for a nursing home concluded that the expansion of home and community-based services were a cost-effective alternative to institutional care in these states.¹⁹ In addition to the cost-effectiveness of home-based services being offered in the community, medical directors should realize the advantage of developing a referral source to the nursing home for those that truly require that level of care. Also by expanding the reach of the clinical team it can afford significantly more depth, including not only the ability to be dedicated full time to this endeavor, but to enable other disciplines that require a larger base population than a traditional nursing facility can afford.

Technology

Often talked about as the cornerstone for improvement in technology in the form of electronic prescribing, health records and monitoring devices – these opportunities have yet to reach their full potential.

To motivate providers to use electronic prescribing²⁰ CMS has included a financial bonus through the Physician Quality Reporting Initiatives. The Medicare Improvement for Patients and Provider Act of 2008 (MIPPA) authorizes a new incentive program for eligible professionals who are successful electronic prescribers (E-Prescribers) as defined by MIPPA. This new incentive program is in addition to the quality reporting incentive program authorized by Division B of the Tax Relief and Health Care Act of 2006 - Medicare Improvements and Extension Act of 2006 (MIEA-TRHCA) and known as the Physician Quality Reporting Initiative (PQRI). The e-prescribing incentive is similar to the PQRI incentive in that reporting periods are 1 year in length and the incentive is based on the covered professional services furnished by the eligible professional during the reporting year. In addition, MIPPA requires that quality measures that can be reported for purposes of qualifying for the PQRI incentive payment not include e-prescribing measures. Reporting periods are for a calendar year, beginning with calendar year 2009 through 2013.

The e-prescribing incentive amount is based on the secretary's estimate (based on claims submitted not later than 2 months after the end of the reporting period) of the allowed charges for all such Physician Fee Schedule (PFS) covered professional services furnished by the eligible professional during the reporting period. The e-prescribing incentive

percent amount for reporting years 2009 to 2010 is 2.0%; for reporting years 2011 to 2012 is 1.0%; and for reporting year 2013, it is 0.5%.

CMS is also making sure that providers have the support they need to take advantage of health information technology (IT) to lower costs and improve quality. First, CMS is working with the Veterans Administration to adapt their VISTA system for electronic records to the public domain. Second, CMS is providing technical support through our state-based Quality Improvement Organizations (QIOs). In their new 3-year quality improvement strategy, the QIOs will assist providers in using evidence-based approaches to achieve measurable quality improvements and get the most benefit from quality-based payment systems. One important method for doing so is to help them choose and implement health IT systems using advice and support that has worked well for similar providers and that is well-coordinated with other administration efforts to support effective, interoperable IT systems. These IT systems will help physician offices and other providers measure quality of care and improve it. The emphasis for technical assistance is on small offices, rural areas, and underserved areas.

Combined with increasing financial support for higher quality and lower overall costs, these steps to make it easier to adopt and use effective health IT. A study supported by the Office of the National Coordinator for Health Information Technology published in the *New England Journal of Medicine* found optimism for expanded use of EHRs; 17% of doctors used some kind of EHR system, 16% had acquired a system but hadn't booted it up yet, and 26% volunteered that they planned to buy one inside of 2 years. A less optimistic view was noted in a survey of about 3,000 doctors by a research team at the Institute for Health Policy at Massachusetts General Hospital.²¹ This study found that only 4% of physicians had a fully functional system that could satisfy some of the basic standards set by the Certification Commission for Healthcare Information Technology. With a price tag of between \$35,000 and \$50,000 per doctor over 3 years implementation of an EHR can be costly (Table 126-2).

Table 126-2. Development of Clinical Records for Quality Data Assessment*

Essential Features of Clinical Records for Quality Data Assessment

Specifies Data Elements

- Establishes linkage capability among data elements and records
- Standardizes the element definitions
- Is automated to the greatest possible extent
- Specifies procedures for continually assessing data quality
- Maintains strict controls for protecting security and confidentiality of the data
- Specifies protocols for sharing data across institutions under appropriate and well-defined circumstances

Preparing for Quality Data Reporting

- Expanding and improving the capture and use of currently available data
- Creating an environment that rewards the automation of data
- Improving the quality of currently automated data
- Implementing national standards
- Improving clinical data management practices
- Establishing a clear commitment to protecting the confidentiality of enrollee information
- Careful capital planning

*Schneide EC, Riehl V, Courte-Wienecke S, et al. Enhancing performance measurement: NCQA's road map for a health information framework. *JAMA* 1999;282(12):1184-90.

RESOURCES: "QUALITY" ORGANIZATIONS

Several government and nongovernmental organizations are dedicated to quality. These organizations work to ensure quality through identification/analysis of quality issues, resources to address these quality issues, including providing accreditation to notate quality organizations.

There are a few key organizations dedicated to identification/analysis of quality issues, the most influential at least to the public is the Institute of Medicine (IOM); the most influential to Congress is MedPAC, which is tasked with providing Congress advice on issues involving Medicare including quality. CMS has tasked the Quality Improvement Organizations (QIO) with the job of helping health care providers, whereas other organizations work with the federal government to place a stamp of quality on organizations and products (Table 126-3).

Identification/analysis: institute of medicine (IOM)

With a focus on quality, the Institute of Medicine (IOM) in 1996 launched a concerted, ongoing effort focused on assessing and improving the nation's quality of care, which is now in its third phase. The first phase of this quality initiative documented the serious and pervasive nature of the nation's overall quality problem, concluding that "the burden of harm conveyed by the collective impact of all of our health care quality problems is staggering."²²

The initial phase built on an intensive review of the literature conducted by Dr. Mark A. Schuster at RAND to understand the scope of this issue and a framework was

established that defined the nature of the problem as one of overuse, misuse, and underuse of health care services. During the second phase, spanning 1999 to 2001, the Committee on Quality of Health Care in America, laid out a vision for how the health care system and related policy environment must be radically transformed to close the chasm between what we know to be good quality care and what actually exists in practice. Phase three of the IOM's Quality Initiative focuses on operationalizing the vision of a future health system described in the Quality Chasm report.

The IOM report *Leadership by Example: Coordinating Government Roles in Improving Health Care Quality* (2002) encourages the federal government to take full advantage of its influential position as purchaser, regulator, and provider of health care services to determine quality for the health care sector. The vision for each of these distinct federal roles is very much in concert with ideas laid out in the Quality Chasm report. Other efforts in this area include *Envisioning the National Healthcare Quality Report* (2001) and *Guidance for the National Healthcare Disparities Report*.

Resources: quality improving organizations

Since the inception of the Medicare program, the quality of care received by beneficiaries has been monitored. The earliest organizations responsible for quality performance measurement were the professional services review organizations (PSROs), local review boards who reviewed care received by a limited number of beneficiaries during an inpatient hospital stay. The jurisdiction of PSROs was typically for one or several counties within a state, and had a primary focus on whether the health care received was medically necessary.

Table 126-3. "Quality" Organizations

Agency Within the Department of Health and Human Services (HHS) – Identification/Analysis	
Agency for Healthcare Research and Quality (AHRQ)	Supports health services research initiatives that seek to improve the quality of health care in America. AHRQ's mission is to improve the quality, safety, efficiency, effectiveness, and cost-effectiveness of health care for all Americans.
Independent Congressional Agency – Identification/Analysis	
Medicare Payment Advisory Commission (MedPAC)	Established to advise the U.S. Congress on issues affecting the Medicare program such as payments to private health plans participating in Medicare and providers in Medicare's traditional fee-for-service program, and analyzing access to care, quality of care, and other issues affecting Medicare.
Private, 501(c)(3) Not-For-Profit Organization – Accreditation	
National Committee for Quality Assurance (NCQA)	Dedicated to improving health care quality. The NCQA seal is a widely recognized symbol of quality. Organizations incorporating the seal into advertising and marketing materials must first pass a rigorous, comprehensive review and must annually report on their performance. For consumers and employers, the seal is a reliable indicator that an organization is well-managed and delivers high-quality care and service.
Utilization Review Accreditation Commission (URAC)	A leader in promoting health care quality through its accreditation and certification programs. URAC offers a wide range of quality benchmarking programs and services that keep pace with the rapid changes in the health care system, and provide a symbol of excellence for organizations to validate their commitment to quality and accountability. Through its broad-based governance structure and an inclusive standards development process, URAC ensures that all stakeholders are represented in establishing meaningful quality measures for the entire health care industry.
Joint Committee for the Accreditation of Healthcare Organization (JCAHO)	To continuously improve the safety and quality of care provided to the public through the provision of health care accreditation and related services that support performance improvement. The Joint Commission accredits and certifies more than 15,000 health care organizations and programs in the United States. Joint Commission accreditation and certification is recognized nationwide as a symbol of quality that reflects an organization's commitment to meeting certain performance standards.
A Private, 501(c)(3) Not-For-Profit Organization – Resources	
Institute of Healthcare Improvement (IHI)	Works to accelerate improvement by building the will for change, cultivating promising concepts for improving patient care, and helping health care systems put those ideas into action.
Quality Improvement Organizations (QIO)	Improving quality of care for beneficiaries and protecting the integrity of the Medicare Trust Fund by ensuring that Medicare pays only for services and goods that are reasonable and necessary and that are provided in the most appropriate setting, and protecting beneficiaries by expeditiously addressing individual complaints.

In 1984, the PSROs were replaced by the peer review organizations (PROs) with jurisdiction for an entire state (and for several of the 43 PROs, jurisdiction for more than one state). Initially PROs monitored inpatient care by selecting random samples of inpatient admissions from computerized Medicare hospital claims records. Initial review of medical necessity and quality of care for the sampled admissions were performed by nurse reviewers. Admissions identified with problems were then reviewed by physician reviewers, who requested medical records for review if they concurred with the initial case review. Admissions judged to have problems after the review of medical records resulted in denial of payment for the admission.

By the end of the 1980s, the PROs extended their review beyond inpatient care to include skilled nursing facilities, outpatient hospital departments, ambulatory surgery centers, and home health agencies. In addition, the reviews by the PROs increasingly focused on quality performance measures. By the early 1990s, the effectiveness of the PROs in successfully monitoring quality performance and improving quality was questioned. The reliability of physician reviews done by the PROs was questioned in some influential studies. In particular, one study showed that the agreement between reviews of PRO reviewers compared with reviewers at Johns Hopkins were no better than what would be expected by chance. The effectiveness of retrospective review in identifying the source of quality problems and preventing them was also questioned, given the elapse in time since specific cases were reviewed. Also, in contrast to provider profiling in which quality performance is based on some or all of the provider's patients, a PRO's retrospective review of a random sample of cases will identify at most very few cases per provider subject to review and no cases for many providers. Under the PRO's system of review, this paucity of cases for any given provider invites attribution of quality problems for a specific case to random variation in outcomes rather than systemic problems with a physician or health care facility.²³

In light of this criticism of PROs, their activities were redefined under the Health Care Quality Improvement Program in 1993. Under this initiative, retrospective case review was replaced by collaborative initiatives with hospitals and physicians to improve quality that was closer to the model of CQI. Although the aggregate impact of this new initiative is difficult to assess, case studies suggest success in specific settings. For example, results from one quality-improvement initiative for patients with congestive heart failure (CHF) showed that evaluation of left ventricular function improved from 53% to 65% and that appropriate use of ACE inhibitors improved from 54% to 74%.²⁴

The mission of these organizations is to improve the effectiveness, efficiency, economy, and quality of services delivered to Medicare beneficiaries. Based on this statutory charge, and CMS' program experience, CMS identifies the core functions of the QIO program as:

- Improving quality of care for beneficiaries
- Protecting the integrity of the Medicare Trust Fund by ensuring that Medicare pays only for services and goods that are reasonable and necessary and that are provided in the most appropriate setting; and
- Protecting beneficiaries by expeditiously addressing individual complaints, such as beneficiary complaints; provider-based notice appeals; violations of the Emergency

Medical Treatment and Labor Act (EMTALA); and other related responsibilities as articulated in QIO-related law

CMS relies on QIOs to improve the quality of health care for all Medicare beneficiaries. Furthermore, QIOs are required under Sections 1152–1154 of the Social Security Act. CMS views the QIO program as an important resource in its effort to improve quality and efficiency of care for Medicare beneficiaries. Throughout its history, the program has been instrumental in advancing national efforts to motivate providers in improving quality, and in measuring and improving outcomes of quality.

The Medicare Quality Improvement Organization (QIO) Program (formerly referred to as the Medicare Utilization and Quality Control Peer Review Program) was created by statute in 1982 to improve quality and efficiency of services delivered to Medicare beneficiaries. In its first phase, which concluded in the early 1990s, the program sought to accomplish its mission through peer review of cases to identify instances in which professional standards were not met for purposes of initiating corrective actions. In the second phase, quality measurement and improvement became the predominant mode of program operation. As a result of significant changes that have occurred in our understanding of how to improve quality, and changes in the environment to promote public reporting of provider performance and the development of performance-based payment programs, the QIO is now positioned as an agent of change.

CMS views the QIO program as a cornerstone in its efforts to improve quality and efficiency of care for Medicare beneficiaries. The program has been instrumental in advancing national efforts to measure and improve quality, and it presents unique opportunities to support improvements in care in the future. Consequently, CMS is undertaking these activities to ensure that the program is focused, structured, and managed so as to maximize its ability for creating value. These improvements support broader initiatives to provide transparency for beneficiaries and create performance-based payment programs for providers. Most health care providers deliver care to Medicare beneficiaries and patients insured by commercial insurers. Recent efforts to improve quality reflect the idea that shared quality improvement goals and consistent quality measures for all patients will result in fewer burdens to providers and an opportunity to identify and achieve meaningful performance improvements. Thus, to achieve demonstrable and significant improvement in care for Medicare beneficiaries, the program is supporting partnerships that engage a broad group of stakeholders for the purpose of improving quality of care for all patients based on common goals and measures. This approach facilitates leveraging private sector resources and expertise at the local and national level, with a potentially more significant impact on the quality and efficiency of the health care system.

Currently on their ninth scope of work (SOW), the QIOs are focused on the following:

- Beneficiary protection - reviewing the quality of care provided to beneficiaries and implementing quality improvement activities as a result of case review activities.
- Patient safety - working with hospitals and nursing homes to improve performance on a set of important processes and results that will reduce patient risk factors.

- Prevention - improving immunization rates for influenza and pneumonia along with key cancer screening. Some QIOs will also work to improve care for chronic kidney disease patients and/or work to reduce health disparities for specific underserved populations.
- Care transitions - selected QIOs will work on encouraging the coordination of care across the spectrum of health care; promoting seamless transitions from the hospital to home, skilled nursing care, or home health care; and promoting efforts to reduce unnecessary rehospitalizations in specified regions of several states.

In addition, through their work in that above themes, the QIOs help CMS promote and achieve three overarching goals for American health care:

- Adoption of value-driven health care
- Supporting the adoption and use of health information
- Technology
- Reducing health care disparities

THE FUTURE OF “QUALITY”

The foundation for CMS quality improvement is focused on the vision of “the right care for every person every time.” This is based on CMS seeking to make care safe, effective, efficient, patient-centered, timely, and equitable (Table 126-4).

To achieve this CMS has strengthened its quality council, which now is chaired by the administrator and meets every 2 weeks, and has created workgroups in the areas of health information technology, performance measurement and pay-for-performance, technology and innovation, prevention, Medicaid and State Children’s Health Insurance Program (SCHIP), long-term care, cancer care, and methods for breakthrough improvement.

These groups, with membership drawn from across CMS, report to the quality council, which reviews, approves, and tracks their work plans. The quality coordination team supports the quality council by managing this tracking and planning process and providing a variety of technical support to the workgroups. Accountability for individual tasks remains with the CMS unit that carries them out, but accountability for overall integration, and for adjusting the plan in response to events, remains with the workgroup and the quality council to which it reports.

The cross-cutting nature of the quality council workgroups has already been mentioned, but the same principles

Table 126-4. Highways on the CMS Quality Roadmap*

The CMS quality roadmap features five main strategies to achieve the goal of high-quality care:

1. Work through partnerships—within CMS, with Federal and State agencies, and especially with nongovernmental partners—to achieve specific quality goals.
2. Develop and provide quality measures and information as a basis for supporting more effective quality improvement efforts.
3. Pay in a way that reinforces our commitment to quality, and that helps providers and patients take steps to improve health and avoid unnecessary costs.
4. Promote effective electronic health systems to support quality improvement.
5. Bring effective new treatments to patients more rapidly and help develop better evidence so that doctors and patients can use medical technologies more effectively.

*<http://www.cms.hhs.gov/CouncilonTechInnov/downloads/qualityroadmap.pdf>

can produce clinical breakthroughs. For example, promoting influenza immunization in nursing homes might involve a partnership with stakeholders (by the CMS Long-term Care Task Force), addressing the payment for administering vaccine (Center for Medicare Management), requiring that vaccine be offered to every patient (Office of Clinical Standards and Quality), enforcing that requirement (Center for Medicaid and State Operations), including immunization status in information that nursing homes report to CMS (Office of Clinical Standards and Quality), publishing each home’s immunization rate (Center for Beneficiary Choices), and providing technical assistance and promoting staff immunization (Office of Clinical Standards and Quality). These actions rarely require new organizational units because existing units of CMS already have responsibility for most of the needed activities, but strong planning and coordination are necessary to make activities of so many CMS components come together to change care.

These are strategies, not goals; highways, not destinations. The destination is safe, efficient, effective, patient-centered, timely, and equitable care. But the five strategies are critical to getting us there and will be carried out through systematic efforts that span all parts of CMS, because all parts of our agency can and must support quality improvement.

It is hoped that through this five-part roadmap, CMS and providers can work together to establish a health care system for seniors that is safe, effective, efficient, patient-centered, timely, and equitable. As we strive to make these improvements to the health care system our collective ideas, thoughtful consideration and broad participation are needed. CMS will work to do its part, by strengthening our partnerships and using them to strengthen ability to identify, support, and improve high-quality, personalized care. This is absolutely essential for the sustainability of Medicare, Medicaid, and our health care system: increasingly, high-quality care is the only kind of care we can afford.

KEY POINTS

Preserving Medicare Through a “Quality” Focus

- The change from the Health Care Finance Administration (HCFA) to the Centers for Medicare and Medicaid Services (CMS) signaled more than a name change; rather it marked a movement beyond simply paying claims to one of value-based purchasing. As a value-based purchaser CMS now plays a critical role in promoting quality outcomes.
- There is now a shift to more comprehensive models of care rather than continued support of a fragmented siloed payment system. In addition there is also a shift toward focusing on quality of life rather than simply extending years lived.
- Use of technology to improve quality through electronic prescribing and health records is being viewed as a major opportunity to reduce waste through improvements in quality.
- By reporting quality outcome data on providers CMS expects seniors to be driven to “quality” providers thus resulting in improvements in outcomes and cost savings.
- Support is available through CMS for improving quality through Quality Improvement Organizations (QIO) and other organizations.

Managed Care for Older Americans

Richard G. Stefanacci

The current care delivery system for older Americans requires significant reform to improve the care of this population.¹ One of the growing delivery systems that is well positioned to improve the care for older adults is provided through managed care. This is in part due to the fact that managed care shares some common goals and processes with geriatric medicine.^{2,3}

In its broadest sense, managed care refers to a system where a payment is made to a provider or health plan that is then responsible for a group of services. A more traditional and focused view of managed care refers just to health plans that are responsible for providing all of the services available under the entire Medicare program with the exception of hospice services. These services can be provided either directly through a closed system of providers or through an open system using contracted community providers. The closed system uses a full complement of employed providers. Medicare Advantage (MA), under The Centers for Medicare and Medicaid Services (CMS), administered this program as provided under the Medicare Part C program. Previous to the Medicare Modernization Act of 2003 these plans were referred to as Medicare+Choice or simply a health maintenance organization.

Medicare managed care plans have several potential advantages over the traditional Medicare fee-for-service program. These advantages include having lower deductibles and copayments, and offering benefits that are not part of the Medicare fee-for-service coverage, such as payments for preventive care including reimbursement for eyeglasses and hearing aids; health education, and health promotion programs such as case management and disease management. Managed care plans can also provide discounts on or improved access to transportation, day care, respite care, or assisted living. Plans are also not restricted by Medicare fee-for-service rules such as the requirement for 3 hospital days plus a discharge day to qualify for subacute services; instead Medicare managed care plans can admit members directly to skilled nursing facilities, thus avoiding a hospitalization and related costs, both financial and health. This subacute level of care is for services requiring skilled nursing care, such as intravenous therapy or rehabilitation.

Although coverage for pharmaceutical costs had historically been a major reason why older adults enrolled in Medicare managed care, the introduction of free-standing prescription drug plans under Medicare Part D, which started Jan 1, 2006, removed this differential from fee-for-service in traditional Medicare. As a result of Medicare Part D both FFS Medicare and Medicare managed care plans both provide the opportunity for coverage of prescription medications.

Thus principles of managed care are moving beyond MA plans into portions of Medicare fee-for-service. Through such programs as pay-for-performance and some unique demonstration programs, Medicare is applying the principles of managed care so older adults in traditional Medicare can also benefit.

MANAGED CARE TIMELINE

The modern era of managed care was heralded by a new law enacted by the U.S. Congress in 1974. This law permitted the establishment of health maintenance organizations (HMOs) whose purpose was to encourage the development of prepaid health plans. From their start in the mid-1970s until the late 1990s, managed care saw a slow and consistent growth. Participation in Medicare managed care increased steadily in the 1990s, reaching a peak of 6.3 million beneficiaries (16%) in 2000.

In 1997 revisions enacted by Congress that increased administrative burden and reduced payments to the health plans resulted in many plans exiting the market or limiting their enrollment.⁴ Enrollment declined between 2000 and 2003 because of plan withdrawals from some areas, reduced benefits, and higher premiums.

A rebirth of managed care for Medicare beneficiaries occurred as a result of the Medicare Modernization Act (MMA). MMA (passed in 2003) changed managed care for older adults in several ways. First, it changed the name from Medicare+Choice (M+C) to Medicare Advantage, and added different managed care options such as demonstration programs and special needs plans (SNP). MA plans also received increased payments, which were used to raise payments to providers, lower enrollee premiums, enhance existing benefits, and increase stabilization funds. As a result of these changes, enrollment in MA plans rose slightly from 2003 to 2004 and continues to rise each year (Figure 127-1).

MEDICARE MANAGED CARE IN FEE-FOR-SERVICE

Under the Medicare Part A benefit, also referred to as hospital insurance, providers are paid a defined amount for providing a bundle of services. Medicare Part A providers include acute care hospitals, skilled nursing facility subacute care, and hospice. It is important to note that while Medicare Part C (Medicare Advantage) includes Medicare Part A, B, and in most cases Part D, hospice is still provided as a separate benefit. Since Medicare Part A providers are paid a capitated payment, they are encouraged to use managed care principles to control cost and improve outcomes.

Medicare Part B, also referred to as medical insurance, covers physician provider services. Although historically these services were paid simply on the basis of the number and type of services provided, (CMS) is applying managed care principles to this program as well. The 2006 Tax Relief and Health Care Act required the establishment of a physician quality reporting system, including an incentive payment for eligible professionals who satisfactorily report data on quality measures for covered services furnished to Medicare beneficiaries. CMS named this program the Physician Quality Reporting Initiative (PQRI). In 2008 PQRI consisted of

Figure 127-1. Percentage of beneficiaries enrolled in Medicare managed care. (Source: Kaiser Family Foundation calculations using data from the Centers for Medicare and Medicaid Services, Medicare Managed Care Contract Plans Monthly Summary Reports for December 1 of each year, at <http://www.cms.hhs.gov/healthplans/statistics/mmcc/>; (Medicare managed care enrollment), and total Medicare enrollment data from the Centers for Medicare and Medicaid Services, Office of the Actuary, personal communication. <http://www.kff.org/insurance/7031/ti2004-2-17.cfm>)

119 quality measures, including two structural measures. One structural measure conveys whether a professional has and uses electronic health records and the other electronic prescribing.⁵ These measures are a movement to encourage the use of managed care principles in the Medicare FFS program.

Prescription drug plans as previously mentioned are authorized under the Medicare Part D program. In addition to general managed care principles to assure appropriate medication use, prescription plans are required by CMS to provide medication therapy management programs (MTMP).⁶ CMS's objective with regard to MTMP is to control costs and improve quality. Plans provide MTMP through implementation of managed care principles.

Care for beneficiaries with chronic illnesses, such as heart disease and diabetes, is a major expense to the Medicare program, and a major detriment to beneficiaries' quality of life. For example, just under one half of all beneficiaries in 1997 were treated for one or more of eight categories of chronic illnesses, and they accounted for three fourths of all Medicare spending in 1998 (Brown et al, 2004). Furthermore, beneficiaries often have multiple chronic illnesses, which compounds the cost and complexity of their care. The 12% with three or more of the eight chronic health problems accounted for one third of all Medicare spending. Coordinating the care of these patients is difficult because patients with chronic illnesses see an average of 11 different physicians per year.⁷

The CMS conducts and sponsors a number of innovative demonstration projects to test and measure the effect of potential program changes. CMS's demonstrations study the likely impact of new methods of service delivery, coverage of new types of service, and new payment approaches on beneficiaries, providers, health plans, states, and the Medicare Trust Funds. Evaluation projects validate CMS research and demonstration findings and help CMS monitor the effectiveness of Medicare, Medicaid, and the State Children's Health Insurance Program (SCHIP).

Many of the demonstration projects are focused on managing care for those Medicare beneficiaries suffering from chronic illnesses. The following are examples of some of the many demonstration projects that CMS has funded in the past and continues to fund.

Coordinated care demonstration⁸

The Medicare Coordinated Care Demonstration (MCCD) tests whether case management and disease management programs can lower costs and improve patient outcomes and well-being in the Medicare fee-for-service population. The evaluation of this demonstration project by Mathematica Policy Research, Inc. showed no clear benefit of this program. Based on the patterns of differences in hospitalizations, Medicare Part A and B expenditures, and total Medicare expenditures including the care coordination fees, six of the programs are not cost neutral, four probably are not, and five may be cost neutral, over their first 25 months of operations. Given the results, the continuation of this demonstration is in doubt.

Senior risk reduction program⁹

The Senior Risk Reduction Demonstration was established to test whether health promotion and health management programs that have been developed and tested in the private sector can also be tailored to and work well with Medicare beneficiaries to improve their health and reduce avoidable health care use.

Care management for high-cost beneficiaries demonstration¹⁰

This demonstration was established to evaluate various care management models for high-cost beneficiaries in the traditional Medicare fee-for-service program.

ESRD disease management demonstration¹¹

The End-Stage Renal Disease (ESRD) Disease Management Demonstration was established to increase the opportunity for Medicare beneficiaries with ESRD to join integrated care management systems. The demonstration is designed to test the effectiveness of disease management models to increase quality of care for ESRD patients while ensuring that this care is provided more effectively and efficiently.

Program for all-Inclusive care for the elderly (PACE)¹²

Some demonstration programs that have proven their value have gone on to become permanent programs. The Program of All-Inclusive Care for the Elderly (PACE) is such a program. The PACE model is centered on the belief that it is better for the well-being of seniors with chronic care needs and their families to be served in the community whenever possible.

PACE serves individuals who are age 55 or older, certified by their state to need nursing home care, are able to live safely in the community at the time of enrollment, and live in a PACE service area. Although all PACE participants must be certified to need nursing home care to enroll in PACE, only about 7% of PACE participants nationally reside in a nursing home. If a PACE enrollee does need nursing home care, the PACE program pays for it and continues to coordinate the enrollee's care.

A study¹³ of the PACE model by Dr. Catherine Eng and her team found positive outcomes. Specifically the results demonstrated good consumer satisfaction, reduction in use of institutional care, controlled use of medical services, and cost savings to public and private payers of care, including

Medicare and Medicaid. The study concluded by stating that the PACE model's comprehensiveness of health and social services, its cost-effective coordinated system of care delivery, and its method of integrated financing have wide applicability and appeal.

Social/health maintenance organization (S/HMO)¹⁴

Another similar program to PACE that did not achieve permanent status but instead was terminated because of the lack of demonstrated effectiveness was the social/health maintenance organization (S/HMO). S/HMOs were a four-site national demonstration located in: Portland, Ore.; Long Beach, Calif.; Brooklyn, N.Y.; and Las Vegas. This program combined Medicare Part A and B coverage, with various extended and chronic care benefits into an integrated health plan.

A social HMO is an organization that provides the full range of Medicare benefits offered by standard HMOs, plus additional services that include care coordination, prescription drug benefits, chronic care benefits covering short-term nursing home care, a full range of home and community-based services such as homemaker, personal care services, adult day care, respite care, and medical transportation. Other services that may be provided include eyeglasses, hearing aids, and dental benefits.

These plans offered the full range of medical benefits that are offered by standard HMOs plus chronic care/extended care services. Membership offers other health benefits that are not provided through Medicare alone or most other senior health plans.

MANAGED CARE PRINCIPLES

Managed Care Principles

- **Screening** enrolled population to identify individuals with special needs.
- **Coordinating** the actions of all providers across the continuum of enrolled beneficiaries' care.
- Offering effective **health promotion**, disease prevention, and self-management programs.
- Making available the services of **interdisciplinary** health care professionals, including physicians, nurses, social workers, pharmacists, and rehabilitation therapists.
- Using **geriatric expertise** available for designing and administering geriatric programs and for consultation with primary care physicians, case managers, and other providers.

Managed care can be an efficient approach for Medicare to finance high-quality, cost-effective geriatrics. The American Geriatrics Society (AGS) wrote in their position statement¹⁵ on Managed Care that to realize the potential flexibility and creativity inherent in capitated financing, MCOs should develop special processes for providing high-quality health care to enrollees who need complex health services.

The starting point is identifying those members most at need for special attention by screening the enrolled population to identify individuals with special needs. Plans should use valid and reliable instruments to screen their enrollees regularly. They should assess the clinical needs of high-risk enrollees for both functional status and quality of life. The rationale for this approach is that about 10% to 15% of beneficiaries, most of who have several chronic conditions, account for 70% to 80% of Medicare's annual payments for health care. Early identification of those who are at highest risk for requiring expensive care—and assessing their clinical needs—would facilitate coordination of care and timely preventive interventions designed to improve the clinical and financial outcomes of care.¹⁶

Assessment for risk is typically accomplished through a health risk assessment (HRA). One of the tools used for identifying members is the Pra and PraPlus.¹⁷ Many organizations use the Pra or the PraPlus to screen older populations to identify individuals who are at risk for using health services heavily in the future. MCOs can then offer special forms of health care, such as case management, comprehensive geriatric assessment (CGA), or geriatric evaluation and management (GEM) to these at-risk individuals.

Coordinating the actions of all providers across the continuum of enrolled beneficiaries' care is important for quality care. The rationale here is that coordination improves the quality and the outcomes of health care, including safety, cost, and satisfaction with care. The coordination of care can be made more efficient and effective by using integrated medical records and improved communication tools.^{18,19} Offering effective health promotion, disease prevention, and self-management programs can prevent or delay the progression of disease, resulting in better patient outcomes and lower costs of health care. In addition programs that provide education of patients and their caregivers with regard to their conditions and self-management initiatives empower them to be proactive and choose wise alternatives.^{20–22} Making available the services of health care professionals from several disciplines, including physicians, nurses, social workers, pharmacists, and rehabilitation therapists is needed. These professionals should function as interdisciplinary teams in managing not only the medical conditions but also social factors that affect high-risk beneficiaries' well-being. The interdisciplinary team approach allows for comprehensive, coordinated assessment and management of beneficiaries' medical, psychological, social, and functional needs—and those of their unpaid caregivers.^{23–26} Geriatric expertise should be available for designing and administering geriatric programs and for consultation with primary care physicians, case managers, and other providers. MCOs would be well served by using a geriatrician in a medical director role to help guide the development and management of programs necessary for success in caring for seniors. Geriatricians have the background necessary in efficiently and effectively managing patients in teams, and managing the care of complex patients with multiple problems across the continuum of care.^{27,28} The quality of the health care provided to beneficiaries by MCOs should be measured consistently and reported regularly to the plans' executives and providers, to CMS, and to the public. New instruments designed to measure the quality of outpatient care and coordination of care must be developed and tested for reliability

and validity. Credible, understandable information about the quality of health care is essential to organizations' processes for improving quality and to consumers' efforts to make informed choices from among the available health plans and providers.²⁹

PLAN REIMBURSEMENT

For payment purposes, there are two different categories of MA plans: local plans and regional plans. Local plans may be any of the available plan types and may serve one or more counties. Medicare pays them based on their enrollees' counties of residence. Regional plans, however, must be PPOs and must serve all of one of the 26 regions established by the CMS. Each region comprises one or more entire states.

Under the MA program, Medicare buys insurance coverage for its beneficiaries from private plans with payments made monthly. The coverage must include all Medicare Part A and Part B benefits except hospice. These payments are based on a number of factors including age and geographic variations in health care costs.

Recommendations to Medicare on payments, including changes to the MA program are made by the Medicare Payment Advisory Commission (MedPAC), the official, independent federal advisory body to Congress on Medicare payment policy. There is pressure to decrease reimbursement to Medicare managed care because of a belief that private plans, which were initially brought into the Medicare program to reduce costs, have actually increased costs. Both MedPAC and the Congressional Budget Office have found that private plans are paid 12% more, on average, than it would cost traditional Medicare to cover the same beneficiaries. According to an analysis by The Commonwealth Fund, these overpayments are estimated to average about \$1000 for each beneficiary enrolled in a private plan. CBO estimates that these overpayments will equal at least \$54 billion over the next 5 years and \$149 billion over 10 years.^{30,31}

In a June 2005 report, MedPAC recommended various changes in how Medicare pays managed care plans under MA to reduce inefficient and wasteful Medicare payments.³² The Congressional Budget Office has estimated that the MedPAC proposals would save \$20 billion to \$30 billion over 5 years.³³ Based on the MedPAC recommendations to decrease payments to MA plans, Congress passed the Medicare Improvements for Patients and Providers Act of 2008, which includes many reductions in MA reimbursement which is likely to force a reduction in benefits and thus a reduction in enrollment.

In the case of prescription drug plans (PDPs), which operate under the Medicare Part D program, payment is made for providing prescription drug coverage for those Medicare beneficiaries that enroll in that specific plan. Overall, for prescription drug plan payments Medicare subsidizes premiums by about 75% and provides additional subsidies for beneficiaries who have low levels of income and assets. Medicare's payments to prescription drug plans are determined through a competitive bidding process, and enrollee premiums are also tied to plan bids. Payments from Medicare to these prescription drug plans is risk-adjusted based on the likely drug spending for that specific enrollee. On average these payments from Medicare equal \$104 per month, which when combined with the average monthly premium equal

about \$124 per month. The prescription plan is responsible for paying the costs of medications (excluding the member's responsibility) and administrative overhead, which include medication therapy management services.

Those health systems that are more integrated, such as the MA plans, typically offer greater pharmaceutical benefits because they benefit from pharmaceutical use that reduces hospitalization and medical services. Evaluations of these plans has shown that MA plans offer greater pharmaceutical benefits; 73% versus 17% of MA plans offered enhanced prescription coverage versus prescription drug plans (PDP). In addition the same evaluation noted that 28% of MA plans versus 6% of PDPs provided coverage in the coverage gap.³⁴ MA plans offering enhanced drug benefits and therefore spending more on medications can reduce other Medicare expenditures.

CAPITATION AND PAY-FOR-PERFORMANCE

Capitation rates in all regions of the country should be sufficient for providing high-quality health care for all Medicare beneficiaries, regardless of the intensity of their clinical needs. Specifically, the CMS should provide capitation that reflects the probable cost of caring for each enrolled beneficiary. This should be accomplished by risk-adjusting capitation payments according to individual beneficiaries' diagnosis, functional status, and use. Capitation payments that acknowledge that beneficiaries with chronic conditions require more health care than those who are healthy would encourage MCOs to enroll beneficiaries who have chronic conditions and to provide them with special services designed to address their needs for complex care. In contrast, inadequate risk-adjustment of capitation payments is a disincentive for plans to enroll frail or medically complex beneficiaries or to offer special services that might encourage such beneficiaries to enroll.³⁵⁻³⁷

Beyond capitation is a movement to base payment on outcomes. Termed pay-for-performance (P4P), it has the potential to improve care to this population. Current payment systems do not consider quality in determining reimbursement. The incentives of the current reimbursement systems sometimes promote poor quality care. The present fee-for-service payment systems pay providers based on the number and complexity of services provided to patients without regard to quality, efficiency, or impact on health outcomes. Pay-for-performance has been proposed as one strategy designed to correct this deficiency.

A value-based purchasing system for the Medicare system must address the care of the large portion of Medicare beneficiaries who have multiple chronic conditions, are frail, of advanced age, or require palliative care and not focus only on the care provided to the typical beneficiary.³⁸ For these beneficiaries, measures should account for comorbidities and assess aspects of health that are common to multiple conditions (e.g., cognitive status, functional status, and pain.) Measures should be constructed so that providers are not penalized when they honor patients' preferences for care or their cultural or religious beliefs.

The older adult population served by Medicare is extremely heterogeneous. Many people are healthy and functional, but up to one third of the Medicare population

are vulnerable, with multiple comorbidities and geriatric conditions (functional and cognitive impairment, falls, and frailty). In addition, some older adults will place different values on participation in self-management and adherence to medical recommendations, especially in the setting of multiple comorbidities and health status vulnerability. Some older adults may put more emphasis on improved functioning and quality of life rather than traditional indicators of clinical care quality.

It is essential that a pay-for-performance program not unwittingly lead to a decrease in quality for vulnerable elders or those who may have different clinical care goals. Assessing and rewarding performance using indicators that have been developed for and commercially (non-Medicare) insured population and may not be relevant to vulnerable older adults has the potential to detract attention away from essential care and services. A pay-for-performance system needs to produce quality results that are meaningful and appropriate to the overall goals of clinical care for the patient population as a whole and for particularly vulnerable populations including the frail elderly. Failing to take this important policy concern into account could adversely affect access to primary and specialty care among those Medicare beneficiaries who might benefit the most from high-quality care.^{39–42}

It has been proposed that payment reform is needed to drive practice change. Effective pay-for-performance systems support and stimulate the structural capabilities necessary for the provision, documentation, measurement, and continuous improvement of high-quality care. The need for different provider settings to care for unique patient populations must also be considered when designing and implementing payment based upon performance. For example, larger practices may have more resources to implement quality care processes. Such resources include providing patient education materials for patients and their caregivers, language translation services, and other outreach activities to facilitate good patient care. A smaller practice may have fewer resources to measure and report quality, yet be an essential care provider, such as a rural care provider or home-bound elderly care team. Certain practices may be focused on a population subset for which there are no performance measures at this time. Payment reform should lead to improved practice design without eliminating essential care providers.

MEASURING QUALITY OF CARE

Providers who use innovative approaches that improve quality of care find that most current payment systems do not provide them with the resources needed to sustain these activities. Today's fee-for-service payment system does not provide payment for services such as health education or development of the infrastructure to measure and report quality. The result is that providers are unable to invest in activities that have great potential to improve quality and avoid unnecessary medical costs. An example of such activities is health information technology (HIT), including electronic health records and ePrescribing. Providers typically cite the cost of these HIT systems and lack of a clear return on investment as barriers to their implementation. In addition to the incentive of higher reimbursement for provision of better quality care, funds should be made

available through direct grants and low interest loans for the infrastructure responsible for implementation of a HIT system within a practice. HIT systems are not only used for the management of clinical records, but are critical elements in data collection, clinician feedback, quality improvement, and population tracking. Each of these is essential to practice improvement as the final desired outcome of pay-for-performance programs.^{43–45}

Structure, process, and clinical outcomes measures used must be valid and relevant for the unique care needs of frail or vulnerable older adults. These measures should be evidence-based, clinically relevant, have clear association with improved outcomes of care, and be applicable to all patients whose care they assess.

Technical specifications for numerators and denominators of measures should be constructed so that measures are not applied to special populations where evidence of linkage to performance of care processes to improved outcomes is lacking. These populations include persons of very advanced age, those with multiple comorbidities, limited life expectancy, or moderate to severe dementia.

More importantly, specific measures are needed to assess the quality of care of persons over age 75, those who are vulnerable and/or frail and who are receiving palliative care near the end of life. Clinical performance measures relevant to the Medicare population are of three types:

1. Structure measures - used to recognize systems of care associated with improved health outcomes. Multidisciplinary teams for care, capacity for patient education in self-care management, disease registries, electronic health records, and systems to support the use of intervisit interval patient contacts, and monitoring are important aspects of the chronic care model. Important processes of care are difficult to deliver absent such structure(s). Initial reward systems should recognize investment in such delivery structure.
2. Process measures - used to determine whether care that is known to be effective is provided. The AGS believes that specific measures are needed to assess the quality of care of persons over age 75, those who are frail or vulnerable, and those who are receiving palliative care near the end of life. The Assessing the Care of the Vulnerable Elders (ACOVE)⁴⁶ measures were developed by the RAND Corporation in response to the needs of persons at risk for frailty or persons aged 75 and older. They have been tested in cohorts of community-dwelling vulnerable older adults. Adoption of some or all of these indicators in addition to disease- and prevention-based measures appropriate for the younger population will greatly enhance attaining the goal that quality of care can be measured for all Medicare beneficiaries and that the providers who care for these patients have measures of accountability.
3. Clinical outcome measures - must be appropriate to the usual health care needs and goals of the patient population in which they are used. Many of these measures are disease-specific, originally developed in commercially insured populations, and do not account for other comorbidities. If not previously

tested in the heterogeneous Medicare population, such measures may be particularly problematic. In frail or vulnerable older persons, the goals of treatment for chronic disease are more variable than in younger adults, and the linkage between process of care delivered and clinical measures is often imperfect.

High-quality geriatric care requires providing services to a heterogeneous population with varied health care service needs and goals of care, including many with multiple chronic illnesses and geriatric conditions. Fundamental to the definition of quality is that the standard of care being measured is applicable to the individual to whom it is applied. Many available clinical performance measures have been developed in the middle-aged commercial population. Some of these measures have been tested in older adult populations, but some have not, so the applicability of untested measures to older adult, heterogeneous populations is not known. The complexity of delivering high-quality care to this population can only be guided by rigorous scientific testing of performance indicator measures. Such testing can allow us to adapt measures to the specific needs of vulnerable patient populations. These measures need to be developed and validated by individuals with expertise in the care of frail elders. Measurement development and testing is a dynamic process so even in the setting of value-based purchasing there should be an established process for continual evolution of performance indicator measures. Key stakeholders should remain involved.⁴⁷⁻⁵⁰

A pay-for-performance system must provide positive reinforcement for quality performance and improvement and not promote the avoidance of patients for whom providing high-quality care will be more challenging. When applied to individual providers, these measures should be constructed so that both achievement of target thresholds (excellence) and progress toward achievement of targets (improvement) can be positively reinforced. In addition, the collection of data that are used to evaluate performance should not be burdensome to providers and should accurately reflect the performance of care processes on an individual patient basis. Failure to consider these factors may unduly penalize providers who practice in small groups or care for special populations.

Linking a portion of payments to valid measures of quality and effective use of resources will result in providers having direct incentives and financial support to implement the innovative approaches that result in improved outcomes. All monies that are set aside for pay-for-performance should be distributed to providers achieving the quality criteria. Savings from improved care are likely to accrue to Medicare funds that are not part of the physician resource pool. Performance-based funds should not be used in a withhold approach or a Medicare Part B budget neutral manner. To the fullest extent possible, norms should be established for like populations and risk adjustment should occur. Although it is recognized that value-based purchasing should not be delayed while such adjustments are refined, such an approach will minimize the risk of providers avoiding patients (e.g., the frail and medically complex) who present the greatest challenge in meeting quality indicators used for pay-for-performance (Figure 127-2).^{51,52}

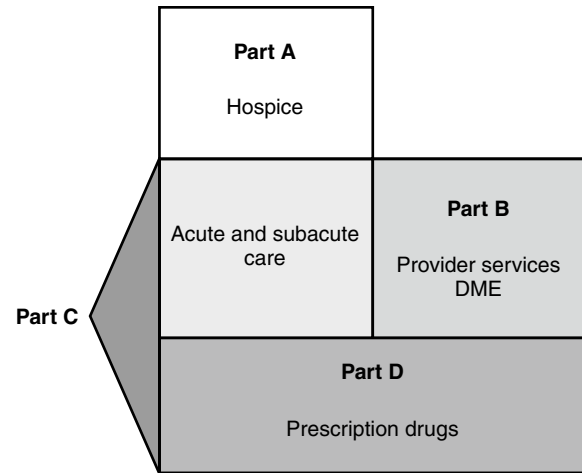

Figure 127-2. Medicare programs.

A VISION FOR CARE IN THE FUTURE

As managed care for older adults evolves a direction likely to follow has been laid out by the Institute of Medicine. The IOM identified three key principles that need to form the basis of an improved system of care delivery for older Americans. These principles are in alignment with the six aims of quality defined in *Crossing the Quality Chasm*.⁵³

First and foremost, the health needs of the older population need to be comprehensively addressed, and care needs to be patient-centered. For most older adults, care needs to include preventive services (including lifestyle modification) and coordinated treatment of chronic and acute health conditions. For frail older adults, social services may also be needed to maintain or improve health. These social services need to be integrated with health care services in their delivery and financing. Furthermore, efforts need to be made to reduce the wide variation in practice protocols among providers, which should further enhance the quality of care for older adults.

The principle of comprehensive care also includes taking into account the increasing sociodemographic diversity of older adults. The number and percent of ethnic minorities in the older population is increasing dramatically, and even within ethnic groups there is tremendous cultural diversity. Health care providers need to be sensitive to the wide variety of languages, cultures, and health beliefs among older adults. Other segments of the older population face additional challenges. For example, older adults in rural areas often face isolation and barriers to access for some services.

The second principle underlying the vision of care in the future is that services need to be provided efficiently. Providers will need to be trained to work in interdisciplinary teams and financing and delivery systems need to support this interdisciplinary approach. Care needs to be seamless across various care delivery sites, and all clinicians need to have access to patients' health information and population data, when needed. Health information technology, such as interoperable electronic health records and remote monitoring, needs to be used to support the health care workforce by improving communication among providers and their patients, building a record of population data, promoting interdisciplinary patient care and care coordination,

facilitating patient transitions, and improving quality and safety overall. Giving providers immediate access to patient information, especially for patients who are cognitively impaired and unable to provide their own clinical history, may reduce the likelihood of errors, lower costs, and increase efficiency in care delivery.

This vision for the future is being tested through the Medicare Medical Home Demonstration. Section 204 of the Tax Relief and Health Care Act of 2006 (TRHCA)⁵⁴ mandates a demonstration in up to eight states to provide targeted, accessible, continuous, and coordinated family-centered care to Medicare beneficiaries who are deemed to be high need (i.e., with multiple chronic or prolonged illnesses that require regular medical monitoring, advising, or treatment.) The objective is to bring managed care principles to the Medicare fee-for-services system.

Efficiency can be further improved by ensuring that health care personnel are used in a way that makes the most of their capabilities. Expanding the scope of practice or responsibility for providers has the potential to increase the overall productivity of the workforce and at the same time promote retention by providing greater opportunities for specialization (e.g., through career lattices) and professional advancement. Specifically, this would involve a cascading of responsibilities, giving additional duties to personnel with more limited training to increase the amount of time that more highly trained personnel have to carry out the work that they alone are able to perform. Although the necessary regulatory changes would likely be controversial in some cases, the projected shortfall in workforce supply requires an urgent response. This response will most likely have to involve expansions in the scope of practice at all levels, while

at the same time ensuring that these changes are consistent with high-quality care.

In the end, the U.S. system of care for older adults will rely on improving the effectiveness and efficiency of our current system. Many of the systems for efficient and effective care are already being provided through today's managed care program. The key will be further improvements in the current managed care system along with allowing these principles to work in the larger fee-for-service Medicare program.

KEY POINTS

Managed Care for Older Americans

- Managed care shares some common goals and processes with geriatric medicine.
- Increasingly managed care principles are being applied outside of traditional managed care organizations in Medicare fee-for-service programs.
- Despite the benefits of managed care there continues to be pressure to decrease reimbursement to these plans.
- Managed care principles include a focus on screening, coordination, health promotion, and interdisciplinary health care professionals with geriatric expertise.
- Future successes of the American system for caring for older adults is reliant on the application of managed care principles for efficiency and effectiveness beyond managed care organizations.

BACKGROUND

Health care systems are struggling with the issue of how to provide high-quality services to the increasing number of older adults in an era of limited financial and workforce resources. Many people recognize that the current system for health care delivery is unsustainable because of increasing costs and a shortage of nurses and other staff to provide care. More effective and efficient models of care based on preventive and person-centered health systems are urgently needed.

The current fee-for-service system of provider payment in the United States is often viewed as a barrier to achieving effective, coordinated, and efficient care.^{1,2} By emphasizing acute episodic care, the current system often rewards the overuse of costly specialized services and involvement of multiple physicians in the treatment of individual patients. There is an emerging consensus and legislative initiatives to "reward" the sharing and exchange of information, provide coordination and continuity of care, and effectively control chronic conditions to prevent hospitalization.³

Care coordination programs blended with technology could prevent or limit hospitalizations and emergency room visits of frail elderly patients with chronic disease. Monitoring and information technology could transform the health care system, lowering costs and increasing benefits. Such approaches and applications would substantially improve the quality of care and reduce the overall economic burden of these chronic diseases.

CARE COORDINATION IN CHRONIC DISEASE MANAGEMENT

The chronic disease model advocates that care should be continuous, coordinated between the patient and the care team, and provide self-management support to patients.⁴ Although distinctions have often been drawn, the terms "care coordination," "case management," "care management," and "disease management" are often used interchangeably. All four terms focus on the chronic disease model and implementation of care standards.

The most promising results in terms of effectiveness and efficiency involving care coordination have been in the management of patients with congestive heart failure (CHF) and diabetes mellitus. Heart failure disease management programs that monitor a patient's self-reported changes in weight and symptoms have been shown to reduce hospital readmissions.⁵ Systematic reviews suggest that nurse case management leads to improvements in patient outcomes and processes of care for diabetes patients.^{6,7}

Using well-established guidelines and carefully scripted protocols, care coordinators are able to provide disease-related education, bolster family support, and identify barriers to medical compliance. Some care coordination programs rely primarily on home-based visits, whereas others employ telephone-based interventions, either by themselves

or in combination with home visits. Establishing such a care coordination program with home-based visits and/or telephone surveillance is normally labor intensive and expensive. Operationally, even telephone surveillance requires a chart review, telephone contact by health care personnel, and often multiple calls to pharmacists or physicians. In many cases, the surveillance protocol is informal; typically the patient is instructed to call the practice if a change in health status is perceived. Reporting may occur at variable intervals.

CARE COORDINATION IN THE MANAGEMENT OF THE FRAIL OLDER ADULT

Although care coordination has had much success when targeted to high users with congestive heart failure and diabetes, models that can improve the quality of care for frail older adults "at risk" have also been developed. The goals of these models may include decreased health care use and decreased institutional placement along with decreased morbidity and mortality. A review of care coordination studies showed decreased readmission rates, emergency department visits, and health care expenditures in some, but not all studies.^{8,9} These studies differed with regard to their success in increasing efficiency and decreasing cost, the population served, the interventional model, and the outcome measures used. Part of the problem is that the care coordinators in these types of programs must address many issues in patients who suffer from multiple chronic illnesses and geriatric syndromes. Another major limitation to these models is the high cost of employing and training staff who can care for the complex frail older adult.

Despite the limitations found in these research studies, many states have taken the initiative to develop care management-based programs for older Medicaid recipients. Florida's Nursing Home Diversion Program, for example, has used care coordination for about 14,000 indigent homebound elders who meet both medical and financial criteria for nursing home placement under Florida Medicaid. The cost to the state per client is less than half of what it would be if the person was living in a nursing home.¹⁰

BASIC PRINCIPLES OF TELEMEDICINE/ TELEHEALTH

The Institute of Medicine defines *telemedicine* as "...the use of electronic information and communications technologies to provide and support health care when distance separates the participants."¹¹ Telemedicine employs telecommunications and computer technology as a substitute for face-to-face contact between provider and client.¹² *Telehealth* and *telecare* are used by some health care professionals to encompass potential preventive and educational applications of telemedicine, such as remote monitoring, patient education, and

data collection.¹³ In reality, the words telemedicine, telehealth, and telecare are often used interchangeably.

Interest in telehealth as a way of providing care is being spurred by the rising cost of medical treatment and by the difficulties patients face accessing care and navigating the complex health care system. Rapid advances in technology and broadband transmission capability and the wider availability of low-cost, patient-friendly equipment are responsible for much of this interest. Some of the perceived benefits of telehealth are listed in Table 128-1.

There are two different categories of clinical telemedicine applications: (1) *Asynchronous* (store-and-forward) applications acquire and store clinical information (e.g., radiographic images, photographs of dermatologic lesions, and pathologic histology) that is then forwarded to (or retrieved by) another practitioner at a later time for the purposes of providing a consultation. (2) *Synchronous* (real-time) applications involve a two-way interactive exchange between the patient and provider(s), which allows physicians to assess patients who are at a distance. Examples of synchronous applications include telemental health, telerehabilitation, telecardiology, and teleneurology.

Telehealth can facilitate chronic management of patients in the home/community environment through video-conferencing and messaging reminders. Electronic sensors can also be used to monitor vital signs, weight, glucose, and movement throughout the home. Ideally, the properly identified technology may make the task of the care coordinator more efficient and effective. For the health care professional, the right technology can improve medication management, identify

early signs of worsening illness, and guide follow-up care after a discharge from the hospital or skilled nursing facility. With all the information that is collected on patients, there is also an opportunity for artificial intelligence and computer analysis for decision support for health care professionals. Telehealth offers other benefits to managed care organizations, providers, patients, and caregivers (Table 128-1).

By providing interactions that are ongoing, disease-specific, and individualized, an in-home messaging device can empower patients and their caregivers to become involved in managing their chronic illness. This sense of empowerment may increase patient adherence and foster self-monitoring. The in-home messaging technology may create a sense of partnership with the health care system as the patients believe that the system is watching over them. This device also provides opportunities for improved communication between clinicians and patients. Telehealth allows for “just-in-time” education in a private learning environment.¹⁴

APPLICATIONS OF HOME TELEMEDICINE/ TELEHEALTH IN THE ELDERLY

Chronic disease management

Telehealth can assist care coordination programs to monitor for potential critical, disease-specific parameters (e.g., blood sugar in diabetes and weight change in CHF). The daily measures allow for the “real time” reassessment and readjustment of the care plan. Telehealth technology may improve monitoring—for example, by the daily prompting of the patient for his or her weight, information that could be used to facilitate behavior modification. Selective daily monitoring via telehealth technology of specific critical parameters leads to focused communications between the patient and care manager. Most systems also offer information and support to improve patient self-control and management. In this patient-centered model, the patient is empowered both in disease self-management and communication with health care providers. Putatively, such a competent patient could take on more of the responsibility and burden of disease management, ultimately leading to earlier and preventive intervention and a decrease in major encounters and health care cost.¹⁵ In all chronic diseases models that have been studied, the frequent assessment and contact through home telehealth appear to increase patient and caregiver confidence and sense of security.¹⁶ In the United States, the Veterans Health Administration and Department of Defense have taken the lead in implementing telehealth technology to about 30,000 patients in their care coordination programs nationally.

Congestive heart failure (CHF)

The Weight Monitoring in Heart Failure (WHARF) trial used twice-daily automated monitoring of signs or symptoms with a system consisting of an electronic weight scale and a monitor for patients to answer questions about symptoms. No differences in terms of health services use were observed. However, there was a 46% reduction in the mortality rate among the monitored group.¹⁷ Another study compared Internet-based monitoring of weight, blood pressure, heart rate, and oxygen saturation, relayed to the patient’s cardiologist, versus nurse home visits. A 40% reduction in heart failure admissions and health care costs was observed among

Table 128-1. Potential Advantages of Home Telehealth Systems

For the Managed-Care Organization
<ul style="list-style-type: none"> • Cost-effective approaches in managing geographically dispersed, multilingual populations • Reliable outcomes assessment • Centralized data management • Patient follow-up and case management by exception • Automated message reminders (e.g., medications, appointments)
For the Patient
<ul style="list-style-type: none"> • Improved patient adherence • Increased patient access to care • Enhanced patient satisfaction • Opportunity for early intervention • Reduced hospital/emergency room visits • Enhanced provider access to patient • Empowered patient participation in care • Improved communication between patient and provider • Access to health care information, resources, and databases • Decreased need for patient to travel • Treatment changes without office visit through feedback to providers
For the Provider
<ul style="list-style-type: none"> • Increased patient access to care • Enhanced clinician access to patients • Enhanced ability to monitor patients • Efficient use of clinician time
For the Caregiver
<ul style="list-style-type: none"> • Support • Access to health care information, resources, and databases • Sense of comfort that their loved one is being watched

the telemonitored group compared with the nurse home-visit group.¹⁸

"Telephone-based" monitoring and education by nurses combined with decision support systems to determine call frequency and prioritize education topics have produced a reduction (20% to 47%) in hospitalizations, death, or emergency room visits in CHF patients.^{19,20} In two studies comparing "telephone-based" systems for CHF to "more complex" telemonitoring, the telephone-based monitoring demonstrated equal effectiveness and was less expensive.^{21,22}

A meta-analysis analyzed data from 14 randomized controlled trials (4,264 patients) of remote monitoring in CHF.²³ Four of these studies had employed telemonitoring, nine had structured telephone support as interventions, and one had evaluated both telemonitoring and structured telephone support. This meta-analysis concluded that remote monitoring programs reduced the rates of hospital admission for CHF by 21% and all-cause mortality by 20%. Four of the nine studies using structured telephone support examined health care costs. Of these, three reduced cost and one had no effect. Other reviews of telehealth interventions in CHF have been equivocal about the benefits of telemonitoring.^{24,25} Although the data have been mixed regarding cost reduction by reducing hospitalizations, overall the results are promising.

Diabetes mellitus

In the Informatics for Diabetes Education and Telemedicine (IDEATel) project, one of the largest randomized controlled trials in diabetics in the United States, telemedicine case management resulted in improved glycemic control, blood pressure levels, and total and LDL cholesterol levels at 1 year of follow-up.²⁶ The elderly patients demonstrated significantly improved diabetes self-efficacy, but depression and diabetes distress did not improve.²⁷ Close monitoring of diabetic patients via technology showed a reduction in Hb A_{1c}, good receptiveness by patients, and patient empowerment and education.^{28,29} In other studies, patients required fewer clinic visits when they were monitored daily via home telehealth.³⁰ Another intervention, which included both a Web-based medical record and longitudinal health care professional support, accomplished significant benefits in Hb A_{1c} levels and compliance with diabetic guidelines.³¹

Hypertension

A recent study randomized patients to usual care, home BP monitoring and secure patient Web site training only, or home BP monitoring and secure patient Web site training plus pharmacist care management delivered through Web communications. In this Web-based intervention, blood pressure control was significantly improved only in the group that had telehealth contact with the pharmacist.³²

Chronic wounds

Telemedicine using video technology has been used to monitor the progress of chronic wounds (e.g., pressure, foot, or venous stasis ulcers among homebound patients who were not receiving routine monitoring by specialized nurses or doctors).³³

Supporting caregivers

DEMENTIA

Several studies have focused on the use of technology to support dementia caregivers.^{34,35} A review of this literature

shows that intervention usage varied between studies and was generally low.³⁶ The outcomes were inconsistent, with only moderate effects on improving caregiver stress and depression. Treatment effects were found to vary by ethnic groups, formal support, and baseline burden. However, these findings should be treated cautiously, since they often come from multiple subgroup analyses.

PALLIATIVE CARE

The use of telemedicine is also being explored in providing support at the end of life, mostly using videophone technology. Telehealth can provide psychological support and symptom monitoring and management, while reducing the need for visits for the nurse.³⁷

Safety and security monitoring

Telemedicine allows care coordinators to closely monitor seniors with limited caregiver support. Care coordinators can use the technology to provide social support and health care reminders. Technology applications have also been examined in the areas of home alert systems and fall-detection devices for seniors at risk for falls. Although it is proposed that home alert systems may reduce hospital admissions and improve discharge rates, leading to cost savings, few good quality studies have been published. One case control study in the United Kingdom found that a home alert system for persons with dementia may help such patients stay in their homes and improve functional status.³⁸ The use of technologies for locating elderly persons with dementia who wander also appears promising.³⁹ Automatic fall detectors have been developed to prevent, detect, and predict falls. A recent small study of older people living in sheltered housing in the United Kingdom examined the results of an intervention consisting of automatic fall detectors. After a 12-month monitoring period, there was no noticeable change in the fear of falling. However, significant improvement was found in the social functioning domain ($P = 0.049$), with scores 8% higher in the intervention group, suggesting a beneficial effect of telecare. Positive trends were also evident in the length of time spent out of the home and in improved feelings of safety during the day and night.⁴⁰

e-Health

e-Health is an emerging field in the intersection of medical informatics, public health, and business, which refers to health services and information delivered or enhanced through the Internet and related technologies. In a broader sense, the term characterizes not only a technical development, but also a way of thinking, and a commitment for networked, global thinking to improve health care locally, regionally, and worldwide by using information and communication technology.⁴¹ e-Health is a broader term than either telemedicine or telehealth, including telehealth, telecare, electronic medical records, and use of the Internet, among many other applications.

The search for health care information and resources is one of the most common uses of the Internet by the elderly. Potential uses of the Internet by seniors are listed in Table 128-2. Unfortunately, many health care Web sites are designed in ways that make them difficult for the elderly to use. Research suggests three main categories of Web design problems, all arising from "ability" changes with aging: (1) visual,

Table 128-2. Potential Roles of the Internet in the Care of the Aged Patient

- Resource for medical information
- Medium for enhanced communication between patients/caregivers and providers/care managers
- Access portal to billing information
- Resource for information about health care facilities and long-term care institutions
- Means for diagnosis and treatment of patients at distant locations
- Monitor of patients with chronic illness/disease
- Delivery of automated message reminders (e.g., medications, appointments)
- Online support groups

(2) motor, and (3) cognitive. For example, visual problems occur for the elderly when type faces are too small or in unusual fonts, and motor problems occur when navigation elements are too small or too closely spaced. Even in the use of the computer mouse there are age-related changes, especially in more complex tasks such as clicking and double clicking, which require longer movement times and more submovements. Errors in such tasks are related to manual dexterity, and not to age, per se, and not to prior mouse experience.⁴² Alternative site designs and navigation elements such as larger keyboard buttons could make these sites more usable for the elderly. Cognitive problems exist when site navigation imposes excessive demands on elders who have reduced working memory capacity. Web sites that will be used by the elderly present specific challenges for designers, who need to pay attention to usability research.⁴³

USABILITY ISSUES IN THE ELDERLY

Although results have been promising in studies with telephone use, many older adults have difficulty learning to use and operate other technologies, such as computers, the Internet, videocassette recorders, automatic teller machines, and telephone menu systems.^{44,45} Yet, many studies have reported the satisfaction and comfort of older patients with carefully selected telehealth technology. In one study older patients with obstructive lung disease or CHF felt comfortable with the videoconference and other peripheral devices used in the study.⁴⁶ In another study, American veterans who were suffering from noncognitive diseases reported that the home messaging technology was easy to use and helpful in managing their chronic conditions.⁴⁷

On the other hand, home telecare is not always user-friendly for people who have Alzheimer's disease; they have difficulties in learning a new task and hence in the use of a telemedicine device. In one study, dementia patients failed to respond to the establishment of a videoconference session after it was initiated from the center.^{48,49} In another study they were unable to transmit their data successfully.⁵⁰

The technology must be simple and user-friendly and operate reliably without interruptions if it is going to be used by a population with a high incidence of cognitive and sensory impairment. In such cases complicated technology will serve only to increase program costs and decrease patient adherence. A selection bias could emerge whereby only the patients who are well-educated and highly motivated will remain. Therefore, technology interfaces should place minimal cognitive demands and provide environmental supports,

such as cues and reminders or navigational aids. Seniors should be adequately trained in a self-paced, comfortable, and nonthreatening environment, where they receive positive feedback.⁵¹ It is also important for care coordinators to properly screen older adults for their ability to use the technology.⁵²

Overall, adoption of technology in the elderly is a complex issue, influenced by a variety of factors, including sociodemographic elements, attitudinal variables, and cognitive abilities.⁵³ Widespread dissemination of telemedicine will be facilitated if the technology is "accepted" and "usable" by the patients and caregivers. The easiest technology to use is whatever elders are already used to. In some cases, a selected device must be adapted to the needs of the patient. We believe that the telehealth field will eventually move to commonly used devices, such as the cell phone, the home phone with a caller-ID box, or the television. For some people, cell phones and other handheld devices are more practical, while for those with poor vision and dexterity, larger devices (larger special cell phones or television) may be more applicable.

BARRIERS TO WIDESPREAD USE OF TELEMEDICINE

In addition to usability factors, several other barriers have limited the widespread use and implementation of telemedicine. These impediments include: (1) clinician attitudes, (2) factors related to the technology, (3) economic elements, (4) policy, and most overwhelmingly, (5) lack of evidence. Each of these areas are briefly described below (Table 128-3).

Clinician attitudes

Many health care professionals express concern that telemedicine applications will not benefit them in their day-to-day practice. Others describe practical difficulties incorporating

Table 128-3. Issues to Be Considered before Instituting a Home-Telehealth Program

- Identify patient most likely to benefit from such an intervention
 - At risk for institutionalization
 - With multiple impairments/chronic conditions
 - Needing multiple services
 - Without available social supports
 - Where preventive services may avoid/delay institutional care
 - Ability to participate
 - Appropriate medical condition
 - Manual dexterity
 - Vision
 - Commitment to program
 - Appropriate technology
- Staffing issues
 - Background and training
 - Workload/census issues
 - Level of decision making/management ability
- Limitations of technology:
 - Connections
 - Picture quality
 - Cost
 - Maintenance
 - Usability
- Policy factors
- Privacy factors
- Reimbursement/workload issues

telemedicine into their existing space, schedule, practice, and clinical workflow.

Technology factors

There are few hardware and software standards; the systems are proprietary, vendor-specific, and often do not interoperate. Rapid advancement and changes in technology also make both hardware and software options confusing and vulnerable to obsolescence. Breakdowns and equipment failures must be expected. Care coordinators need to have procedures in place for expected malfunctions and equipment repair downtime.

Most users are patients and families, often with little or no training in using complex electronic devices. Telehealth technology must therefore design fail-safe systems and operating procedures. Set-up and use should not require instruction manuals.

Economic elements

Lack of reimbursement by agencies, including Medicare, is probably the biggest disincentive in telehealth. To overcome the other barriers, providers must have incentives to use telehealth technology, either financial or as a model advocated by the health care umbrella under which they practice. Quickly changing hardware and software options are confusing and also result in an expensive capital investment that is vulnerable to being outdated. Capital investment costs include the units given to the patient, the equipment used by the care coordinators, and the coordinating/decision support software. The overall cost per patient will decrease as the program increases the number of subjects enrolled. Once a system is in place, it cannot be immediately replaced because of the cost. The use of telemedicine must also budget for equipment maintenance and replacement.

Policy factors

Policy affects how telehealth is implemented and regarded. There are a number of legal issues, such as cross-state licensure and potential physician malpractice risk. Security and privacy issues will be decisive to the success of future telemedicine services. Robust ethical guidelines must be debated and developed so as to best preserve the appropriate control, privacy, and dignity of all users under all circumstances.

Lack of evidence

Many telemedicine programs have not been subject to rigorous comparative studies to assess their effects on quality, accessibility, cost, or acceptability.^{54,55} Some limited studies have shown the benefits of home-based telemedicine interventions in chronic diseases. However, the potential benefits described above of telehealth interventions are difficult to generalize since the studies have had significant variation in patient characteristics (e.g., demographics, ability for self-management, medical condition), sample selection, care coordination design, and technology modalities and devices. The interventions assessed are very heterogeneous, with regard to outcome measures and length of follow-up. The exact contribution of telehealth technology to the effectiveness and efficiency of care provision for chronic diseases cannot now be determined, given the broad range of interventions and absence of standard practices. Other shortfalls include difficulty discerning how much of

the observed benefit is actually because of commitment of the research staff.

Telehealth care coordination programs have met with variable degrees of success, and the basis for success in these programs is not fully understood. Good results may depend on the ability of the care coordinator to influence physician and patient behavior. Care coordination programs vary as to the participation/involvement of the treating physician. In most cases, the care coordinators alert the physician about issues involving the patient. Programs where the coordinator can make management decisions about a patient's treatment and implement decisions independently may be more efficient than care coordination models where the information is simply passed on to the physician. The effects and relative importance of other staffing and operational issues to the success of a telehealth care coordination program remain to be identified and understood: qualifications and training of the care coordinator, frequency of monitoring, the ideal technology, the ideal duration of an intervention, the ideal morbidity, and patient characteristics.

Good evaluation is also restricted by limited resources for conducting studies. Choices among measurement options are often shaped by practical considerations, such as cost, human resources, timetable, and organizational relationships. Once an investment is made, it may discourage rigorous research designs, including experimental clinical trials and quasi-experimental clinical studies.

FUTURE DIRECTIONS

Despite the concern expressed about the progressive dehumanization of interpersonal relationships encouraged by widespread telemedicine use, technology's rapid evolution appears to be moving toward more sophisticated and invasive forms of interventions. Telehealth technology will address three main functions: information gathering, information exchange, and intelligence processing. Electronic health records (EHR) and information technology connectivity will lead to an information explosion and lend the capability of making the electronic communication seamless. Artificial intelligence and advanced computational capabilities could generate very sophisticated decision-support programs that would themselves generate decisions, occasionally with human help. Novel methods for the delivery of quality health care could increase the effectiveness of management while containing costs and using scarce human resources to maximum effect. Increasing access to the millions who do not have health care is also envisioned as one of the possibilities of telemedicine.

In a perfect world, every elder would be monitored 24/7, looking for any change in status, and intervening. But because resources are always finite in an era of infinite wants, it will be crucial to tailor the intervention, targeting it to patients and conditions with the highest probability of benefiting from the introduction of telemedicine, patients who will provide the best "bang for the buck," so to speak. Different times in the history of the world bring different prime movers. Although outcomes and quality are important, the main driver of the telemedicine innovation will be the extreme and ever increasing cost of health care for the elderly. Although telemedicine is not the solution in and of

itself, the current view is that telemedicine holds promise to make health care cheaper, safer, and better quality and therefore deserves further exploration.

The ultimate goal is that the increase in benefit should exceed the cost. Therefore, telemedicine programs will have to be rigorously evaluated for cost-effectiveness, efficiency, scalability, safety, and acceptability to patients.⁵⁶ Greater attention must be given to issues associated with scientific rigor such as sample size, statistical power, and research design.

The use and the speed of dissemination of telemedicine in any health care environment depend on the value being added to that system of care. The value added will depend on the careful selection of technology that meets the specific needs of the administrators, health care professionals, and patients. In the managed care sector, technology will be implemented only if it shows immediate profitability in a financial cycle from the administrators' viewpoint. From the point of view of health care professionals, telemedicine must improve quality of care while improving productivity. It must also not result in an increase in costs or workload. Consideration also must be given to how best to integrate technologies with more traditional intervention approaches.

The patient's perspective is also essential in the development of these models; it will be important to use technology suited to patient needs. Users will need training in the use of specific technology, taking into account level of expertise (if any) and comorbidities. The training of patients and caregivers must be culturally and ethnically sensitive. Telemedicine can enable care coordination organizations to deploy limited multilingual staff to provide support to minority patients and caregivers over a large geographic area.⁵⁷

Other metrics must also be taken into account, such as compliance issues and process efficiency. By providing the evidence base for all these metrics, the concerns of the payers and the policymakers will be addressed and the full potential of the telemedicine dream can be approached.

KEY POINTS

Telemedicine Applications in Geriatrics

- Health care as it is structured now is fragmented and inefficient, with a lot of duplication and inefficiency in the system, leading to rising health care cost.
- Coordination of care is a key focus of the Institute of Medicine and of the chronic disease model, both of which advocate that care should be accessible, centered around patients and families, comprehensive, continuous, and coordinated.
- The coordination of care can be greatly facilitated through proper use of telemedicine technologies, in combination with appropriate organizational changes and skills.
- Telemedicine is viewed as a promising tool for improved management for chronic diseases, improved efficiencies of care provision, enhanced self-management, timely medical decision making, improved outcomes, enhanced access to health care services, and as a tool to potentially decrease the economic burden of chronic diseases in the elderly.
- The effectiveness and efficacy of telemedicine needs to be rigorously evaluated for impact on quality, accessibility, cost, or acceptability of health care, to impact policy and payment.
