clinical centers, patients with internal carotid stenosis and a history of a hemispheric or retinal transient ischemic attack or nondisabling stroke within 120 days of onset were randomized to surgery or best medical care. In patients with 70% to 99% stenosis (diameter reduction on angiography) of the symptomatic artery, the cumulative estimated risk at 2 years of an ipsilateral stroke was 26% in the 331 medical patients and 9% in the 328 surgical patients. For a major or fatal ipsilateral stroke, the corresponding rates were 13.1% and 2%. The perioperative stroke and death rate was 5.8%, but only 2.1% for major stroke and death.

In the European Carotid Surgery Trial,⁵³ patients with a stenosis of the relevant carotid artery who after a carotid territory nondisabling ischemic stroke, a transient ischemic attack, or amaurosis fugax were also randomized to surgery or best medical care. In patients with mild carotid stenosis (less than 69%), there was low 3-year risk of ipsilateral stroke, so any benefit from surgery was outweighed by the risks. In patients with severe carotid stenosis (greater than 70%), there was a 7.5% risk of stroke or death within 30 days of surgery. However, during the next 3 years the risks of ipsilateral stroke were only 2.8% for surgery patients and 16.8% for control patients. At 3 years, the total risk of death or any stroke was 12.3% for surgery and 21.9% for control patients.

Asymptomatic carotid artery stenosis

The role of carotid endarterectomy in patients with asymptomatic carotid artery disease remains unanswered. The Asymptomatic Carotid Atherosclerosis Study⁵⁴ suggested that endarterectomy halved the risk of stroke in patients with greater than 70% carotid stenosis. However, there were methodological anomalies and this is the first large randomized study to reach such a conclusion. This finding would also have massive cost implications as the rate of stroke was only 4% to 5% each year without surgery. The European equivalent, the asymptomatic Carotid Surgery Trial,

is ongoing and so a conservative approach is recommended until the results of that study are known.

Mortality from carotid surgery

Current mortality and complication rates for carotid endarterectomy in the United Kingdom and Ireland are low: there is a 1.3% mortality and 2.1% stroke rate by 30 days postoperatively.⁵⁵ Over half of all perioperative strokes are caused by intraoperative or postoperative thrombosis and embolization.⁵⁶ Studies have confirmed that carotid endarterectomy can be performed safely in the elderly population, including nonagenarians, but outcome is dependent on the individual surgeon.⁵⁷⁻⁶⁰ Clearly, the key issues in the decision to offer carotid surgery are the risk of stroke, the quality of life enjoyed by the patient, and life expectancy.

Timing of carotid surgery after stroke

Traditionally, surgery is delayed for 2 months following acute stroke. In the 1960s, several studies of the role of urgent carotid surgery were published. The results were poor, and postmortem studies often demonstrated intracerebral hemorrhage.^{61,62} It was concluded that urgent surgery precipitated hemorrhage within the infarct. However, CT was not available then to exclude a primary intracerebral hemorrhage, where surgery would be clearly inappropriate. Furthermore, many of the patients in those early studies had dense neurologic deficits and were in "coma, semicoma or stupor."⁶³

Interest in the role of urgent carotid surgery following acute stroke was renewed by reports of improvement in neurologic deficits in patients with progressing stroke and limited deficit.⁶⁴ The rationale for carotid surgery in such patients is twofold: first to restore cerebral perfusion and limit neuronal death; and second, to reduce early recurrence or progression of stroke as a result of further emboli from the diseased carotid. Urgent surgery in patients with progressing strokes and acute stable strokes have shown better results than the natural history of acute stroke in small studies, but there has been no adequate trial on carotid surgery in acute stroke since CT scans were introduced.^{65,66} A recent feasibility study concluded that trials of urgent carotid surgery should focus on partial anterior circulation infarcts and yet would still need large numbers of patients to be randomized.⁶⁷

Carotid angioplasty and stenting

A future alternative in the treatment of carotid stenosis may lie in angioplasty and stenting. A recent multicenter randomized trial comparing these techniques with endarterectomy showed similar rates of disabling stroke or death in the two groups, at around 6%.⁶⁸ Concern has been raised, however, that lower complication rates than demonstrated in this study should be achievable by surgery.

ABDOMINAL AORTIC ANEURYSM

Prevalence and natural history

PREVALENCE

Abdominal aortic aneurysms are common. Mortality statistics from the U.K. Office of Population Censuses and Surveys show that each year approximately 10,000 deaths are

due to aortic aneurysm in England and Wales. However, quoted statistics may vastly underestimate the number of deaths related to aortic aneurysms as most aneurysms remain undiagnosed and may be certified as myocardial infarction following sudden unexplained death in an elderly person. The true figure is estimated at nearer 25,000. Deaths from rupture are rare below the age of 50 years; deaths from rupture peak in men aged 75 to 79 years.⁶⁹

The prevalence of aortic aneurysms is increasing, though some would argue that this finding merely reflects improved diagnosis, changing patterns of referral, and an increased awareness of the disease.^{70,71} Difficulties arise in estimating the prevalence and mortality of aneurysms because of varying definitions of aneurysm and operative mortality, especially because an aneurysm is still most frequently diagnosed on postmortem examination.

The Vascular Surgery Society proposed that an aneurysm was by definition 50% dilated above normal, "normal" being an estimate taken from the literature and adjusted for gender and radiologic modality.⁷² Collin⁷³ suggested that an abdominal aortic aneurysm was present by definition when the infrarenal aorta was at least 4 cm in diameter or exceeded the maximum diameter of the aorta between the origin of the superior mesenteric and left renal arteries by at least 0.5 cm. Sterpetti⁷⁴ has suggested that an abdominal aneurysm is present when the ratio of infrarenal to suprarenal measurements is 1.5 or greater. Screening of 4237 men and women aged 65 to 80 years around Chichester, U.K., yielded aneurysms of 3 cm or more in 4.3% of cases and aneurysmal changes can be detected in 10.7% of men in the eighth decade of life.^{75,76} The prevalence of aneurysms is higher in men over the age of 50, in first-degree male relatives of patients with proven aneurysms, and inpatients with hypertension or peripheral vascular disease.⁷⁷⁻⁷⁹

Natural history

Aneurysms less than 5 cm in diameter seldom rupture, but the outlook for larger aneurysms is grim without surgery; the 2-year mortality for aneurysms greater than 6 cm may be 72%, though this high mortality does reflect a bias against operating on patients who are unfit at diagnosis. However, the majority of deaths in patients with large aneurysms are due to rupture.^{80,81} The expansion rate of aortic aneurysms depends on aneurysm size and in small aneurysms is approximately 2 mm per year, but growth is neither consistent, steady, or predictable.⁸² Smoking may increase the rate of aneurysm growth.⁸³ Growth rates tend to accelerate as the aneurysm size increases, and the only reliable predictor of aneurysm rupture is aneurysm size and female sex.^{74,80,84} Irrespective of size, symptomatic or tender aneurysms should be investigated with a view to surgery as soon as possible because more than 25% of these will rupture in the next year.

Clinical presentation and diagnosis

PRESENTATION

Although most aortic aneurysms are asymptomatic or occur with a rupture, they may cause back or abdominal pain. This is not always classic lumbar back pain, and all abdominal or back pain in patients with an abdominal aortic aneurysm should be attributed to the aneurysm unless another diagnosis is obvious. Alternatively, the first

presentation may be that of acute leg ischemia due to distal emboli from the aneurysm, although this is surprisingly rare considering the frequency of thrombus within the aneurysm sac.

When an aortic aneurysm ruptures, the vast majority of patients die immediately and without reaching a hospital. The early survivors have severe back or abdominal pain and hemorrhagic shock. Patients with retroperitoneal rupture, where the bleed is contained by the pressure of surrounding tissues, are more likely to reach the hospital alive, but still the majority of patients die before reaching a hospital.⁸⁵ Less common presentations include rupture of the aneurysm into the vena cava (leading to a massive arteriovenous fistula and high-output cardiac failure) or into the gastrointestinal tract (hematemesis and melena) because of an aortoduodenal fistula.

DIAGNOSIS

Most aneurysms are detected incidentally, usually either on physical examination or on abdominal ultrasound (Figure 47-6). Physical examination tends to overestimate aneurysm size by about 20% owing to overlying retroperitoneal tissue and the thickness of the abdominal wall.⁸⁶ Although ultrasound is the most cost-effective imaging method for diagnosis and follow-up, further information should be obtained before elective repair. The relationship to the origin of the renal arteries should be defined, and patency and diameter of the iliac arteries confirmed. Most aortic aneurysms are infrarenal. If there is suprarenal extension of the aneurysm, the operative difficulty increases, as does the operative mortality because of the need to cross-clamp above the renal arteries with subsequent increased risk of renal embolization and renal failure. Specialist centers favor either computed tomography (Figure 47-7) or nuclear magnetic resonance imaging (MRI) for this assessment. Both are noninvasive and are sensitive to the level of the renal arteries.⁸⁷ Neither provides adequate information on occlusive arterial disease, either viscerally or peripherally, although MR angiography is an option. Arteriography has been found to be unhelpful as it underestimates the size and extent of the aneurysm owing to luminal thrombus.

Figure 47-6. Abdominal ultrasound image demonstrating a large abdominal aortic aneurysm in transverse section.

Figure 47-7. An 8-cm abdominal aortic aneurysm with calcified wall on CT imaging.

Complications of aneurysm surgery

MORTALITY FROM RUPTURE

The operative mortality for a ruptured aneurysm varies between centers, from 31% to more than 75%.^{88,89} However, this represents only the tip of the iceberg because the overall mortality is greater than 80% because only a minority of patients reach the hospital alive.⁸⁵ Mortality rates for emergency surgery have improved very little over the years, with an overall rate in the United Kingdom of around 70% but with lower rates in specialized vascular centers.⁹⁰

OPERATIVE MORTALITY

The 30-day mortality for elective aneurysm surgery has been quoted from zero to 8.4% depending on the series of patients and the center.^{91,92} However, independently assessed mortality in clinical trials is invariably much higher, at around 10% to 12%. Generally, in the United Kingdom mortality rates for elective surgery should be around 5%.

In a recent study of more than 16,000 patients, operative mortality was increased by cerebral vascular occlusive arterial disease, chronic pulmonary disease, and impaired renal function.⁹³ Cardiac failure and diabetes have also been shown to adversely affect outcome.⁹⁴ Intraoperative hypotension, left renal vein ligation, and blood loss greater than 4 units are known to be associated with increased mortality,⁹⁵ and postoperative renal failure is the strongest predictor of death.⁸⁹ Following successful aneurysm repair, prognosis is excellent, with a life expectancy comparable to that of an age- and sex-matched population.⁹³

Cardiac complications

Aneurysm patients tend to have increased operative risk owing to concomitant cardiac and pulmonary disease. Just under half of these patients have electrocardiographic evidence of ischemic heart disease.⁹⁶ Myocardial infarction is the most frequent cause of death in patients undergoing elective aneurysm repair. If there is a history of significant angina, coronary angiography should be considered to define the coronary disease before elective surgery. An echocardiogram may be of some value in identifying segmental

wall motion abnormalities indicative of underlying ventricular dysfunction, and in providing an estimate of the left ventricular ejection fraction. Patients with an ejection fraction greater than 60% are unlikely to experience significant cardiac problems postoperatively, but a low ejection fraction is a poor predictor of complications.

Respiratory complications

Severe pulmonary insufficiency with dyspnea at rest is a contraindication to surgery. A simple clinical assessment based on ability to walk or climb a flight of stairs without needing to rest identifies most "problem" patients, but arterial blood gases and pulmonary function tests may be useful in defining the severity of pulmonary insufficiency. Patients with obstructive lung disease require careful preoperative physiotherapy and bronchodilators to increase pulmonary capacity, thereby reducing postoperative morbidity and mortality.

Surgical approach may also influence outcome. Abdominal aortic aneurysm repair has traditionally been performed via a transperitoneal approach, but an extended retroperitoneal approach may be less stressful for elderly patients and those with limited pulmonary reserve.⁹⁷

Renal complications

After cardiac causes, renal insufficiency is the next most frequent cause of death following aortic aneurysm repair. Elevated preoperative serum creatinine is significantly associated with postoperative mortality risk.⁹⁸ This preexisting renal insufficiency may be caused by repeated embolization from an atheromatous aorta, coexisting atheroma of the renal arteries, or concomitant disease such as hypertension or diabetes. It is especially important to avoid perioperative hypovolemia in these patients.

Cerebrovascular complications

Stroke is an infrequent complication of aneurysm repair.⁹⁴ Noninvasive duplex Doppler investigation reliably identifies potentially treatable carotid artery stenosis, but carotid surgery is of proven benefit only in patients with appropriate symptoms in the relevant carotid territory.

Decreasing operative mortality

There are many ways to improve the outcome for patients undergoing elective abdominal aortic surgery. Patients should have the benefit of standard intensive monitoring including, electrocardiography (ECG), arterial pressure monitoring, and pulse oximetry. Intensive or high-dependency facilities must be available for postoperative care, ventilation, and monitoring as required. This type of monitoring has led to a progressive decrease in morbidity and mortality, and a decrease in the incidence of renal complications, by minimizing periods of hypotension.⁹⁹ Perioperative β -blockade reduces cardiovascular mortality significantly in patients with preexisting cardiac disease.^{100,101}

Modern vascular surgery should also include a strategy for managing blood transfusion. Techniques such as preoperative donation, perioperative hemodilution, and the use of salvage autotransfusion result in an appreciable saving of bank blood transfusion and a reduction in systemic inflammatory response. The many risks inherent in blood transfusions are obviated.¹⁰²

The osmotic diuretic mannitol has been used sporadically in aortic surgery for the last 30 years to maintain urine output during aortic cross-clamping.¹⁰³ More recently, mannitol has been shown to scavenge oxygen-free radicals produced by restoration of blood flow to ischemic tissues, and these are important in the development of ischemia/reperfusion injury. A prospective randomized clinical trial in elective aortic aneurysm repair has shown a significant benefit in postoperative pulmonary function in patients who received mannitol before cross-clamping.¹⁰⁴

Aortic aneurysm repair in the elderly population

Aneurysm surgery can be well tolerated in octogenarians, but mortality for aneurysm repair is undoubtedly increased in those aged over 75, mainly owing to comorbid conditions.⁹⁵ Regrettably, in a recent British survey nearly 50% of general practitioners would not refer to a specialist an 80-year-old with a palpable aneurysm.¹⁰⁵ Clearly, we should take advantage of the current enthusiasm for continued medical education to ensure that appropriately selected patients are offered elective repair before rupture occurs.

ENDOVASCULAR TECHNIQUES

Endovascular stent-grafts have been used successfully to exclude abdominal aortic aneurysms in selected patients. Currently, endovascular aneurysm repair (EVAR) is offered in the United Kingdom only as part of randomized controlled trials comparing this technique either to surgery or, in those unfit for surgery, to best medical care. The results of this study will not be available before 2003, but national audit data from the United Kingdom suggest a 1%, 30-day mortality from EVAR if the patient is considered fit for surgery and a 17% mortality in those considered unfit.¹⁰⁶

The stent-graft is assembled within the aorta via the femoral artery at operation. This avoids a laparotomy with its associated cardiac and respiratory morbidity in these high-risk patients. However, only a minority of patients are suitable for this technique because a widely patent and not too tortuous iliac system is required through which the graft can reach its destination. A suitable length of nonaneurysmal aorta below the renal arteries is essential, as is a normal aorta above the bifurcation or acceptable iliac arteries for stent attachment.² These measurements are all taken during spiral CT or MR imaging.

MANAGEMENT OF SMALL ANEURYSMS

For many years it remained unclear how to manage aortic aneurysms less than 5.5 cm in diameter. The UK Small Aneurysm Trial¹⁰⁷ randomized 1090 patients with aneurysms 4 to 5.5 cm in diameter to either surgery or regular surveillance by ultrasonography. No significant difference in survival was found between the two groups despite follow-up of up to 6 years. Hence surgery should now be reserved for aneurysms greater than 5.5 cm and smaller aneurysms monitored with regular ultrasound imaging. The cost-effectiveness of screening for aortic aneurysm compares favorably with breast and cervical cancer screening, provided surgery is offered only for asymptomatic aortic aneurysms greater than 5.5 cm in diameter.¹⁰⁸

CONCLUSIONS

Informed consent for surgery in elderly people is especially important because of the concomitant risks but surgical intervention in selected patients is well tolerated.

Carotid endarterectomy or revascularization for peripheral vascular disease is intended primarily to enhance quality of life. Without such treatments the elderly patient may lose independence through a stroke or limb amputation. The loss of independence and long-term care costs after limb amputation or stroke argue for the cost-effectiveness of an aggressive policy of early revascularization for limb salvage or carotid disease.

KEY POINTS

Vascular Surgery

- Intermittent claudication should be managed by lifestyle advice, exercise, and antiplatelet agents such as aspirin. Angioplasty/stenting and surgery are usually reserved for severe symptoms sufficient to impair quality of life or ischemic rest pain.
- Cardiorespiratory comorbidity indicates the risk of mortality after vascular surgery.
- Carotid endarterectomy is appropriate for symptomatic internal carotid artery stenosis of greater than 70%, provided the quality of life is good. Lesser symptomatic stenoses should be managed medically.
- Aortic aneurysms greater than 5.5 cm in diameter require open or endovascular repair. Below this diameter, regular ultrasonographic surveillance is indicated.

Venous Thromboembolism in the Elderly

Hamsaraj G. M. Shetty
Ian A. Campbell
Philip A. Routledge

INTRODUCTION

Venous thromboembolism (VTE) causes 25,000 to 32,000 deaths in hospitalized patients in the United Kingdom. It accounts for 10% of all hospital deaths. This, however, is likely to be an underestimate because many hospital deaths are not followed by a postmortem examination. The cost of managing VTE in the United Kingdom is estimated to be approximately £640 million. About 25% of patients treated for deep vein thrombosis (DVT) subsequently develop debilitating venous leg ulceration, treatment of which is estimated to cost £400 million in the United Kingdom. The most serious complication of VTE is pulmonary embolism (PE), which untreated has a mortality of 30%. With appropriate treatment, mortality is reduced to 2%.¹ The diagnosis of VTE is often delayed until the occurrence of a clinically obvious (and occasionally fatal) PE.

VTE is more common in older adults. The incidence of DVT and PE increases with increasing age. Between 65 and 69 years of age, annual incidence rates per 1000 for DVT and PE are 1.3 and 1.8, respectively, and rise to 2.8 and 3.1 in individuals aged between 85 and 89 years. Older men are more likely than women of similar age to develop pulmonary embolism. About 2% develop PE and 8% develop recurrent PE within 1 year of treatment for DVT.² The diagnosis of PE is more often missed in elderly people and is sometimes made only at postmortem.³

The Virchow's triad (named after Rudolf Virchow, 1821–1902) describes the three main predisposing factors for development of thrombosis. The first is alteration in blood flow, which may be reduced in heart failure—a common problem in the elderly, less mobile individual. The second factor (injury to the vascular endothelium) is more relevant to arterial thromboembolism than to VTE. The third factor (hypercoagulability) is important since increases in clotting factor concentration, platelet and clotting factor activation, and a decline in fibrinolytic activity have all been reported in the elderly.⁴

Risk factors

The risk factors for VTE are well recognized (Table 48-1). Many of these (e.g., poor mobility, hip fractures, stroke, and cancer) are more frequently present in the elderly, who are also more likely to be hospitalized and to have orthopedic surgery. Hospitalization itself is associated with an increased risk of VTE (the incidence is 135 times greater in hospitalized patients than in the community). The risk of VTE is greatest in “medical” inpatients. It is estimated that 70% to 80% of hospital-acquired VTEs occur in this group. Without prophylaxis, 45% to 51% of orthopedic patients develop DVT. It is estimated that in Europe approximately 5000 patients per year are likely to die of VTE following hip or knee replacement, when prophylactic treatments are not given. About a third of all surgical patients developed VTE before the introduction of prophylactic treatments.¹

Clinical presentation and diagnosis

DEEP VEIN THROMBOSIS

Unilateral swelling of a leg is the most common feature in elderly patients having DVT. Calf pain may sometimes be present. Normally there is a history of recent hospitalization for orthopedic surgery, stroke, or for some other illness. There may occasionally be a history of anorexia, weight loss, or other symptoms suggestive of an underlying neoplasm. However, the patient is often otherwise asymptomatic.

It is well recognized that the clinical diagnosis of DVT can be difficult because the physical signs may often be subtle, and diagnosis may be more difficult in the elderly. Some individuals may be unable to complain about a swollen leg because of dementia or dysphasia. In addition, other conditions mimicking DVT, such as a ruptured Baker's cyst, are also more likely to occur in this age group. The clinical diagnosis of DVT relies on observing a swollen, warm, lower limb, which may sometimes be associated with engorged superficial veins. Calf tenderness may also be present. If there is a difference of more than 2 cm in circumference between the two lower limbs, DVT must be excluded by appropriate investigations, unless there is another obvious explanation.

Doppler ultrasonography has a sensitivity of 96% and specificity of 98% for proximal DVT and so it is the investigation of first choice to diagnose DVT.

Contrast venography may be necessary in selected patients, especially if clinical suspicion is high and the Doppler scan

Table 48-1. Risk Factors for VTE

Low Risk

- Minor surgery (<30 min) + no risk factors other than age
- Minor trauma or medical illness

Moderate Risk

- Major general, urologic, gynecologic, cardiothoracic, vascular, or neurologic surgery + age >40 yr or other risk factor
- Major medical illness or malignancy
- Major trauma or burn
- Minor surgery, trauma, or illness in patients with previous DVT or PE or thrombophilia

High Risk

- Prolonged immobilization
- Age over 60 years
- Previous DVT or PE
- Active cancer
- Chronic cardiac failure
- Acute infections (e.g., pneumonia)
- Chronic lung disease
- Lower limb paralysis (excluding stroke)
- BMI >30 kg/m²
- Fracture or major orthopedic surgery of pelvis, hip, or lower limb
- Major pelvic or abdominal surgery for cancer
- Major surgery, trauma, or illness in patients with previous DVT, PE, or thrombophilia
- Major lower limb amputation

Modified from references 1 and 42.

is negative. Estimation of the concentration D-dimer levels (a fibrin degradation product of thrombolysis), especially when combined with a clinical probability score, has a good negative predictive value but poor positive predictive value.⁵ Other investigations such as magnetic resonance imaging are currently being evaluated.

PULMONARY EMBOLISM

Sudden onset of dyspnea is the most common presenting feature of PE in the elderly. Sudden onset of a pleuritic chest pain, cough, syncope, and hemoptysis are other common presenting symptoms. In an elderly patient with stroke or recent orthopedic surgery, onset of any of these symptoms should greatly increase the suspicion of underlying PE. Because of high incidence of cardiovascular disease and age-related decline in cardiovascular function in general, the elderly are less likely to tolerate cardiovascular decompensation because of moderate or severe pulmonary embolism. They are, therefore, more likely to have syncope after a PE.⁶ Patients with smaller PEs may present with very nonspecific symptoms and the diagnosis is often missed in this group.

Clinical features will depend on the severity of the PE. In patients with moderate to severe PE, tachycardia, hypotension, cyanosis, elevated jugular venous pressure, right parasternal heave, loud delayed pulmonary component of the second heart sound, tricuspid regurgitation murmur, and pleural rub may be present. However, in patients with smaller PEs, clinical examination may be normal, except possibly for a sinus tachycardia. Unexplained tachycardia in a patient who is potentially at risk for VTE should alert the clinician to the possibility of PE.

Arterial blood gas analysis is a useful initial test in patients with suspected PE. Presence of hypoxia or worsening of preexisting hypoxia makes the diagnosis more likely, unless there are other comorbid conditions to account for it.

An ECG may show sinus tachycardia, S wave in lead I, Q wave and T inversion in lead III, right bundle branch block or a right ventricular strain pattern. In patients with severe PE, a P "pulmonale" may be seen. New onset of atrial fibrillation may also be a feature of PE.

A chest radiograph may show elevated hemidiaphragm, atelectasis, focal oligemia, an enlarged right descending pulmonary artery, or a pleural effusion. Many elderly patients have coexistent cardiac failure or chronic pulmonary diseases, which may also cause some of the radiographic abnormalities associated with PE.

At present, ventilation perfusion (V/Q) scans are still widely used in the United Kingdom for diagnosing PE. A medium or high probability scan is diagnostic, whereas a low probability scan virtually rules out PE.

Computed tomography pulmonary angiography (CTPA) is increasingly being used as the diagnostic test for detecting PE. A meta-analysis has indicated that the rate of subsequent VTE after a negative CTPA is similar to that following conventional pulmonary angiography.⁷ One randomized single blind noninferiority trial has demonstrated that CTPA is equivalent to a V/Q scan in ruling out PE. In the study, CTPA also diagnosed PE in significantly more patients.⁸ Although this study was conducted in younger patients, CTPA is likely to replace the V/Q scan as the investigation of first choice in elderly patients because of its greater ability to detect PE even in patients with coexistent cardiac and respiratory disease.

The British Thoracic Society has recommended CTPA as the initial lung imaging modality of choice for nonmassive PE.⁹

Although the measurement of D-dimer concentration has high sensitivity and negative predictive value in the elderly patient with PE, it has a very poor specificity and positive predictive value and therefore cannot be recommended for routine diagnostic use.¹⁰

Contrast enhanced magnetic resonance imaging appears to be a promising imaging technique for detecting PEs. An echocardiogram is also particularly useful in evaluating the severity of PE. Invasive investigations such as pulmonary angiography are very rarely performed in the elderly patients.

Treatment

Anticoagulant therapy is the most widely used treatment for VTE. Other less frequently used treatments and interventions include thrombolytic therapy, thromboembolectomy, and the use of vena caval filters.

For initial treatment of both DVT and PE, low molecular weight heparins (LMWHs) are the drugs of first choice. Because they produce predictable anticoagulation with a weight-based (per kg body weight), once daily dose by subcutaneous route—and do not require routine laboratory monitoring (except for grossly overweight or underweight patients and those with renal failure)—they have almost replaced unfractionated heparin (UFH), which is now generally used only in special circumstances such as during the perioperative period. Randomized clinical trials have shown that LMWHs are as effective as UFH for treatment of both DVTs and PEs.^{11,12} LMWHs appear to cause less hemorrhagic complications and for the reasons described earlier, are much more convenient to use. With the widespread use of LMWHs in hospitals within the United Kingdom, many patients with DVT can now be treated as outpatients.

Once the diagnosis of DVT or PE is confirmed, warfarin therapy is commenced immediately and LMWHs are continued for at least 5 days or until therapeutic international normalized ratios (INRs) have been maintained for 48 hours. The recommended target INR for treatment of VTE is 2.5 (range 2 to 3).¹³ A higher intensity of 3.5 (range 3 to 4) is recommended for treating patients who develop recurrent VTE while in a therapeutic INR range between 2 and 3.¹⁴

As elderly patients are more sensitive to the effects of warfarin, they are much more likely to be over-anticoagulated during initiation of the treatment. Use of a tailored induction dosing regime is likely to reduce this possibility. One such regimen¹⁵ uses a first dose of 10 mg and subsequent doses are adjusted daily thereafter, depending on the INR (Table 48-2). Another induction regimen that has been shown to be safe and accurate in elderly hospitalized patients (over 70 years) involves giving 4 mg of warfarin daily for 3 successive days.¹⁶

The various recommendations with regard to the duration of warfarin therapy following VTE have generated a considerable amount of debate. One guideline recommended a minimum of 6 months of treatment.¹⁴ However, a randomized trial has shown that 3 months of anticoagulation is adequate for patients with a first episode of VTE (idiopathic or otherwise) and is less likely to be associated with serious hemorrhages.¹⁷ It is now being increasingly recognized that the duration of warfarin therapy should depend on the risk of recurrent VTE in an individual patient. If the

VTE occurred following surgery, the risk of recurrence after 1 year of stopping anticoagulant therapy is approximately 3% and in such a situation it is safe to discontinue warfarin therapy after 6 weeks if there are no persistent risk factors. In patients with minor reversible risk factors (e.g., soft tissue leg injury), who have a recurrence risk of 5%, anticoagulants can be stopped within 3 months. On the other hand, patients who have a major, nonreversible risk factor such as cancer are at high risk of recurrence, and therefore should be considered for long-term anticoagulant therapy.¹⁸ One author has recently recommended long-term anticoagulation after unprovoked (idiopathic) VTE,¹⁹ but a recent study does not support this view and the BTS guideline recommends 3 months of anticoagulation after the first episode.^{9,17}

Practical aspects of oral anticoagulant therapy in the elderly

Older people are more sensitive to the anticoagulant effect of warfarin. This is probably due to a combination of pharmacodynamic and pharmacokinetic factors.^{20,21} Warfarin dose requirement declines with age and in one study patients aged less than 35 years required a mean of 8.1 mg/day, more than twice as much to maintain the same INR as in those older than 75 years.²¹ The relationship between age and warfarin requirements is, however, rather weak.²¹ Warfarin clearance (wholly by metabolism since no warfarin is excreted unchanged in the urine) has been shown to decline with age in one study.²²

Figure 48-1. CT head showing intracerebral hemorrhage.

Chronologic age does not appear to be a risk factor for bleeding with warfarin therapy, except possibly in those older than 80 years.²³ Hemorrhagic complications due to warfarin are more likely to occur in the first 90 days of anticoagulant therapy (especially in the first month), either because of poor control of anticoagulation or the unmasking of an underlying lesion, such as a peptic ulcer or malignancy. High INRs (>4.5), poor control of anticoagulation, and inadequate patient education regarding anticoagulant therapy are likely to increase the risk of bleeding.

Studies have reported a log-linear relationship between the intensity of anticoagulation and the risk of bleeding.²⁴ The risk of bleeding rises threefold between INRs 2 and 3 and further threefold between 3 and 4.²⁵ As a high INR is one of the most important risk factors for bleeding in the elderly, the aim of treatment should be to maintain the lowest intensity of anticoagulation consistent with effective treatment or prophylaxis.

Polypharmacy is very common in the elderly and it increases the chances of drug interactions, which may result in overanticoagulation. Using medicines that are well known to enhance anticoagulant effect (e.g., antibiotics [particularly macrolides], amiodarone, etc.) with care and adjusting the dose of warfarin appropriately will reduce the likelihood of overanticoagulation and consequent bleeding.

Fatal hemorrhages tend to be intracranial and are more likely to occur in older people.²⁵ (Figure 48-1). The elderly are more predisposed to intracranial bleeding because of the increased prevalence of leukoaraiosis and other cerebrovascular diseases. Older people are also more likely to

have falls and so are at a greater risk of developing subdural hematomas.

An outpatient bleeding risk index included four risk factors for major bleeding (attracting 1 point each): age over 65 years, history of gastrointestinal bleeding, history of stroke, and one or more specific comorbid conditions (recent myocardial infarction, hematocrit of less than 30%, presence of diabetes mellitus, and serum creatinine of greater than 1.5 mg/dL). The authors indicated that a score of zero was associated with low risk, 1 to 2 with medium risk, and 3 to 4 with high risk (23% in 3 months and 48% in 12 months).²⁶ The drawback of this clinical tool is that it places all people aged over 65 years in the medium risk category for bleeding, which may not necessarily be the case.

Hemorrhage associated with anticoagulant therapy should always be investigated to exclude an underlying pathology, even if the bleeding occurred when the INR was high. Unexplained anemia in an anticoagulated patient may well be due to occult bleeding (e.g., retroperitoneal hemorrhage). Sometimes atypical bleeding sites and presenting symptoms may pose diagnostic difficulties (e.g., alveolar hemorrhage [having unexplained anemia or dyspnea]).

Management of overanticoagulation and bleeding

Because of the high risk of bleeding associated with overanticoagulation, measures to bring the INR down to the therapeutic range should be instituted as soon as possible. If the INR is less than 8 (and depending on the indication for anticoagulation), warfarin is temporarily discontinued and reinstated once the INR has fallen to less than 5, providing there is no bleeding or only minor bleeding.¹⁴ If the INR is over 8 and there is no bleeding or minor bleeding, temporary discontinuation of warfarin is also recommended, but if the patient has other risk factors for bleeding, low dose vitamin K either orally (0.5 to 2.5 mg) or intravenously (0.5 mg) will help to bring it within the therapeutic range in the majority of patients.^{13,27} Anaphylactoid reactions with intravenous vitamin K have rarely been reported, but their incidence seems to be lower with newer preparations, and when the dose is administered very slowly. In patients with major bleeding, warfarin should be discontinued and anticoagulation reversed urgently with prothrombin complex concentrate (factors II, VII, IX, and X) or fresh frozen plasma if the concentrate is not available. In addition, vitamin K₁, 5 to 10 mg by slow intravenous injection is recommended to sustain the reversal. Urgent reversal of anticoagulation is particularly important in patients with intracerebral bleeding as it will prevent the continued expansion of the hematoma (the latter is associated with an even poorer outcome).

Monitoring warfarin therapy

Close monitoring of warfarin therapy will reduce the likelihood of over- or under-anticoagulation. Currently, most patients are either monitored by their general practitioners or in a hospital-based anticoagulation clinic. With appropriate training, patient self-management of anticoagulation has been shown to be feasible, effective, and safe. A randomized controlled trial, which compared routine care with patient self-management (with twice weekly use by patients, at

home, of an INR measurement device and a simple dosing chart), showed that percentage of time in therapeutic range and serious adverse events were similar between the two groups. Patients who had poor control before the study showed an improvement with self-management.²⁸ At present, the point of care INR measurement devices are quite expensive. They are, nevertheless, particularly useful for patients living in remote areas or those who have difficulty in accessing services of an anticoagulation service in primary or secondary care.

Inferior vena caval filters

In patients who have contraindications for anticoagulation, and those who bleed or continue to have thromboembolism during anticoagulant therapy, placement of an inferior vena caval (IVC) filter can be lifesaving. The PREPIC study, which included 400 patients with proximal DVT, with or without PE, followed up for 8 years, reported a significant reduction in the incidence of symptomatic PE, but an increase in the incidence of DVT in patients treated with filter compared with those who received standard anticoagulant therapy. There was no significant difference in the development of postphlebotic syndrome or mortality between the two groups.²⁹ Complications of IVC filters include misplacement or embolization of the filter, vascular injury or thrombosis, pneumothorax, and air embolus.

A limited number of small studies have reported no inferior vena caval thrombosis with the use of retrievable inferior vena caval filters.³⁰ Further studies are needed to confirm these encouraging initial findings.

Treatment of PE with hemodynamic instability

Massive PE may have acute cor pulmonale or cardiogenic shock. Elderly patients are much more likely to develop right heart failure and shock with massive PE. Such patients should be managed in an intensive therapy unit unless they have a terminal illness or have previously had a very poor quality of life. In addition to cardiovascular and respiratory resuscitation, treatment options include thrombolysis or thromboembolectomy. The most commonly used thrombolytic agent is recombinant tissue plasminogen activator (rt-PA). Intracranial hemorrhage occurs in about 3% of patients treated with thrombolytic agents. In patients with massive PE who have contraindications for thrombolysis, or when it has failed, pulmonary embolectomy can be attempted. Despite these measures, mortality is very high in patients with PE having cardiogenic shock.

Prevention

Many hospitalized elderly patients are at risk for VTE. Those with stroke, hip fractures, and those who have had orthopedic surgery are at particularly high risk. In such patients, prophylaxis implementation rates have been reported to range between 13% and 64%. Prophylactic treatments are particularly underused in medical patients. A very large multinational cross-sectional survey, designed to assess the VTE risk in an acute hospital setting, found 51.8% to be at risk (64.4% surgical, mean age 60 years and 41.5% medical patients, mean age 70 years); of these 58.5% of surgical and only 39.5% of medical patients received appropriate thromboprophylaxis.³¹

A meta-analysis of thromboprophylaxis in hospitalized medical patients showed that, compared with controls, treatment with low dose UFH or LMWH reduced the risk of DVT (risk ratio 0.33 and 0.56, respectively) and PE (risk ratio 0.64 and 0.37, respectively). Treatment with LMWH was associated with a greater reduction in DVT risk (relative risk: 0.68) compared with UFH. There was no difference in the risk of bleeding or thrombocytopenia between the two drugs and neither of them reduced mortality.³²

The American College of Chest Physicians (ACCP) recommends LMWH, low-dose UFH, or fondaparinux for thromboprophylaxis in hospitalized, acutely ill, medical patients. In those who have contraindications for anticoagulant use, graduated compression stockings or intermittent pneumatic compression can be used.¹³

A meta-analysis involving 9 studies compared extended thromboprophylaxis (for 30 to 42 days) with heparin (8/9 studies used LMWH) or warfarin with a placebo or untreated controls after total hip replacement (THR) and total knee replacement (TKR). It showed a significant reduction in symptomatic VTE (equivalent to 20 symptomatic VTEs per 1000 patients treated) without an associated increase in major hemorrhage in the treatment group.³³

A number of new anticoagulants are currently being investigated for thromboprophylaxis. Orally administered factor Xa inhibitors and direct thrombin inhibitors have already been investigated in randomized clinical trials in patients undergoing THR and TKR.

A randomized, double-blind study compared subcutaneous, once daily, preoperative enoxaparin, with postoperative fondaparinux in patients undergoing elective THR (age range: 24 to 97 years; mean age 67 years). The risk of VTE was significantly reduced in those receiving fondaparinux (relative risk reduction 55.9%, CI 33.1 to 72.8). Frequency of deaths and clinically relevant bleeding were similar in the two groups.³⁴

Another double-blind, randomized study compared postoperative oral dabigatran etexilate with preoperative enoxaparin in patients undergoing THR (mean age range: 63 to 65 years). In this study, oral dabigatran was found to be as effective as enoxaparin in reducing VTE risk and there was no difference in the risk of major bleeding between the two drugs.³⁵

The randomized, double-blind studies, Regulation of Coagulation in Orthopaedic Surgery to Prevent Deep Vein Thrombosis and Pulmonary Embolism 1 (RECORD 1)³⁶ and RECORD 3,³⁷ compared a 10-mg once-daily dose of rivaroxaban, an oral direct factor Xa inhibitor, with 40 mg of enoxaparin, for extended thromboprophylaxis in patients undergoing THR and those undergoing TKR, respectively. Rivaroxaban was significantly more effective in reducing DVT (symptomatic and asymptomatic), nonfatal PE, and death from any cause (at 36 days for THR patients and within 13 to 17 days for TKR patients). There was no significant difference in the risk of major bleeding.

The RECORD 2 study compared oral rivaroxaban 10-mg dose once daily given for 31 to 39 days with subcutaneous enoxaparin 40-mg dose once daily given for 10 to 14 days in patients undergoing elective THR. Extended thromboprophylaxis with rivaroxaban significantly reduced VTE, including symptomatic events.³⁸

Although these studies are encouraging, LMWH and warfarin presently remain the most frequently used agents for thromboprophylaxis in most circumstances in elderly people.

Graduated compression stockings

Graduated compression stockings (GCS) reduce the risk of VTE in surgical patients, but they are not superior to LMWHs. Ideally, they should be used along with LMWHs. In patients who are at high risk of bleeding, they can be used on their own. As most elderly patients have peripheral vascular disease, the GCS should be used with extreme caution: inappropriate use has been known to cause ischemic complications.

The role of GCS in medical patients needs further investigation. A large multicenter clinical trial (the CLOTS trial) is currently investigating its role in stroke patients.

After proximal DVT, approximately 60% of patients develop postphlebotic syndrome. A randomized trial has shown that, when sized-to-fit, GCS reduce the incidence by about 50%.³⁹ Patients with proximal DVT should start wearing GCS as soon as possible after the diagnosis and continue to wear them for at least 2 years.³⁹

Prognosis

A population-based cohort study of patients with VTE found that the overall probable and definite (in parentheses) cumulative percentage of VTE recurrence at 7, 30, and 180 days and 1 and 10 years was 1.6% (0.2%), 5.2% (1.4%), 10.1% (4.1%), 12.9% (5.6%), and 30.4% (17.6%), respectively.

KEY POINTS

Venous Thromboembolism in the Elderly

- Venous Thromboembolism (VTE) is an important cause of mortality in hospitalized patients and is more common in the elderly.
- Risk factors for VTE, such as immobility, hip fracture, and stroke are more common in older people.
- In an elderly patient with stroke or recent orthopedic surgery, sudden onset of dyspnea, chest pain or syncope should markedly increase the suspicion of underlying PE.
- Computed tomography pulmonary angiography (CTPA) is the initial lung imaging modality of choice for nonmassive PE.
- For prevention and initial treatment of both DVT and PE, low molecular weight heparins are the drugs of first choice.
- Older people are more sensitive to the anticoagulant effect of warfarin.
- Studies have reported a log-linear relationship between the intensity of anticoagulation and the risk of bleeding.
- In patients with massive pulmonary embolism, treatment options include thrombolysis or thromboembolectomy.
- Orally administered factor Xa inhibitors and direct thrombin inhibitors are being investigated in randomized clinical trials for treatment of VTE.
- Prompt clinical diagnosis and carefully monitored institution of therapy will reduce morbidity and mortality from VTE in the aging population.

The risk of recurrence was greatest in the first 6 to 12 months after the initial VTE. Independent predictors of first overall VTE recurrence included increasing age and body mass index, neurologic disease with paresis, malignant neoplasm, and neurosurgery.⁴⁰

A prospective international registry, which studied clinical predictors for fatal PE in patients with VTE, has reported 3-month mortality and fatal PE rates of 8.65% and 1.68%, respectively. Patients with symptomatic nonmassive PE at presentation were found to have a 5.42-fold higher risk of fatal PE compared with patients with DVT without symptomatic PE ($P < 0.001$). The risk of fatal PE was 17.5 times higher in patients having a symptomatic massive PE. Other independent risk factors for fatal PE were immobilization for neurologic disease, age greater than 75 years, and cancer.⁴¹

Long-term complications of VTE include postphlebitic syndrome and chronic thromboembolic pulmonary hypertension.

CONCLUSION

VTE continues to be an important cause of morbidity and mortality in older people. There have been major advances in its diagnosis and treatment over the past 15 to 20 years. A number of new antithrombotic drugs (e.g., orally administered factor Xa inhibitors and direct thrombin inhibitors) are currently being investigated and may provide an alternative to warfarin therapy. Whatever treatment is advocated in the future, prompt clinical diagnosis and carefully monitored institution of therapy will reduce morbidity and mortality from VTE in the aging population.

Asthma and Chronic Obstructive Pulmonary Disease

Sidney S. Braman
Muhanned Abu-Hijleh

DISEASES OF AIRFLOW OBSTRUCTION

There are three common airway diseases of older adults that cause limitation of airflow: chronic bronchitis, emphysema, and asthma. All have in common a reduction of maximum expiratory flow and a slow forced emptying of the lung on spirometric testing. Chronic bronchitis and emphysema share common clinical and pathologic abnormalities. Most patients with these conditions have a significant smoking history and attempts were made to incorporate both conditions under the term chronic obstructive lung disease (COPD). As asthma became recognized as an inflammatory disease with a different cellular and inflammatory mediator profile, it was no longer considered under the term COPD. This was also justified by the fact that asthma is felt to be distinct because airflow obstruction is predominantly reversible and the airways of asthmatics are notably hyperresponsive to a variety of specific (aeroallergens) and/or nonspecific (methacholine, histamine, cold air) inhaled substances. Current definitions of these diseases of the airways are presented in [Table 49-1](#).

Although it is still clinically useful to distinguish asthma from COPD (chronic bronchitis and emphysema), it is important to recognize three problems with this nosology:

- Remission rates for adults with asthma are much less than those seen in children and this probability increases with age. As a result, most asthmatics, even those who have never smoked, who are at the age when COPD is most often recognized (over age 60), have evidence of poorly reversible airflow obstruction on pulmonary function testing. This is thought to be caused by a structural remodeling of the airways with what may be permanent changes. This is supported by data from longitudinal studies that the average FEV₁ in asthmatics declines over a period of years. Despite these findings, there are many patients who show no correlation between their FEV₁ and the duration of their disease.
- Bronchial hyperresponsiveness—the exaggerated bronchoconstrictive response to nonspecific agonists such as methacholine is a constant feature in asthmatics that is so important to its pathogenesis. On the other hand, increased responsiveness to constrictors such as methacholine and histamine (but not indirect bronchoconstrictors such as cold air and bradykinin, which do not act directly on airway smooth muscle) is seen in the majority of older smokers with COPD. This was shown to be a strong predictor of progression of airway obstruction in younger smokers who continue to smoke. In asthma, bronchial hyperresponsiveness is not related to baseline airway caliber, whereas in COPD the increased responsiveness to bronchoconstrictors can be explained entirely by the geometric effect of fixed airway narrowing.
- Unfortunately, many adult patients with asthma are current or former smokers. It is likely that such

patients have more than one pathologic process with several pathways of inflammation. Although studies on the effects of smoking on the rate of decline of FEV₁ in asthma have given conflicting results, most smoking asthmatics will have some degree of fixed airflow obstruction. This has raised a complexity of semantic issues that have not been solved. One attempt has been to combine two of the major pathologic processes and describe such patients using the term “asthmatic bronchitis” but this has not been widely accepted.

Although there are distinct differences between asthma and COPD in older patients, the clinical differentiation in some individuals is quite problematic. Fortunately, although the pathologic mechanisms leading to asthma and COPD differ, the pharmacologic and nonpharmacologic therapeutic approaches to these two conditions are quite similar as described later in this chapter, making clinical decisions less problematic. An overview of the distinguishing clinical features of these conditions is seen in [Table 49-2](#).

ASTHMA IN THE ELDERLY

Introduction

Asthma is a common debilitating disease that affects 300 million people globally with a 50% increase in the prevalence every decade, in addition to climbing morbidity and mortality. In response to these alarming statistics of the twentieth century, the National Asthma Education and Prevention Program (NAEPP) commissioned an expert panel that would help bridge the gap between current knowledge and clinical practice. The panel was charged to develop guidelines for the care of asthma that would raise public awareness, improve physician recognition that asthma is a growing health problem, and improve asthma control. The first expert panel report was offered in 1991. Based on new evidence from the medical literature, updates were published in 1997 and 2002. The most recent update was made available in 2007 as the Expert Panel Report 3, entitled “Guidelines for the Diagnosis and Management of Asthma” www.nhlbi.nih.gov/guidelines/asthma.¹

The NAEPP guidelines offered a new definition of asthma (see [Table 49-1](#)) that is now widely accepted and appropriate for any age. This description of asthma clearly established it as an inflammatory disease and provided the basis for anti-inflammatory therapy. This has been the foundation of treatment for asthma over the last 2 decades.² In fact, there is strong evidence linking anti-inflammatory therapy with inhaled corticosteroids to a reduction in asthma mortality.³

Epidemiology: prevalence

The prevalence of asthma has risen over the last several decades with recent data showing that 22 million Americans are affected by this disease. The overall prevalence of asthma

Table 49-1. Definitions of Obstructive Lung Diseases

- Asthma: a chronic inflammatory disease of the airways in which many cells play a role, in particular, mast cells, eosinophils, and T-lymphocytes. In susceptible individuals, this inflammation causes recurrent episodes of wheezing, breathlessness, chest tightness, and cough, particularly at night and/or in the early morning. These symptoms are usually associated with widespread but variable airflow limitation that is at least partially reversible either spontaneously or with treatment. This inflammation also causes an associated increase in airway hyperresponsiveness to a variety of stimuli. Reversibility of airflow limitation may be incomplete in some patients with asthma.
- COPD: a preventable and treatable disease state characterized by airflow obstruction that is no longer fully reversible. The airflow limitation is usually progressive and is associated with an abnormal inflammatory response of the lungs to noxious particles and gases, primarily caused by cigarette smoking. Although COPD affects the lungs, it also produces considerable systemic consequences:
 - Chronic bronchitis: a condition characterized by the presence of chronic cough and sputum expectoration that is present for most days for a minimum of 3 months per year, for at least 2 successive years and not attributable to other pulmonary or cardiac causes
 - Emphysema: a condition defined anatomically by enlargement of air spaces distal to the terminal bronchiole, accompanied by destruction of their walls and capillaries, without obvious fibrosis

Table 49-2. Distinguishing Clinical Features of Asthma and COPD in Elderly Patients

Asthma	COPD
History of allergy is common	Normal prevalence of allergy
Smoking history in some patients	90% have smoked cigarettes
Episodic attacks of dyspnea	Progressive dyspnea over years
Nocturnal attacks of dyspnea	Daytime exertional dyspnea
Reversible airflow obstruction	Minimal or no reversibility
Good QOL	Progressively poor QOL

QOL, Quality of life.

in the U.S. population is approximately 6% to 7%.⁴ Although the diagnosis and treatment of asthma are often focused on younger population, it is estimated that more than 1 million adults older than 65 years of age in the United States carry a diagnosis of asthma.

In a survey of the elderly in the United States, the prevalence of physician-diagnosed asthma was 4%, with an additional 4% having probable asthma (symptoms of asthma without a diagnosis).⁵ Other estimates of prevalence have shown a broad range from 4% to 9%. In many older patients, it is not possible to distinguish asthma from chronic bronchitis or COPD, especially in current or former cigarette smokers. In population surveys that inquire about asthma and COPD, subjects frequently reported more than one disease. In an investigation of two databases⁶ from the United States and the United Kingdom, 8.5% of the participants from the U.S. population reported asthma, chronic bronchitis, or emphysema. Of these subjects, the asthma-only group was the largest, accounting for 50.3% and 79.4% of these patients in the United States and United Kingdom, respectively. This number decreased with increasing age. Overall, 17% and 19% of patients in the United States and in the United Kingdom, respectively, reported more than one condition, and this percentage increased with age. In

those over 50 years of age in the U.K. cohort, individuals with more than one condition accounted for as many as 50% of the patients with obstructive lung disease. This proportion was 25% in a 45- to 69-year age group in another study from Australia.⁷

Community surveys in which a physician diagnosis of asthma was required have provided data on asthma in the general population. The prevalence of active asthma in one study, which represented new cases excluding those in remission, peaked in early childhood at about 8% to 10%, declined to approximately 5.5% during late adolescence and then rose again to about 7% to 9% during late adulthood (over age 70). In 1987, data from the National Center for Health Statistics showed that in the 65- to 74-year age group, the rate of active asthma or wheeze was 10.4% compared to 5.7% in teenagers, 6.9% in the 18- to 44-year-old age group, and 9.6% in the 45- to 64-year-old age group. In another report from a population-based cohort of elderly individuals living in Rochester, Minnesota, a group of asthmatics were identified with the onset of asthma after age 65. The age-specific incidence of asthma in those aged 65 to 74 years of age was 103/100,000; it was 81/100,000 in those aged 75 to 84 years, and 58/100,000 in those older than 85 years.

Epidemiology: morbidity and mortality

Asthma in the elderly is associated with a significant number of hospitalizations and emergency department visits, which leads to substantial health care cost. In 1999, the United States rate for asthma hospitalization for patients older than 65 years of age was 21.1/10,000.⁴ Elderly patients with asthma are more likely to die from their disease than younger individuals and although mortality rates in some age groups have decreased, this is not the case in the elderly, especially women.⁸

According to the U.S. Centers for Disease Control and Prevention (CDC), asthma deaths in the elderly account for more than 50% of asthma fatalities annually with an approximately 5.8 asthma deaths per 100,000 in this group reported in the years 2001–2003.^{4,9} In a U.S. study of asthma deaths of patients who had died in hospitals or nursing homes, 80% of the deaths occurred in patients age 55 and older. Seventy-five percent of these patients were known to be smokers or ex-smokers. A careful analysis of these cases revealed that many younger asthmatics did clearly have asthma and had died of a severe sudden attack. In those over age 55, confounding factors were much more prevalent. These patients frequently had underlying chronic bronchitis or COPD, were admitted to the hospital for nonrespiratory problems, and died of chronic respiratory failure. Less aggressive therapy was given to these elderly patients, both in the outpatient setting and during hospitalization. This study suggested that many elderly patients with asthmalike symptoms and a history of previous smoking have COPD as an underlying or even dominant feature of their disease. This undoubtedly overestimated the true mortality from asthma in this age group. Factors that may increase risk of death in the elderly include the delay in seeking diagnosis and treatment, poor cardiopulmonary reserve, impaired perception of increasing airway obstruction, blunted hypoxic ventilatory drive, and psychosocial and cognitive problems, which are very common in this age group.

Pathogenesis

Asthma is caused by a complex interaction of cells, mediators, and cytokines that result in airway inflammation,¹⁰ which results in a number of typical histopathologic findings in the airways. This inflammation results in the three cardinal features described in the definition of asthma that are involved in the pathogenesis of the disease: airflow obstruction, reversibility of obstruction, and bronchial hyperresponsiveness.

Histopathologic findings

Infiltration of the airways by inflammatory cells such as mast cells, eosinophils, activated T-lymphocytes, and neutrophils was demonstrated on biopsies and bronchoalveolar lavage. The number of activated lymphocytes found in bronchial biopsies has been correlated with the number of local activated eosinophils and the severity of asthma. Specific cytokines, most of which are products of lymphocytes and macrophages, appear to direct the movement of cells to the site of airway inflammation. Mast cells, usually as a result of IgE-mediated stimulation, also release preformed mediators, such as histamine and proteases, and further act as a regulator of inflammation by producing cytokines that promote eosinophil infiltration and activation. Several mast cell products induce bronchoconstriction and cause increased mucus secretion.

Edema of the airway mucosa occurs as a result of increased capillary permeability with leakage of serum proteins into the interstitium. Denudation of the airway epithelium can lead to airway edema and loss of substances in the mucosa that protect the airway. Epithelial damage promotes bronchial hyperresponsiveness since access by irritating substances to sensory nerve endings is increased. Another characteristic finding in severe asthma is the presence of tenacious mucus plugs in the airways. Death from asthma usually occurs from blockage of the airways by diffuse mucus plugging.

Thickening of the reticular basement membrane, the lamina reticularis, is a constant feature of asthma. There is evidence of increased bronchial smooth muscle mass that contributes considerably to the thickness of the airway wall. The airway architecture is also changed by the deposition of type III and V collagen and fibronectin beneath the basement membrane (referred to as "subepithelial fibrosis"). The architectural changes seen in and beneath the basement membrane and in the bronchial smooth muscle are referred to as airway remodeling and are thought to cause permanent changes that result in fixed airflow obstruction.

Histopathologic findings in elderly asthmatics

Sputum, bronchoalveolar lavage, and bronchial mucosal biopsy specimens from elderly stable asthmatics have confirmed the presence of prominent eosinophilia, and CD4+ T lymphocytes, as seen with younger asthmatics.¹¹ Thickening of the reticular basement membrane and disruption of the epithelial lining has also been described. Pathologic findings have been compared in young and older subjects who have died of fatal asthma attacks.¹² Both old and young patients with asthma have thickened airway smooth muscle compared with normal subjects. However, older asthmatics with a longer duration of disease demonstrate an increase in airway wall thickness predominantly due to an increase in the adventitial area. Greater postmortem reduction in airway

lumen is also found in elderly asthmatics. The luminal content and subepithelial collagen deposition are similar in both asthma groups. This supports the concept that aging and/or asthma duration result in airway remodeling, causing "fixed" or irreversible airflow obstruction in this population.

Airflow obstruction

Airflow obstruction is a cardinal feature of asthma. Objective measures of lung function such as spirometry and peak flow measurements are generally underutilized in elderly patients, which contributes to the delay or absence of diagnosis.¹³ Lung function testing is especially important in this age group since there is an age-related reduction in the perception of dyspnea seen in the elderly. However, spirometry may be difficult to perform in some situations because of physical or poor cognitive impairments. In addition, it is hard to define the lower limits of predicted normal values in this age group, which may vary considerably.

During an acute asthma attack, lung hyperinflation occurs, protecting airway narrowing. This happens because of the interdependence of lung volume and airway caliber since parenchymal attachments cause greater tethering of the airways at higher lung volumes. Inflammation of the bronchial wall, however, may uncouple the mechanical linkage between the parenchyma and the airway. This may contribute to airway narrowing and also to bronchial hyperresponsiveness. During an acute attack of asthma, airway resistance increases and all measures of airflow (peak expiratory flow rate [PEFR], forced expiratory volume in 1 second [FEV₁], forced expiratory volume in 1 second as a fraction of the forced vital capacity [FEV₁/FVC %], airway resistance [R_A], etc.) are abnormal. During remission, these tests may normalize, and yet considerable dysfunction may be present in peripheral airways. Studies using bronchoscopic measurements have shown that peripheral resistance can be tenfold higher than in normal subjects.

Reversibility of airflow obstruction

Another hallmark of asthma is that the airflow obstruction reverses to normal or toward normal after treatment. This may occur rapidly, after treatment with a short-acting inhaled β -agonist, or after weeks or months of intense anti-inflammatory therapy. Although complete reversibility is frequently seen with young asthmatics, most elderly asthmatics, and those of any age group with more severe and persistent symptoms, show only partial reversibility despite continuous intense anti-inflammatory and bronchodilator therapy. In one random survey of 1200 elderly asthmatics older than 65 years from the Mayo Clinic, only one in five patients had normal pulmonary function (FEV₁ >80% predicted) whereas a similar number showed moderate to severe airflow obstruction (FEV₁ <50% predicted) even after administration of an inhaled short-acting bronchodilator.¹⁴ There is growing evidence that the airway function of young and middle age asthmatics declines at a greater rate than normal subjects. The rate of decline increases with increasing age and in those who smoke cigarettes. However, these effects on asthmatics are variable since not all individuals show a steep rate of decline. The precise reasons for this individual variability have not been defined, although there is evidence that atopy and marked bronchial hyperresponsiveness are two important risk factors for airflow obstruction.

In addition, the long duration and severity of previous disease are also important factors.¹⁵ On the other hand, for those who develop asthma at an advanced age, there is evidence that lung function is reduced, even before a diagnosis is made, and declines rapidly shortly after diagnosis. Thereafter, it remains fairly stable. Hence, many elderly asthmatics with severe airflow obstruction report a short duration of symptoms for months to a few years. The cause of chronic persistent airflow obstruction in older asthmatics with long-standing disease or with recently acquired asthma has not been explained, and airway remodeling is thought to be the main cause.

Diagnostic tests for reversible airflow obstruction

The presence of airflow obstruction can be easily confirmed by simple office spirometry. A reduced FEV₁ and ratio of FEV₁/FVC is demonstrated with the timed vital capacity maneuver or by the flow volume loop. The loop is produced by the simultaneous measurement of airflow and lung volume during forced exhalation and inhalation (Figure 49-1). The configuration of the flow volume loop can be helpful in the differential diagnosis of airflow obstruction in the elderly. Traditionally, an FEV₁/FVC ratio of less than 70% increases the probability of asthma in an elderly patient with asthma symptoms. A brisk response to a short-acting

bronchodilator may demonstrate the second cardinal feature of asthma, reversible airflow obstruction ("a responder"). Evidence of reversibility (postbronchodilator FEV₁ or FVC increases more than 12% and 200 mL) increases the probability of asthma. However, many patients with COPD will also meet the reversibility criteria on any given testing day although the response to an inhaled bronchodilator is generally greater with asthma (16% asthma vs. 11% COPD). A positive response in a patient with COPD may not persist over time; over 50% of patients will change "responder" status between visits. This makes the test less than reliable to confirm the diagnosis of asthma especially in the elderly. In general, when complete reversibility of airflow obstruction is documented, COPD, a disease of fixed airway obstruction becomes less likely. As noted above, many patients with asthma will not meet the reversibility criteria and airway remodeling may be the cause. Additionally, reduced β_2 -adrenoreceptor responsiveness has been demonstrated in normal elderly men and women, and asthmatics. When compared to young and elderly normal subjects, elderly late-onset asthmatics have been shown to have reductions in β -adrenergic receptor affinity while maintaining normal receptor density. There is also evidence that post receptor events are impaired in the aged as cyclic AMP production by pathways that are independent of adrenergic receptor stimulation is depressed. Although the bronchodilator response to inhaled β -agonists declines with age, this is not the case with anticholinergic agents.

Bronchial hyperresponsiveness

Airway inflammation is thought to be a key factor in producing the third cardinal feature of asthma, BHR. This can be described as an exaggerated bronchoconstrictive response by the airways to a variety of stimuli, such as aeroallergens, histamine, methacholine, cold air, and environmental irritants. It is not clear whether BHR is acquired or is present at birth and genetically determined to appear with the appropriate stimulus, such as during allergen exposure, respiratory viral illness, or the inhalation of noxious agents, such as ozone or sulfur dioxide. Anti-inflammatory agents such as inhaled corticosteroids are effective in reducing bronchial hyperactivity.

The degree of bronchial hyperresponsiveness can be determined in the pulmonary function laboratory by standard inhalation bronchoprovocation challenge testing. The methacholine inhalation challenge is the most frequently used clinical tool to determine the presence and degree of bronchial hyperresponsiveness. When the patient has asthma symptoms, and the tests looking for airflow obstruction are normal, the methacholine challenge can be used for diagnosis. A positive test is not specific for asthma. A strongly positive test coupled with a high pretest probability offers a high likelihood of asthma. A negative bronchoprovocation test rules out asthma as a cause of pulmonary symptoms. Bronchoprovocation testing is a safe and effective method to uncover asthma in the elderly.

There is evidence that some sympathetic and parasympathetic nervous system functions are diminished with age. This decline in autonomic nervous system function is consistent with a generalized diminution of peripheral somatic nerve function with aging. However, although the protective laryngeal gag reflex appears diminished in

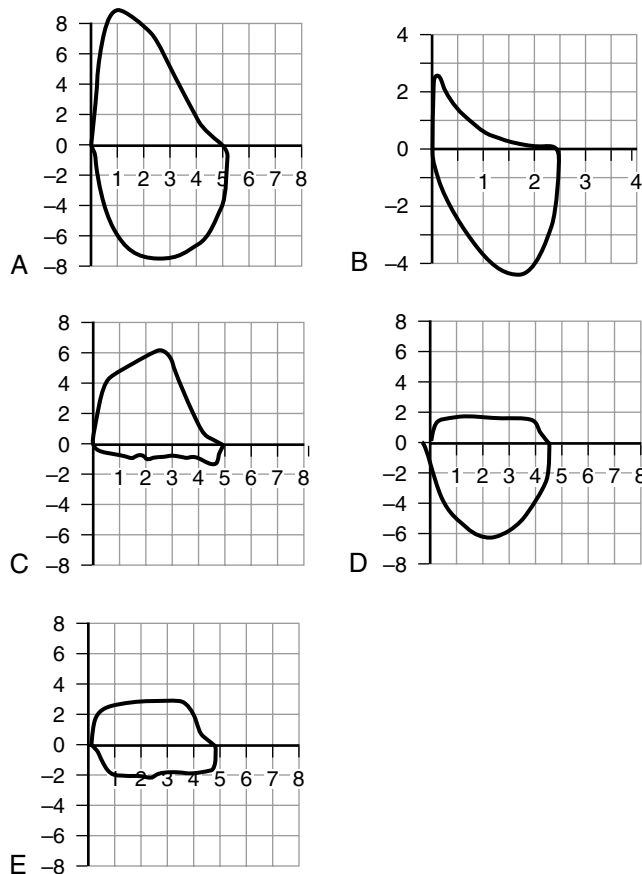

Figure 49-1. Flow-volume loops in a normal subject (A), a patient with COPD (B), extrathoracic dynamic airway obstruction with airflow limitation during inspiration (C), intrathoracic dynamic airway obstruction with airflow limitation during expiration (D) and fixed airway obstruction with airflow limitation during inspiration and expiration (E).

normal elderly subjects, there is evidence that the cholinergically mediated cough reflex may not be similarly affected. Measurements of cholinergic bronchoconstrictive reflexes have shown mixed results although most studies have shown a positive correlation between aging and airway hyperresponsiveness.¹⁶ There is also a relationship between the degree of bronchial hyperresponsiveness and prechallenge pulmonary function; a low FEV₁ predicts heightened responsiveness. Although this may explain why some studies have shown that bronchial responsiveness is heightened in the elderly, aging may be an independent factor influencing airway responsiveness. Other factors that may contribute to heightened airway responsiveness in the older population are atopy and current or previous smoking history.

Atopic asthma

Allergic or atopic reactions in the upper (nose, sinuses) and lower airways are both important in the pathogenesis of asthma in childhood and young adulthood. Their role in the elderly is less clear. Atopy is defined by the presence of abnormal amounts of IgE antibodies in response to contact with environmental antigens. This can be demonstrated clinically by elevated total or specific serum IgE levels in the blood or by positive skin prick tests to a variety of standardized aeroallergens. In elderly patients with or without asthma, an elevated level of IgE may be an important risk factor for the development of chronic airflow obstruction. This is especially true in current smokers, but also seen in former smokers.

Atopy is an age-related phenomenon; in community surveys the peak prevalence of immediate skin test reactivity occurs during the third decade and falls rapidly after age 50. The proportion of asthmatics that are atopic varies with age; in childhood about 80%; between ages 20 to 40, 50%; and after age 50, less than 20%. Elevated serum IgE levels are closely related to the likelihood of a subsequent asthma diagnosis in younger asthmatics and this may be seen with elderly asthmatics. More likely, those that acquire asthma after age 60 are nonatopic. In the Cardiovascular Health Study,⁵ many elderly asthmatics reported respiratory problems that started in childhood and half stated that wheezing was triggered by contact with plants, animals, or pollens and that it was seasonal. Elderly urban dwelling patients with asthma may show evidence of cockroach-specific IgE antibody and are more likely to have more severe asthma and airflow obstruction.¹⁷ IgE specific antibodies to cat and dog dander, cockroach, and dust mite can also be present in elderly asthmatics with atopy.¹⁸ A history of atopy is the strongest predictor of asthma in the elderly.¹⁹ Those who are capable of becoming sensitized will usually have done so by the time they are older adults. Avoidance of potential allergens in the environment of the elderly asthmatic should be advised.

Clinical features

The distinctive features of asthma in older adults have been described in an NIH consensus conference²⁰ and also the subject of a comprehensive clinical review.²¹ In adulthood, there is a steady incidence of new-onset asthma through all ages, even in the elderly. Many patients begin with symptoms following respiratory viral infections. This pattern

may gradually or abruptly develop into persistent symptoms and often severe, poorly responsive disease. Classic symptoms of asthma, including episodic wheezing, shortness of breath, and chest tightness, are typical of elderly and young asthmatics. These symptoms are generally worse at night and with exertion and are often precipitated by an upper respiratory tract infection. These symptoms of asthma in the elderly are nonspecific and may be caused by a variety of other conditions. Shortness of breath, especially on exertion, is a common symptom and may be attributed to different underlying diseases, including heart or lung diseases. Many elderly patients limit their activity to avoid experiencing shortness of breath, and others assume that their dyspnea is resulting from their aging process and, thus, avoid seeking early medical attention. However, aging per se does not cause dyspnea, and a cause always needs to be pursued in assessing an elderly patient with breathlessness. Underreporting of symptoms in the elderly may have many causes, including depression, cognitive impairment, social isolation, denial, and confusing symptoms with those of other comorbid illnesses. On the other hand, elderly patients have been shown to have a reduced perception of bronchoconstriction and this also may delay medical intervention. Cough is another prominent symptom of asthma and may occasionally be the only presenting symptom.²⁰ The presence of wheezing is not very specific and does not correlate with the severity of airflow obstruction. Asthma symptoms are often triggered by environmental exposures and can also be provoked by medications, such as aspirin, nonsteroidal anti-inflammatory agents, or β -blockers, commonly used by this population; this fact emphasizes the need for the physician to perform a comprehensive review of medications upon presentation.

Physical examination in elderly patients with asthma is usually nonspecific and may misguide the diagnosis. During an acute attack of asthma, tachypnea and tachycardia are present. Sinus tachycardia is also a complication of asthma therapy with such drugs as sympathomimetics and theophylline. As airway function improves with sympathomimetic treatment, sinus tachycardia usually improves rather than worsens. In acute asthma, premature ventricular contractions occur occasionally, whereas atrial arrhythmias are extremely uncommon. Other abnormalities seen in acute severe asthma include P pulmonale, right axis shift, right bundle branch block, and right ventricular strain. Diffuse musical wheezes are characteristic of asthma, but their presence or intensity does not reliably predict the severity of asthma. By the time wheezing can be detected by the stethoscope, peak flow rates may be decreased by as much as 25% or more. In general, wheezing during inspiration and expiration, loud wheezing, and high-pitched wheezing are associated with greater airway obstruction. In very severe cases, wheezing may be absent. This suggests very poor air movement and impending respiratory failure. A prolonged phase of exhalation is typically seen, as is chest hyperinflation. These are due to airflow obstruction and air trapping, respectively. Accessory muscle use, pulsus paradoxus, and diaphoresis are associated with severe airflow obstruction, although their absence does not rule out a severe attack. Cyanosis and signs of acute hypercarbic acidosis, such as mental obtundation, can be observed in extreme cases.

Table 49-3. NAEPP Goals of Asthma Care

Control chronic and nocturnal symptoms
Maintain normal activity levels, including exercise
Prevent acute episodes of asthma
Minimize emergency room visits and hospitalizations
Minimal need for reliever medications
Maintain near-normal lung function
Avoid adverse effects of medications

Management

The NAEPP guidelines have set goals to care for asthmatics.¹ The goals of asthma therapy are seen in Table 49-3. Short-term objectives are the control of immediate symptoms and response to falling peak flow rate measurements. Long-term objectives are those directed at disease prevention since there are now well-proven strategies to avoid serious exacerbations of acute bronchospasm that often lead to emergency room visits or hospitalization. To meet these therapeutic objectives, four components of asthma care should be addressed:

1. Environmental control measures to avoid or eliminate factors that precipitate asthma symptoms or exacerbations: Symptoms may be minimal or nonexistent at any time and can appear suddenly with no apparent cause. They may result from specific (aeroallergens) or nonspecific (dust, cigarette smoke, fumes, cold air, exercise, etc.) exposures. For those patients that have persistent asthma symptoms, the clinician should evaluate the patient for environmental causes, particularly indoor inhalant allergens such as house-dust mites, indoor pets and cockroaches, household products, medications, and passive exposure to tobacco smoke.
2. Use of objective measures of lung function to assess the severity of asthma and to monitor the course of therapy: It is recommended to monitor lung function before and after treatment to insure adequate response. The degree of reversibility in a "responder" correlates with the degree of airway inflammation. Patients with a high degree of reversibility have a greater risk of hospitalization and mortality, and a greater chance of developing irreversible airflow obstruction in subsequent years. The test can, therefore, be useful in identifying high-risk patients who need close monitoring.
3. Comprehensive pharmacologic therapy for long-term management designed to reverse and prevent airway inflammation: Therapeutic approach to asthma in elderly patients does not differ from what is recommended for young patients. The medications used to treat asthma are listed in Table 49-4. Treatment protocols in the NAEPP guidelines use step-care pharmacologic therapy based on the intensity of asthma symptoms and the clinical response to these interventions. As symptoms and lung function worsen, step-up or add-on therapy is given. As symptoms improve, therapy can be "stepped down." When disease is well controlled and symptoms are infrequent a short-acting β -agonist can be used for symptom relief. When this agent is used two or more times a week,

Table 49-4. Medications Used to Treat Asthma

Controller Medications

These are agents that are capable of reducing airway inflammation and thus improve lung function, decreasing bronchial hyperreactivity, reduce symptoms, and improve the overall quality of life.

Corticosteroids are the most useful anti-inflammatory agents.

- Inhaled corticosteroids are safe and effective
- Prevent migration and activation of inflammatory cells
- Reduce microvascular leakage
- Enhance the action of smooth muscle β_2 -adrenergic receptors
- They are recommended for persistent asthma
- High doses (>1000 $\mu\text{g}/\text{d}$) may suppress hypothalamic-pituitary axis
- Local adverse effects are hoarseness and dysphonia
- Oral candidiasis can be avoided by rinsing mouth
- Poorly controlled asthma may require oral therapy

Long-acting β -agonists are effective bronchodilators

- Available in different formulations
- May be helpful for long-term maintenance therapy
- Useful when added to inhaled corticosteroids
- Should not be used as single agents

Leukotriene pathway modifiers

- 5-lipoxygenase inhibitors (zileuton)
- Cysteinyl leukotriene antagonists (montelukast, zafirlukast)
- Less effective in older asthmatics

Omalizumab: a humanized murine monoclonal antibody that inhibits the binding of IgE to mast cells by forming complexes with circulating free IgE

- Effective in patients with atopic asthma
- Available for parental use twice a month
- For moderate to severe asthma
- Reduce asthma exacerbation rates and corticosteroid use
- Not useful in older adults who are nonatopic

Theophylline: an effective bronchodilator with some anti-inflammatory properties

- Available as a sustained-release oral preparation
- Monitor theophylline blood levels to avoid toxicity
- Elderly asthmatics more susceptible to adverse effects
- GI side effects are seen with mild toxicity (20 to 30 $\mu\text{g}/\text{mL}$)
- Serious cardiac arrhythmias and seizures with blood level in excess of this range
- A range of 8–15 $\mu\text{g}/\text{mL}$ is generally considered therapeutic

Rescue Medications

Inhaled short-acting β -adrenergic agonists

- The treatment of choice for the acute exacerbation of asthma symptoms
- Inhaled agents can be delivered by metered-dose inhaler, dry-powder capsules, and compressor-driven nebulizers

Parenteral corticosteroids

- Useful for acute exacerbations of asthma
 - Intravenous corticosteroids every 6 to 8 hours
 - Oral prednisone in doses of 40 to 60 mg/day
 - Therapy can be slowly tapered after response
- Associated with many side effects
- Risk of osteoporosis, cataracts, and diabetes mellitus
- May rarely depress immunity to infection

anti-inflammatory therapy is needed and inhaled corticosteroids are the preferred agents. Several considerations have to be taken into account when choosing appropriate pharmacologic therapy in elderly patients with asthma (Table 49-5).

Table 49-5. Special Considerations for the Pharmacologic Therapy of Asthma and COPD in the Elderly

Consideration	Contributing Factor(s)
Delivery of medication	Poor inhaler technique is common in the elderly and should be recognized.
Effectiveness of medication	Different pharmacodynamics and pharmacokinetics from younger population, diminished response. β_2 -agonists may occur and comorbidities such as cardiac disease may increase side effects.
Compliance with medication	Complex regimens, prohibitive cost, poor memory, and delivery technique may lead to poor adherence to recommendations and inadequate response.
Safety of medication	Increased risk from comorbid conditions (cardiac, osteoporosis) and interaction with other medications should be monitored.

Table 49-6. Levels of Asthma Control

Characteristic	Controlled (all of the following)	Partly Controlled (any measure present in any week)	Uncontrolled
Daytime symptoms	None (twice or less/wk)	More than twice/week	Three or more features of partly controlled asthma present in any week
Limitation of activities	None	Any	
Nocturnal symptoms/awakening	None	Any	
Need for reliever/rescue treatment	None (twice or less/week)	More than twice/week	
Lung function (PEF or FEV ₁) [‡]	Normal	<80% predicted or personal best (if known)	
Exacerbations	None	One or more/year*	One in any week [†]

*Any exacerbation should prompt review of maintenance treatment to ensure that it is adequate.

[†]By definition, an exacerbation in any week makes that an uncontrolled asthma week.

[‡]Lung function is not a reliable test for children 5 years and younger.

In previous years, treatment decisions have been based on assessing the disease severity and its intrinsic intensity. A severity classification of mild intermittent, mild persistent, moderate persistent, and severe persistent disease encouraged the application of a step-care approach for asthma. The use of the severity scale is advocated in the 2007 NAEPP guidelines, but only during the initial assessment of the asthmatic before initiating therapy. A major difference in the new 2007 guidelines is the focus on the assessment of asthma control rather than severity. Control is defined as the degree to which the manifestations of asthma are minimized by therapeutic interventions and the goals of asthma therapy are adequately met. Table 49-6 shows the NAEPP levels of asthma control. A number of measures of asthma control have been offered in the medical literature. Some are more suited for research and others, such as the Asthma Control Test (ACT), are more suited for clinical use but have not been validated in an elderly population.²²

4. Patient education that fosters a partnership among the patient, his or her family, and clinicians: Asthma self-management education is essential to provide patients with the skills necessary to control asthma and improve outcomes. The goals of asthma care should be discussed and agreed upon by the patient and all members of the health care team. Sites for self-management education outside the usual office setting should be explored. The actions of the medications should be discussed and the potential complications should be understood. Action plans should be written down and used as guidelines for daily care. An action plan for the acute exacerbation of asthma is essential, including when to use oral corticosteroids, when to call the physician, and when to use emergency services. For asthmatics that have frequent symptoms

and exacerbations or those who poorly perceive their symptoms, the use of hand-held peak flow meters may be useful to monitor daily lung function. An action plan for worsening lung function may be extremely helpful in avoiding emergency room visits and near-fatal attacks.

Outcomes

Elderly asthmatics with severe symptoms, long-standing disease, reduced pulmonary function, or a concomitant diagnosis of COPD are much less likely to have a remission. Like other chronic diseases in this age group, asthma in the elderly population has a major impact on patient well-being and is a cause of significant impairment in overall health status. Patients with asthma may consequently suffer from poor general health, symptoms of depression, and significant limitation of daily activity.^{20,23}

The number of unscheduled ambulatory visits, emergency visits, and hospitalizations are high in elderly asthmatics, confirming the high degree of morbidity in this age group.^{25,26} Quality of life scores are also low in patients with persistent asthma when compared with elderly patients with mild asthma or no asthma at all.⁵ The prevalence of comorbidities, such as sinusitis, heartburn, chronic bronchitis, emphysema, and congestive heart failure, was also higher in older compared with younger asthmatics.

These conditions can cause respiratory symptoms and can obscure the diagnosis of asthma or enhance asthmatic symptoms. Despite at times severe symptoms and physiologic impairment, most elderly patients with asthma can lead active productive lives if their asthma is detected early and is appropriately managed. In fact, if elderly patients with severe or difficult to treat asthma have been identified by physician assessment, they appear to do better than younger patients. In the Epidemiology and Natural History of Asthma: Outcomes and Treatment Regimens (TENOR)

study, despite lower lung function, older asthmatics (mean age 72 years) had lower rates of unscheduled office visits, emergency department visits, and corticosteroid bursts.²⁷ Patients reported in this study received more aggressive care than younger adults, including higher use of inhaled and oral corticosteroids, and this undoubtedly had an impact on outcomes.

COPD IN THE ELDERLY

Introduction

Cigarette smoking is the major cause of chronic obstructive pulmonary disease (COPD) in the developed world. Cigarettes cause widespread lung injury and destruction that occur over many years. Yet, clinical manifestations usually do not become apparent in the smoker or ex-smoker until many decades have passed. Unfortunately, when the disease does become apparent, the clinical course persists for a considerable period of time, even many decades. Therefore COPD is a disease seen predominantly in the geriatric population in our society and one that causes considerable morbidity and mortality. During the latter part of the twentieth century, smoking increased dramatically among American women. This has resulted in a dramatic demographic change. The prevalence of the disease is now greater in women and in 2000, for the first time, more women died of COPD than men.

The smoking epidemic of the twentieth century has resulted in a large number of adults with COPD, a largely preventable disease. It is estimated that 24 million U.S. adults have COPD and only 12 million have been diagnosed by a physician.²⁸ Based on lung function testing, it is believed that an additional 12 million COPD patients are undiagnosed.²⁹ COPD has risen to become the fourth leading cause of death in the United States. It is projected to become the third leading cause of death in the United States and worldwide, and will rank fifth as a worldwide health burden within the next 20 years.

COPD is associated with significant comorbidities, such as cardiovascular disease and cancer. It has a tremendous impact as a comorbid condition, often as a silent partner until a serious complication arises. What may begin as a simple elective surgical procedure in an elderly patient may result in a prolonged complicated hospital admission as a result of postoperative pneumonia or respiratory failure because of unrecognized COPD.

The statistics of COPD have caused considerable alarm around the world.³⁰ To address this growing problem, the Global Initiative for Chronic Obstructive Lung Disease (GOLD) was established. In 2001 this offered a global strategy to increase awareness of the disease and guidelines for disease prevention and treatment (GOLD Guidelines), which was frequently updated.³¹ These guidelines and the evidence-based guidelines published by the American Thoracic Society (ATS) and European Respiratory Society (ERS) will be incorporated into this chapter.³² The term COPD defined by GOLD differs from previous consensus statements. It does not incorporate the terms chronic bronchitis and emphysema into the definition but rather highlights the major physiologic consequence of this disease—airflow obstruction—that is no longer fully reversible and is usually progressive over years. In this description, it was first acknowledged that the pathology of COPD, and the

symptoms, the pulmonary function abnormalities, and complications all could be explained on the basis of the underlying inflammation. In 2006 the ATS and ERS added to the definition of COPD the phrase “preventable and treatable” to emphasize these two important aspects of the disease (see Table 49-1). This was done to encourage a positive outlook for patients and the health care community toward COPD and to stimulate effective management programs to treat patients with this disease.

Epidemiology of COPD

The National Health Interview Survey (NHIS) is an annually conducted, nationally representative survey of about 40,000 U.S. households. In 2000, it was estimated that 10 million U.S. adults reported “physician-diagnosed COPD.” By adding spirometry testing, it was possible to determine the presence of airway obstruction, the prevalence of diagnosed COPD, and the estimated prevalence of COPD in the population. By including anyone with airflow obstruction by spirometry, it was estimated that 23.6 million adults (13.9%) have COPD; the majority of the subjects had evidence of mild to moderate airflow obstruction and only 1.4% of the population suffered from more advanced disease. International COPD prevalence rates in adult populations have been reported to be in the 5% to 10% range.

Another manifestation of the importance of COPD is its burden determined by using disability-adjusted life-years (DALY). In 1996 COPD was estimated to be the eighth leading cause of DALY among men and the seventh leading cause of DALY among women. Worldwide, COPD is expected to move up from the 12th leading cause of DALY in 1990 to the 5th leading cause in 2020. In 2000, COPD was responsible for 8 million physician office and hospital outpatient visits, 1.5 million emergency department visits, 726,000 hospitalizations, and 119,000 deaths.³⁰

COPD is also associated with significant comorbid disease.^{30,33,34} In a nationally representative sample of 47 million hospitalizations from 1979 to 2001, hospital discharges with a diagnosis of COPD were more likely to be re-admitted to the hospital with pneumonia, hypertension, heart failure, ischemic heart disease, pulmonary vascular disease, thoracic malignancies, and ventilatory failure, when compared with age-adjusted discharges without COPD. Further, having a diagnosis of COPD was associated with higher age-adjusted in-hospital mortality for pneumonia, hypertension, heart failure, ventilatory failure, and thoracic malignancies, when compared with hospital discharges with these co-morbidities who did not have a COPD diagnosis.⁵ These results suggest that the burden of disease associated with COPD is largely underestimated since having a diagnosis of COPD is associated with increased risk for hospitalization and in-hospital mortality from other common diagnoses.

During the period 1980–2000, the most substantial change was the increase in the COPD death rate for women, from 20.1/100,000 in 1980 to 56.7/100,000 in 2000, compared with the more modest increase in the death rate for men, from 73.0/100,000 in 1980 to 82.6/100,000 in 2000. The number of women dying from COPD surpassed the number of men dying from COPD in 2000. Progressive respiratory failure accounts for approximately one third of the COPD-related mortality, therefore factors other than progression of lung disease must play a substantial role.³⁰

Figure 49-2. Mechanisms underlying airflow limitation in chronic obstructive pulmonary disease. (From NIH/NHLBI: *Global Initiative for Chronic Obstructive Lung Disease*. NHLBI/WHO Workshop Report 2001. Available at: <http://www.goldcopd.com/workshop.html> (accessed Sept. 8, 2008).)

Pathogenesis of COPD

The pathologic changes in COPD are found in the large and small (<2 mm) airways and in the lung parenchyma^{34,36} (Figure 49-2). In advanced stages, there are also changes in the pulmonary circulation, the heart, and the respiratory muscles. Alveolar hypoxia causes medial hypertrophy of vascular smooth muscle with extension of the muscularis layer into distal vessels that do not ordinarily contain smooth muscle. Intimal hyperplasia also occurs in advanced stages. These latter changes are associated with the development of pulmonary hypertension and its consequences—right ventricular hypertrophy and dilation. Loss of vascular bed also occurs with emphysema in association with the destructive alveolar processes. In some patients with advanced COPD, there is atrophy of diaphragmatic muscle, loss of skeletal muscle, and wasting of limb muscles.

Changes in the airways of smokers

Early structural changes have been described in otherwise healthy smokers even as young as 20 to 30 years old. The burden of gases and particles that are inhaled into the lungs results in inflammatory and immune responses. Inflammatory cells migrate into the epithelial layer including polymorphonuclear cells, eosinophils, macrophages, natural killer cells, and mast cells. Uncommitted B cells and CD4 and CD8 lymphocytes also participate in the inflammatory response.

Cigarette smokers have an increase in the number of neutrophils and macrophages. Macrophages likely play an important role in perpetuating the inflammatory process of COPD. They may release neutrophil chemotactic factors and proteolytic enzymes such as matrix metalloproteinases (MMPs) that damage the epithelial barrier. Neutrophils are also thought to be important in causing the tissue damage of COPD. They release a number of mediators including proteases, such as neutrophil elastase and MMPs; oxidants, such as the oxygen free radical H_2O_2 ; and toxic peptides, such as defensins. The repair process that ensues includes the secretion of antiproteases to regulate the proteolytic process. Although CD4⁺ lymphocytes are found in the airways of atopic asthmatics, the T lymphocytes of patients with cigarette-induced COPD are CD8⁺ cells. These cells are also thought to cause cell damage. Eosinophilic inflammation is a hallmark of asthma and not usually seen in chronic bronchitis. However, the number of tissue and sputum eosinophils is greatly increased during attacks of acute bronchitis. Bronchial biopsies from former smokers show similar inflammatory changes to the active smokers,

suggesting that inflammation may persist in the airway once established.

Progression to COPD

Other structural changes in the airways of smokers include mucus hypersecretion, bronchiolar edema, smooth muscle hypertrophy, and peribronchiolar fibrosis. These changes result in narrowing of the small airways (<2 mm). As the inflammation and peribronchiolar fibrosis progress, lung function and the symptoms of COPD become progressively worse.³⁸

In addition to the structural abnormalities seen in the small airways, there is also a loss of alveolar attachments to the airway perimeter and there is permanent enlargement of the gas-exchanging units of the lungs (acini).³⁶ This impairs elastic recoil and favors increased tortuosity and early closure of the small airways during expiration. The pathogenesis of COPD that targets the airways (chronic bronchitis) and lung parenchyma (emphysema) is thought to occur because of a complex interaction between extracellular signaling proteins, oxidative stress, and proteolytic digestion of connective tissue.

Smokers with chronic bronchitis produce larger amounts of sputum each day, averaging about 20 to 30 mL/day and even as high as 100 mL/day. This occurs as a result of an increase in the size and number of the submucosal glands and an increase in the number of goblet cells on the surface epithelium.

Pulmonary function testing in COPD

Early in the course of COPD, the expiratory flow-volume curve shows a scooped-out lower part of the expiratory limb as a result of abnormal flow at low lung volume. In later stages there is decreased expiratory flow at all lung volumes (see Figure 49-1). Nonuniform ventilation of the lungs is seen even in the earlier stages of COPD and this leads to low ventilation/perfusion ratios. This type of mismatch causes arterial hypoxemia. Lung and thoracic wall hyperinflation occur as a consequence of the loss of elastic recoil. Airway obstruction and hyperinflation, especially during exertion (dynamic hyperinflation), increases the work of breathing and contributes to the sensation of dyspnea.

Pulmonary function studies are important for the diagnosis and staging of COPD.^{31,32} The FEV₁ has been shown to correlate with morbidity, mortality, and severity scoring on the basis of the degree of airflow obstruction. The GOLD guidelines include four stages based on the spirometric severity of airflow obstruction (Figure 49-3).

Natural history of COPD

Cigarette smoking is the agent causing COPD in at least 85% to 90% of cases. Other factors linked to the development of COPD include occupational or environmental exposures to dusts, gases, vapors or fumes,³⁹ exposure to biomass smoke, malnutrition, early life infections, increased airways responsiveness, and asthma.^{30,31} As only 15% to 20% of heavy smokers will develop an accelerated decline of lung function over time and clinically evident COPD, a genetic predisposition is also an important factor. One genetic abnormality that has been known and well studied is α_1 -antitrypsin (AAT) deficiency, which accounts for less than 1% of COPD in the United States. Cigarette smoking is the most

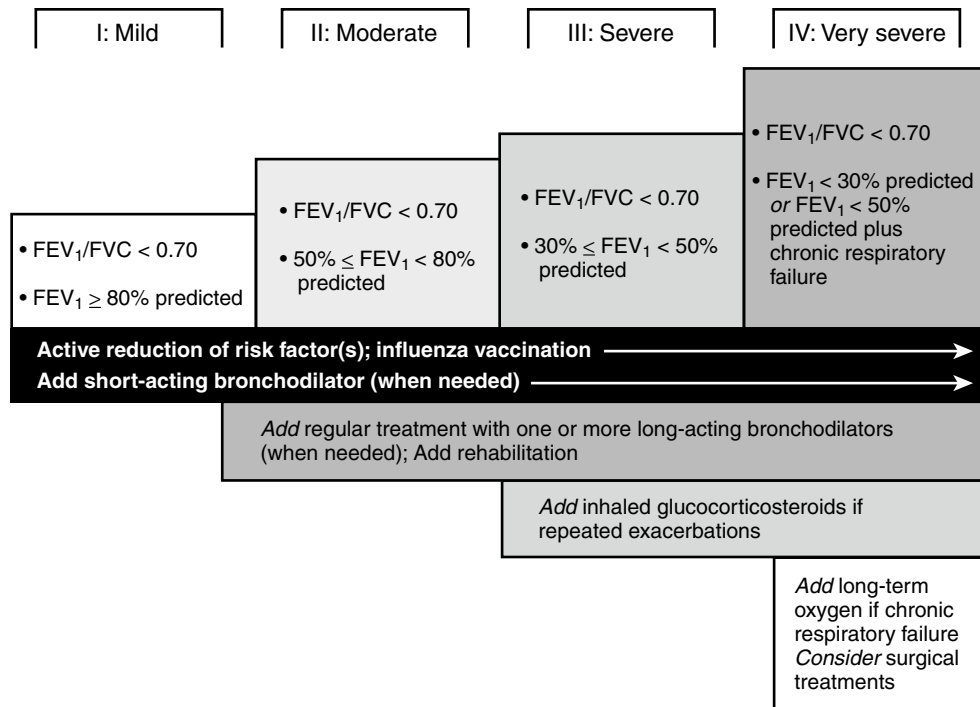

Figure 49-3. GOLD severity scale based on symptoms and lung function with treatment algorithm based on severity (accessed on Sept. 8, 2008). (Adapted from Global Initiative for Chronic Obstructive Lung Disease [GOLD], www.goldcopd.org.)

Figure 49-4. Natural history of COPD. A rapid decline in lung function (FEV₁) occurs over decades in the patient with COPD (solid line) leading to disability and death. This is compared with a slow decline in normal aging (dotted line). The smoker who does not develop COPD has a greater decline than normal but does not become disabled (dashed line). (Adapted from Fletcher C, Peto R. *BMJ* 1977;1:1645–48.)

important risk factor for the development of COPD in patients with AAT deficiency. Symptoms begin early in adult life in cigarette smokers. Patients with this deficiency who do not smoke may develop COPD; their age at onset of dyspnea is 48 to 54 years compared with 32 to 40 years in smokers. In older patients with COPD and no previous smoking history, especially those with a strong family history, a blood test to determine the level of AAT should be considered.

Patients who develop COPD have a prolonged preclinical period of approximately 20 to 40 years (Figure 49-4). During this asymptomatic period, there is deterioration of lung function in marked excess of the normal age-related decline.

Nonsmokers, without respiratory disease, can expect to lose 25 to 30 mL of lung function per year after age 35. The rate of decline appears to accelerate slightly with aging, but sudden large irreversible falls are uncommon. Although nonsmokers lose FEV₁ slowly, they never develop significant airflow obstruction; this is also true of the nonsusceptible smokers. Susceptible smokers on the other hand develop varying degrees of airflow obstruction as they often demonstrate a decline in lung function of 60 mL or more per year. This ultimately causes exertional dyspnea when the FEV₁ is between 40% and 59% of its predicted value and becomes disabling when the FEV₁ declines by about 70%. Such an inexorable decline may lead to fatality. When the FEV₁

falls below 1 L, the 5-year mortality is approximately 50%. Smoking cessation in the susceptible smoker will not result in recovery of lost FEV₁, but will slow the rate of decline to similar rates of nonsmokers. Smoking cessation in the patient with early changes of COPD at age 45 can make the difference between a normal life span and premature death.

Clinical features of COPD

SYMPTOMS OF COPD

The symptoms that are associated with COPD are usually not present until the patient has been smoking a pack of cigarettes a day for at least 20 years.^{30,31} The patient usually presents in the fifth decade with chronic cough often worsened after a viral respiratory infection. Dyspnea, the second major symptom, usually does not present until the sixth or seventh decade. Over the last several decades, as a result of an intense antismoking campaign, the rate of smoking in the United States has been reduced from about a third of the adult population to its current level of about 22%. Since there is a slow decline in lung function with normal aging, COPD patients who stopped smoking in midlife may only delay the onset of COPD symptoms until late in life. It is not unusual to see a former smoker with COPD present for the first time with symptoms at age 75 and beyond.

PHYSICAL EXAM AND LABORATORY TESTS

The signs of COPD are well known: slow and prolonged expiration, wheezing, chest wall hyperinflation, limited diaphragmatic motion on auscultation, distant breath sounds and heart sounds, and often coarse early inspiratory crackles. The accessory muscles of respiration may be in use and the patient may be using pursed-lip breathing. Signs of cor pulmonale include pedal edema, a tender congested liver, and neck vein distention. Cyanosis may be present, and asterixis that is associated with severe hypercapnia may be observed. The roentgenographic signs of COPD include a low flat diaphragm, an increased retrosternal airspace, and a tear-drop shaped heart. Pruning of the pulmonary arterial vessels and bullae are seen in emphysema. The high resolution CT scan has a much better sensitivity and specificity, but is not recommended for routine use.

COPD EXACERBATION

The slowly progressive course of COPD is often interrupted by a sudden change in symptoms and lung function requiring a change in management, including medication and sometimes hospital admission.³² These acute respiratory illnesses or exacerbations are usually caused by viral or bacterial infections and are heralded by an increase in symptoms and associated with an increase in pulmonary and systemic signs of inflammation. Patients with mild and moderate stages of COPD may develop one to two exacerbations per year; those with more severe disease could possibly have many more. Risk factors for hospitalization include admissions for COPD in the previous year, a low FEV₁, under-prescription of long-term oxygen therapy, current smoking and systemic inflammation as evidenced by nonspecific markers of inflammation such as serum fibrinogen.^{39,41} The exacerbations usually cause a modest decrease in lung function for up to 90 days. COPD exacerbations have been associated with a poor quality of life and an accelerated decline of airflow obstruction.

Table 49-7. Systemic Consequences of COPD

Osteoporosis
Metabolic disease (diabetes mellitus)
Gastrointestinal disease
Anorexia
Weight loss
Skeletal muscle dysfunction
Anemia of chronic disease
Generalized fatigue
Depression
Altered sleep
Cor pulmonale

SYSTEMIC INFLAMMATION AND COPD

There is growing evidence that the inflammatory response of COPD is not limited to the lungs.^{33,42} There are a number of systemic consequences of the disease that are considered related to systemic inflammation (Table 49-7). Individuals with stable COPD have significantly raised blood levels of C-reactive protein (CRP), fibrinogen, TNF- α , endothelin-1, interleukin 6, and circulating leukocytes and vascular endothelial growth factor (VEGF), compared with normal. Elevated levels of inflammatory cytokines in the blood of COPD patients suggest a persistent level of systemic inflammation, possibly caused by a "spill over" from lung inflammation. This latter theory, however, has not been proven.

Management of COPD

Once the diagnosis of COPD is established, pulmonary function testing can be helpful to stage the disease. Pharmacologic intervention is offered according to disease severity and the patient's tolerance for specific drugs (see Figure 49-4). The goals of therapy are to induce bronchodilation, decrease airway inflammation, and improve mucociliary transport. The patient who still smokes should be encouraged to quit. Preventive therapy with a pneumococcal vaccine and a yearly influenza vaccine is recommended. Vaccination with the flu shot has been shown to result in 52% fewer hospitalizations for pneumonia and influenza in patients with COPD. Vaccinated patients also have fewer outpatient visits for respiratory symptoms. Current COPD guidelines are evidence-based and offer treatment algorithms.^{30,31} Evidence-based medical reviews are also available to guide treatment of stable COPD⁴⁴ and COPD exacerbations.⁴⁵

SMOKING CESSATION

Cigarette smoking compromises airway function: it damages airway epithelial cells, increases mucous viscosity, and slows mucociliary clearance. There is a greater bacterial adherence to oropharyngeal epithelial cells in smokers compared with nonsmokers. Smokers are prone to acute exacerbations of COPD. As a result, they show increased rates of unexpected office visits, use of emergency services, work absenteeism, and medication use. Smokers also show greater decline in lung function, worsening of respiratory symptoms, and lower quality of life scores than a comparable group of nonsmoking patients with COPD. Unfortunately most studies have shown that the presence of respiratory illness such as COPD is not a motivator for smoking cessation. Physician-delivered smoking cessation interventions can significantly increase smoking abstinence rates. Smoking cessation interventions

for COPD include physician intervention, group smoking cessation programs, and pharmacologic therapy, which may be needed in highly dependent smokers who smoke a pack a day or more, require their first cigarette within 30 minutes of arising in the morning, and find it difficult refraining from smoking in places where it is forbidden. Therapy with nicotine replacement modalities, the antidepressant bupropion hydrochloride, and with varenicline (a partial agonist of nicotinic acetylcholine receptors) has been shown to be effective.

PHARMACOLOGIC THERAPY

Short-acting β_2 -agonists achieve variable degrees of bronchodilation, relieve acute dyspnea, and improve exercise capacity. They have a rapid onset of action with duration of 4 to 6 hours. The use of these agents by metered dose inhaler as β_2 -selective agents is safe when given three or four times a day. Higher doses may cause hypokalemia, cardiac arrhythmias, and reduced arterial oxygen tension. Long-acting β_2 -agonists have a maximal effect comparable to the short-acting β_2 -agonists but have a longer duration of action (12 hours or longer). Agents such as salmeterol and formoterol have been shown to improve symptoms and quality-of-life measures and reduce COPD exacerbations over time. They have a good safety profile with recommended doses and no tachyphylaxis with chronic use.⁴⁶ Occasional tremor is seen but it usually improves after several days of use. Nonbronchodilating effects, such as inflammatory mediator release, stimulation of mucociliary transport, and cytoprotection of the respiratory mucosa, have also been reported.⁴⁷

The short-acting anticholinergic ipratropium offers bronchodilation and relief of symptoms for 4 to 6 hours. The long-acting anticholinergic tiotropium offers improved bronchodilation and has a duration of 24 hours. It has the advantage of a once-daily dosage. These agents have not been associated with tachyphylaxis. Tiotropium has been shown to reduce exacerbation rates and hospitalizations due to exacerbations.^{48,49} The side effects are usually mild and include occasional dry mouth. Because of the anticholinergic effects, the drug should be used with caution in patients with narrow-angle glaucoma, myasthenia gravis, bladder neck obstruction, prostatic hyperplasia, and moderate to severe renal impairment. The use of a short-acting and long-acting anticholinergic together is discouraged. The combination of ipratropium and albuterol is available by metered dose inhaler or nebulizer. They provide a small additional benefit to either drug alone with no additional side effects.

The use of theophylline for COPD was very popular before other safer and more effective agents became available. This agent can produce small improvements in FEV₁, relieve symptoms, and improve exercise capacity with chronic use. It can be used safely in elderly adults when additional agents are needed for symptom relief.⁵⁰ Frequent adverse effects are seen even with therapeutic blood levels (nausea, diarrhea, headache, and irritability). Seizures and cardiac arrhythmias are considerably (10 to 15 times) more common in the elderly with toxic blood levels. Frequent close monitoring is mandatory to insure therapeutic blood levels when theophylline is used in the elderly.

Twenty to thirty percent of patients with COPD report improvement in symptoms if given oral steroid therapy. Responders have more eosinophils in induced sputum and

bronchial biopsies and likely have concomitant asthma. Long-term treatment with oral corticosteroids is not recommended for patients with COPD. Treatment of hospitalized patients with an acute exacerbation of COPD results in fewer treatment failures and shorter hospital stays.⁴⁵ Two weeks of therapy is sufficient and longer treatment programs can be associated with more side effects. Complications of therapy include cataracts, osteoporosis, secondary infection, diabetes, and skin damage. Milder exacerbations of COPD can be managed with a short course of oral corticosteroids.

Inhaled corticosteroids have been shown to provide small but significant improvements in lung function, reduce exacerbation rates, and improve the quality-of-life indices. The benefits of inhaled corticosteroids are enhanced when coupled with long-acting β -agonist treatment. Combination agents are available with favorable effects like improved lung function and symptoms, fewer exacerbations, and better quality of life.⁵¹ COPD practice guidelines recommend starting inhaled corticosteroids when the FEV₁ percent predicted is less than 50% (Stage III and IV) and the patient is having repeated exacerbations.

Mucoactive drugs are agents that can modify mucus production and secretion or can change the nature and composition of the mucus. Examples include expectorants that may induce cough or increase the volume of secretions and mucolytics that reduce the viscosity of mucus. There is little evidence that oral expectorants such as guaifenesin improve lung function or objective measures of well-being in COPD, although some patients do report subjective improvement. Guaifenesin is available without a prescription and has minimal side effects at recommended doses. Mucolytics such as acetylcysteine are not approved for this indication in the United States. The results of multiple trials favor the use of antibiotics for acute exacerbations of COPD that include worsening dyspnea, increased sputum volume, sputum viscosity, and purulence. There is no evidence to support prophylactic use.

Several controlled studies of oxygen use in COPD have been completed: oxygen versus no oxygen (Medical Research Council [MRC]) and continuous versus nocturnal oxygen (Nocturnal Oxygen Therapy Trial [NOTT]). In patients with hypoxemia and congestive heart failure, death rates are significantly lower and quality of life indices are improved when oxygen is chronically used. Patients who use oxygen for at least 15 hours per day have a significant fall in pulmonary artery pressures and an increase in cardiac output. Oxygen should be prescribed when: (1) the arterial PaO₂ is less than 55 mm Hg or SaO₂ is less than 88%, (2) PaO₂ is 56 to 59 mm Hg with ECG evidence of pulmonary hypertension, pedal edema, and/or secondary erythrocytosis. Long-term oxygen therapy does not improve survival in patients with moderate hypoxemia (PaO₂ 56 to 65 mm Hg) or in patients with isolated nocturnal hypoxemia.

PULMONARY REHABILITATION

Pulmonary rehabilitation is a multidisciplinary program that attempts to return the patient to the highest functional capacity possible. Evidence supports the use of lower-extremity exercise training as it improves exercise tolerance. Upper-extremity strength and endurance training is also recommended. Pulmonary rehabilitation improves dyspnea,

improves quality of life scores, and reduces the number of hospitalizations and days in the hospital; the effects on survival are not proven.⁵²

Surgery for COPD

Lung volume reduction surgery (LVRS) has emerged as a treatment for far-advanced COPD due to emphysema.⁵³ It involves resection of functionless areas of emphysematous lung to improve lung elastic recoil in addition to lung and chest wall hyperinflation. Overall mortality with the procedure is less than 3% within 30 days of surgery and less than 6% within 90 days. In patients with very severe degrees of airflow obstruction ($FEV_1 < 20\%$ of predicted with evidence of homogeneous emphysema and/or very severe impairment in the diffusion capacity [$< 20\%$ of predicted]), the rates are significantly higher and prohibitive. Significant surgery-related morbidity remains as a major concern when considering this approach. LVRS could be considered for patients with severe upper lobe predominant emphysema with significant impairment in baseline exercise capacity with potential overall mortality and morbidity benefit. Patients with homogeneous (nonupper lobe predominant disease) and high baseline exercise capacity should not be considered for this approach because of higher expected morbidity and mortality when compared with medical management alone. Emphysema patients within the spectrum between the two mentioned groups could have functional and symptomatic benefits from LVRS without overall mortality advantage. In appropriate candidates, improvement in the FEV_1 , dyspnea scores, and distance walked on the 6-minute walk test were reported. Oxygen requirements can improve in responders. Resection of large bullae is occasionally beneficial. The best results occur when the bullae occupy more than one third of the hemithorax. Lung transplantation can be life-saving in end-stage disease but is not offered to those of advanced age. Several bronchoscopic approaches with various goals, including volume reduction, improvement in dynamic hyperinflation, redistribution of ventilation from the emphysematous areas to the relatively spared areas, improving ventilation/perfusion ratio, and influencing collateral ventilation, are undergoing clinical trials with promising early results.

Weight loss and malnutrition

Malnutrition occurs in one quarter to one third of patients with moderate to severe COPD and is an independent risk factor for mortality.⁵⁴ Both fat mass and fat-free mass are depleted; the latter caused by depressed protein synthesis. It is believed that weight loss, and, particularly, skeletal muscle mass loss, is associated with a systemic inflammatory response in malnourished patients with COPD as the pro-inflammatory cytokines IL-6 and TNF- α have been shown to be elevated. Recent studies have shown that leptin, an adipocyte-derived hormone involved in the control of body weight, is decreased in patients with COPD. Serum leptin levels have been correlated with TNF- α levels, thus creating a link between nutritional status and systemic inflammation in COPD. Resting energy expenditure is elevated and contributes to the negative energy balance. Nutritional supplements alone do not reverse the loss but some early evidence suggests that it may when coupled with a pulmonary rehabilitation programs.

Prognosis of COPD

Traditionally, the FEV_1 has been used as the main indicator of clinical outcomes including mortality in COPD. A composite of predictors, the body-mass index, the degree of airflow obstruction, the degree of dyspnea, and a measure of exercise capacity offer an index of severity, the BODE index, that offers a superior grading system for COPD mortality.⁵⁵ The two-year mortality among patients with severe COPD (FEV_1 in the range of 27%) that received medical or surgical treatment was almost 26% for both groups in the National Emphysema Treatment Trial (NETT).⁵³

Differential diagnosis of asthma and COPD

A number of studies have shown that symptoms of obstructive lung disease, whether asthma or COPD, are underreported by elderly patients and underdiagnosed or misdiagnosed by their physicians. Several factors contribute to this problem. The symptoms of these two diseases are similar to other diseases seen in this age group. The hallmark symptoms of asthma and COPD, including shortness of breath, wheezing, and cough, are nonspecific in the elderly and are mimicked by and often confused with such diseases as congestive heart failure, chronic aspiration, gastroesophageal reflux (GERD), and upper airway obstruction.

Upper airway obstruction (UAO) can occur at any level of the central airways and can involve the extrathoracic portion of the airway above the thoracic inlet or the intrathoracic portion, with dynamic (functional) or anatomical (fixed) obstruction. The integrity and tone of the upper airway are important to maintain a functional lumen. The loss of airway tone (e.g., weakness of the airway structure or loss of muscle tone), extrinsic compression, or intraluminal pathology can result in dynamic obstruction that occurs when the functional lumen of the upper airway is compromised in response to changes in the transmural pressures during inspiration and/or expiration. Fixed obstruction is usually not responsive to changes in the transmural pressures. The incidence of UAO in the elderly is unknown. However, this appears to be increasingly recognized because of the higher incidence of malignancy and airway instrumentation (e.g., endotracheal intubation and tracheostomy) in this age group, in addition to advances in thoracic imaging, physiologic evaluation, and endoscopic techniques.^{56,57}

The signs and symptoms of UAO are usually nonspecific, develop after significant obstruction, and considerably overlap with those of the more common small airway disorders (COPD and asthma). This leads to significant delays in the appropriate diagnosis and management. UAO symptoms can be exacerbated by activity that is also nonspecific. Symptoms usually develop with activity when the airway lumen is compromised to the range of 8 mm, whereas dyspnea at rest and stridor develop when the airway lumen is in the range of 5 mm. Positional exacerbation of symptoms, especially in the supine position with sleep disordered breathing, is one of the clues to the diagnosis of UAO. Thus daytime sleepiness and fatigue can be a prominent feature. Chronic respiratory failure and cor pulmonale can also develop. Additional signs and symptoms related to the specific UAO cause (e.g., hemoptysis and hoarseness) can suggest a diagnosis other than small airway disease. The configuration of the

Table 49-8. An Overview of the Potential Causes of Upper Airway Obstruction

- Malignancy:
 - Primary head and neck cancer
 - Primary tracheal malignancies
 - Metastatic malignancy to the airway
 - Direct extension to the airway
- Tracheomalacia (and tracheobronchomalacia):
 - Localized
 - Diffuse
 Other classification:
 - Saber-sheath trachea (lateral): in patients with COPD
 - Crescent (anteroposterior)
- Laryngeal and tracheal stenosis:
 - Endotracheal intubation
 - Tracheostomy
 - Airway instrumentation
 - Posttraumatic
 - Inhalational injuries
 - Radiation therapy
 - Infection
 - Inflammatory and postinflammatory:
 - Wegener's granulomatosis
 - Relapsing polychondritis
 - Polyarteritis
 - Sarcoidosis
 - Scleroderma
 - Primary or secondary amyloidosis
 - Inflammatory bowel disease
 - Idiopathic progressive subglottic stenosis
- Infection:
 - Deep cervical space infections
 - Supraglottitis
 - Laryngotracheobronchitis
 - Bacterial tracheitis
 - Tuberculosis
 - Other infections (e.g., histoplasmosis, papillomatosis, rhinoscleroma)
- Neuromuscular disorders:
 - Vocal cord paralysis or paresis
 - Bulbar muscle dysfunction
 - Vocal cord dysfunction
- Foreign body aspiration
- Trauma:
 - Blunt trauma
 - Penetrating injuries
 - Postintubation (e.g., stenosis, vocal cord paralysis, contact granuloma, arytenoid dislocation)
 - Inhalational injuries
- Extrinsic compression:
 - Mediastinal masses and adenopathy
 - Esophageal pathology
 - Thyromegaly
 - Cervical osteophytes
 - Parathyroid cysts
 - Fibrosing mediastinitis
 - Laryngoceles
 - Saccular cysts
 - Hematomas
 - Aneurysms and pseudoaneurysms
 - Vascular anomalies
- Other causes:
 - Tracheobronchopathia osteochondroplastica
 - Laryngo-pharyngeal reflux; can contribute to the symptoms and severity of UAO
 - Postpneumonectomy syndrome
 - Mucous balls (with transtracheal oxygen catheters)

KEY POINTS

Asthma and Chronic Obstructive Pulmonary Disease

- Asthma and COPD are common disorders associated with significant morbidity and mortality in the elderly.
- The NAEP and GOLD guidelines are valuable in the management of asthma and COPD in the elderly.
- Recognizing the role of inflammation in the pathogenesis of asthma and COPD is important in the management of both disorders.
- COPD is a systemic disease associated with extrapulmonary manifestations, including muscle wasting and systemic inflammatory response.
- The symptoms and signs of airway disease in the elderly can be nonspecific and overlap considerably with other common disorders in this age group.
- Upper airway obstruction in the elderly can mimic asthma and COPD. Special vigilance is necessary to diagnose upper airway obstruction in the elderly.

flow volume loops can be helpful to diagnose upper airway obstruction (see [Figure 49-2](#)).

UAO can be related to a variety of airway and systemic disorders.^{58,59} Common causes of UAO include malignancy, infection, inflammatory disorders, trauma, and extrinsic compression related to enlargement or pathology of adjacent structures. It appears that malignancy and benign strictures related to airway interventions are becoming more prevalent. [Table 49-8](#) provides an overview of the potential causes of UAO in the elderly.

Nonobstructive Lung Disease and Thoracic Tumors

Katie Pink
Ben Hope-Gill

Respiratory disease is a major cause of morbidity and mortality, affecting 1 in 10 of the population over 65 years old.¹ The presentation and management of respiratory disease often differs in the elderly and this chapter aims to provide some insight into these differences while reviewing current evidence.

RESPIRATORY INFECTIONS

Respiratory infection is common in the elderly. This is explained by a number of factors. A decline in lung function and structural changes to the chest wall and muscles result in a loss of chest wall compliance.² In addition, mucociliary function declines with age and the immune system can be depressed. With increasing age there is an increase in oropharyngeal colonisation with potential respiratory pathogens as well as an increased incidence of microaspiration. Comorbid conditions resulting in dysphagia or a reduced conscious level may increase the risk of aspiration.³ Malnutrition, in particular hypoalbuminaemia, has also been associated with an increased risk of infection in the elderly.⁴ Finally, institutionalisation leads to increased exposure to respiratory pathogens.

INFLUENZA

Influenza tends to occur in seasonal epidemics each winter. In the United States, influenza causes 20,000 to 40,000 deaths per year. Although 60% of cases of influenza occur in adults less than 65 years old, more than 80% of deaths as a result of seasonal influenza occur in adults aged over 65.^{5–7} The elderly are more likely to be hospitalized⁸ and to experience significant functional decline.⁹ Complications such as infective bronchitis and secondary bacterial pneumonia also occur more frequently in the elderly, most commonly because of *Staphylococcus aureus* and *Streptococcus pneumoniae* infection.¹⁰ In addition, cerebrovascular and cardiovascular deaths may be precipitated by influenza infection.¹¹

Vaccination

National guidelines in the United Kingdom recommend influenza vaccination for all adults aged over 65 years and those in long-term care. Influenza vaccination is effective in long-term care facilities. It has been shown to prevent 45% of pneumonia episodes and reduce hospital admissions and influenza-related deaths.¹² In one study the vaccine was less effective in elderly populations living in the community; however, a 25% reduction in the proportion of people hospitalized from influenza or related illness was achieved.¹² There is some evidence that vaccination of health care workers in long-term care institutions is also associated with a reduction in influenza-related mortality among patients.¹³ However, a recent Cochrane review concluded that further studies were required.^{12,14}

In the United States national vaccination uptake is only 65%¹⁵ and in the United Kingdom and Europe only a minority of those eligible for vaccination receive it.^{16,17} Possible

explanations include patient concerns regarding side effects, frustration that previous vaccination has not prevented influenza-like illness, and the deferment of vaccination by doctors when patients have a mild upper respiratory tract infection.¹⁵

Treatment

Neuraminidase inhibitors (zanamivir, oseltamivir) are effective at preventing and treating influenza.¹⁸ These agents must be taken within 48 hours of the onset of symptoms. United Kingdom guidelines recommend their use for at-risk groups, including adults aged over 65 years.¹⁹ Clinical trials have shown that these agents reduce symptom duration by 1 to 2 days and decrease hospitalization and death rates in the elderly.^{18,20,21} The neuraminidase inhibitors are well tolerated and the safety profile among the elderly is similar to that in younger adults. The most common adverse effects are nausea, vomiting, and abdominal pain. Zanamivir may cause bronchospasm.²² Amantadine and rimantadine are only effective against influenza A and are associated with toxic side effects and with rapid emergence of drug-resistant variants.^{22,23} Routine use of these agents is not recommended.^{19,23}

In the United Kingdom the National Institute for Clinical Excellence (NICE) guidelines recommend that postexposure prophylaxis with oseltamivir is given to all adults living in residential care facilities, regardless of vaccination status. When given within 48 hours, this has been shown to reduce influenza rates by 92%.²⁴ In the community setting, postexposure prophylaxis is only recommended to high-risk adults (including those over 65 years) if they have not been vaccinated or if the circulating strain of influenza is known to be different than the vaccination strain. Amantadine is not recommended for postexposure prophylaxis.²⁵

PNEUMONIA

Community-acquired pneumonia has an incidence of 5 to 11/1000 adult population.^{3,26,27} The incidence is higher in the elderly, with those over 75 having six times greater risk compared with those less than 60 years.^{27–30} Older adults in residential care are particularly vulnerable.^{3,31} This is largely explained by the increase in comorbidities in this population. Chronic obstructive pulmonary disease (COPD), diabetes, heart failure, malnutrition, malignancy, and dysphagia are all risk factors for pneumonia in the elderly.^{3,32} Mortality is 5.7% to 14% and increases with age. In the United States lower respiratory tract infection is the eighth leading cause of death.^{26,33–36}

The most common causative organism is *S. pneumoniae*. Other pathogens include *Haemophilus influenzae*, viruses, gram-negative bacilli and *S. aureus*. In the elderly infections with "atypical" organisms, such as *Mycoplasma* and *Legionella*, are less common.^{33,34} Infection with gram-negative bacilli and anaerobic organisms may occur after aspiration.^{3,37} There is no evidence that the pathogens associated with nursing home-acquired pneumonia are different from other older adults in the United Kingdom, although studies in

Table 50-1. Pneumonia Severity Prediction; CURB-65 Score

- Confusion of new onset. (or worsening of existing state for those with background cognitive impairment)
- Serum urea >7 mmol/L
- Respiratory rate \geq 30/min
- Blood pressure (systolic BP <90 mm Hg or diastolic BP \leq 60 mm Hg)
- Age \geq 65 years

A score is awarded for each variable present. A score \geq 3 represents severe pneumonia.

North America have reported an increased incidence of gram-negative bacilli and *S. aureus*.³⁸⁻⁴⁰

Presentation in the elderly is frequently nonspecific and the classic symptoms and signs of pneumonia may not be present. Confusion, lethargy, anorexia, and falls are common presenting symptoms.³ For example, a chest x-ray will demonstrate pneumonia in nearly a quarter of elderly patients having acute confusion and no clinical signs.⁴¹ Fever is less likely to be present in elderly patients.^{3,26,42} An important clinical sign in the elderly is the presence of tachypnea.⁴²

A number of scoring systems can be used to assess severity in community-acquired pneumonia, including the Pneumonia Severity Index and the CURB-65 score.^{43,44} Current BTS^{26,45} and ATS⁴⁶ guidelines recommend the use of the CURB-65 score (Table 50-1) because of its simplicity and strong predictive power for severe pneumonia, particularly in the elderly. Those patients with a low score (0 to 2) have a low mortality risk and may be suitable for outpatient treatment with oral antibiotics.⁴⁴ However, in the elderly this may not be appropriate because of comorbidities and psychosocial concerns.

Management

The investigation and management of community-acquired pneumonia is discussed in guidelines published by both the British and the American Thoracic Societies.^{26,45,46} Initial empirical treatment is with broad-spectrum antibiotic therapy with activity against *Pneumococcus* and "atypical" organisms. Current recommendations suggest the combination of β -lactam plus macrolide antibiotics for patients requiring admission to hospital. An alternative in penicillin-allergic patients is a fluoroquinolone with enhanced pneumococcal activity, such as levofloxacin.⁴⁵ Local antibiotic resistance patterns will need to be taken into account. Intravenous antibiotic therapy is only required in severe pneumonia or in patients who are unable to take oral preparations. In the elderly antibiotic associated colitis and *Clostridium difficile* infection is a particular concern with intravenous antibiotics.⁴⁷⁻⁴⁹ There is evidence that in severe pneumonia delay in the administration of the first antibiotic is associated with increased mortality.⁵⁰⁻⁵²

Following an episode of pneumonia it is important to ensure that radiologic changes resolve, particularly in the elderly and in smokers who are at increased risk of an underlying malignancy. Radiologic clearance is slower in the elderly.^{26,34}

Nosocomial pneumonia

The incidence of hospital-acquired pneumonia increases significantly with age⁵³ and the mortality rate can be 50%.³ Treatment regimes should cover gram-negative anaerobic

bacteria and *Pseudomonas* sp. Methicillin-resistant *S. aureus* (MRSA) should also be considered.

Vaccination

Polysaccharide pneumococcal vaccination is recommended for all adults over 65 years.^{26,46} There is no need for reimmunization. A recent meta-analysis concluded that there was insufficient evidence to support the routine use of pneumococcal vaccination to prevent all-cause pneumonia or mortality.⁵⁴ However, vaccination did prevent invasive pneumococcal disease in the elderly.

TUBERCULOSIS

The incidence of tuberculosis is now declining in the Western world, although it continues to rise in Africa because of the HIV epidemic. WHO surveillance data from 2006 showed an incidence of 4 cases/100,000 population in the United States and 15 cases/100,000 population in the United Kingdom.⁵⁵ In those born in either the United Kingdom or the United States, the incidence of active TB increases with age, with a doubling of the incidence in adults over 80 years old.⁵⁶ The reason for this is multifactorial. Most cases of TB in the elderly represent reactivation of previous disease.⁵⁶ This may be precipitated by an age-related reduction in cell-mediated immunity or secondary to other factors such as malnutrition, alcoholism, cancer, diabetes mellitus, HIV infection, and treatment with corticosteroids.²

TB is particularly common among care home residents in the United States⁵⁷ with the incidence of active TB being two to three times higher than in the community-dwelling elderly^{58,59} because of reactivation of disease and institutional outbreaks.⁶⁰

Presentation

Presentation in the elderly may be insidious and nonspecific; weight loss, weakness, or a change in cognitive function may be the only manifestation.^{2,61} Dyspnea is often present, whereas hemoptysis and fevers are observed less frequently in the elderly.⁵⁷ It is important to consider TB if a patient has a cough or pneumonia that incompletely responds to conventional treatment.

The chest radiographic changes of TB are similar in all age groups although in the elderly there is a greater prevalence of mid and lower zone shadowing.² In addition, cavitating disease is less common.⁵⁷ Miliary TB is likely in older adults, although the diagnosis is frequently missed.² The presence of radiographic manifestations of previous TB infection in an elderly patient with nonspecific infective symptoms should alert physicians to exclude reactivation. Extrapulmonary TB is uncommon and is often difficult to diagnose. Sites involved include the genitourinary tract, the central nervous system, the lymphatics, and bone. Extrapulmonary TB is more common in children and the elderly.⁶²

Investigation

Pulmonary TB is usually diagnosed by culturing *Mycobacterium tuberculosis* from sputum. Guidelines suggest that three sputum samples should be sent for culture.⁶³ In elderly patients it may be difficult to obtain spontaneous sputum samples, and sputum induction or bronchoscopy with bronchial washings may be required. The presence of acid-fast

bacilli (AFB) on Ziehl-Neelsen staining (smear positive) suggests the diagnosis; however, *Mycobacterium tuberculosis* can take up to 6 weeks to be cultured using conventional techniques. It is important to remember that AFB smear positivity alone does not distinguish *M. tuberculosis* from nontuberculous mycobacterial infection (NTM). Rapid culture techniques, including polymerase chain reaction (PCR) or gene probe analyses allow earlier diagnosis. Once a patient is diagnosed with TB, consideration should be given to HIV testing.

Patients with suspected TB are usually investigated as outpatients; however, smear-positive elderly care home residents may benefit from isolation to prevent transmission.⁵⁹ If admitted to the hospital, patients should be isolated until their sputum status is known. If multidrug-resistant tuberculosis (MDR-TB) is suspected, patients should be managed in a negative air pressure room. Patients who are smear-positive need to remain isolated until they have completed 2 weeks of antituberculous treatment.^{59,63}

Tuberculin skin test

The tuberculin skin test measures cell-mediated immunity against TB. It is positive in both active and latent disease and also individuals that have received BCG immunization. False negatives can occur in immunocompromised patients because of anergy. Anergy is more prevalent among the elderly because of a decline in cellular immunity, and the value of the tuberculin skin test is therefore reduced.⁵⁶ It is mainly used in the diagnosis of latent TB.

Gamma interferon tests

Gamma interferon tests are a recent development. A blood test can detect tuberculosis infection by measuring interferon-gamma release from T cells in response to antigens that are highly specific to *M. tuberculosis*, but are absent from BCG vaccine. In the United Kingdom they are primarily used to confirm the diagnosis of latent TB in the presence of a positive tuberculin skin test.⁶³ It is likely that their role will increase in the future.

Management

Recommendations for antituberculous therapy do not differ in the elderly. Initial empirical therapy should consist of a four-drug regimen for 2 months (rifampicin, isoniazid, pyrazinamide, ethambutol), followed by a two-drug regimen for 4 months (rifampicin and isoniazid). Extrapulmonary TB is treated in the same way, with the exception of TB meningitis, which requires 12 months' treatment.⁶³ Directly observed therapy may be useful in selected individuals who are at risk of poor compliance. Contact tracing is an important aspect of management and current recommendations are available in national and international guidelines.⁶³

Multidrug-resistant TB (resistance to rifampicin and isoniazid) is uncommon in the elderly population at present in the United Kingdom and United States. This is probably because active TB in the elderly usually results from reactivation of latent infection that was acquired when there was no effective antituberculous chemotherapy.⁵⁶

Drug toxicity and intolerance is more common in the elderly. Older adults are more likely to be coprescribed other medication and this increases the likelihood of drug interactions. Rifampicin in particular may reduce the levels of many

medications through induction of the cytochrome P450 system. The use of isoniazid has been associated with increased levels of some anticonvulsants and benzodiazepines.⁶⁰

Rifampicin, isoniazid, and pyrazinamide are all associated with gastrointestinal side effects and hepatotoxicity. Hepatic toxicity is increased in elderly patients.⁶⁴ Ethambutol can cause a loss of visual acuity and color discrimination and close monitoring is required in elderly patients whose visual acuity may already be impaired. Isoniazid can cause peripheral neuropathy, particularly in patients with coexisting renal failure. This can be prevented by pyridoxine. Finally, rifampicin may cause bodily fluids to become discolored orange.

Latent TB

Latent TB is defined as a positive tuberculin skin test, with a normal CXR and no symptoms of TB. Individuals who are identified as having latent TB through contact screening should be offered chemoprophylaxis. In the United States all residents of care homes are screened for latent TB on admission. Those with latent TB are treated with chemoprophylaxis. Treatment regimens comprise either isoniazid alone for 6 months or isoniazid and rifampicin combined for 3 months.⁵⁹

Prognosis

Tuberculosis-related deaths are more common in the elderly. In 2004 in the United Kingdom there were 328 deaths from active TB, 68% of which occurred in adults aged over 65 years.¹ Many elderly patients will have long-term sequelae from tuberculous infection. Pulmonary fibrosis is a recognized complication as is pleural thickening and restrictive lung disease from pleural infection. Historical surgical techniques can also lead to chest wall deformities.

NONTUBERCULOUS MYCOBACTERIAL INFECTION

Pulmonary infection with nontuberculous mycobacteria has become increasingly recognized in the elderly population over recent years.⁶⁵ Predisposing factors include chronic lung diseases, such as COPD and bronchiectasis, along with immunosuppression, particularly HIV infection. Clinical and radiologic features are similar to pulmonary tuberculosis. Treatment in the elderly can be difficult because of drug intolerance. Guidelines on the diagnosis and treatment of nontuberculous mycobacteria have been published by both the British and the American Thoracic Societies.^{66,67}

BRONCHIECTASIS

Bronchiectasis is characterized by the permanent dilation of bronchi, with chronic airway inflammation and excess sputum production. Bronchiectasis is a relatively rare condition affecting 1 to 2/100,000. A Finnish study suggested a prevalence of 39 cases per million population rising to 104 cases per million in those over 65.⁶⁸ However, the advent of high-resolution computed tomography (HRCT) scanning means milder forms of bronchiectasis are now being identified.

In the elderly population bronchiectasis is often a sequela of childhood infections such as pertussis, measles, tuberculosis, and severe pneumonia.⁶⁹ Bronchiectasis is increasingly being recognized as a complication of COPD. A causative

Table 50-3. Causes of Unilateral Pleural Effusion

Transudative Effusions	Exudative Effusions
Very Common	Common
- Left ventricular failure	- Malignancy
- Liver cirrhosis	- Parapneumonic effusion
- Hypoalbuminemia	
- Peritoneal dialysis	Less common
	- Pulmonary infarction
Less common	- Rheumatoid arthritis
- Hypothyroidism	- Autoimmune disease
- Nephrotic syndrome	- Benign asbestos effusion
- Mitral stenosis	- Pancreatitis
- Pulmonary embolus	- Post-MI syndrome
Rare	Rare
- Constrictive pericarditis	- Yellow nail syndrome
- Urinothorax	- Drugs
- Superior vena cava obstruction	- Fungal infections

factor cannot be identified in many cases and these are termed idiopathic bronchiectasis. Causes and investigation of bronchiectasis are outlined in Table 50-2.

Management

The aims of treatment are to reduce symptoms, promptly treat exacerbations, and prevent disease progression. A multidisciplinary approach with input from physiotherapists, respiratory nurses, and dietitians is particularly important for elderly patients. Bronchodilators are effective in treating associated airflow obstruction and mucolytics are useful to aid sputum clearance.⁷⁰ Daily physiotherapy with postural drainage or cough augmentation is important, particularly during exacerbations. Inhaled corticosteroids may be useful in improving lung function and reducing exacerbation infrequency.^{71,72} Surgery remains an option for selected patients with localized disease or those with troublesome hemoptysis.

Table 50-4. Light's Criteria for Classification of Unilateral Pleural Effusion

The pleural fluid is an exudate if one or both of the following criteria are met: Pleural fluid protein divided by serum protein >0.5 Pleural fluid LDH divided by serum LDH >0.6

Acute exacerbations should be treated promptly with antibiotics. Regular oral or nebulized antibiotics may be necessary for those individuals who have frequent exacerbations. Azithromycin twice weekly has anti-inflammatory and antimicrobial properties and has shown promise in reducing exacerbation frequency in bronchiectasis.⁷³ The results of microbiologic investigations may be difficult to interpret because most patients are chronically colonized by a variety of organisms, most commonly *H. influenzae*. *Pseudomonas aeruginosa* infection is often difficult to treat and may require more prolonged courses of combination intravenous antibiotics.⁷²

PLEURAL EFFUSION

The investigation and management of pleural effusions are summarized in guidelines from the British Thoracic Society and are beyond the scope of this chapter.⁷³ Investigation in the elderly does not differ from younger individuals. A diagnostic pleural tap will differentiate exudative from transudative effusions and will often ascertain the cause (Table 50-3). Light's criteria should be used to classify effusions with pleural fluid total protein content between 25 and 35 g/dL, particularly in the elderly in whom a single pleural fluid protein value is less reliable (Table 50-4). Other parameters that may be diagnostically useful include pleural fluid cytology, culture and sensitivity, glucose, pH and cell profile, depending upon the clinical scenario.⁷⁴ If the cause of an exudative effusion remains unclear after pleural fluid analysis, a CT scan of the thorax is advised. This is most useful if performed before drainage of the effusion. If diagnostic uncertainty still remains following a CT scan, then medical thoracoscopy should be considered. Thoracoscopy is more sensitive than the Abram's blind pleural biopsy and is well tolerated in all ages. It is a useful diagnostic technique, allowing direct visualization of the pleura and has the added advantage of offering fluid drainage and in a single procedure.⁷³

PNEUMOTHORAX

The incidence of pneumothorax in the United Kingdom is 24/100,000 per year for men and 9.8/100,000 per year for women. There is a biphasic age distribution with peaks seen in the 20 to 24 and 80 to 84 year age groups⁷⁵ and is attributed to primary and secondary spontaneous pneumothorax, respectively. Elderly patients tend to have secondary pneumothorax related to underlying chronic lung disease, most commonly COPD.

Pneumothorax in the elderly usually presents with acute dyspnea, which is often out of proportion to the size of the pneumothorax. Pleuritic chest pain occurs less frequently than in younger patients.⁷⁶ The diagnosis is usually confirmed on a chest radiograph; however, in rare cases a CT scan of the thorax may be necessary to differentiate a pneumothorax from complex bullous lung disease.⁷⁷

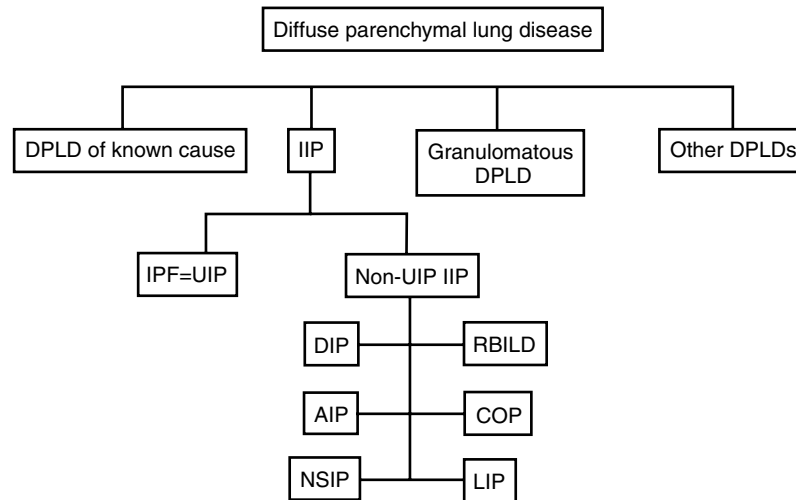

Figure 50-1. Classification of diffuse parenchymal lung disease. (IIP, idiopathic interstitial pneumonia; UIP, usual interstitial pneumonia; DIP, desquamative interstitial pneumonia; AIP, acute interstitial pneumonia; RBILD, respiratory bronchiolitis associated ILD; NSIP, nonspecific interstitial pneumonia; COP, cryptogenic organizing pneumonia; LIP, lymphocytic interstitial pneumonia.)

The treatment of secondary pneumothorax in the elderly involves hospital admission and intercostal drain insertion. Simple aspiration is unlikely to succeed and is not recommended.⁷⁷ Small asymptomatic pneumothoraces (<1 cm) can be managed by close observation.

Indications for surgical intervention include persistent air leak, second ipsilateral pneumothorax, and first contralateral pneumothorax. The aims of surgery are to resect or suture the bleb that caused the pneumothorax and to perform pleurodesis to prevent recurrence. Thoracoscopy and VATS (video-assisted thoracic surgery) can be performed safely in the elderly population with a low morbidity and mortality.^{78,79} In those patients who are either unable or unwilling to undergo surgery, chemical pleurodesis can be attempted; however, recurrence rates are high with this approach.⁷⁷

DIFFUSE PARENCHYMAL LUNG DISEASE

Diffuse parenchymal lung disease (DPLD) is a term used to describe a heterogeneous group of disorders characterized by damage to the lung parenchyma by varying patterns of inflammation and fibrosis.⁸⁰ The most important distinction among the idiopathic pneumonias is between idiopathic pulmonary fibrosis (IPF) and the other interstitial pneumonias.⁸⁰ Figure 50-1 outlines the current classification system.

The diagnosis of DPLD is complex and elderly patients with suspicious features should be referred for a specialist respiratory opinion. Clinical, radiologic, and pathologic features frequently overlap, making accurate diagnosis difficult. Therefore diagnosis should be undertaken in the context of a multidisciplinary team meeting comprising respiratory clinicians, thoracic radiologists, and pathologists with expertise in the evaluation of DPLDs. The diagnostic process requires a comprehensive clinical and physiologic evaluation followed by HRCT scanning in most cases. Surgical biopsy is recommended if clinical or radiologic features are not typical and preclude accurate diagnosis. Surgical lung biopsy is well tolerated; however, specific studies in the elderly are lacking.⁸¹ Video-assisted thoracoscopic biopsy is increasingly being performed in place of open lung biopsy.

Transbronchial biopsy is less invasive although, with the exception of sarcoidosis, samples are usually nondiagnostic. A history of systemic involvement (eye, joint, skin) or the presence of serum auto-antibodies may suggest an underlying connective tissue disorder. It is particularly important to distinguish UIP from other idiopathic interstitial pneumonias (IIP) because survival is significantly worse in this condition.⁸² In addition, these other IIPs have a better response to immunosuppressive therapy.

IDIOPATHIC PULMONARY FIBROSIS

Idiopathic pulmonary fibrosis (previously termed cryptogenic fibrosing alveolitis) is the commonest of the idiopathic interstitial pneumonias. The diagnosis requires either a radiologic or pathologic diagnosis of usual interstitial pneumonia (UIP). The prevalence of IPF is estimated to be between 4/100,000 for persons aged 18 to 34 to 227/100,000 for those 75 years or older.⁸³ It is therefore a disease of the elderly with the age at symptom onset usually greater than 50 years.

Patients typically have progressive breathlessness and an irritating dry cough. Clinical examination will reveal digital clubbing in 25% to 50% of patients and fine end-inspiratory crackles, usually in a posterobasal distribution, on auscultation of the chest.^{80,84} Lung function tests typically show a restrictive deficit with a reduction in vital capacity, total lung capacity, and transfer factor. Chest radiograph changes include reticulonodular shadowing with reduced lung volumes. High resolution computed tomography scan appearance is pivotal to establishing the diagnosis. Typical HRCT features of UIP include subpleural reticulation with honeycombing and traction bronchiectasis with basal predominance. Surgical lung biopsy is not required in patients with typical clinical and radiologic features of UIP, but should be considered in the presence of atypical features.⁸⁰

The prognosis in UIP is poor. Median survival from diagnosis is less than 3 years.⁸⁰ However, the course of the disease can be highly variable in individual patients, with some declining rapidly whereas others remain stable.

Management

There is no good evidence that any treatment alters the course of idiopathic pulmonary fibrosis. Corticosteroids have traditionally been the mainstay of treatment; however, there have been no controlled trials comparing them to placebo, and no data to show that they improve either survival or quality of life.^{85,86} Previous studies suggesting a favorable response to steroid treatment included patients with conditions other than UIP that are associated with a better treatment response and prognosis (e.g., nonspecific interstitial pneumonia). Significant adverse effects with oral corticosteroids are more prevalent in the elderly.⁸⁷

Immunosuppressant therapy, in particular azathioprine, has been used in combination with corticosteroids in idiopathic pulmonary fibrosis. However, a recent meta-analysis concluded that there was little evidence to justify their use.⁸⁸ One controlled trial did show a nonsignificant trend toward improvement in lung function with azathioprine, and when adjusted for age, a statistically significant improvement in survival.⁸⁹ It is on this basis that azathioprine is used; however, patient numbers were small. Other agents such as cyclophosphamide, methotrexate, and mycophenolate mofetil have been tried; however, evidence regarding their efficacy is lacking. Immunosuppressant therapy is associated with significant toxicity including myelosuppression and hepatic toxicity. In the elderly population drug interactions are also a particular problem because of frequent comorbidities and polypharmacy. For example, the concomitant use of allopurinol with azathioprine leads to increased azathioprine levels.⁹⁰

A recent trial suggests that treatment with oral N-acetylcysteine may slow decline in vital capacity and transfer factor in patients with UIP when added to prednisolone and azathioprine.⁹¹

Current management guidelines suggest withholding treatment unless there is advanced disease (FVC <50%, TLCO <40%) or evidence of significant disease progression.⁹² Standard treatment includes combination therapy using prednisolone plus azathioprine with N-acetylcysteine. Patients younger than 65 years should also be considered for referral for lung transplantation.⁹³ Best supportive care includes oxygen therapy, pulmonary rehabilitation, and palliative care.

DRUG-INDUCED INTERSTITIAL LUNG DISEASE

Drug-induced interstitial lung disease is most prevalent in the elderly by virtue of their increased exposure to multiple drugs. The most commonly prescribed causative agents are amiodarone, methotrexate, ACE inhibitors, and nitrofurantoin. Treatment involves withdrawal of the causative agent and immunosuppressive therapy in some cases.

CONNECTIVE TISSUE DISEASE

Autoimmune disorders including rheumatoid arthritis, Sjögren syndrome, SLE, systemic sclerosis, and polymyositis are all associated with lung fibrosis. Respiratory symptoms may precede other manifestations of the disease. The association between rheumatoid and interstitial fibrosis is strongest

in the elderly and has a mean age of onset in the fifth or sixth decade. The incidence, clinical presentation, prognosis, and response to therapy vary depending on the underlying disorder and the histologic pattern of disease. In general interstitial lung disease associated with the collagen vascular disorders has a better prognosis and response to treatment than IPF.⁹⁴

SARCOIDOSIS

Sarcoidosis is a multisystem disorder that most frequently affects the lungs. It occurs less commonly in the elderly, with case series suggesting older adults represent between 7.8% (adults >65 years) and 17% (adults >50 years) of cases.^{95,96} Presentation is usually with breathlessness and cough, although symptoms may be nonspecific, with a decline in general health.⁹⁷ Löfgren syndrome is rarely seen in adults aged over 50 years.⁹⁸ Serum angiotensin-converting enzyme (ACE) levels are of limited value diagnostically, particularly in the elderly who have an increased incidence of renal failure and diabetes (which are associated with raised serum ACE levels).^{97,98} Diagnosis should be confirmed histologically if possible.⁹⁹ The course of disease seems to be similar in younger and older patients.⁹⁷ Corticosteroids are used to treat selected patients with pulmonary involvement and should be supervised by clinicians with expertise in the management of sarcoidosis. Other indications for systemic corticosteroid use in sarcoidosis include hypercalcemia, ocular disease, and cardiac, neurologic, or renal involvement.

PULMONARY VASCULITIS

The vasculitides are broadly subclassified according to size of vessel involvement, clinical features, and associated conditions. Small vessel vasculitis is further subdivided according to the presence or absence of antineutrophil cytoplasmic antibodies (ANCA). The incidence of ANCA-associated vasculitis is increasing. Wegener granulomatosis is a small vessel, systemic necrotizing vasculitis with a peak age of onset at 55 years. Clinical presentation in the elderly is similar to that seen in younger adults although ear, nose, and throat involvement is observed less frequently.^{100–102} Some studies suggest elderly patients have an increased incidence of renal and neurologic involvement at diagnosis,¹⁰² although other studies dispute this.^{100,101} Diagnosis may be difficult because of the presence of coexistent disease such as COPD that influences clinical and radiologic features.⁹⁰ Circulating ANCA levels are positive in the majority of patients with renal involvement but are frequently negative in more limited disease. Biopsy of affected organs is recommended to confirm the diagnosis. Therapy is subdivided into phases with different treatment regimens for remission induction and maintenance therapy. There have recently been several large scale multicenter trials, which have provided clarification regarding the most appropriate treatment regimens. The combination of oral corticosteroids and cyclophosphamide will induce remission in 90% of patients. However, relapse rates are high and survival is worse in those over 60 years of age.^{100–102} Renal involvement is also associated with a poorer prognosis. Death usually results from uncontrolled vasculitis or systemic infection.

HYPERSENSITIVITY PNEUMONITIS

Hypersensitivity pneumonitis is caused by an immunologic reaction to the inhalation of organic antigens. It is often associated with the formation of systemic precipitating antibodies. Common precipitating antigens include bird proteins (bird fancier's lung) and thermophilic actinomycetes (farmer's lung). Most commonly it presents as a chronic illness related to repeated exposure but an acute form is recognized. Management centers on antigen avoidance although in some patients the disease will progress despite this. Corticosteroids can be used to improve lung function, although their effect on long-term outcome is unclear.

OCCUPATIONAL LUNG DISEASE

Pneumoconiosis

Pneumoconioses are pulmonary diseases caused by the inhalation of mineral dusts. Common causative mineral dusts include coal dust, silica, beryllium, and asbestos. The incidence of pneumoconiosis appears to be decreasing in the United Kingdom with a 5.7% reduction in reported cases between 1999 and 2005.¹⁰³ In 2004 there were 3000 deaths from pneumoconiosis of which 90% occurred in adults over 65 years of age.¹

Coal workers pneumoconiosis

There has been a steady reduction in the numbers of underground coal miners in Western Europe and the United States, with a consequential fall in the incidence of coal workers pneumoconiosis. Other countries still employ large numbers of miners. Dust exposure results in inflammation and fibrosis of the lung parenchyma. Coexistent COPD is common. Simple pneumoconiosis is usually asymptomatic and is identified as nodular shadowing on a chest x-ray. Progressive massive fibrosis is associated with exertional breathlessness and a cough (often productive of black sputum) and may lead to cor pulmonale and respiratory failure. Chest x-ray features include fibrotic masses, usually in the upper zones, on a background of simple coal workers pneumoconiosis.

Asbestosis

Asbestosis is a fibrotic lung disease caused by exposure to asbestos dust. Diagnosis depends on a reliable history of significant asbestos exposure (usually a 10 to 20 year exposure period). Markers of exposure, such as pleural plaque or pleural thickening, are invariably present. Occupations at greatest risk include shipyard workers, asbestos factory workers, plumbers, insulation workers, electricians, and builders. There is a latency period of at least 15 to 20 years between exposure and the development of asbestosis, hence it is predominantly a disease of middle to old age. The incidence of asbestosis has increased over the last 10 years in both the United Kingdom and United States.^{104,105} Treatment is supportive and patients should be informed of their eligibility for compensation.

LUNG CANCER

Lung cancer is the commonest malignancy in developed countries and is the leading cause of cancer deaths. It is predominantly a disease of the elderly with more than 50% of

cases being diagnosed in patients over the age of 65, and about 30% of cases being diagnosed in patients over the age of 70.¹⁰⁶ Most patients have advanced disease at presentation and as a result the 5-year survival rate is poor. In the United Kingdom, the 1-year survival rate is ~21%, with a 5-year survival rate of only 5.5%.¹⁰⁷ In the United States, the 5-year survival rate is higher (13% to 17%).¹⁰⁸ Guidelines on the diagnosis and management of lung cancer have been published by the American College of Chest Physicians.¹⁰⁹

Presentation and investigation

Most cases of lung cancer have symptoms of breathlessness, recurrent chest infections, chest pain, hemoptysis, or weight loss. Other cases may be diagnosed as an incidental finding on routine chest x-ray. The aims of investigation are to make a definitive diagnosis and to stage the cancer appropriately, facilitating treatment decisions. A staging computed tomography (CT) scan of the thorax, followed by bronchoscopy, is the usual approach. In patients with peripheral tumors, a percutaneous CT-guided biopsy will be more likely to obtain a histologic diagnosis. Bronchoscopy is well tolerated in all age groups, with a low risk of significant complications. In very frail patients, invasive investigation may not be appropriate and a clinical diagnosis of lung cancer may suffice. Positive emission tomography (PET) scanning is indicated for any patients who are being considered for potentially curative treatment. It also has a role in the investigation of the solitary pulmonary nodule. The specificity of PET is not high and many benign inflammatory lesions produce false-positive results.¹⁰⁷

Non-small cell lung cancer (NSCLC) (including adenocarcinoma, squamous cell carcinoma, and large cell carcinoma) accounts for 85% of all new diagnoses. Small cell lung cancer accounts for the remaining 15%.¹¹⁰ Non-small cell lung cancer is staged using the TNM system. This staging system is currently under review. Small cell lung cancer is staged as limited disease if the tumor is confined to one hemithorax (including ipsilateral mediastinal and supraclavicular nodes). Spread beyond the hemithorax is staged as extensive disease.

Management

Treatment decisions in lung cancer are based on the stage of disease, histology, the presence of co-morbid diseases, and on performance status (Table 50-5). They should not be based on chronologic age. Despite this there is evidence that the elderly are undertreated and are underrepresented in clinical trials, making evidence-based decision making difficult.^{111,112} When assessing patients it is useful to perform a comprehensive geriatric assessment including measures of functional status, comorbidity, cognitive state, and nutritional status. Aging is associated with a physiologic decline

Table 50-5. WHO Performance Status Score

Asymptomatic

1. Symptomatic but ambulatory (able to perform light work)
2. In bed <50% of day (unable to work but able to live at home with some assistance)
3. In bed >50% of day (unable to care for self)
4. Bedridden

in organ function and a number of changes in drug pharmacokinetics and pharmacodynamics. This results in differences in treatment tolerance between older and younger patients.¹¹⁰ Clinical trials specifically designed for the elderly population are needed.

NON-SMALL CELL LUNG CANCER

Surgery

Surgery is the treatment of choice for all patients with stage I/II NSCLC who are fit enough for the procedure. Improvements in surgery and perioperative care mean that an increasing number of elderly patients are eligible for curative treatment. Video-assisted thoracic surgical techniques (VATS) are increasingly useful.⁷⁸ Age has no influence on long-term survival after surgery.¹¹³

Adjuvant chemotherapy

Adjuvant treatment of NSCLC in elderly patients is controversial because of a lack of prospective trials. Randomized trials suggest that postoperative chemotherapy improves survival in the general population with stage II to IIIA NSCLC. There is no evidence that any group of patients specified by age benefited more or less from adjuvant therapy.¹¹⁴

Radical radiotherapy

Elderly patients with stage I/II disease are frequently unable to undergo surgery because of comorbidities or reluctance to proceed. In these cases radical radiotherapy is effective with reported mean survival times of 20 to 27 months and 5-year survival rates of 15% to 34% in patients over 70 years old. Treatment outcomes and toxicity rates do not differ with age.¹¹³ Continuous hyperfractionated accelerated radiotherapy (CHART) is high-dose radiotherapy given three times a day for 12 days. A large randomized trial has shown an improvement in 2-year survival from 20% with conventional radiotherapy to 29% with CHART.¹¹⁵

Locally advanced disease

Patients presenting with locally advanced NSCLC (stage III) are usually treated with radiotherapy or combined chemo/radiotherapy. Combined treatment may offer a chance of cure although conflicting evidence exists regarding this approach in elderly patients. Treatment outcomes are comparable to younger patients; however, there is a higher risk of toxicity. For patients with an impaired performance status or severe comorbidity, radiotherapy alone is an alternative.^{116,117}

Palliative chemotherapy

Chemotherapy is the mainstay of treatment for patients with advanced disease at presentation.¹⁰⁷ A standard regimen would include a platinum-based chemotherapy agent with a single third generation agent (e.g., carboplatin/cisplatin plus vinorelbine/gemcitabine/paclitaxel/docetaxel). This has a modest survival benefit (increase in median survival by 1.5 months, 10% improvement in 1-year survival) compared with supportive care alone.^{107,108} Platinum-based chemotherapy is efficacious in older individuals; however, it is associated with significant toxicity (nephrotoxicity, ototoxicity, neurotoxicity).¹⁰⁶ Furthermore, the survival benefit of chemotherapy is limited to patients with a good

performance status (WHO 0–1).¹¹⁷ It is therefore only an option in fit elderly patients.

In elderly patients who are unable to tolerate a platinum combination, a single third generation drug can be used. The ELVIS trial showed that single agent vinorelbine significantly improved both survival and quality of life when compared with supportive care alone (mean survival time 27 vs. 21 weeks).¹¹⁸ The MILES study demonstrated that combination treatment has no advantage over single-agent therapy.¹¹⁹

Palliative radiotherapy

Radiotherapy can be used to improve symptoms, particularly hemoptysis, chest pain, dyspnea, and cough. Elderly patients tolerate radiotherapy well and gain equivalent palliation to their younger counterparts.¹²⁰ Performance status does not influence benefit from radiotherapy.

New therapies

Knowledge of cancer biology has enabled the development of new agents that specifically block pathways involved in oncogenesis. Gefitinib and erlotinib are selective inhibitors of epidermal growth factor receptors that have demonstrated activity in patients with NSCLC.¹²¹ These agents are well tolerated in the elderly and may have a role in the future.

SMALL CELL LUNG CANCER

Small cell lung cancer is an aggressive form of cancer that tends to metastasize early. As a result chemotherapy is the mainstay of treatment. Two thirds of patients have extensive disease at presentation. The median survival is only 2 to 4 months without treatment.¹²²

Limited disease

In limited disease, response rates to chemotherapy are between 70% and 80%, with a median survival of 12 to 16 months. Only 4% to 5% of patients can be considered cured.¹²¹ The standard treatment for limited disease SCLC is four to six cycles of a platinum-based chemotherapy regimen (commonly etoposide plus carboplatin) combined with thoracic radiotherapy. In patients that achieve complete remission, prophylactic cranial irradiation is offered. Prophylactic cranial radiotherapy has been shown to reduce the incidence of brain metastases and is associated with a slight survival benefit (5.4% at 3 years).¹²²

Many trials have looked at chemotherapy regimens for elderly patients with SCLC. Standard regimens remain the most effective, and therefore the treatment of choice despite their significant toxicity. For those with significant comorbidity, less aggressive regimens can be used. Such regimens include dose reduction, shortened treatment duration, and single-agent chemotherapy. At present the optimal treatment is not established.^{123,124}

Thoracic radiotherapy is associated with considerable toxicity (bone marrow and esophageal), particularly in elderly patients. Sequential chemoradiotherapy is less toxic than a standard concurrent approach. A meta-analysis looking at thoracic radiotherapy showed a small but significant survival benefit (5.4% ± 1.4% at 3 years) for the use of thoracic radiotherapy. However, this effect was lost in patients over 70 years old.¹²⁵

Extensive disease

Response rates to chemotherapy are between 60% to 70%, with a median survival of 7 to 11 months. Virtually no patients survive to 5 years.¹²³ Chemotherapy alone is the standard treatment of extensive disease as radiotherapy only has a palliative role. Dual-agent platinum-based regimens are the most effective and usually six cycles are given. Quality of life should be the goal. There is evidence that prophylactic cranial radiotherapy in extensive SCLC reduces the incidence of symptomatic brain metastasis and improves overall survival (1-year survival rate 27.1% vs. 13.3%).¹²⁶

Palliative care

Supportive care is particularly important in lung cancer as most patients have incurable disease. Symptom control, psychological support, and social requirements all should be addressed. A multidisciplinary approach is recommended involving the respiratory physicians, palliative care teams, oncologists, physiotherapists, occupational therapists, and dieticians.¹²⁵

MALIGNANT MESOTHELIOMA

Pleural mesothelioma has been increasing in incidence in the United Kingdom since the 1960s. The annual number of deaths from mesothelioma is predicted to peak at between 1950 and 2450 between 2011 and 2015.¹²⁷ Asbestos exposure is the cause of 85% of cases of mesothelioma.^{128,129} The latency period is typically long with a mean of 41 years (range 15 to 67).¹²⁹ As a result mesothelioma is typically a disease of older men. The prognosis is poor with a median survival of 14 months from symptom onset.¹²⁹ Patients with mesothelioma may be eligible for compensation if they are able to verify occupational exposure to asbestos.

Presentation is classically with chest pain and dyspnea, which is related to pleural fluid or thickening. Mesothelioma of the peritoneal cavity can also occur. A CT scan of the thorax may identify pleural nodules or diffuse thickening. Pathologic diagnosis can be made by examination of pleural fluid cytology (sensitivity of 60% to 76%^{74,128}); however, a pleural biopsy is usually required. Thoracoscopy is increasingly used to diagnose mesothelioma because of its superior sensitivity compared with blind Abram's needle biopsy (90% vs. 43%).^{130,131}

Management

The management of mesothelioma is largely palliative. Dyspnea is relieved by drainage of pleural fluid and pleurodesis. Palliative chemotherapy can be given to patients who have a good performance status although there is no randomized control trial evidence to show that

chemotherapy confers better quality of life and survival than active supportive care alone.¹²⁸ Pemetrexed in combination with cisplatin is licensed for treatment of malignant mesothelioma after a randomized controlled trial showed a survival benefit compared with cisplatin alone (median survival time 13.2 vs. 9.3 months).¹³² Combination treatment was associated with a higher incidence of significant toxicity. Pemetrexed has been shown to be efficacious and well tolerated in elderly patients,¹³³ although trials have not specifically addressed this treatment in elderly patients with mesothelioma.

The role of surgery in mesothelioma remains controversial. Radical surgical resection (extrapleural pneumonectomy) is associated with a relatively high risk of morbidity and mortality and does not have a significant beneficial impact on survival.¹³¹ Debulking surgery is effective in preventing fluid recurrence and may be associated with increased survival although it has not yet been tested in a randomized control trial.

Radiotherapy can be used as a palliative treatment to provide pain relief and is also used as part of the management strategy when extrapleural pneumonectomy is performed. Prophylactic radiotherapy is administered to scars produced by biopsy and/or pleural drainage. A randomized trial has shown that this prevents the risk of seeding of malignant cells¹³⁴ although more recent trials have questioned this.¹³⁵

KEY POINTS

Nonobstructive Lung Disease and Thoracic Tumors

- Age-related changes to the lungs predispose the elderly to higher rates of respiratory disease.
- Respiratory infections, diffuse parenchymal lung disease, and thoracic tumors are common in the elderly.
- Most respiratory illness in the elderly requires a multidisciplinary approach to care including care of the elderly and respiratory physicians.
- Management strategies require a careful evaluation of performance status, comorbidity, and concurrent medication.
- Respiratory disease is diverse and frequently presents nonspecifically in the elderly. Accurate diagnosis usually requires careful systematic evaluation.

OVERVIEW

Dementia is a critical public health problem worldwide, especially as populations age. In consequence, physicians dealing with a range of other age-associated problems can expect to see them in patients with dementia. Dementia diagnosis is evolving. Here, we build on a recent review to highlight aspects of the differential diagnosis of dementia.¹ Generally defined in terms of multifocal cognitive impairment sufficient to impair function, dementia is distinguished from cognitive decline of lesser severity and impact. This distinction might have a quantitative rather than a qualitative basis since pathologic changes consistent with pathologically defined entities, including Alzheimer's disease (plaque and tangles), Parkinson's disease (Lewy bodies), and cerebrovascular disease (large and small vessel strokes, white matter changes) can be seen in patients with cognitive decline short of dementia. Individuals can also have clinical dementia without clear pathologic markers. Recent developments in frontotemporal dementia highlight the fact that novel pathologic markers are continually being identified.² Less common but clinically distinguishable entities can sometimes be seen, alerting physicians to the need for careful consideration of presenting features in patients with cognitive impairment.

LIMITATIONS OF CURRENT CLASSIFICATION

Most people, as they age, find that their memory is not as good as it used to be. Many fewer actually have dementia.³ Where to draw the line between memory complaints and dementia—and how many lines to draw—is controversial, highlighting the artificiality of the definition.⁴ In addition, other aspects of behavior such as psychiatric problems (including depression) and mobility difficulties precede dementia and are associated with cognitive decline, highlighting the restrictive nature of current classifications based mainly on cognitive criteria.⁵ Nevertheless, the recognition of severity of cognitive impairment and significant impact on activities of daily living has practical implications in terms of care needs and assists with specificity in terms of linking cognitive and behavioral syndromes to pathology. Another limitation of the current nosology for dementia surrounds the issue of onset. Delirium is considered a syndrome of acute onset with fluctuating attention and an identifiable cause. Delirium does not always reverse. Whether this is because the delirium causes the chronic cognitive impairment or simply because the delirium occurred in the setting of dementia is not clear. Nevertheless acute onset of dementia can occur and needs to be put in the context of delirium.⁶ Another issue to consider is that of overlapping pathology, which may be more the rule in the elderly where Alzheimer pathology can overlap with vascular or Lewy bodies, findings which are complicated by the fact that all of these pathologies can be present in patients who are apparently cognitively intact and that older people can decline cognitively without obvious brain changes, by current techniques. Patients with dementia can have other comorbid conditions

contributing to cerebral dysfunction, which are difficult to diagnose in life.⁷ This can complicate diagnostic classifications based on pure syndromes. In the future, although biomarkers may increase the certainty of a certain type of pathology, which may assist with diagnosis and treatment decisions, it will have to be kept in mind that in vivo tests will most likely not have 100% accuracy and that gold standards may evolve.⁸

DEMENTIA DEFINITIONS

General criteria for dementia include the DSM-IV criteria and ICD-10 criteria; each features the requirements of both cognitive impairment (in more than one domain of cognition) and functional impairment. Memory impairment is specified as a domain for both DSM-IV and ICD-10. The NINCDS-ADRDA criteria for Alzheimer's disease and those of NINCDS-AIREN for vascular dementia have standardized definitions, but in the case of criteria for vascular dementia other criteria such as the California and Mayo clinic criteria exist.⁹ In general, although specific, these vascular dementia criteria may be insensitive.¹⁰ Dementia with Lewy bodies has had revision of criteria, recently acknowledging the presence of distinctive clinical features, such as REM sleep behavior disorder, and laboratory findings such as decreased dopamine transporter binding.¹¹ The definition of Parkinson's dementia has been addressed,¹² although its main distinction in relation to Lewy body dementia (how long motor symptoms preceded cognitive ones) is artificial. Criteria for frontotemporal lobar degeneration that predict pathologic findings have also been put forward.^{13,14}

RISK FACTORS**Age**

Age is the most potent risk factor for most dementias.¹⁵ These include Alzheimer's disease, dementia with Lewy bodies, and Parkinson's disease with dementia and vascular cognitive impairment/dementia. Since age is associated with each of these, overlapping pathology is common.¹⁶ Despite the obvious relationship with age, the NINCDS-ADRD criteria place age limits, with a lower limit of 40 years of age and upper limit of 90 years of age for a diagnosis of Alzheimer's disease.¹⁷ In familial Alzheimer's disease, onset in the 30s is not unheard of and even though more unusual disorders such as childhood metabolic disorders become more common, Alzheimer's remains an important consideration in younger cases. Although a number of genetic and metabolic conditions cause dementia in younger people, these will not be covered.¹⁸ Practically, in very old age, both Alzheimer's disease pathology and cerebrovascular disease are common and often contribute to dementia.

Frontotemporal dementias (FTDs) are a group of clinically defined syndromes associated with dementia, typically with onset younger than age 65.¹⁹ However, many patients with FTLD syndromes, including frontotemporal degeneration, progressive nonfluent aphasia, semantic dementia,

corticobasal ganglionic degeneration, frontotemporal dementia with motor neuron disease, have onset in old age, where clinical features, such as memory loss and visuospatial impairment, may be confused with Alzheimer's disease,²⁰ which itself can have focal presentations.²¹

Distinct pathologic entities, including argyrophilic grain disease²² and hippocampal sclerosis,²³ have been recognized as entities that overlap phenotypically with more common dementias. Given their predilection for medial temporal lobe involvement, not surprisingly, memory impairment is evident, which leads to confusion with Alzheimer's disease.²⁴ Their distinction from other pathologic disorders such as the FTD syndromes is not clear.

Family history and genetics

Young onset dementia is more often associated with a strong family history consistent with autosomal dominance. As examples, familial Alzheimer's disease, frontotemporal dementia, and Huntington's disease typically occur in the younger age range but late onset individuals are not that unusual in practice. Patients with frontotemporal dementias are more likely to have a family history.²⁵ The range in age of onset can vary within a family with a genetic family history, and sometimes family history might not be known.²⁶ In Alzheimer's disease, mutations in the *presenilin-1* gene predominate among patients who are less than 60 years of age, but can have a range in age of onset.²⁷ Occasional families with late onset dementia occur. A family history, with dementia occurring more than one first degree relative is not uncommon, even in old age. A history of more than one first-degree relative is more common in young onset dementia than in those with onset in the oldest old age range (>80 years). Although the apolipoprotein E4 (*ApoE4*) allele is a risk factor for Alzheimer's dementia, it does not account for all of the increased risk associated with family history.²⁸

Gender is a factor that affects the differential diagnosis on an epidemiologic basis, with men more likely to have vascular dementia and dementia with Lewy bodies and women more likely to have Alzheimer's disease.²⁹ More than a genetic factor, gender influences behavior (i.e., exposure to environmental risk factors) and hormonal levels, which could influence dementia risk. Moreover, women may be at greater risk for autoimmune disorders.

Psychiatric disorders

As noted, neuropsychiatric symptoms may precede a dementia diagnosis and are more common in people with mild cognitive impairment than in cognitively intact elderly people.³⁰ Depression has been identified as a risk factor for dementia and a depression syndrome of dementia has been identified.³¹ Even so, disentangling the two can be complicated. Reactive depression can occur as a consequence of a dementia diagnosis. Given that depression is common in the elderly, occurrence of dementia with depression might occur by chance. However, common causes (i.e., cerebrovascular disease, dementia with Lewy bodies, and Alzheimer's disease) can lead to both depression and dementia and, in several studies, depression precedes dementia.³²

Psychosis, specifically visual hallucinations, are part of the core criteria for dementia with Lewy bodies and commonly occur in Parkinson's disease, where such symptoms can precede dementia or occur in the setting of dementia.^{33,34}

Delusions, notably paranoia, are commonly seen in Alzheimer's disease and impaired insight and judgment are part of the spectrum of symptoms of frontotemporal dementia and are seen in vascular dementia.³⁵

Other risk factors

Cardiovascular disease-related risk factors (i.e., hypertension, diabetes, smoking, hypercholesterolemia) increase the risk of late life dementia.³⁶ It is not clear if vascular risk factors cause damage via stroke or ischemia that lowers cognitive reserve or if they incite a pathologic cascade that leads to accelerated cognitive decline. Related risk factors are educational attainment and physical activity level, which have been associated with dementia risk, but are confounded by socioeconomic status, which in turn affects general health, especially cardiovascular health.³⁷

Head trauma is another fairly consistently identified risk factor for late life dementia, which may similarly affect brain function.³⁸ Both acute cerebrovascular events and head injury in older people can be associated with global cognitive decline and can accelerate the course of an established dementia. Data regarding mild cognitive impairment are less clear.

DEMENTIA ASSOCIATED WITH OTHER DISORDERS

Numerous disorders can cause dementia because of effects on brain function and about 7% to 10% of dementia can come on suddenly, often indicating a cerebrovascular event or other medical problem.³⁹ When onset is abrupt, it is possible that the onset marks a delirium, and investigations and interventions should proceed accordingly. Although the differential diagnosis of delirium can overlap with that of dementia, and people with dementia are at risk for delirium, they should be considered distinct. The disorders discussed in this section can give rise to prolonged illness that can lead to confusion with degenerative disorders. In some cases they are treatable and can potentially be cured, although this is unusual.^{40,41} Strictly speaking such disorders are among issues that should be excluded for a patient to meet criteria for a degenerative dementia; however, sometimes they can cause irreversible change in the absence of a neurodegenerative disorder.

Alcohol/drugs/toxins

Alcohol is an important covert cause of dementia worldwide. Abuse of alcohol is underrecognized in general, and it should be screened for.⁴² Direct effects of alcohol on central nervous system function can produce syndromes, such as Wernicke encephalopathy (nystagmus, restricted extraocular movements, ataxia) and Korsakoff syndrome (with persistent executive and memory dysfunction), which are recognizable causes of cognitive impairment since they often present in association with other examination features in the setting of alcohol abuse.⁴³ This clinical picture can also occur in the absence of alcohol exposure with severe malnutrition where similar imaging and clinical changes are present, with involvement of the medial thalami and the periventricular region of the third ventricle, the periaqueductal area, the mamillary bodies, the tectal plate, and rarely the dorsal medulla.⁴⁴ It can be difficult to separate effects

of chronic exposure of alcohol from other effects, such as effects on vascular risk and brain injuries. Associated lifestyle habits, such as smoking, and socioeconomic status can also compound risk for dementia in a population prone to alcohol abuse. Lower levels of intake of alcohol are reported to be protective, but it is difficult to separate this from other risk factors.

Although alcohol is a common cause of hepatic disease, including cirrhosis, hepatic dysfunction from any cause can lead to an encephalopathy and cognitive impairment. Although in principle reversal of liver damage will lead to normalization of cognitive function, this may not always be the case. Direct effects of toxins such as manganese accumulation and unmeasured substances may be responsible for neurologic dysfunction in the setting of hepatic dysfunction.⁴⁵

Medications for various conditions have been associated with chronic cognitive impairment. Particular drugs include corticosteroids, anticholinergic medications, benzodiazepines, psychiatric medications, and antiepileptic medications, among others. Drugs should be discontinued if they might be temporally associated with cognitive decline. Aging is associated with pharmacokinetic and pharmacodynamic changes that might lead to a chronic medication becoming toxic without clearly being temporally associated with cognitive decline. Accidental overdosing due to forgetfulness can also contribute to amplified effects of medications.⁴⁶

Other toxins, especially metals such as aluminum, mercury, bismuth, and lead, have been associated with chronic cognitive dysfunction. Toxins affecting cholinergic or mitochondrial function (i.e., pesticides) or those causing white matter damage (i.e., solvents) can be related to chronic cognitive impairment. Metals such as copper, zinc, and iron are involved in normal cellular processing and have been examined in relation to dementia.

Autoimmune/inflammatory disorders

Autoimmune and inflammatory causes are rare but treatable causes of dementia in the elderly. Vasculitis can cause dementia through ischemic damage. All forms of vasculitis (i.e., small vessel or large vessel) can lead to progressive neurologic dysfunction. There are often clues to the diagnosis, such as systemic complaints, headache, and sometimes evidence for an associated autoimmune disease. Large vessel vasculitis such as giant cell (temporal) arteritis, Churg-Strauss syndrome, polyarteritis nodosa, Wegener's granulomatosis, and Behcet's and Sjögren syndromes often show evidence for systemic disease and inflammatory markers (increased C-reactive protein and sedimentation rate). Serological investigations can identify vasculitis associated with other autoimmune disorders; however, primary central nervous system vasculitis can cause progressive cognitive decline unassociated with other markers.⁴⁷ Angiography and brain biopsy may be necessary to diagnose inflammatory disorders causing dementia,⁴⁸ although evidence for an inflammatory process can often be identified by examining spinal fluid (elevated cell count, increased immunoglobulin synthesis, elevated protein level).

Inflammatory disorders can also lead to a hypercoagulable state, which can be seen in association with anticardiolipin or antiphospholipid antibodies, sometimes with evidence for a lupus anticoagulant. Sneddon syndrome is characterized

by livedo reticularis associated with hypercoagulability, which typically occurs in younger people but can also occur in older people.⁴⁹

Nonvasculitic autoimmune meningoencephalitis is a relatively recently recognized cause of dementia, sometimes, but not necessarily, associated with collagen vascular disorders such as Sjögren syndrome, antiphospholipid antibody syndrome, systemic lupus erythematosus, mixed connective tissue disease, or Hashimoto encephalitis.⁵⁰ In some patients brain biopsy may be warranted, which may be justifiable given that it is treatable.⁵¹ Drugs, notably nonsteroidal anti-inflammatory medications, can be associated with a meningoencephalitis, which can mimic a subacutely progressive dementia.⁵²

Multiple sclerosis (MS), which typically begins in younger people, can have onset in old age and can manifest as dementia. Although often relapsing and remitting early in its course, MS can be gradually progressive and primary progressive MS can also occur. Typical patients with onset of MS accumulate deficits and can have strategic lesions that can lead to cognitive impairment. White matter changes are nonspecific and can be associated with a number of disorders and in older people suggest ischemic disease. Hence the diagnosis of white matter disease such as MS can be difficult.

Sarcoidosis is a great mimicker among inflammatory disorders. It can have ocular, central, and peripheral nervous system involvement. Since it can present at any age, it should be considered in the differential diagnosis of dementia in older people.⁵³

Endocrine disorders

Metabolic and endocrine dysfunction are common, but occasionally are associated with potentially treatable causes of dementia.⁵⁴ Thyroid disorders, including hyperthyroidism and hypothyroidism, are associated with chronic cognitive impairment, and hence screening for thyroid dysfunction is recommended by most consensus guidelines. Autoimmune thyroid disease is associated with Hashimoto encephalitis, which is a treatable cause of dementia, with an abrupt or insidious onset, elevated antithyroid antibodies, and response to steroids.⁵⁵ Thyroid disease has also been identified as a risk factor for dementia.

Hyper- and hypoparathyroidism have been associated with cognitive impairment. Hyperparathyroidism is associated with hypercalcemia, which itself can lead to cognitive dysfunction. Hypoparathyroidism is commonly caused by surgical removal of the parathyroid glands, and treatment with calcium replacement and vitamin D are necessary. Parathyroid dysfunction is common in renal failure. Parathyroid disorders can be associated with brain calcification.

Secondary or primary adrenal dysfunction can lead to cognitive dysfunction. Clues such as a history of steroid treatment or electrolyte abnormalities are often present. Assessment of adrenal function and possibly empirical therapy should be considered.

Diabetes is diagnosed by the presence of sustained hyperglycemia, which increases risk for cerebrovascular disease, but it may also lead to cognitive dysfunction without intervening cerebrovascular events.⁵⁶ Other secondary consequences include hyperlipidemia. Moreover, treatment of diabetes can lead to hypoglycemic episodes. Whether recurrent mild

hypoglycemia causes direct nervous system damage is not clear, but severe and prolonged episodes clearly can cause permanent brain dysfunction.

The metabolic syndrome defined by the presence of truncal obesity, hyperglycemia, high triglycerides, low HDL, and hypertension may increase the risk of cognitive impairment, but separating the effects of each component and elucidating direct from indirect (i.e., via strokes or accelerating progression of Alzheimer pathology) may be challenging.⁵⁷ Nevertheless, given a proven association and treatment targets, it may become prudent to treat metabolic syndrome.

Head trauma and dementia in older adults

Head injury is a risk factor for dementia. Although profound head trauma can clearly cause cognitive impairment, and repeated severe injury can lead to a dementia (i.e., dementia pugilistica), the mechanism by which (and if) less severe head injury leads to cognitive impairment is not as clear.⁵⁸ Whether minor head injuries can trigger dementia also is not clear.

In older people, subdural hematoma is a consequence of head injury, but can occur spontaneously.⁵⁹ Anticoagulant use is a risk factor for hemorrhage and is a clear indication for brain imaging in patients with cognitive decline. Other states, such as renal failure should be kept in mind. Relatively rapid progression and focal signs are indicators that should prompt imaging. The decision to image can be challenging in patients with an existing dementia, but intervention can lead to improvement in function and should be considered in the case of superimposed subdural hematoma.

Infectious disorders

Acute infections of any kind can lead to delirium, for which dementia is an important risk factor, and which in turn is a risk for dementia.⁶⁰ Chronic infection of the nervous system can be associated with progressive cognitive decline without obvious systemic manifestations. Among these HIV and syphilis are diseases for which serologic testing is diagnostic, although cerebrospinal fluid examination is needed to confirm central nervous system involvement.⁶¹ Although these disorders are more likely considerations in younger patients, it is important to realize that they can occur at any age. Given successful chronic treatment for HIV infection, more people will be living into old age and hence at risk for dementia.⁶² In addition, HIV has a worldwide reach and is an important contributor to cognitive dysfunction on a global scale.

Other chronic central nervous system infections such as cryptococcus and tuberculosis should be considered in atypical patients with dementia. Although these often occur in the setting of immunosuppression, where other opportunistic infections occur (i.e., toxoplasmosis, *Nocardia*, aspergillosis), they can occur without obvious predisposing factors. Another progressive infection that can cause insidious cognitive decline in a setting of immunoincompetence is primary multifocal leukoencephalopathy (PML). This generally presents as a patchy white matter disease.

Viral encephalitis can present insidiously and cause sufficient brain damage to lead to dementia. These often have additional clinical features and risk factors (including exposures), which raises one's index of suspicion.

Whipple disease, Lyme disease, West Nile virus, and listeriosis are unusual infectious disorders with central nervous

system predilection. Both Whipple disease and Lyme disease can be associated with a chronic course. West Nile and other viral encephalopathies generally occur as an acute illness. Whipple disease is associated with other neurologic findings (see later discussion) on examination, such as vertical gaze palsy and parkinsonism, and is important to consider in unusual subacute central nervous system disorders since it is treatable.⁶³

Prion disease can occur at any age. It can occur in sporadic, genetic, and iatrogenic or infectious forms. Although sporadic Creutzfeldt-Jakob disease (CJD) is common in the elderly, some genetic mutations associated with CJD can have late life onset and specific polymorphisms can affect the clinical presentation. Clinically CJD leads to a rapidly progressive dementia, usually with other clinical findings, including myoclonus, visuospatial impairment, and cerebellar ataxia, parkinsonism/pyramidal signs, and akinetic mutism being features of the diagnosis.⁶⁴ Laboratory evidence for CJD includes EEG findings of periodic sharp waves, MRI changes on T2, FLAIR or diffusion weighted scans, and CSF evidence for elevation of the 14-3-3 protein. MRI changes are both sensitive and specific, whereas EEG changes are not sensitive, but in the appropriate clinical setting are highly suggestive, and, like elevated 14-3-3 protein levels are not specific. EEG and CSF examinations remain useful in ruling out other clinical mimics such as nonconvulsive seizures or chronic infections. Mimics include lithium toxicity, dementia with Lewy bodies, and vasculitis of the central nervous system and nonvasculitic autoimmune encephalopathy.

Metabolic disorders and nutritional deficiencies

Most guidelines recommend assessment of metabolic conditions in the setting of dementia. Although criteria for degenerative conditions require exclusion of a potentially contributory condition, a common scenario is the co-occurrence of metabolic and degenerative conditions. With this in mind, assessment of complete blood count, glucose, electrolytes, renal function, liver function, vitamin B₁₂, and thyroid-stimulating hormone (TSH) is commonly recommended. Including calcium, magnesium, and phosphates among electrolyte assessment may uncover abnormalities contributing to cognitive impairment. Similarly, folate levels and those of other B vitamins, such as thiamine, riboflavin, and niacin, can sometimes be associated with cognitive impairment, but are usually normal. A sedimentation rate or C-reactive protein can be associated with a chronic inflammatory process of any cause, but also specifically with giant cell arteritis. Testing for syphilis was recommended routinely in the past, but should be considered when appropriate. A search for chronic systemic infections by chest x-ray, urinalysis, and spinal fluid examination should be done if there are clinical clues or rapid onset. Immunoglobulins are elevated in inflammatory disorders, but monoclonal elevation can be associated with multiple myeloma.

Hepatic and renal dysfunction can be associated with delirium, but also with a chronic picture of cognitive impairment. Although conditions leading to dysfunction in these organs, such as alcohol in the case of hepatic dysfunction or diabetes in the case of renal dysfunction, can also lead to cognitive impairment, toxin accumulation as a consequence of hepatic or renal dysfunction can directly affect cognition.

Hepatic dysfunction can lead to manganese accumulation, which is associated with parkinsonism and cognitive impairment. Hyperammonemia on the basis of hepatic dysfunction can be associated with a chronic encephalopathy, even in the absence of elevated transaminases or bilirubin. It is increasingly recognized that patients with renal failure on dialysis can have dementia, which has important implications in terms of decision making.⁶⁵ In dialysis patients, cognitive impairment can be a consequence of secondary hyperparathyroidism in addition to other factors, such as elevated creatine.⁶⁶

Neoplastic and paraneoplastic disorders

Direct effects of central nervous system neoplasms are usually self-evident and would be sought out using imaging if there are systemic clues or a history of a malignancy. Signs of physical examination generally progress along with cognitive dysfunction. Occasionally patients do not have a prior history, making this possibility one of the important reasons for brain imaging. Some primary central nervous system neoplasms, such as lymphomas or gliomas, can present relatively insidiously, and imaging might not declare their presence or can be nonspecific. Angiocentric lymphomatosis is an example where proliferating cells are perivascular and imaging may be normal.⁶⁷ Although CNS lymphomas are often seen in the setting of immunosuppression on the basis of medications or HIV, they can occur independent of these risk factors.

Indirect effects of malignancy can be associated with paraneoplastic syndromes that include dementia-like presentations. Limbic encephalitis is associated with CNS directed antibodies, which can occur in the absence of a neoplasm.⁶⁸

Chemotherapy and central nervous system radiation therapy for malignancy can complicate the picture by causing central nervous system effects that can be immediate and direct, or delayed. Radiation-induced leukoencephalopathy can sometimes be confused with recurrence or emergence of central nervous system malignancy.

Respiratory and sleep disorders

Hypoxemia and hypercarbia have direct effects on cognitive function, hence pulmonary problems such as chronic obstructive pulmonary disease should be considered in the assessment of both acute and chronic cognitive decline. Acute anoxic injury is a well-recognized form of brain damage, and selective vulnerability of specific cell groups such as hippocampal neurons is recognized.

Disruption of sleep is common in dementia. Increased sleep fragmentation is common in aging and exaggerated in Alzheimer's disease. Insomnia and hypersomnolence can occur in the course of a number of dementias. Familial fatal insomnia is a prion disease associated with dementia that can also present sporadically. A specific problem such as REM sleep behavior disorder is a common symptom in synucleinopathies such as dementia with Lewy bodies. Sleep apnea is another sleep problem that should be considered in the differential diagnosis of patients with day-to-day fluctuations in cognitive complaints. Sleep apnea alone is associated with problems on cognitive test performance. Recent studies have shown sleep apnea to be a risk factor for cerebrovascular disease, which provides another mechanism for causing cognitive impairment.

Structural lesions/normal pressure hydrocephalus

Structural lesions of all types provide deficits that are localization related. The presence of rapid progression, focal features (including gait impairment and incontinence, which suggest frontal-striatal damage), and risk factors for structural lesions (i.e., evidence for systemic malignancy, anticoagulation, or renal disease) merit cerebral imaging. In patients with existing cognitive impairment, the search for an additional structural cause may be necessary in cases of rapid decline. One consequence of structural problems near sites of ventricular drainage is hydrocephalus, which should be differentiated from normal pressure hydrocephalus (NPH).

Normal pressure hydrocephalus is a specific entity where hydrocephalus is present in the setting of the clinical triad of dementia, gait difficulty, and urinary urgency and incontinence. Since these clinical symptoms/signs are each common in older people for various reasons, it is plausible to have all three occur by chance. Moreover, cerebrovascular disease can affect the same frontostriatal circuits affected in NPH. The presence of comorbid CNS disease does not preclude improvement from shunting in individual patients. Currently the presence of the clinical triad with imaging evidence for hydrocephalus is necessary for the diagnosis. Improvement with lumbar puncture removal of a large volume of CSF, continuous external lumbar drain, or increased compliance on infusion into the lumbar space may be helpful in predicting patients who will improve from shunting. Clinical features such as longstanding clinical features, especially dementia, and the presence of verbal memory impairment make improvement less likely.⁶⁹

CLINICAL EXAMINATION FEATURES IN DIFFERENTIAL DIAGNOSIS

Aging is associated with physical changes that need to be differentiated from those of age-related disease. Features on the neurologic examination can assist in the differential diagnosis of degenerative dementias, as well. Although patients with Alzheimer's disease and frontotemporal dementia often have normal basic neurologic examinations, subtle findings such as slowing are often present early on. Over time and in subsets of patients, features such as extrapyramidal signs (bradykinesia and rigidity, often without resting tremor) can develop. Cerebrovascular disease commonly coexists with Alzheimer disease; hence focal pyramidal findings (including the Babinski sign) and gait impairment can confound the diagnosis.

AUTONOMIC DYSFUNCTION

Older people can have autonomic problems such as postprandial hypotension, which can be exaggerated in the setting of systemic disorders such as diabetes. Autonomic dysfunction is more commonly seen in dementia with Lewy bodies and in Parkinson's disease with or without dementia.⁷⁰ This can be identified by history and confirmed by autonomic testing. Cardiac MIBG nuclear medicine scans can be seen in dementia with Lewy bodies and Parkinson's disease. This can also occur in vascular dementia, where it might be, in part, related to risk factors such as diabetes. Multiple system atrophy, which is characterized by autonomic dysfunction, parkinsonism, and

cerebellar dysfunction, is associated with executive dysfunction, which if severe enough can lead to dementia. Prion disease has also been associated with autonomic dysfunction.

OCULAR AND VISUAL FINDINGS

Pupillary irregularities and abnormalities in accommodation, impaired pursuit movements, and diminished upgaze are seen in aging. Dementing disorders associated with eye movement abnormalities include Huntington's disease, which is associated with an inability to perform saccades. Patients need to move their head (head thrusts) during saccades. Impaired downgaze, which can be overcome with oculocephalic head maneuvers, is characteristic of progressive supranuclear palsy. Dementias affecting the frontal lobes, including PSP, can affect initiation of saccades.⁷¹ Opsoclonus (rapid nonstereotyped irregular involuntary eye movements) is seen in postviral encephalitis and as a paraneoplastic syndrome. Rhythmic eye movements associated with jaw and palate movements (oculomasticatory myorhythmia) is characteristic of Whipple disease. Nystagmus is characteristic of multiple system atrophy.

Visuospatial impairment is common in Alzheimer's disease and marks a clinical feature seen in CJD. This can occur early in the course of Alzheimer's disease and indicates a phenotypic variant with some (but not absolute) diagnostic confidence.^{72,73}

PYRAMIDAL DISORDERS

Pyramidal (upper motor neuron) signs (decreased fine motor function, spastic increase tone, brisk reflexes, upgoing plantar responses) are common with cerebrovascular disease affecting the grey or white matter as well as in amyotrophic lateral sclerosis (motor neuron disease), which is also associated with lower motor neuron signs (weakness, wasting, fasciculations, which can be associated with progressive cognitive decline. Motor neurone disease can also be seen in frontotemporal dementia. Upper motor neuron signs are also seen in multiple system atrophy. Structural lesions of the nervous system often cause upper motor neuron signs.

PARKINSONIAN DISORDERS

Parkinsonism is defined by two signs among rest tremor, rigidity, and bradykinesia. These signs are nonspecific, but are seen in Parkinson's disease, dementia with Lewy bodies, progressive supranuclear palsy, multiple system atrophy, vascular parkinsonism, and normal pressure hydrocephalus and occur in late Alzheimer's disease and frontotemporal dementias. Thus parkinsonian features are very helpful in the differential diagnosis of dementia. Although gait impairment can occur early in Parkinson's disease, it is more common in the other parkinsonian disorders noted and, if present at the time of diagnosis, provides a diagnostic trigger that the diagnosis is not Parkinson's disease.

CEREBELLAR SIGNS

Cerebellar dysfunction can also lead to gait ataxia. It is prominent in alcohol-related dementia and along with parkinsonism can be seen in CJD. The cerebellar variant of multiple

system atrophy, which can be associated with executive dysfunction, is also characterised by nystagmus on extraocular motility testing, appendicular dysmetria, and gait ataxia along with autonomic features.

NEUROPATHY AND OTHER LOWER MOTOR NEURON FINDINGS

Evidence of neuropathy can be seen in a number of systemic problems associated with dementia, such as alcoholism, diabetes, renal dysfunction, and vitamin B₁₂ deficiency. More ominously, rapidly progressive lower motor neuron problems can indicate a process involving the subarachnoid space (i.e., infection, carcinomatous meningitis). Neuropathy can be seen in paraneoplastic syndromes.

GAIT IMPAIRMENT

Balance and gait are integrated functions that involve all levels of the nervous system and require intact musculoskeletal and cardiorespiratory function, therefore impaired balance or gait in the setting of dementia provides important clues to the differential diagnosis and raises concern for systemic disorders that might be contributing to cognitive dysfunction. Obviously gait and balance impairment impact mobility and safety and need to be addressed if they are causing functional impairment. Dementias associated with gait impairment include Parkinson's disease with dementia, vascular dementia, dementia with Lewy bodies, and normal pressure hydrocephalus.⁷⁴

SEIZURES AND MYOCLONUS

Seizures increase in frequency with aging, often in association with central nervous system disease and metabolic insults. It is always important to consider reversible causes of seizures. Intermittent nonconvulsive seizures can mimic dementia by affecting cognitive function. Conversely, drugs used to treat seizures can themselves affect cognitive function.

Myoclonus is defined as rapid jerking movements associated with motor activation (positive myoclonus) or loss of activation (negative myoclonus). Myoclonus is common in CJD, but can be seen in other disorders associated with cognitive dysfunction such as Alzheimer's disease and corticobasal ganglionic degeneration. Asymmetric apraxia and overlapping features with primary progressive aphasia and frontotemporal dementia are characteristic of corticobasal ganglionic degeneration. Jerking movements can be clues to the presence of seizures as well.

LABORATORY INVESTIGATIONS IN DEMENTIA

Laboratory investigations in dementia can be looked at from two perspectives; one is to obtain positive evidence for a diagnosis. A brain biopsy can provide proof of the presence of an entity associated with dementia.⁷⁵ This must be kept in clinical context since the diagnosis is based on the presence of a clinical picture accompanied by pathologic evidence. In living patients, other laboratory tests can provide strong evidence for the cause of dementia in an individual.

An example is vascular dementia caused by an acute stroke in a location that makes sense with the clinical picture. Another example is identification of a potentially reversible metabolic or infectious problem, which when reversed leads to reversal of dementia. Although reversible dementia was emphasized until the 1990s, since the publication of reviews drawing attention to the relative rarity of reversible dementia, enthusiasm for reversible dementia has been tempered.^{76,77} This too came about with the move from the long tradition of seeing Alzheimer's disease as a "diagnosis of exclusion" in which a long list of competing diagnoses must be "ruled out" to the recognition of more characteristic staging. Covert causes of cognitive impairment form the basis for recommendation of laboratory testing formed by consensus groups.^{3,78} In many cases disorders so identified do not account for the full clinical picture in a patient with dementia, yet it still can help with improving a patient's function and, hence, quality of life. This highlights the importance of identifying and considering treatment of "treatable" conditions even in a patient in whom a degenerative dementia might be considered. Treatments need to be addressed in the context of a patient's overall prognosis.

SUMMARY

In summary, dementia is a syndrome with a range of causes and contributing conditions. A framework for diagnosing degenerative dementias (discussed in other chapters) must take into consideration the possibility of other coexisting

conditions that can contribute to cognitive dysfunction in the elderly. To do this one must not only understand the natural history of degenerative dementias, including atypical presentations, but the ways in which systemic problems interact with older people with and without dementia.

KEY POINTS

Dementia Diagnosis

- Dementia is generally defined as multifocal cognitive impairment which is sufficient to impair function. It is distinguished, though not always without arbitrariness, from cognitive decline of lesser severity and impact.
- The differential diagnosis of dementia is long, but as people age, a diagnosis of Alzheimer's disease, commonly in the presence of cerebrovascular disease, becomes more likely.
- This approach of starting with what is common, and looking for features that make this diagnosis less likely is distinct from the long tradition of seeing Alzheimer disease as a "diagnosis of exclusion" in which a long list of competing diagnoses must be "ruled out."

Presentation and Clinical Management of Dementia

Antony Bayer

Dementia is a syndrome, especially common in old age, describing a characteristic pattern of symptoms that can result from many different brain diseases. It is not a diagnosis, nor can it be identified neuropathologically or by neuroimaging, nor is it the result of normal aging. Once recognized, it requires further assessment to identify the likely subtype (e.g., Alzheimer's disease, vascular dementia, dementia with Lewy bodies, Parkinson's disease, or frontotemporal dementia). This discussion will help the medical professional to indicate prognosis and guide best management.

The word *dementia* is derived from the Latin "demens" meaning without mind. In lay use, it can have a pejorative meaning, and this negative connotation impacts on public and professional attitudes. Chronic brain failure (to parallel heart failure, kidney failure, liver failure, etc.) is an alternative, first suggested by Bernard Isaacs and Francis Caird longer than 30 years ago,¹ but does not seem to have gained favor. More recently it has been suggested that alternative umbrella terms of cognitive impairment or neurocognitive impairment are clear and less stigmatizing and may be preferred when dealing with patients and families.² When there is a need to distinguish the illness before and after age 65, the terms young- and late-onset dementia are preferable to the old terminology of presenile and senile dementia.

Too great an emphasis on the biomedical aspects of dementia can detract from the human impact of the condition and management can cease to be person centered.³ In contrast to the more usual clinical terminology, Keady and Nolan for example have described the dementia process as one of slipping, suspecting, covering up, revealing, confirming, surviving (or maximizing), disorganization, declining, and finally death.⁴ Social models view the disability of dementia not as an intrinsic characteristic of the individual but as an outcome produced by social processes of exclusion and therefore greatly influenced by factors such as culture, income, housing, and environment.⁵ The biomedical and social models are not mutually exclusive, and best practice should incorporate evidence from both traditions.⁶

PRESENTATION

Diagnostic criteria

Dementia is defined in the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR) of the American Psychiatric Association⁷ and in the International Classification of Diseases, 10th Edition (ICD-10) of the World Health Organization.⁸ Both operational definitions are broadly similar and are based primarily on clinical criteria of multiple cognitive deficits, including memory impairment, associated with a decline in ability to carry out daily activities and often personality and behavioral changes. The deficits must represent a decline from a previous level of functioning (to distinguish from learning disability) and occur in the absence of disturbed or clouded consciousness (to distinguish from delirium). The condition is usually (but not always) irreversible

and progressive and of chronic duration (ICD-10 requires deficits to have been present for at least 6 months). The criteria identify similar groups of patients.⁹

Although these criteria are generally accepted, the essential requirement for presentation with memory impairment means that they are closely tied to Alzheimer's disease and may exclude cases of frontotemporal dementia and vascular cognitive impairment until late in their course. Fluctuations of consciousness may be seen in dementia with Lewy bodies and in vascular dementia and are characteristic of delirium, a syndrome that often develops in association with underlying dementia. Thus, discussions around revisions of the criteria for DSM-V and ICD-10 have concluded that the definition of dementia should be reconfigured to not require memory impairment but to be based on a decline in two or more cognitive abilities lasting at least 1 year. There may also be greater emphasis on impairment of instrumental activities of daily living (ADL) and on positive indicators of Alzheimer's disease, rather than regarding it mainly as a diagnosis by exclusion. Genetic, imaging, and biomarkers are considered to have tremendous research promise but are not yet ready for clinical diagnostic use.¹⁰

The main subtypes of dementia each have standardized diagnostic criteria. The NINCDS-ADRDA criteria have long been the diagnostic standards for research in Alzheimer's disease,¹¹ although revised criteria incorporating biomarkers have recently been suggested.¹² The consensus diagnostic criteria for dementia with Lewy bodies are widely accepted,¹³ as are criteria for dementia associated with Parkinson's disease¹⁴ and frontotemporal dementia.¹⁵

The NINDS-AIREN criteria¹⁶ or ADDTC criteria¹⁷ are used for vascular dementia, but mainly only in research studies as their sensitivity is only about 50%.¹⁸ The Hachinski Ischemic Score has been used clinically for longer than 30 years to differentiate between multi-infarct dementia and Alzheimer's disease.¹⁹ A low score (4 or less) makes a vascular etiology unlikely. The higher the score, the greater is the likelihood of stroke disease. Despite reservations about its reliability and validity,²⁰ the simplicity of the Ischemic Score means that it remains useful in the absence of anything better. There are no evidence-based clinical diagnostic criteria for the common neuropathologic finding of mixed dementia.²¹

Clinical presentation

Regardless of the cause, the clinical syndrome of dementia is manifested by cognitive and functional deficits, often associated with behavioral and psychological symptoms (Table 52-1). Poor performance on formal cognitive testing, but without significant impairment of activities of daily living is not sufficient for diagnosis of dementia. However, it may suggest a predementia state and justifies follow-up with repeated assessments. Early recognition and intervention reduces risk of misdiagnosis of dementia and inappropriate management, facilitates optimal care, and delays the morbidity associated with progressive deterioration.²²

Table 52-1. Aspects of Cognition, Daily Living Activities, and Behavior Affected by Dementia

Cognition	Daily Living Activities	Behavioral and Psychological Symptoms
Working memory	Handling financial affairs/money	Agitation/restlessness
Episodic (anterograde) memory	Managing medication	Eating behavior
Remote memory	Maintaining hobbies/interests	Aggression/rage/violence
Semantic memory	Using public transport	Anxiety/phobias/fears
Language	Driving safety	Apathy
Orientation	Using telephone	Compulsive behaviors
Praxis	Traveling away from home	Delusions/illusions/misidentifications
Recognition/agnosia	Shopping	Depression
Visuospatial ability	Housekeeping	Disinhibition
Calculation	Preparing meals	Hallucinations
Attention/concentration	Dressing/undressing	Personality change
Planning/organization/sequencing	Grooming	Sexual behaviors
Abstract thinking	Bathing/showering	Shouting/screaming
Judgment	Continenence	Social awareness
Writing/reading	Feeding	Sleep-wake disturbance
	Mobility/falls	Sundowning

Predominantly cortical or subcortical patterns of impairment can be described.^{23,24} Cortical dementias present with impaired memory, language, praxis, and visuospatial abilities with relatively preserved attention and executive function, as is characteristic in Alzheimer's disease. Subcortical dementia is characterized by cognitive slowing (bradyphrenia), with deficits of attention and retrieval of information from memory, apathy, personality change, reduced spontaneous speech, and often associated gait disturbance and slowing of movement (bradykinesia). The prototypical subcortical dementias are progressive supranuclear palsy and Huntington's disease. A mixed cortical and subcortical picture is most often seen in vascular dementia and dementia with Lewy bodies, reflecting pathology in the deep white matter and basal ganglia, as well as the cortex.

It is characteristic of dementia, especially when the result of Alzheimer's disease, that patients themselves tend to deny any significant difficulties and do not present themselves to clinicians. Rather, concerned relatives or caretakers who have noticed a change in the person's ability to cope with everyday life or are frustrated by repetitiveness and unreliability bring them to the attention of health or social care professionals. Sometimes the abrupt loss of support from a caretaker who has been quietly compensating for the person's cognitive deficits will suddenly reveal the presence of dementia.

COGNITIVE SYMPTOMS

The cognitive or neuropsychological symptoms of dementia reflect the location of brain pathology, and particular patterns of symptoms are characteristic of particular underlying diseases. Alzheimer's disease, for example, usually develops in the hippocampus and temporal lobe and the typical presentation is with an amnesic syndrome, frontotemporal dementia will be associated with impairment of executive or language abilities, and dementia with Lewy bodies is associated with visuospatial deficits. Vascular disease may affect any part of the brain and so is not associated with any typical clustering of cognitive deficits, but focal cognitive deficits or executive dysfunction are the most common presentations. Eliciting a history of the cognitive deficit that was first recognized, as well as the nature of its onset and subsequent progression, is therefore very important. The patient's recall and insight will often be compromised by the underlying illness; when

addressed with any questions directly, the patient will turn his or her head toward a relative looking for the relative to answer.

Typical complaints initially reported by patients with early dementia include problem-solving difficulties, poor concentration, thought block, inability to quickly recall names, losing track of conversations, a feeling of disassociation from surroundings, feeling and becoming lost in familiar surroundings, not being able to fully coordinate and control speech and actions, and writing block,²⁵ although there is considerable overlap with the everyday cognitive deficits of "normal aging."²⁶

ACTIVITIES OF DAILY LIVING

The consequence of cognitive impairment is to interfere with ability to carry out activities of daily living (ADL), initially higher-level skills such as handling finances, coping with medication and driving (instrumental ADL [IADL]), and subsequently personal care skills such as dressing and bathing (basic ADL [BADL]).²⁷ This progressive loss of functional ability is a reversal of the pattern observed in normal human development, with the early loss of complex activities followed by later deterioration in simpler overlearned tasks leading to increasing dependency and caregiver burden.

Assessment of IADL and BADL is necessary before a diagnosis of dementia can be made and subsequently will guide provision of appropriate advice and care and input from practical support services. The ICD-10 criteria are perhaps easiest to operationalize, requiring "interference with everyday living" so that "complicated daily tasks or recreational activities cannot be undertaken." The DSM-IV criteria specify "cognitive deficits ... (that) each cause significant impairment in social or occupational functioning and ... a significant decline from a previous level of functioning." This may be more difficult to interpret in elderly people whose opportunity to continue an active occupational and social life may be already compromised by comorbid medical and psychiatric illness, sensory deficits, retirement, and shrinking social networks.

Functional ability is assessed generally by history rather than by completion of the many available formal measurement scales, which are most commonly used to evaluate treatment efficacy in research studies. A large number of scales have been adapted or developed for use in dementia,

but some have problems of gender bias or are not culturally sensitive. The most widely used scales that are sensitive to clinically significant change are the Disability Assessment for Dementia scale (DAD), the Bristol Activities of Daily Living scale (BADL),²⁸ and the Alzheimer's Disease Cooperative Study–Activities of Daily Living (ADCS-ADL).²⁹ The Functional Assessment Staging (FAST) is a seven-stage scale that reflects the hierarchical pattern of gradual functional loss from normal aging to severe Alzheimer's disease (further broken into 11 substages) and is valuable in characterizing the severity and sequence of functional loss.³⁰

In familiar surroundings and with a regular routine, people may cope surprisingly well with usual day-to-day activities until dementia is well established. However, if there is a change in circumstances, such as a bereavement or an overnight stay away from home, then the developing functional impairment can be unmasked. This may suggest erroneously that the problems are of sudden onset, but a careful history is likely to reveal a background of minor lapses and gradual decline over the previous few months, the significance of which had not been appreciated.

In younger people with dementia, impairment may first become apparent in performance at work, whereas in the majority it will concern maintaining the household to their normal standard, keeping up interest in hobbies and social activities, remembering appointments, using the telephone, dealing efficiently with financial affairs, taking medication reliably, getting from place to place in unfamiliar environments, and driving safely. Gradually independent living becomes compromised, with problems handling money, shopping, navigating even in familiar surroundings, and meal preparation. Finally problems with basic ADL emerge, initially choosing appropriate clothing and grooming and then with dressing, bathing, and toileting and finally urinary and fecal incontinence, immobility, and total dependency.

Behavioral and psychological symptoms

The noncognitive symptoms of dementia have been grouped together by the International Psychogeriatric Association under the term *behavioral and psychological symptoms* (BPSDs),³¹ although many of those working in mental health settings prefer to talk about “challenging behaviors.” A division can be made between observed behaviors (physical aggression, screaming, restlessness, agitation, wandering, sexual disinhibition, hoarding, swearing, and shadowing) and psychological symptoms elicited by interview with the patient or caretakers (anxiety, depression, hallucinations, and delusions). An alternative classification distinguishes between behavioral excesses (e.g., screaming, wandering, physical and verbal aggression) and deficits (e.g., excess dependency, lack of social interaction/communication).³² However, symptoms from different groups can overlap (e.g., depression in dementia may be diagnosed on the basis of observed behavior as much as elicited symptoms) and some symptoms tend to cluster together (e.g., restlessness and agitation with anxiety, and hallucinations, delusions, and misidentifications as the “psychosis of Alzheimer's disease and related dementias”).³³ A factor analysis of a large sample of patients from the European Alzheimer's Disease Consortium identified four neuropsychiatric subsyndromes: hyperactivity, psychosis, affective symptoms, and apathy.³⁴

Although BPSDs are not features of the diagnostic criteria of dementia, most patients will demonstrate at least one noncognitive symptom at any time. Different symptoms tend to be more common at different phases of the illness. Mood disturbances are more likely to occur early and agitation, wandering, and psychotic symptoms later, although BPSDs become less evident in the advanced stages of dementia. Symptoms are often transient, persisting for a few days to months. Wandering and agitation, however, tend to be more enduring.³⁵ Frontal dementia is dominated by BPSDs, and visual hallucinations can be persistent in patients with dementia with Lewy bodies. Caretakers find BPSDs especially burdensome, and they are often the trigger for referral to specialist services.

DIFFERENTIAL DIAGNOSIS

Cognitive problems or any suggestion of “confusion” (an ill-defined and unhelpful term) in someone over the age of 50 is too often assumed to indicate dementia, without sufficient effort being made to confirm that it is indeed the cause. Mild cognitive impairment (MCI) or cognitive impairment not dementia (CIND) is about twice as common as dementia and may evolve into a dementing illness, although this is not inevitable. The commonest mental health problem in older people in the community is depression, and the commonest cause of cognitive impairment in hospital patients is delirium. The major differential diagnosis of dementia is therefore from these two D's, whereas drugs, deafness, and isolated dysphasia or dyspraxia should not be overlooked. A careful history will be of most value in reaching the correct diagnosis, although the presence of one condition superimposed on another is common and may complicate the clinical presentation.

Delirium will be of relatively abrupt onset and brief duration (hours or days) and characterized by fluctuating disturbance of attention, behavior, and wakefulness, as well as cognitive impairment. An underlying physical cause of the delirium will often be evident, such as infection, pain, metabolic disturbance, or dehydration. Most cases of delirium will rapidly and completely resolve with appropriate management. The fluctuating performance and not infrequent visual hallucinations associated with delirium will need to be distinguished from the symptoms of Lewy body disease.

Subjective memory complaint may be a prominent feature of depression in older people, especially in the “young old,” whereas severe depression may be associated with objective cognitive impairment, particularly on complex tasks and timed tests. Cerebrovascular disease is often responsible. Questions on cognitive testing are more likely to be answered by “don't know” or refusals, rather than guesses or near misses, and performance may be inconsistent, with the subjects typically highlighting their failings. In contrast to dementia, sense of time and direction is often relatively intact; there is an absence of rapid forgetting and improvement with practice.

Major depressive illness presenting with the clinical picture of dementia has been termed *pseudodementia*, although mild dementia presenting with depressive symptoms (which might be termed *pseudodepression*) is more common. The true diagnosis is perhaps most often established only in retrospect, after the depressive symptoms have been treated

successfully.³⁶ However, up to 50% of elderly patients presenting with depression and cognitive impairment develop full-blown dementia within 3 to 5 years,³⁷ and depression often precedes the dementia syndrome in vascular dementia, dementia with Lewy bodies, and other subcortical dementias.³⁸

The reduced cognitive reserve of the aging brain means that it is especially sensitive to the adverse effects on higher mental functions of many prescribed and over-the-counter drugs. Sedative medication and anticholinergics are the most common culprits, but any drug with central nervous system activity may be implicated. Symptoms generally respond rapidly to drug withdrawal or dose reduction.³⁹ Identification of reversible causes of dementia will ensure that appropriate interventions can be mobilized that may stabilize, improve, or even cure the underlying condition.

Reaching a diagnosis

There is no quick and simple way to reliably diagnose dementia and its subtypes, particularly in the early stages. The NICE Guidelines⁶ summarize the process as depending on “pattern recognition, deductive reasoning and accumulation of diagnostic evidence from multiple sources. These processes tend to be iterative and may be relatively prolonged.” An adequate assessment should consist of a detailed history from both patient and someone who knows the patient well, a physical examination, a mental state and cognitive assessment, and appropriate investigations, including laboratory tests and neuroimaging (Figure 52-1). This may be best carried out in a memory clinic setting.⁴⁰

HISTORY TAKING

Independent histories should be obtained from patient and informant, ideally out of earshot of each other. The priorities should be to establish the nature, onset, evolution, and impact of the presenting symptoms. Areas to investigate include ability to find their way around independently and use public transport, driving, taking medication, using the telephone, interest in hobbies, dealing with financial affairs, shopping, housework and meal preparation, social behavior, relationships and self-care skills (bathing, grooming, dressing, toileting).

Establishing the very earliest symptom, its onset, and its subsequent course is especially valuable. A slow, insidious decline of working memory is typical of Alzheimer's disease, whereas a fluctuating course is suggestive of dementia with Lewy bodies. Frontotemporal dementia will present with progressive change in personality and social conduct and language. A more acute onset of cognitive impairment with a stepwise progression is characteristic of vascular dementia.

Other important areas of the history include psychiatric and behavioral symptomatology, education, employment and premorbid functional ability, past and present medical problems (especially stroke, Parkinson's disease, head injury, and diabetes mellitus), medication (prescribed and nonprescribed, especially centrally acting drugs and those with anticholinergic effects), past and present alcohol intake, family history, and social support. Specific attention also should be given to the caretakers' emotional and physical state, how much practical care and supervision they need to undertake, and how much they understand about the nature of the patient's condition.

A structured interview schedule covering the essential elements of the history forms the first two parts of the CAM-DEX (Cambridge Examination for Mental Disorders of the Elderly).⁴¹ The Informant Questionnaire on Cognitive Decline in the Elderly (IQCODE) may be used to document an informant's report of changes in the everyday cognitive function of an elderly person compared with 10 years earlier.⁴²

PHYSICAL EXAMINATION AND MENTAL STATE ASSESSMENT

The medical examination of the person with possible dementia may help to elucidate the cause of the illness, identify physical consequences of the condition, or identify important coexisting morbidities. Especially relevant are the neurologic examination (for focal motor and sensory signs, primitive frontal reflexes, involuntary movements, and gait disturbance, especially parkinsonism), cardiovascular system examination, assessment of vision and hearing, and recognition of signs of self-neglect or injury, either unintentional or related to possible physical abuse. A mental state examination should look for presence of BPSD and psychiatric conditions that may cause diagnostic confusion.

COGNITIVE TESTING

Testing cognitive function can start with a brief screening assessment and proceed to more detailed neuropsychological testing if necessary. The Mini Mental State Examination (MMSE)⁴³ is probably the most widely used cognitive screening test, taking about 5 to 10 minutes to complete and covering orientation, attention, memory, language, and visuoconstructional skills. It yields a score from 0 to 30, with cutoff below about 23 or 24 said to be indicative of dementia. However, total scores need to be interpreted cautiously and the nature and pattern of deficits is more instructive than the total score. As well as acquired cognitive impairment, performance will be influenced by premorbid ability, education, language, culture, sensory deficits, and motivation. Other short tests include the Abbreviated Mental Test Score (AMT),⁴⁴ the 7-minute screen,⁴⁵ and the 6-CIT.⁴⁶ Clock-drawing⁴⁷ is quick and nonthreatening, testing comprehension, planning, visuospatial skills, and memory, but it is difficult to score. Verbal fluency (naming animals or words starting with a particular letter of the alphabet in one minute) is a quick screening measure of frontal lobe function.

More comprehensive standardized cognitive tests are used routinely in specialist dementia services, such as memory clinics. The Addenbrooke's Cognitive Examination (ACE-R)⁴⁸ includes the MMSE, clock drawing, and verbal fluency and consists of 26 tasks divided into five domains: attention and orientation, memory, verbal fluency, language, and visuospatial skills. It takes about 15 minutes to administer and has value in distinguishing dementia from affective disorders and mild cognitive impairment and that because of Alzheimer's disease from frontotemporal dementia and atypical parkinsonian syndromes. Other more detailed tests that are commonly used include the Cambridge Cognitive Examination (CAMCOG-R)^{41,49} and the Repeatable Battery for the Assessment of Neuropsychological Status (RBANS).⁵⁰

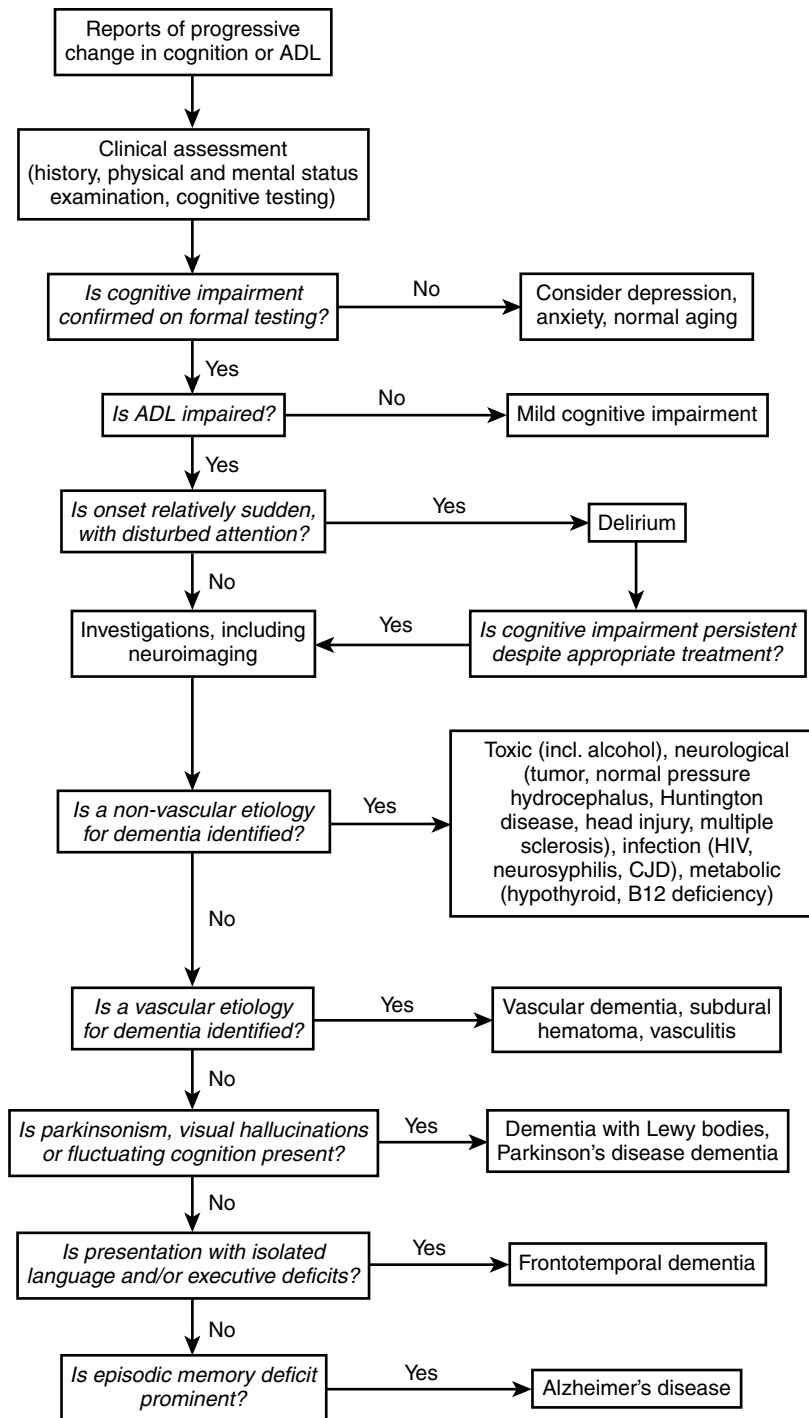

Figure 52-1. Diagnostic process for dementia. This simplified diagram ignores the possibility that dementia might have a mixed etiology—a common finding in practice.

LABORATORY TESTING

Recommended laboratory investigations include full blood count, urea and electrolytes, liver function, calcium, blood glucose, thyroid function, vitamin B12, folate, and C-reactive protein (CRP). Syphilis serology, lipids, and HIV testing are not necessary routinely but should be undertaken if indicated by the clinical circumstances. An electrocardiogram may be indicated if vascular disease is suspected. Other tests are appropriate if delirium is a possibility, such as a midstream urine sample, blood cultures, and chest x-ray.⁶

NEUROIMAGING

Structural neuroimaging with magnetic resonance imaging (MRI) or computed tomography (CT) is a necessary part of the dementia workup in most patients.⁵¹ They will rule out potentially treatable intracerebral lesions causing dementia, such as subdural hematoma or normal pressure hydrocephalus and rule in cortical and subcortical infarcts and white matter changes indicative of vascular disease and localized atrophy characteristic of particular neurodegenerative dementias. For example, atrophy of the hippocampus and medial temporal

lobe is an early and sensitive marker for Alzheimer's disease and atrophy of the frontal or anterior temporal lobe may be seen in frontotemporal dementia. The choice of MRI or CT will depend on local availability, cost considerations, patient acceptability, and contraindications, but MRI is generally more sensitive and is the preferred modality.^{6,52}

Functional imaging with single-photon emission computed tomography (SPECT) or positron emission tomography (PET) shows regionally distinct patterns of underperfusion or hypometabolism and can help to differentiate Alzheimer's disease from frontotemporal dementia or vascular dementia.^{53,54} PET scanning remains largely a research tool because of its high cost and lack of general availability. Study of the dopamine transporter (DaTSCAN) can be used to distinguish dementia with Lewy bodies from Alzheimer's disease.⁵⁵

Recent neuroimaging advances, such as the Pittsburgh Compound-B (PIB) ligand for positron emission tomography imaging in Alzheimer's disease, look to have a major future role in differentiating among the neurodegenerative dementias and monitoring treatment effects.⁵⁶ Other studies are under way to identify specific imaging markers for different types of dementia, including cerebral volumetric measurements, diffusion weighted MRI, MR spectroscopy, and very-high-field MRI scans of senile plaques in Alzheimer's disease.

OTHER INVESTIGATIONS

Examination of cerebrospinal fluid (CSF) is diagnostically valuable in patients with suspected infectious, inflammatory, autoimmune, or demyelinating disease. In normal pressure hydrocephalus, it may help to predict response to surgery. The presence of the CSF 14-3-3 protein confirms the diagnosis of Creutzfeldt-Jakob disease. CSF markers of Alzheimer's disease (reduced beta amyloid 1–42 and elevated total tau and phosphorylated tau) may also allow earlier and more accurate diagnosis, but problems with patient acceptability of lumbar puncture and of standardization of laboratory assays limit their routine use.⁵⁷

Studies of plasma biomarkers of Alzheimer's disease have shown significant overlap with control cases, but plasma concentrations of beta amyloid40 and low plasma concentrations of beta amyloid42 indicate an increased risk of dementia and may have a future role in therapeutic monitoring.^{57,58} Genetic testing is rarely indicated and should only be undertaken after appropriate counseling, preferably in a specialist genetics clinic. Testing may be indicated in suspected Huntington's disease (Huntington gene), cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy or CADASIL (notch 3 gene mutation), familial Alzheimer's disease (presenilin and amyloid precursor protein gene mutations), or frontotemporal dementia (tau gene mutations). Determination of apolipoprotein genotype is not diagnostically useful, the e4 allele being neither sufficient nor necessary for development of Alzheimer's disease, although it may have a role in predicting therapeutic response.⁵⁹

The electroencephalogram (EEG) is usually diffusely abnormal in dementia but may be normal in frontotemporal dementia and the presence of triphasic spikes is helpful diagnostically in prion disease.⁶⁰ Brain biopsy may be indicated very rarely when a treatable disorder is thought to underlie dementia.⁶¹

TELLING THE DIAGNOSIS

Sharing the diagnosis of dementia can be challenging and the practice of diagnosis disclosure among dementia specialists is changing. In the 1990s, less than a third of old age psychiatrists and geriatricians usually told people with mild dementia their diagnosis, but more recent studies report that half or more of specialists now regularly disclose diagnosis, with few still seeing no benefit in doing so.⁶²

It is now established good practice that, in most cases, it is best for the person with dementia to be told sensitively what is wrong, what the implications are, and what can be done (Table 52-2).^{63,64} Certainly, all should be given the opportunity to learn as much or as little as they want to know, and people should routinely be asked if they wish to know the diagnosis and with whom this should be shared.⁶ Reactions of patients to being told their diagnosis include relief (as it provides an explanation for their difficulties), disbelief (as they may lack insight and do not feel ill), loss (grieving for failing intellectual abilities), and fear (of becoming a burden and of limitations in the future).⁶⁵ Family members and caretakers also need to understand the diagnosis, with specific attention given to comprehensible and practical information about coping strategies, care services, likely course of the disease, available treatment, and plans for follow-up.

Communication of the diagnosis should ordinarily occur in a joint meeting with patient and family.⁶⁶ Sufficient time needs to be allowed for an adequate discussion, perhaps outside the standard clinic schedule. Simple language should be used, avoiding technical jargon that may conceal the truth, but including the specific medical diagnosis (e.g., Alzheimer's disease) rather than just dementia. Both terms will need to be explained. The bad news can be mellowed with information about available therapeutic approaches to maintain quality of life and care must be taken to avoid conveying the feeling that nothing more can be done. A graded approach to disclosure and information provision can be adopted, which is patient-led and ensures that what is said answers what the patient wants to know. At the end of the discussion, the patient and family's understanding should be assessed and

Table 52-2. Arguments for and against Disclosure of a Diagnosis of Dementia

Against Disclosure

- Making an accurate diagnosis is complex and uncertain in the absence of neuropathology.
- There is no curative intervention.
- Giving such a diagnosis may cause avoidable anxiety and depression.
- People with dementia will not be able to understand or retain the information given to them.

For Disclosure

- Maximizes individual autonomy and choice by providing information necessary for decision-making and advance planning
- Increases opportunities for accessing appropriate and specialist support services and symptomatic treatments
- Demonstrates respect for individual rights, especially the "right to know" and avoids paternalism
- Relieves the anxiety of uncertainty
- Provides an explanation for cognitive failures and problems in everyday life, allowing the person to make sense of them
- Promotes positive coping strategies and fulfillment of short-term goals

follow-up arranged, to reinforce information provided, clarify misunderstandings, and answer questions that are outstanding. A telephone call or a home visit by an informed professional a few days later will be helpful.

Verbal information should be backed up by written information,⁶⁷ with recommendations for further reading and trustworthy Web sites and mention made of local support groups and meetings, with contact details of local Alzheimer associations. Postdiagnostic counseling, individually or in a group setting, can be of great value.⁶⁸

MANAGEMENT

Treatment goals in early dementia center on improving or stabilizing cognitive ability and mood, maintaining or reestablishing independence, promoting autonomy, and effective planning for the future. As the condition progresses, emphasis shifts to facilitating mental and physical stimulation, managing behavioral disturbances, and providing practical care for patients and respite for their families. Finally there should be the timely introduction of appropriate end-of-life care.⁶⁹

The concept of personhood and person-centered dementia care, pioneered by Kitwood⁷⁰ in the late 1980s, is central to best management. Brooker³ has identified the key components as valuing people with dementia and those who care for them, treating people as individuals, looking at the world from the perspective of the person with dementia, and promoting a positive social environment in which the person living with dementia can experience relative well-being. The technique of Dementia Care Mapping (DCM)⁷¹ is closely linked to person-centered care and is an attempt to help professionals to take the standpoint of the person with dementia when evaluating the quality of care, using a combination of empathy and observational skills. This information can be used to plan more person-centered care on an individual, group, and organizational level.

Good practice requires clinicians to try nonpharmacologic approaches to managing problems related to dementia before pharmacologic treatment,⁶ although disease-modifying drugs, should they become available, would be required to be used from an early stage. Often a combination of interventions tailored to the needs of the individual is most

appropriate (Figure 52-2). Although the professional's primary responsibility will always be to the patient, addressing caretakers' needs as well will often result in a better outcome for all. However, sometimes the patient's and caretaker's wishes can conflict (for example, a patient not wishing to attend day center, although the caretaker is in need of respite), and in these circumstances decisions about best management can be especially difficult. Disagreements within families can also cause conflict, commonly involving accusations of neglect, exploitation, lack of communication, or sequestration of the person with dementia.⁷²

Safety and risk

Impaired judgment and insight, perceptual problems, deficits of attention, slow reaction time, and impaired memory will all contribute to the person with dementia being at increased risk of accidents and unwanted outcomes. Caretakers often use concern about people being "at risk" as the justification for management decisions, from the need for regular uninvited home visits, whether by family or professionals, to the need for admission to institutional care. However, there is a need to balance the desire to reduce risk as much as possible, against that of encouraging the person's continuing independence and dignity. An emphasis on total safety and risk prevention is likely to erode people's personhood and autonomy. Everyone, whether or not they have dementia, has a right to reasonable freedom of choice, as long as they do not put others at significant risk. A stimulating environment and positive and interesting activities are incompatible with total safety and some occasional minor accidents are inevitable. Good risk management will involve a carefully considered trade-off between efforts to maximize environmental and emotional security and the promotion of individual and community rights.⁷³

The commonest unsafe behaviors reported by relatives of demented patients living at home are wandering and problems in the kitchen and with driving. The most common accidents are falls, injuries arising from sharp objects, and getting lost. Examples of simple measures to improve safety include use of personal identification bracelets, keeping a spare set of house keys with a neighbor, installing smoke alarms, providing community alarm systems so that help can be summoned immediately if needed, ensuring good

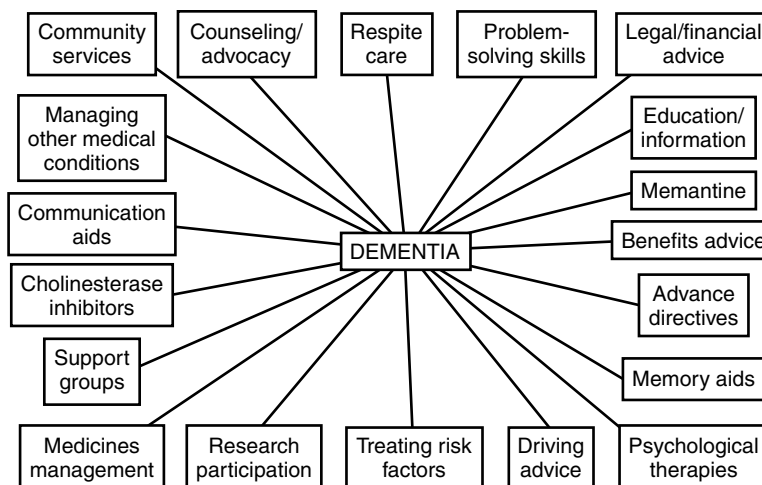

Figure 52-2. Potential interventions in management of dementia.

lighting, fitting a gas detector, or disconnecting supplies and installing hot water thermostats. Simplifying drug regimens, dispensing medication in prepacked pillboxes and ensuring unused medication is stored safely out of reach will help to improve compliance and reduce risk of overdose. Alarms on front doors can immediately alert caretakers that someone is leaving the building, or unfamiliar locks or difficult-to-use door handles on exits can act as an effective barrier. A pressure mat placed next to the bed or in doorways can be used to alert caretakers when a patient is up and about. There is a growing industry developing electronic aids and “smart homes” that make use of new technologies to monitor patients’ activities, but empirical evidence of their value is so far lacking.⁷⁴

Driving is an especially difficult issue as safety will be inevitably lost as dementia progresses. Clinicians and family members can help patients realize when it is no longer safe for them to drive, but sometimes close relatives have selfish motives for minimizing driving difficulties. It has been suggested that the risk of crashes is acceptably low for up to 3 years after onset of Alzheimer’s disease, but this varies between people.⁷⁵ Cognitive testing cannot determine whether individuals with dementia are able to drive safely.⁷⁶ Regulations on driving and dementia differ from country to country, with mandatory reporting to licensing authorities in many, but not all. The clinician must make an immediate decision on safety to drive, ensure that the licensing agency is notified as appropriate, and help patients and their families to accept and adapt to the new limitations in mobility if driving must stop.

Loss of mental capacity will place people at risk of being unable to cope with everyday decisions and open to abuse. Arranging a power of attorney allows the person with dementia (the donor), while still capable, to delegate to another (the attorney) the ability (power) to act on their behalf in relation to financial, property, and legal affairs. It can also be extended to include welfare and health decisions. An advanced directive or living will allows the person to state his or her wishes about future treatment and potentially life-saving interventions, such as artificial feeding and resuscitation in the event of cardiorespiratory arrest. Powers of attorney are widely regarded as good practice in dementia care and are widely used, although fewer people currently arrange an advanced directive.⁷⁷

Memory aids and cognitive training

The most simple and effective methods of helping patients (other than asking other people to remember things for them) are the establishment of everyday routines and careful planning of daily activities, allowing sufficient time and avoiding unnecessary overcomplication. Use of environmental cues, such as labeling or color coding of switches and doors, can be useful, as may systematic use of external memory aids such as diaries and checklists and strategically positioned notes as reminders. Electronic aids and smart house technology can also be used to generate prompts. None of these approaches requires the patient to learn new strategies of thinking or remembering and may thus be useful for most people with mild to moderate dementia.⁷⁸ Personal memory albums are a visual record of the key facts of a person’s life, both past and present, and can serve as a valuable orientation and reminiscence aid in people with more severe dementia.

They stimulate conversation and provide opportunity for life review, allowing patient and caretakers to focus on the good times and help raise confidence and self-esteem. Optimizing communication, using both verbal and nonverbal techniques, will help patients to maintain a sense of control and minimize misunderstandings that can lead to BPSD. Efforts should also be made to compensate for any hearing and visual deficits. Professionals should always introduce themselves face-to-face and fully explain what they are doing using a clear, relaxed, and normal speech rhythm and simple, concrete language.⁷⁹

Formal cognitive training programs may have some benefits in improving, retaining, or regaining skills in motivated individuals with mild dementia, although empirical evidence in support is limited.⁸⁰ Any advantage is not sustained for long and gains in one particular skill tend not to generalize to other areas. Specific approaches to memory training have included relaxation techniques, regular and repeated practice sessions (using spaced retrieval to rehearse information), organization of material (e.g., use of categorization or mnemonics), techniques for improving visual imagery (e.g., peg-word methods, face-name association, etc.), verbal strategies (rhymes, first letter cueing, alphabet searching, etc.), and most recently computer-aided cognitive training.⁸¹ Training in groups with other people with memory impairment or with family members and caretakers may provide opportunities for mutual support and education.

Nonpharmacologic therapies

A number of psychological and complementary therapeutic approaches have been developed for use in dementia.^{82,83} No one approach is suitable for all patients or is likely to continue to suit any single patient throughout the course of his or her illness.

*Reminiscence*⁸⁴ involves recall of events in a person’s life, in conversation with another, in a group, or alone. Relevant pictures, music, objects, and sounds are used to trigger the store of memories. It can be an enjoyable diversionary activity for patients and encourages those involved in care to get to know more about patients as individuals. Proponents have reported benefits to include an increase in interaction, improved orientation, and a reduction in behavioral disturbance.

*Reality orientation (RO)*⁸⁵ provides information about the time, place, or person to give the person with dementia a greater understanding of his or her situation, with the aim of improving sense of control and self-esteem. The currently favored approach, especially in care homes, is to provide 24-hour RO by providing clocks, clear signposting, large notice boards, and consistent information in all interactions. Sustained improvement in verbal and spatial orientation has been claimed, but it needs to be employed skillfully to avoid confrontation.

*Cognitive stimulation therapy (CST)*⁸⁶ aims to promote cognitive function through regular sessions of themed activities, using quizzes, word and number games, and everyday objects to actively stimulate and engage people with mild to moderate dementia. When undertaken in a group setting, there are both learning and social benefits.

*Validation therapy*⁸⁷ emphasizes the importance of relating to the inner reality of the patient rather than encouraging the patient to be concerned with external factors as with

RO. The therapist acknowledges and empathizes with the patient's feelings, whether or not they are based on reality. The emphasis is on accepting and validating feelings rather than factual content. Validation can be delivered individually in formal sessions, as group therapy, or as 24-hour informal therapy.

*Animal-assisted therapy*⁸⁸ involves introducing pets, such as resident cats or visits by a dog, to institutionalized patients (provided that they do not scare people). It can significantly increase the number of interactions while the therapy dog is present, producing longer conversations and increased rates of touch, as well as promoting a homely environment and facilitating the expression of emotions. Installation of fish tanks in the dining area of specialized dementia units has even been reported to increase nutritional intake and weight gain.

*Music therapy*⁸⁹ can be undertaken, either individually using recorded tapes or simple instruments or in groups using old songs or dance music. People respond best when they listen to music they prefer. Group music therapy can significantly improve speech content and fluency and some severely impaired patients may respond to music, even when other forms of communication have been lost. Individualized music therapy can significantly decrease agitation.

*Physical exercise*⁹⁰ may be undertaken either through informal walks or using structured exercise sessions. Walking combined with conversation in nursing home residents with dementia helps to maintain functional mobility, and student-led one-to-one exercise sessions can result in significant fitness gains, is inexpensive, and gives family caretakers some respite.

*Relaxation therapy*⁹¹ can take various forms. Progressive muscle relaxation, in those who can learn the technique, can decrease behavioral disturbance and improve memory in people with mild to moderate dementia. Interventions incorporating aspects of touch may also help some people. Hand massage and intermittent gentle touch on the arm and shoulder, accompanied by calm soothing talk, were shown to have a temporary benefit on disturbed behavior in one study. Rocking chairs can also improve emotions and relaxation.

*Bright light therapy*⁹² has been claimed to improve cognition and behavior in people with Alzheimer disease, even though the exposure must be for several hours each day for several weeks and the light must be of high intensity. Low-intensity dawn-dusk simulation, a naturalistic form of light therapy, was ineffective.

*Snoezelen therapy*⁹³ involves multisensory stimulation using a variety of lights, gently stimulating music, aromas, and tactile objects. Regular snoezelen sessions may improve behavior and mood in people with moderate to severe dementia.

*Aromatherapy*⁹⁴ may also prove to be beneficial. Studies have shown reduction in agitation associated with regular application of *Melissa officinalis* (lemon balm) oil applied to the hands, with lavender oil via an aromatherapy stream and with a course of aromatherapy combined with massage. There were no major adverse effects.

*Creative activities*⁹⁵ encourage normalization, provide mental stimulation, and enable the person with dementia to recognize an ability to achieve, lessening the feeling of helplessness. Care must be taken to ensure that the activity is of interest to the patient rather than to the helper and, whatever the activity, the emphasis should always be on enjoyment

while taking part, not on what is finally produced. Suitable activities might include painting and collage, pottery, flower arranging, indoor gardening, traditional games, and puzzles.

Drug management

As the etiology of dementia is so varied, no one drug is likely to be beneficial in all patients. The choice of medication should clearly relate to the underlying condition or the specific symptom that is to be treated. A small minority of dementing conditions can be effectively halted or reversed by specific drug treatment; for example, hypothyroidism by levothyroxine, pernicious anemia by parenteral vitamin B₁₂, neurosyphilis by penicillin, cerebral vasculitis by corticosteroids or immunosuppressants, and Wernicke-Korsakoff's syndrome and possibly alcoholic dementia by thiamine. However, truly reversible dementia is probably rare.

Of the many drugs that have been claimed to be of more general benefit in the prevention and management of dementia, few have withstood the critical test of large, prospective, randomized, placebo-controlled trials. Thus, over the years, vasodilator drugs, nootropics, cholinergic supplementation with lecithin and choline, antioxidants (notably vitamin E and ginkgo biloba), anti-inflammatory drugs, and estrogen have all been shown ineffective.

The association of cardiovascular risk factors with Alzheimer's disease as well as vascular dementia suggests a potential value of vascular preventive treatment,⁹⁶ and there is some evidence of benefit for antihypertensive drugs.⁹⁷ However, despite strong epidemiologic support, randomized controlled trials of statin drugs have so far not shown positive effects on cognition when used for primary prevention⁹⁸ or treatment of established Alzheimer's disease.⁹⁹ Likewise, low-dose aspirin is ineffective in preventing cognitive decline in asymptomatic middle-aged to elderly adults.^{100,101}

Available drugs of proven efficacy in Alzheimer's disease are the acetylcholinesterase inhibitors (AChEIs), donepezil, galantamine, and rivastigmine, and the *N*-methyl-D-aspartate (NMDA) receptor antagonist, memantine. The three AChEIs differ in their pharmacologic properties but have broadly similar efficacy and safety. They work by blocking the enzyme acetylcholinesterase and so inhibit the breakdown of the neurotransmitter acetylcholine. Numerous placebo-controlled clinical trials have shown consistent, if modest, benefits on cognitive and global measures in a majority of patients with mild to moderate Alzheimer's disease and most studies show improvement (or less deterioration) in activities of daily living, behavior, caretaker burden, and use of resources.^{102,103} Side effects are generally mild and dose-related, typically nausea, vomiting, and diarrhea. The effects of AChEIs are also seen in patients with severe dementia, although trial evidence is limited.¹⁰⁴ Despite their clinical efficacy and safety in Alzheimer's disease, the cost-effectiveness of AChEIs has been questioned and, in the United Kingdom, the NICE appraisal process controversially recommended their use only in moderate dementia.¹⁰⁵ In vascular dementia there is also some evidence of limited benefit,¹⁰⁶ and rivastigmine is the drug of first choice for treating cognitive impairment in dementia with Lewy bodies and Parkinson's disease dementia.¹⁰⁷

Memantine blocks pathologically elevated glutamate and consequent calcium overload while still allowing physiologic receptor activation. It is available for treatment of

moderately severe and severe Alzheimer's disease, either given alone or in combination with an AChEI. In systematic reviews, memantine shows benefit on cognitive and global function of the same order of magnitude as seen for the AChEIs,¹⁰⁸ and it also seems to have specific benefit against agitation.¹⁰⁹ It is very well tolerated.

Neuroleptic drugs were for many years commonly used to treat BPSD, but their efficacy is limited and it is now recommended that their use is restricted to the short-term (e.g., not more than 3 months) treatment of aggression or psychotic symptoms associated with serious distress or risk when other therapies have proven ineffective.¹¹⁰ The evidence is best for the atypical drugs, risperidone and aripiprazole. Adverse effects can be significant and include excessive sedation, parkinsonism, falls, hastening of cognitive decline, increased stroke risk,¹¹¹ and premature death.¹¹² In dementia with Lewy bodies and Parkinson's disease dementia, neuroleptics may precipitate severe sensitivity reactions in up to 50% of patients treated and should only be used with particular caution.¹¹³

Non-neuroleptic drugs to treat BPSD have not been studied extensively in clinical trials, but there is some evidence for benefit from carbamazepine, sodium valproate, trazodone, and citalopram to treat aggression and agitation.¹¹⁴ Depressive symptoms are best treated with a selective serotonin reuptake inhibitor (SSRI) antidepressant such as citalopram or sertraline, or mirtazapine or trazodone if sleep is disturbed.

There is a lot of activity investigating novel therapeutic strategies that aim to fundamentally alter the natural history of dementia by targeting the underlying pathologic process. The main area of interest has been interfering with the deposition of beta amyloid protein in Alzheimer's disease. In animal models, immunization with beta amyloid reduces plaque formation and protects against learning and memory impairment. Initial human trials of active immunization in Alzheimer's patients were discontinued because of meningoencephalitis in about 1 in 20 patients treated, although some cognitive, functional and biochemical outcomes proved promising.^{115,116} Subsequent clinical trials are focusing on passive immunization with monoclonal antibodies against amyloid, which are thought unlikely to generate an inflammatory response. Long-term follow-up of early trial patients has confirmed the clearance of amyloid plaques from the brain, although patients are still dying with severe dementia.¹¹⁷

Alternative anti-amyloid approaches involve secretase inhibitor drugs that target its production and those that inhibit its aggregation, but initial large-scale human trials in established Alzheimer's disease have been disappointing. Other approaches in Alzheimer's disease include drugs targeting the abnormally phosphorylated tau protein, neurotrophic agents, and drugs impacting on multiple neurotransmitters. There remain many unanswered questions.¹¹⁸

KEY POINTS

Presentation and Clinical Management of Dementia

- Dementia is a syndrome (not a diagnosis) describing a characteristic pattern of multiple cognitive deficits, usually including memory impairment, associated with a progressive decline in the ability to carry out daily activities and often associated with personality and behavioral changes.
- The diagnostic process requires confirmation from history and cognitive testing of the presence of dementia and then identification of the likely subtype (e.g., Alzheimer's disease, vascular dementia, dementia with Lewy bodies, Parkinson's disease, frontotemporal dementia, etc.). This may be best carried out in a memory clinic setting.
- Early recognition and intervention reduces risk of misdiagnosis of dementia and inappropriate management, facilitates optimal care, and can delay morbidity associated with progressive deterioration.
- Sharing the diagnosis can be challenging, but in most cases people with dementia benefit from being told sensitively what is wrong with them, what the implications are, and what can be done for them. Caretakers need to understand the diagnosis and be given comprehensible and practical information about coping strategies, care services, likely course of the disease, available treatment, and plans for follow-up.
- Both pharmacologic and nonpharmacologic treatments are effective. Management goals in early dementia center on improving or stabilizing cognitive ability and mood, maintaining or reestablishing independence, promoting autonomy, and effective planning for the future. As the condition progresses, emphasis shifts to facilitating mental and physical stimulation, managing behavioral disturbances, and providing practical care for patients and respite for their families.

Neuropsychology in the Diagnosis and Treatment of Dementia

Margaret C. Sewell
Andrew Vigarío
Mary Sano

INTRODUCTION

The aging of the United States population has given rise to a significant increase in the prevalence of Alzheimer's disease with estimates of 10.3% of those over 65 and 47.2% of those over 85.¹ It is estimated that in the next 50 years 1 in 45 Americans will have Alzheimer's disease.² Dementia represents significant impairment in cognitive functioning, defined as a decline in memory and at least one other cognitive domain (most commonly executive function, aphasia, or agnosia) serious enough to interfere with daily life, and not accounted for by other medical conditions. Many cases remain undiagnosed and untreated, an estimated half of elderly primary care patients³, in part because health care providers may not regularly use screening instruments or refer for comprehensive evaluations. Neuropsychologists can assist in characterizing cognitive loss, its causes and consequences, and aid in the determination of decisional capacity.

This chapter will (1) outline why a neuropsychological evaluation may be needed, what it entails for the patient, and identify challenges to assessment of elderly patients, (2) explain the role of neuropsychology in the development of pharmacologic treatment for dementia, (3) describe screening instruments and common neuropsychological tests, and (4) review recent research that has identified typical patterns of impairment that distinguish one dementia from another, including depression.

REASONS FOR NEUROPSYCHOLOGICAL ASSESSMENT

A geriatric neuropsychological evaluation, unlike a brief cognitive screening or clinical interview, can distinguish the cognitive changes associated with normal aging from mild cognitive impairment (MCI) or dementia (both cortical and subcortical), distinguish dementia from depression, and arguably, differentiate one form of dementia from another.

A common referral question regards differentiating MCI or preclinical Alzheimer's disease from normal aging. Since cognitive changes with aging are well documented, including reduced processing speed, mental flexibility, and psychomotor slowing, cognitive complaints may be difficult to distinguish from changes attributed to aging or medical problems that may be associated with aging. This is important in individuals with particularly high or low levels of formal education and when other aspects of the medical or psychosocial history may leave doubt about how to interpret cognitive complaints. Well-established normative data on cognitive tests can provide a method for evaluating cognitive performance.

In the presence of clear cognitive impairment, however, neuropsychological assessment may be of value in distinguishing underlying causes. Historically, the pattern of neuropsychological deficit has been used to pinpoint deficit

and to identify impairment in local neural networks. Longitudinal samples of well-characterized disease groups provide signature patterns of cognitive strengths and weaknesses, which may be used to support the diagnosis of specific types of dementia.

Neuropsychological assessment can also be useful to predict course or progression of cognitive disease. The characterization of syndromes such as mild cognitive impairment (MCI) allows prediction of future diagnoses with fair reliability. This can help determine the need for present and future assistance and support.

Neuropsychologists are also called upon to determine functional abilities, including decisional capacity, which is task specific. Neuropsychological evaluation of memory and executive functions (e.g., planning, reasoning) are important in this area as they document the cognitive strengths and weaknesses that can help determine a patient's current ability to drive, make medical decisions, live alone, or manage finances. There are also several measures available, including the widely used structured interview, the MacCAT-T,⁴ which can aid in the direct assessment of specific decisional capacities.

In the research setting, cognitive testing is used to assess the effectiveness of treatments for dementia and in particular for Alzheimer's disease, the most common type of dementia. In this setting performance, differences between active and placebo conditions are used to assess efficacy of agents in combination with other global and functional measures (e.g., activities of daily living, behavioral symptoms). Baseline neuropsychological performance may also be used to assess an intervention or the cognitive impact of a medical procedure or treatment.

A comprehensive neuropsychological battery to determine the presence and nature of a dementia can be accomplished in several hours. The battery consists primarily of paper and pencil type of tests, with a few that can be administered on a computer—though the wisdom of using a computer with elderly patients needs to be determined on a case by case basis. Typically the assessment includes a clinical interview, and well-normed tests of memory, language, attention, visuospatial function, motor function, executive function, and depression. Because of beliefs that psychological testing of any kind is necessarily lengthy and expensive, it may be useful to reassure family members that the testing is relatively brief and is covered by Medicare.

CHALLENGES TO NEUROPSYCHOLOGICAL ASSESSMENT IN THE ELDERLY

There are several challenges to neuropsychological assessment, particularly in the elderly, which should be kept in mind as one selects tests and interprets results. First sensory

impairment, common in elders, may interfere with testing. Since many tests present stimuli, visually or orally, serious hearing and visual loss can make interpretation of test performance difficult. However, these can be addressed by direct assessment, and sample items are often used to ensure sensory capacity is adequate for the test. Another challenge is mobility limitations as arthritis in hand joints may slow performance on timed tests and limit the validity of such procedures. This can be overcome in some cases by measuring differences in time for low and high cognitive demand tests rather than depending on the absolute time of a single test.

Low literacy, defined as not reading in any language, due to low levels of formal education or life-long disability can also impede testing but can be addressed by selecting assessment tools that use oral presentation, pictures, or other stimuli that do not require reading or knowledge of the alphabet. In this situation, it is important to rely on normative data of comparable individuals in order to have confidence about deficits. When this is not available, one must depend on clinical experience.

Language and culture can also challenge selection and interpretation of testing. Ideally a patient should be assessed in the language in which they are most competent by an evaluator who is equally competent in the language. Translation can be used but adequate normative samples against which to compare performance are sparse. Cultural specificity may figure into test items that can also compromise scoring. For example, literal translations may not provide the same complex meaning as demonstrated in the original version but experienced translators can help overcome these pitfalls.

Brief cognitive screening tools

Because of the increasing elderly population and subsequent demand on the primary care provider to screen for dementia, there has been a proliferation of screening tools developed in the past 15 years. There is no shortage of brief and easy screens, with reasonable reliability, sensitivity, and specificity. The challenge is in persuading physicians and health care providers of the value of using them. The goal of these instruments is to provide a quick and reliable method of identifying cognitive impairment that is easy to administer and score and may be used as part of routine care in those over 65 years old. The advantage of them, as a group, is the opportunity to distinguish patients with normal age-related changes in cognition from those who may need a thorough diagnostic neuropsychological work-up. The disadvantages include poor normative data, and varying levels of sensitivity/specificity. Below, several of the most popular screening tools are described.

*Mini-Mental Status Examination (MMSE)*⁵: The MMSE was intended to be a brief, easy to use tool for grading cognitive impairments. A major advantage of the MMSE is that most health care providers use the instrument in daily practice, thus facilitating communication among various clinicians.⁶ This 30-point, 10-minute screening instrument is particularly useful when used repeatedly to measure change in cognitive status. The MMSE has been criticized for its limited usefulness among those with low levels of English literacy or formal education.⁷

To address this, different cut-off points for an abnormal result have been created for those of differing ages and educational levels.⁸ Overall, the MMSE's ability to detect dementia ranges from 71% to 92% sensitivity and 56% to 98% specificity.⁷ In a meta-analysis conducted by Mitchell, the MMSE had very limited ability to distinguish MCI from either normal controls or those with Alzheimer's disease.⁹

Clock Drawing Test (CDT): The CDT, a simple task of drawing a clock face set to a particular time, is an easy to administer and frequently used screening measure that taps visuospatial and constructional abilities along with executive function (planning, abstract thinking)—areas frequently compromised in early dementia and is free of some of the biases inherent in other tests (e.g., non-English speaking). The test has been used to distinguish normal aging from dementia,¹⁰ and track progress over time,¹¹ though it has not been as useful in distinguishing normal aging from MCI.^{12,13} There are numerous methods of scoring, some simple, some complex, and some researchers suggest that with more comprehensive scoring systems, the clock can be useful in identifying MCI patients at high risk for progressing to dementia.¹⁴ Naïve raters have been shown to judge the normalcy of a clock and most rating systems in healthy elders or moderate/severe demented patients, but not in those with mild dementia.¹⁵

Mini-Cog: The Mini-Cog¹⁶ consists of a three-word recall task and a clock drawing. The results designate someone as demented or not demented, and while useful in distinguishing demented patients from normal elderly,¹⁷ it has not been as useful in identifying those with MCI.¹⁸

*The Montreal Cognitive Assessment (MoCA)*¹⁹: This brief screening instrument which requires same training is a relatively new measure that takes approximately 10 minutes to administer and was designed for those suspected of mild cognitive dysfunction. It assesses orientation, attention and concentration, executive function, memory, visuospatial skills, language, conceptual ability, and calculation. It has been shown in those with a MMSE of at least 26, to detect MCI with 90% sensitivity, and early AD with 100% sensitivity.

*The Telephone Interview for Cognitive Status (TICS)*²⁰: This 11-item test takes approximately 10 minutes to administer on the telephone and is a brief cognitive screen that measures global cognitive functioning. It is normed on those 60 to 98, and because it is given on the telephone, and therefore not reliant on visual ability, may be useful for visually impaired patients. Patients are classified as unimpaired, ambiguous, mildly impaired, and moderately to severely impaired. There are two sets of norm groups for those with less and greater than 12 years of education.

In summary, these screening measures as a group can be useful "quick and dirty" measures that can be administered by those with a minimal amount of training and serve as useful "red flags" to identify those in need of further evaluation. Because we lack reliable biologic markers to identify Alzheimer's disease, neuropsychological testing remains the most accurate method to identify and characterize very early

symptoms and distinguish them from other types of cognitive impairment.

NEUROPSYCHOLOGICAL TESTS: DOMAINS OF ASSESSMENT AND NORMATIVE DATA

Most neuropsychologists do not use ready-made batteries but rather select specific tests or sets of tests that assess the major domains of cognition affected in dementia, namely verbal and visual memory, attention, naming, fluency, executive function, visuospatial function, motor function, and depression. A summary of commonly used tests may be found in Table 53-1. All test results are compared to normative data based on age, often education, and sometimes gender. Results are then examined for typical patterns that may suggest different types of cognitive impairments. Additionally, the neuropsychologist will determine the presence of neuropsychiatric symptoms and level of independence with ADL and IADL. The presence of a caregiver for the interview portion of the evaluation is critical.

Premorbid functioning estimates

To determine whether someone has significantly declined from a previous level of cognitive functioning, it is necessary to estimate premorbid level of functioning. This can be accomplished through a careful review of someone's educational and occupational history, tests of vocabulary that tend not to decline even in the presence of dementia, or, for those with at least 8 years of formal education, word reading tests that use a formula taking into account education,

and number of reading errors to provide a crude estimate of premorbid verbal IQ.²¹

Alzheimer's disease. Though postmortem diagnosis is still the gold standard, Alzheimer's, the most common form of dementia in those over 65, can be accurately clinically diagnosed greater than 90% of the time.²² The two standard sets of criteria for Alzheimer's disease (AD) include the Diagnostic and Statistical Manual of Mental Disorders, fourth edition (DSM-IV-TR)²³ and the National Institute of Neurological Disorders and Stroke-Alzheimer's Disease Related Disorders (NINCDS-ADRDA).²⁴ The DSM-IV-TR criteria require impairment in memory and in one other area of cognition (e.g., apraxia, aphasia, agnosia, executive function, attention, visuospatial ability), with concomitant functional impairment (either social or vocational). The NINCDS-ADRDA also includes criteria that the progression is insidious and that other diseases that could cause cognitive decline have been ruled out.

AD, characterized by damage (plaque and neurofibrillary tangles, synapse loss, atrophy) beginning in the medial temporal lobe (hippocampus and entorhinal cortex), is usually marked by a slow and steady progression. The dementia associated with these neuropathologic changes includes significant memory loss as the central core, with other impairments in language (semantic and phonemic fluency, naming), executive function (parallel processing, planning, switching cognitive sets, abstraction), and later in the illness, attention, and visuospatial function.

Recent neuropsychological research has focused on identifying the very earliest cognitive impairments associated with AD, usually episodic memory. Verbal memory is most commonly assessed with either word lists (e.g., CVLT, RAVLT) or stories (e.g., logical memory), and normative data for initial and delayed recall along with recognition is well-established on these tests across age and education categories well into the ninth decade. A substantial amount of research has indicated that AD is associated with a particular pattern of cognitive deficits that distinguish it from normal aging,²⁵ and, in some cases, from other forms of dementia.

The ability to learn and retain verbal information distinguishes between those with mild AD and healthy elders.²⁶⁻³¹ Neuropsychological performance on verbal memory tests is marked by difficulty not only in the free recall of recently learned information, but in the aided retrieval of that information with cues.³² In very early AD, initial learning may be relatively well-preserved, though, compared to normal controls, deficits in both acquisition and consolidation of information may still be present, along with evidence of a shallower learning curve.^{33,34} Deficits in both encoding and delayed recall become more severe as the disease progresses.³⁵

Examination of specific patterns of responses on delayed recall suggests that normal controls tend to recall words equally from the beginning and end of a list but AD patients rely heavily on words only from the end of the list (recency effect), arguing that the AD patient, not having transferred the information from primary to secondary memory, has not really "learned" the words at all.^{36,37} AD patients are sensitive to interference,³⁸ and this is evidenced by a high number (relative to normal controls) of intrusions (e.g., when words from a second list of words appears while the patient

Table 53-1. Neuropsychological Tests

Domains to be Assessed	Commonly Used Tests Used with Age-Corrected and/or Education Norms for Those >65
Premorbid ability	North American Reading Test (NART) Vocabulary (WAIS-III)
Verbal memory	Rey Auditory Verbal Learning Test (RAVLT) California Verbal Learning Test (CVLT) Logical Memory Test (from WMS) CERAD Word List Test
Visual memory	Visual Reproduction (from WMS-III) Rey Osterrieth Figure Drawing Test (RFDI)

Depression	Geriatric Depression Scale (GDS) Hamilton Depression Rating Scale (HDRS)

WAIS-III. Wechsler Adult Intelligence Scale, ed 3; WMS-III. Wechsler Memory Scale, ed 3.

is attempting to recall words from a previously learned list), and repetitions.³⁹ This finding is observed on tests of both word lists and stories.⁴⁰

Very recent research has focused on clarifying other aspects of episodic memory problems, highlighting the attentional and organizational skills required that may help better characterize the deficits in very mildly impaired patients.⁴¹

Visual memory may also be assessed, although there is some evidence that visuospatial skills naturally deteriorate with age, making these tasks less discriminatory. However, some recent studies have identified nonverbal memory impairments in very mildly impaired AD patients compared with normal controls. For example, performance on the recall portion of the Rey-Osterrieth Complex Figure Test (RCFT) has been shown to be impaired even in very mild AD patients.⁴²

Difficulties with executive functioning may be the first symptom to appear after episodic memory impairments.⁴³ Those with AD exhibit marked difficulty relative to normal controls with various executive functions including cognitive flexibility, problem solving, parallel processing, planning, set shifting, and abstract thinking. These deficits, which worsen as the disease progresses, are observed on lower than expected performance on common tests of executive function including phonemic fluency, card sorting, and trail-making. The careful measurement of various executive abilities is important in those with early AD because deficits in this area have been consistently related to poorer functional ability,⁴⁴ ability to manage finances,⁴⁵ and higher need for care.⁴⁶

Language abilities are also impaired in early AD. Important language domains include naming, commonly assessed with a picture naming task such as the Boston Naming Test (a test of 60 pictures covering high and low frequency words), and fluency, which is assessed by assessing the rate of production of words beginning with a given letter (phonemic fluency) or within a given category (semantic fluency).

Confrontation naming is impaired early,⁴⁷ and unlike healthy elders who also have benign "senior moments," those with AD often do not benefit from cues, either semantic (giving hints about what the object is) or phonemic (saying the beginning of the sound of the word). A considerable amount of research indicates that scores on the BNT can effectively discriminate among normal controls, MCI, and AD patients.^{48,49} Difficulties with naming and fluency worsen as AD progresses.⁵⁰ However, in early AD patients, basic comprehension and verbal expression are intact.

Semantic fluency test performance (e.g., naming as many animals as possible in 60 seconds) is impaired very early in AD, relative to phonemic fluency.^{51,52} Some suggest⁵³ that animal naming is more difficult due to impairment of semantic knowledge and executive function required for any category test.

Simple attention (measured, for example, by Digit Span) is usually preserved in early AD. However, tasks that require divided attention (Trails B) or selective attention (the Stroop Test) are usually difficult for the AD patient⁴³ and may reflect problems with working memory, which involves the ability to process and respond to several pieces of information simultaneously. Some researchers have observed relatively

intact divided attention ability in very mild AD patients,^{41,35} though problems are more significant at the moderate stages of the illness.⁵⁴

Visuospatial functioning may be preserved, relative to memory, language, and executive function. However, deficits may be seen on visuoconstructional tests, such as clock drawing and complex geometric figure drawing.⁵⁵ Deficits in visuospatial abilities have been associated with wandering and driving difficulties.⁵⁶ Performance on tests of visuospatial functioning (e.g., the copy portion of the Rey-Osterrieth Drawing Test) may be confounded by cognitive demands that are more executive than visuospatial, namely planning and organization, and difficulties with these abilities may artificially lower test scores. Other tests of visuospatial function that do not have a high executive demand, such as the Judgment of Line Orientation Test, may be a more accurate measure of pure visuospatial ability.

In summary, a typical early AD profile, in the absence of significant depression, might reveal (1) moderately impaired initial learning with significantly impaired delayed recall on tests of verbal memory, (2) relatively well-preserved performance on phonemic fluency in context of impaired semantic fluency and naming, (3) intact simple attention, (4) impaired performance on executive functioning tests measuring cognitive flexibility and planning through abstraction may be well-preserved, and (5) mildly impaired performance on tests of visuospatial and visuoconstructional ability.

Mild cognitive impairment

Mild cognitive impairment (MCI) has been characterized as a transitional phase between the cognitive changes associated with normal aging and dementia.⁴⁹ Though there are no universally accepted criteria for the diagnosis of MCI,⁵⁷ criteria include memory complaint and objective memory impairment compared to age-matched elders with other cognitive domains and daily function relatively intact. Conversion rates for this group of MCI patients to AD may range 12% to 15% a year⁵⁸ and up to 80% at 6 years⁵⁷ (Petersen, 2004). Furthermore, a group of MCI patients with multiple cognitive domain impairments including memory impairment (but who do not meet criteria for dementia) have been shown to convert to AD at a rate of 50% at 3-year follow-up,⁵⁹ suggesting that this group may represent the highest conversion risk.

Recently, the MCI criteria have expanded to include non-amnesic MCI, representing impairments in nonmemory domains (e.g., language, executive function), that may place one at a high risk for developing another form of dementia, such as vascular or frontotemporal dementia.^{60,61} One large study⁶² observed that those with nonamnesic multidomain MCI were in fact more likely to develop a non-Alzheimer's type dementia.

Recent studies⁶³ have observed that neuropsychological testing can identify those at highest risk for progressing to dementia within 5 years, even among these patients with very mild cognitive impairments who do not meet formal research criteria for MCI. A review by Twamley and colleagues⁶⁴ highlighted the importance of the role of attention in context of memory, language, executive function, and processing speed regarding those who later developed dementia.

There is intense interest in neuropsychological measures that can identify impairment in its earliest stages and in better understanding the cognitive decline evident years before a diagnosis of dementia,^{65,66} as this could allow the development of useful clinical trials and earlier intervention.⁶⁷ Poor performance (usually defined as >1.5 standard deviations below age-adjusted norms) on standardized tests of verbal memory (e.g., delayed recall of word lists) or executive ability (e.g., Trails B, Stroop Interference Test) have been shown in numerous studies to be sensitive predictors of progression to AD in those with amnesic MCI^{68–72} and in discriminating MCI from AD.⁷³ In some studies⁵⁹ but not all,⁶⁹ naming and semantic fluency tests have also distinguished between amnesic MCI patients who convert to AD and those who do not.

Efforts have been made to identify simple screening tests that could be conducted in the primary care office to diagnose MCI, with limited success. Mitchell⁹ reported in his meta-analysis of eight studies examining the ability of the MMSE to distinguish AD from MCI or MCI from healthy controls, that overall, the measure did not discriminate well between either normal aging and MCI or MCI and early dementia. Some have suggested⁷⁴ that examining specific scores of the MMSE, rather than the total score, may help better distinguish amnesic and non-amnesic MCI patients from normal controls. Among those with non-amnesic MCI, neither the MMSE nor the Mini-Cog had adequate sensitivity as screening instruments.¹⁸ However, the Montreal Cognitive Assessment (MoCA) has shown some promise in its ability, in those with a MMSE of at least 26, to distinguish normal controls from MCI and MCI from early AD with a high degree of accuracy¹⁹ and has been used with those with Parkinson's disease to identify MCI in patients whose MMSE scores were in the normal range.⁷⁵

To identify the largest group of at-risk patients (including amnesic, nonamnesic, and multi-domain MCI), a thorough neuropsychological evaluation that includes measures of delayed recall, executive function, and language still remains the most effective way to identify MCI.⁷⁶

In summary, patients with MCI may have cognitive complaints but no significant functional decline; neuropsychological testing can identify significant memory impairment relative to normal controls in those with amnesic-MCI, with a significant number ultimately converting to AD. Those who have cognitive complaint and a nonamnesic area of decline (e.g., language, executive function) may be at greater risk of developing a non-Alzheimer's dementia.

Vascular dementia

Vascular dementia is the most common cause of dementia after Alzheimer's disease and it is estimated to account for approximately a third of all dementia cases. Many diagnostic classification schemes exist for vascular dementia and vascular cognitive impairment but most exclude the focal cognitive deficits of stroke and consider those conditions with impairment in multiple cognitive domains. The diagnosis is largely dependent on the history or presence of clinical stroke or radiologic findings of infarct. The diagnostic problem is further complicated by the fact that vascular disease and cerebrovascular disease often co-occur with Alzheimer's disease and other dementias. Critical issues

related to the criteria for diagnosis of vascular dementia include the definition of the cognitive syndrome (i.e., the type, extent, and combination of cognitive impairments), attention to additive effects on cognitive impairment in the presence of comorbidity, and temporal occurrence of symptoms and deficits.

Accurately identifying vascular dementia requires careful attention to historical information. The onset may be both rapid and temporally related to a stroke-like event, or it may be gradual with a progression that is described as stepwise. Reports of an accumulation of cognitive worsening and functional incapacity are common.

Wiederkehr and colleagues⁷⁷ examined diagnostic criteria for eight cognitive syndromes in vascular disease. Although DSM-IV VaD criteria require memory impairment,⁷⁸ the widely used NINDS-AIREN criteria for vascular dementia (VaD) include memory impairment (either in anterograde or retrograde memory) along with deficits in two or more other cognitive domains, which are sufficient to interfere with activities of daily living.⁷⁹ In clinical practice, among those with a history of stroke, the cognitive criteria may be assessed by the report of cognitive deficit in the absence of formal testing. However, several studies suggest that when these individuals are diagnosed clinically, group comparisons with AD subjects often find the VaD group to have less severe memory impairment. The pattern that is often reported within VaD is one in which working memory is more likely to be impaired than delayed recall, a pattern which is the opposite of AD.⁸⁰ Cued recall and recognition of previously learned material is generally intact, unlike AD.

Executive function is commonly impaired in VaD and the deficit may be disproportional to other cognitive deficits such as memory.⁸¹ Executive function deficit is also more commonly reported in VaD than in AD, at least at the mild and early forms of dementia.

Regarding language, naming and verbal fluency impairments are common particularly with subcortical and thalamic infarcts. Verbal fluency is usually impaired, though the distinctive pattern of preserved phonemic fluency and impaired semantic fluency so often seen in AD, is uncommon.⁸² In fact, some studies suggest that in contrast to AD, patients with VaD have worse phonemic fluency scores relative to semantic fluency,^{83,84} which may reflect an executive function impairment severe enough such that even the structure of the alphabet is not sufficient to organize the patient's responses.

Another area reported to be impaired in VaD is psychomotor speed and measures of attention. Although focal deficits can be responsible for some such impairments, they may be exacerbated by depression, which is a common concomitant of VaD.⁸⁵

A prodromal condition of vascular cognitive impairment (VCI) has been described. This condition, characterized by cognitive complaints observed by the patient or others, is associated with impairment in any of a wide range of neuropsychological functions.^{86,87} Recent longitudinal data suggests that the presence of multiple cognitive impairments is predictive of the transition from VCI to VaD.⁸⁷

In summary, VaD and VCI may have a less robust episodic memory deficit with the possibility of a range of

impairments. The likelihood of executive function deficit and depression are higher than in AD. Although the precision of diagnosing VaD and other cognitive syndromes is hampered by the breadth of the possible deficits, it is important to consider vascular condition and risks because many may be controlled, hopefully stabilising cognition.

Frontotemporal dementia

Frontotemporal dementia (FTD) is a common cause of dementia in those under 65 years old⁸⁸ and may account for 20% of dementia cases in those 45 to 65 years old.⁸⁹ It is important to distinguish AD and FTD because treatment and prognosis may differ, yet efforts to distinguish the two clinically have been met with limited success. The efficacy of cholinesterase inhibitors is perceived to be highest in AD and poorest in FTD. Perceived efficacy is affected more by whom is treated than by what is used.⁹⁰ In the past several decades, numerous terms have been proposed to describe this complex group of related but distinct conditions associated with pathology in the frontal and anterior temporal areas, including dementia of the frontal lobe type,⁹¹ frontotemporal lobar degeneration,⁹² Pick's disease,⁹³ and familial chromosome 17-linked frontal lobe dementia,⁹⁴ among others.

Currently, the term frontotemporal dementia (FTD) is frequently used with two variations, semantic dementia (SD) and progressive nonfluent aphasia (PNFA). Typically, the primary characteristics of FTD are early age of onset (45 to 65) relative to AD, a more precipitous course, and early behavioral changes including disinhibition, apathy, hyperorality, and inappropriate social interaction.²⁶ The striking and early behavioral symptoms necessitate a differential diagnosis not just among dementias, but between dementia and psychiatric illness.⁹⁵

Neuropsychological profiles in FTD patients are, compared with AD patients, characterized by poor executive and language function and relatively spared memory function, particularly early in the illness. Efforts to distinguish FTD from AD patients using neuropsychological tests have been inconsistent, in part due to small sample sizes, different stages of illness, and varying diagnostic criteria.

Regarding memory function, performance on the delayed recall and retention portion of word list tests is better preserved in FTD patients relative to those with AD.⁹⁶ Overall better memory performance (compared with other cognitive functions) has been noted in other studies as well regarding both delayed recall and the ability to use cues.⁹⁷

On language tests, studies have suggested that those with FTD are more impaired than those with AD on tests of verbal fluency. Specifically, Rascovsky and colleagues⁹⁶ found that compared with AD patients, those with autopsy-confirmed FTD exhibited more impairment on verbal fluency tests (both semantic and phonemic) perhaps due to the significant executive demand of search strategies. Some have observed more impaired phonemic fluency compared with semantic fluency in those with FTD,^{98,52} the reverse of the pattern typically observed in AD.

On tests of executive function, FTD patients may be proportionately worse on tests of cognitive set switching and cognitive flexibility than memory tests.⁹⁹ FTD patients may have difficulty with selective and divided attention, but these results are not consistent.¹⁰⁰

Visuospatial skills are relatively intact relative to other cognitive deficits,¹⁰¹ though visuospatial tasks that include significant executive ability such as organization and planning (e.g., the Rey Osterrieth Copy Test) may prove difficult. Clock drawing and block design may be better measures of visuospatial ability in FTD.

In summary, early behavioral change is the "red flag" of FTD, accompanied by relatively spared memory and visuospatial skills, but impaired language and executive function.

PRIMARY PROGRESSIVE APHASIAS: SEMANTIC DEMENTIA (SD) AND PROGRESSIVE NONFLUENT APHASIA (PNFA)

Semantic dementia

Semantic dementia (SD), characterized by atrophy in the left anterior temporal lobe, is associated with severe and progressive problems with naming, category fluency, picture naming, and comprehension.¹⁰² Language problems begin first and by definition, one must have had a 2-year period of language impairment in the relative absence of other cognitive difficulties. Scores on category fluency may be worse than letter fluency, and naming may be worse than comprehension.¹⁰³ Later in the illness, despite profound deficits in semantic memory and meaning, expressive language may retain its fluency (e.g., normal prosody and volume), but often grows increasingly empty.

Early in the illness, visuospatial, attentional, and executive abilities generally remain relatively intact, and the significant behavioral symptoms associated with FTD absent. Regarding memory function, one study observed poor delayed recall, but normal new learning in those with semantic dementia.⁹⁸

Progressive Nonfluent Aphasia (PNFA)

Progressive nonfluent aphasia (PNFA), associated with damage in the left perisylvian language areas, is characterized by preserved comprehension, but poor expressive language. Speech may be hesitant, accompanied by poor articulation, dysarthria, and profound word finding difficulty not accounted for by stroke. The behavioral problems associated with FTD are generally not present.

Performance is poor on tests of verbal fluency. Some researchers¹⁰⁴ argue that category and letter fluency tests can help distinguish among SD, PNFA and AD, with AD patients least impaired and PNFA patients most impaired on letter fluency. However, others have found that fluency tests do not distinguish among FTD, PNFA, and SD patients.⁹⁸ This may be because many cognitive abilities are involved in this test. However, Hodges and colleagues¹⁰⁵ observed that a simple "Repeat and Point" test was effective in distinguishing semantic dementia from PNFA, with poor performance by SD patients on pointing (comprehension), and poor performance by PNFA patients on repeating.

There is evidence of slower executive functioning performance compared with patients with either semantic dementia or AD.⁹⁸ However, compared with patients with FTD, executive function and attention may be relatively well-preserved.¹⁰⁶ Episodic memory scores are generally intact early in the illness,¹⁰⁴ though due to the nature of the illness

(poor expressive language), nonverbal tests of memory may be more useful.

Parkinson's disease dementia (PDD) and dementia with Lewy bodies (DLB)

The dementia associated with Parkinson's disease, which may develop in 20% to 40% of Parkinson's patients,¹⁰⁷ is consistent with a typical subcortical pattern, namely impairments in attention (including working memory and divided attention), executive function (particularly planning and set shifting), and visuospatial function. The onset is typically insidious, with variable rates of progression, and the dementia must follow onset of motor symptoms by at least 1 year.¹⁰⁸ The cognitive deficits are in the context of a mildly impaired episodic memory, with problems with delayed recall but intact cued recognition. Compared with other impairments, language function is relatively well-preserved.¹⁰⁹ Neuropsychiatric symptoms, including hallucinations and depression, are frequent.¹¹⁰

Most research concurs that episodic memory deficits are milder in PDD than in AD, and that the problems are due more to deficits in retrieval than encoding and storage.^{111–113} This is illustrated by the ability to recall previously learned information when provided cues.

Compared with AD, PDD patients exhibit poor executive functioning^{114,115} noted by poor performance on tests of initiation/perseveration and card sorting.¹⁰⁶ Deficits on attention tests distinguish PDD from AD,¹¹⁶ particularly on tasks that require divided attention.¹¹⁷

Visuospatial task performance may be more impaired in PDD than AD, including pentagon copy.¹¹⁸ Patients with PDD exhibit cognitive slowing, but measuring this is often complicated by the fact that most tests have some motor component,¹¹⁹ making it difficult to distinguish the physical from the cognitive.

It is important to measure depression as it occurs in up to 50% of Parkinson's patients, and its presence may exacerbate poor neuropsychological test performance.¹²⁰ Furthermore, the presence of depression is associated with more significant cognitive impairment, even in those Parkinson's patients without dementia.¹²¹

There is a long literature describing cognitive deficit in PD patients without dementia. Recently, these deficits have been labeled mild cognitive impairment (MCI) with the observation that it frequently progresses to dementia.^{122,123} This notion is controversial and still being developed. One study¹²⁴ found that single and multiple nonmemory domain PD-MCI patients were more likely to convert to dementia than the PD-MCI amnesic group.

In summary, the dementia associated with PDD is characterized by high rates of depression and by a subcortical pattern of poor attention, visuospatial and executive functioning, slowed processing speed with relatively spared memory and language abilities.

Dementia with Lewy bodies

The complex role of Lewy body pathology in dementia with Lewy bodies (DLB) and its relationship to PDD is not fully understood.¹¹⁸ The primary triad of symptoms associated with DLB includes fluctuating cognition (e.g., attention and alertness that vary noticeably day to day), Parkinson-like symptoms (e.g., bradykinesia, rigidity, and gait disturbance)

and visual hallucinations. Other symptoms may include rapid eye movement sleep disorders, and frequent falls. Accurate diagnosis of DLB is critical because DLB is associated with a dangerous sensitivity to neuroleptic medications.¹²⁵ The cognitive changes observed in PDD and DLB are so similar that the two disorders are clinically distinguished by the timing of the onset of symptoms: the motor symptoms in DLB patients occur no more than 1 year before the onset of dementia and frequently after the onset of dementia in contrast to PDD, where motor symptoms must precede dementia by at least a year.¹⁰⁷

Characterizing DLB with neuropsychological testing can be difficult, as the cognitive deficits often overlap with those of AD and PDD, but most closely resemble PDD.¹¹¹ Memory is impaired, though not as severely as in AD, and, as in PDD, the problem is more one of retrieval than encoding.¹²⁴ Taken together, studies suggest that DLB patients, compared with AD patients, exhibit more severe deficits in executive functioning, visuospatial functioning, and attentional abilities.^{111,126,127} Poor visuospatial function appears to be a predictor of further cognitive decline in those with DLB but not AD.¹²⁸ In DLB, the poor performance on tests of visuo-perceptual and spatial functions may be related to the fact they are vulnerable to visual hallucinations.¹²¹ Though it is difficult to distinguish DLB from PDD with neuropsychological testing, a handful of studies have observed poorer performance by DLB patients on tests of attention, visuo-perceptual skills, and executive function, controlling for illness severity.^{111,129}

In summary, DLB is difficult to distinguish from PDD and AD with neuropsychological testing, though the cognitive impairments, which usually precede any Parkinsonian symptoms, are more likely to resemble PDD and be accompanied by fluctuating attention and visual hallucinations.

Mood: distinguishing depression from dementia

Older adults may have symptoms of forgetfulness and apathy that relate to depression, dementia, or both. Distinguishing dementia from depression is critical because of the comparative success with which depression can be treated. Patterns on test performance emerge that suggest depression or early dementia, and in conjunction with clinical history, results may help in predicting which nondemented depressed patients are at high risk for developing dementia.

In the past, the term "pseudodementia"¹³⁰ was used to describe the presence of forgetfulness and confusion in the presence of depression. However, recent research shows that even after depressive symptoms are successfully treated, for many the cognitive deficits remain.¹³¹

In elderly patients with depression, significant cognitive impairment is common¹³² and the severity of impairment on tests of memory, executive function, processing speed, attention and language generally falls somewhere between normal controls and those with early AD. Among depressed nondemented patients, difficulties with attention and executive function may be the primary cognitive complaints. Elderly patients experiencing a first-time depression exhibit problems with executive function and attention, with less relative memory impairment, compared with either those with recurrent depression or normal controls.¹³³ Older depressed adults without dementia perform poorly on tests

of psychomotor speed and various aspects of executive function compared to those without depression.^{134,135}

Some have observed¹³⁶ that the cognitive deficits associated with depression fit a more subcortical than cortical pattern, with the relative preservation of language, memory, and praxis relative to AD patients. On tests of verbal memory, depressed patients perform better than AD patients with less impairment in retention and recognition of previously learned material.¹³⁷

Regarding language, a meta-analysis of fluency in depressed elderly patients observed that AD patients were more impaired on both phonemic and semantic fluency than depressed patients, though the relative severity of semantic fluency impairment in AD patients remained.¹³⁸

Some research suggests that specific neuropsychological profiles may predict which depressed patients are at high risk for developing dementia. In a small retrospective study, Jean and colleagues¹³⁹ observed in a group of elderly depressed patients that baseline performance on tests of attention and memory were more impaired in those with subsequent dementia—with additional deficits in orientation in those who went on to develop AD, and in executive and visuospatial function in those who developed Lewy body or vascular dementia. Repeated neuropsychological evaluations may be useful in those with depression with cognitive complaints, as one large prospective study¹⁴⁰ suggests that cognitive functioning will continue to decline in depressed patients who eventually develop dementia, and that baseline neuropsychological test performance (including executive function, visuospatial ability, and delayed recall) was lower at baseline in those depressed patients who went on to develop

dementia. These studies underscore the usefulness of neuropsychological evaluation in depressed patients who also have cognitive complaints.

The relationship between depression and AD is complex.¹⁴¹ The issue centers on whether depression in late life (whether recurrent or initial onset) may herald incipient dementia.^{142,143} or whether the presence of depression is a risk factor for the later development of dementia.^{144,145} A considerable amount of recent research has examined factors that may affect this distinction, including the proximity of depression and dementia,¹⁴⁶ whether the depression onset is early or late,¹³⁸ the presence of vascular illness,¹⁴⁷ and gender.¹⁴⁸

In summary, though the relationship between depression and dementia is complex and not fully understood, a clinical presentation of depression, particularly with symptoms of apathy and cognitive complaints, warrant neuropsychological evaluation. The results, particularly if measured on more than one occasion, may help in determining whether the patient has depression, dementia, or both. A summary of the pattern of cognitive deficits associated with different dementias and depression may be found in [Table 53-2](#).

Other areas that may be measured

Level of independence with activities of daily living (ADL) and instrumental activities of daily living (IADL) should always be evaluated, either informally or with standard measures. Impairment in these areas has a dramatic impact on both the patient and caregiver regarding quality of life, caregiver burden, and decisions regarding nursing home placement. Activities of daily living include highly overlearned tasks, such as dressing, toileting, and grooming, whereas

P, Preserved; V, Variable; I, Impaired.

instrumental activities of daily living refer to more complex tasks with greater cognitive demand such as managing money, cooking, and shopping. Decline in ability to manage IADL may happen relatively early in AD, and is related to deficits in memory, sustained attention, and problem-solving. Most patients in the mild to moderate stages of AD evidence some difficulty with medication, cooking, and shopping.¹⁴⁹

SUMMARY

Neuropsychological testing is a valuable tool in the identification and description of many cognitive disorders and can aid in the differential diagnosis of normal aging, MCI, AD, and other dementias, including depression. Screening tools are useful for quick assessment of those who may be in need of further evaluation.

The variability among neuropsychological profiles is most apparent in the first several years of the illness, underscoring the importance of early evaluation, diagnosis, and treatment. Knowledge of a dementia diagnosis early on can improve health outcomes in several ways: by initiating pharmacologic treatment during the time of illness in which it works best, by providing clinical research opportunities to families that could lead to better treatment, and by giving the patient the opportunity, while they still retain decisional capacity, to prepare for the future by creating advance directives, and making decisions about finances and other family matters.

A frank and empathic discussion may also help alleviate the guilt and blame that occurs when the patient or caregiver has been under the erroneous impression that the cognitive deficits would disappear if only one "tried harder." The role of the caregiver cannot be underestimated, and as psychosocial interventions for caregivers are effective,¹⁵⁰ an early and accurate diagnosis of a loved one

may open the door for the caregiver to seek both support and education.

KEY POINTS

Neuropsychology in the Diagnosis and Treatment of Dementia

- Neuropsychological testing is an effective way of identifying very early cognitive impairments and distinguishing them from normal aging, MCI, and various types of dementia using relatively brief batteries of tests.
- Neuropsychologists can assist in characterizing cognitive loss, its causes and consequences, distinguish between dementia and comorbidities such as depression, and determine decisional capacity.
- Patients who have cognitive impairments in context of either motor symptoms (e.g., gait changes) or behavioral symptoms (disinhibition) should be referred for a neuropsychiatric evaluation.
- Early diagnosis of a dementia or depression is critical in terms of treatment effectiveness, future planning, and quality of life.
- Screening measures (e.g., MMSE, clock drawing) are useful tools to monitor changes in functioning over time and to identify "red flags" that may warrant referral to a neuropsychologist or other specialist, though they lack diagnostic reliability.
- Comprehensive assessment of memory loss is the core feature of a dementia evaluation. Non-Alzheimer's dementias may be characterized by other cognitive or behavioral impairments, such as language (SD, PNFA), executive function (PDD, VD), personality changes (FTD), and psychotic symptoms (DLB).
- A clinical presentation of depression, particularly with symptoms of apathy and other cognitive complaints, warrants neuropsychological evaluation.

Alzheimer's disease (AD) is the most common cause for dementia afflicting older adults. The illness was first described by Alois Alzheimer in 1906 in a 51-year-old woman with well-described features of dementia. After death her brain was examined and found to have numerous cortical plaques and tangles, characteristic of the illness.¹ The disease was thought to be rare for six decades until its clinical and neuropathologic features were recognized to be largely identical to those occurring in elderly dementia patients.²

The illness is by far the most frequent cause of dementia in the United States, currently afflicting as many as 5.2 million mostly elderly individuals.³ The incidence doubles every 6 years after the age of 50. As the over-age-80 population has rapidly grown, with improved health care leading to longer survival, it is estimated that the prevalence of AD in the United States by 2050 will almost triple to 11 million to 16 million Americans.⁴ This disabling disease is by far the most common cause of neurodegeneration and the major condition leading to nursing home placement. The economic costs are huge with direct health care, nursing home costs, and caregiving costs at home globally totaling greater than \$315 billion.⁵ Only symptomatic therapies are currently available, but no known therapy delays or halts disease progression. If a drug or lifestyle alteration (e.g., diet, exercise) could be found that delayed functional deterioration by as little as 1 to 2 years, it would substantially reduce the costs to both families and society.

PATHOLOGY AND MECHANISMS OF DISEASE

In AD, the illness begins with atrophy in the entorhinal cortex and hippocampus, and as clinical symptoms worsen, there is spread to, more generally, most areas of the cortex, excepting only the occipital lobes.⁶

Microscopic examination of cortical sections from the brain of a patient with AD reveals global loss of neurons and increased numbers of extracellular amyloid plaques.⁷ The amyloid plaques are both "diffuse," possibly benign, since similar deposits may be found in normal elderly individuals, and "compact," often associated with neuritic changes, possibly caused by the effects of the deposited amyloid or by smaller oligomers of the β -amyloid protein on surrounding dendrites and axons (Figure 54-1). β -Amyloid proteins are also frequently found deposited diffusely in cerebral blood vessel walls. In addition to β -amyloid plaques, intracellular lacy fibrillar accumulations of material are present in neurons, called neurofibrillary tangles (NFTs)⁸ (Figure 54-2). NFTs are composed of paired helical filaments largely consisting of abnormally hyperphosphorylated tau. These are the defining features originally described by Alzheimer 102 years ago.

The amyloid plaques are made of β -amyloid proteins of various lengths from 39 to 42 amino acids long.⁹ The β -amyloid 1–40 amino acid type is in plasma and CSF, but the 1–42 form comprises the major component of the cores of these amyloid plaques. The β -amyloid proteins are derived

from a larger widely present transmembrane protein in the brain called the amyloid precursor protein (APP). They are cleaved from APP by the β -secretase and γ -secretase enzymes, which have been recently characterized and are active targets for drug therapy.¹⁰

Mutations have been found to be associated with familial AD, as will be described later in this chapter, in both the genes coding for the β -amyloid proteins and for the presenilins, which likely are a component of γ -secretase.¹¹ Studies of the effects of these mutations in cell lines and transgenic animals that develop amyloid deposits and plaques in their brains similar to patients with AD have provided insights into how these proteins normally function and how, when disturbed by mutation, their functions are altered, leading to dementia. Those findings should give insights into sporadic AD, and, using these models, several drugs have been developed to reduce production of the amyloid β proteins or speed their metabolism and clearance. It is hoped that these drugs will also be effective for sporadic AD.

Interestingly, although considerable evidence suggests that β -amyloid and its toxic effects on the brain may initiate the cascade of pathophysiologic processes that leads to AD, progression of dementia correlates more closely to numbers of NFTs or number of synapses lost.

Clearly a cascade of processes involving different mechanisms, including inflammation and disturbed calcium homeostasis, occurs as AD progresses (Figure 54-3). Neurotransmitter systems are differentially affected. The cholinergic system is susceptible to early dysfunction, and increasing cholinergic deficiency has been correlated with clinical progression. As AD progresses, the glutaminergic, noradrenergic, and serotonergic systems deteriorate, causing further cognitive losses and often behavioral abnormalities. Therapeutic research since the late 1980s has focused on correcting these neurotransmitter deficits, with some modest success and resulting clinical benefits.

Extracellular amyloid plaques and intraneuronal NFTs in the cortex are the cardinal features of AD. Stereotypic spread of the NFTs, as originally described by Braak and Braak (1991),⁶ defined a basis for neuropathologic criteria for AD staging that still is useful today. NFTs are found in the entorhinal cortex and adjacent areas of the hippocampus. Braak stages I and II typically are not associated with clinical symptoms. In stages III and IV, NFTs have spread to the limbic regions, and cognitive deficits are present. By stages V and VI, NFTs have spread to other regions of the cortex excepting the occipital cortices, and the severity of the dementia is worse.

Substantial evidence suggests, however, that plaques and tangles can be found in substantial numbers in many elderly individuals with normal cognitive functioning and that considerable overlap exists in plaque and tangle pathology between very elderly normals (over age 90) and those in this age range with dementia, reemphasizing the necessity for clinicopathologic correlation in diagnosis.¹² Newer criteria assessing both plaque and tangle densities have been developed. Khachaturian criteria count numbers of amyloid

Figure 54-1. Neuritic plaques revealed by silver stain from cortex of patient with Alzheimer's disease.

Figure 54-2. Neurofibrillary tangles in cortical section of brain from patient with Alzheimer's disease.

plaques in a 1 mm² field of the neocortex with numbers adjusted for age.¹³ The Consortium to Establish a Registry for Alzheimer's Disease criteria count plaques in three designated brain regions using defined stains.¹⁴ More recently the Reagan criteria assess both plaques and tangle numbers in a highly specified way and appear to have generally high correlation in confirming the diagnosis of AD and in assessing disease stage.¹⁵

EPIDEMIOLOGY AND GENETICS OF ALZHEIMER'S DISEASE

Aging is the biggest risk factor for Alzheimer's disease. Rarely patients in their 20s and 30s have been reported to have AD, but onset of clinical symptoms is uncommon until the 50s with yearly probability of incidence rapidly increasing to age 65 to 75, when 1% to 5% of the general population is affected. By age 75, the prevalence is as high as 15% in the United States, and by age 85 it has been estimated to afflict 35% to 50% in the very old age range.¹⁶ Studies suggest the prevalence continues to climb, with the majority of individuals by their 90s showing clinical signs of at least early dementia. However, in these oldest old with dementia, underlying brain pathology may differ little from age-matched normal subjects other than demented patients have greater neuronal losses, and their rate of disease progression may be relatively slow. Therefore, even though these patients meet current clinical criteria for AD, it is unclear that these individuals really have the same illness. The second most common risk factor for AD is family history, with approximately 20% of patients with AD having two or more first-degree relatives affected. The pattern of inheritance is typically autosomal dominance.

In families with AD, several genetic mutations have been identified that are causative for the disease. Almost all of the known mutations cause presenile forms of the disease. A few dozen families with onset of AD predominantly in the 40s and 50s have mutations in the APP gene, usually in the region of the gene that codes for the β -amyloid proteins. It is thought that these mutations result in abnormal

Figure 54-3. The cascade of mechanisms in Alzheimer's disease. Hypothetical cascade of processes occurring as Alzheimer's disease progresses. The specific abnormalities are well established, but their order with regard to causality remains controversial. MCI = mild cognitive impairment; AD = Alzheimer's disease.

β -amyloid metabolism with resultant chronically higher levels of amyloid β proteins leading to AD.¹⁷

The other mutations causing early onset familial disease have been localized to the presenilin-1 (PS-1) gene on chromosome 14 and the presenilin-2 (PS-2) gene on chromosome 1. Again, only a few dozen families have been found in which PS-2 gene mutations are associated with AD, whereas more than 160 different mutations in the PS-1 have been found in several hundred families to cause AD and occasionally other symptoms such as spasticity or seizures.¹⁸ The presenilins are part of a complex that acts functionally as γ -secretase.¹¹ As previously mentioned, γ -secretase slices APP to produce β -amyloid.

Increased levels of β -amyloid are also found in AD patients with PS-1 or PS-2 mutations.¹⁷ These mutations are the most commonly known cause of autosomal dominant familial AD, but they still cause less than 1% of all cases of AD. Even in patients with family history of onset of dementia under the age of 65, these mutations are causative in less than 10%. An early-onset patient with AD is more likely to have one of these mutations if there is family history of multiple other affected family members having similar early age of onset. Rather than aid in confirming the diagnosis or risk for AD in a limited number of these relatively rare families, the major importance of these mutations has been to create transgenic animals that have been useful in unraveling disease mechanisms and to speed development of new drugs and testing and other novel therapeutic approaches, such as targeted immunologic stimulation by β -amyloid vaccination or administering monoclonal antibodies targeted to the β -amyloid proteins to accelerate their degradation.

The major genetic risk factor identified for AD in both late onset, sporadic and familial patients is the $\epsilon 4$ polymorphism of the APOE4 gene.¹⁹ APOE is one of the major cholesterol- and lipid-carrying proteins in peripheral blood. In the brain and spinal fluid compartments, it is the only significant lipid transport protein and also functions as a transport protein for β -amyloid. It comes in types $\epsilon 2$, $\epsilon 3$, and $\epsilon 4$, with the $\epsilon 2$ allele being relatively uncommon. The $\epsilon 4$ allele is carried by 15% to 20% of the general population, and the $\epsilon 3$ allele by almost everyone else. The 1% to 2% of individuals who are homozygous for the $\epsilon 4$ have a 50% risk of developing AD by their mid to late 60s. Those who are heterozygous for the $\epsilon 4$ allele have a 50% risk of developing AD by their mid to late 70s.¹⁹ Women heterozygous for $\epsilon 4$ are more likely to develop AD at an earlier age than men. Individuals who carry only the $\epsilon 3$ or $\epsilon 2$ alleles are likely not to develop AD in their 80s or not at all. Some evidence suggests inheriting the $\epsilon 2$ allele may be protective, reducing risk for AD. Inheritance of the $\epsilon 4$ allele confers similar risk for AD regardless of whether or not there is family history. Determination of APOE genotype in a patient with dementia does improve diagnostic specificity in the subset of subjects with the $\epsilon 4$ genotype, but it is arguable whether diagnostic accuracy is improved enough to be clinically helpful. If subjects who are homozygous or heterozygous for $\epsilon 4$ and do not develop dementia in their at-risk age range, current evidence suggests their future risk of dementia is no greater than that of an age-matched non- $\epsilon 4$ carrier in the general population for developing AD. Therefore, presymptomatic APOE4 genotyping for future risk for AD is currently not recommended. Recently, it has been found that in individuals with

mild cognitive impairment (MCI), the APOE $\epsilon 4$ genotype is associated with a significantly greater risk for conversion to AD,²⁰ and that $\epsilon 4$ -carrying patients with MCI were more responsive to donepezil therapy.²¹ Clinical disease progression after conversion to AD is not influenced by APOE genotype, so the ApOE4 protein may be more influential in the earlier biologic stages of the illness, but once disease spreads and the cascade of destructive pathophysiologic processes begin, APOE genotype no longer influences rate of progression. Considerable evidence suggests in late onset Alzheimer's disease other, as yet unidentified, genetic polymorphisms play a role in increasing their risk for developing the disease.

Other factors that influence risk for AD are gender and education. Women are at greater risk for AD, even with adjustment for their greater survival to older ages. In the past, this greater risk for AD has been suggested by several epidemiologic studies to be due to postmenopausal estrogen deficiency, and estrogen replacement was believed to be a primary prevention for AD. However, the Women's Health Initiative Memory Study of estrogen in elderly women has shown that estrogen replacement may increase, rather than decrease, the risk for dementia.^{22,23}

In several studies, increased education has been associated with reduced overall risk for AD and/or later onset of the illness. It has been hypothesized that better-educated individuals have a greater cognitive reserve, so the underlying biologic process disease for the must progress further for clinical symptoms to develop.^{24,25} However, the protective effects of cognitive training and mental exercises have not demonstrated convincing benefits in delaying disease onset. Interestingly, several studies have suggested that physical exercise may be protective and decrease brain atrophy and/or delay disease progression.²⁶

Epidemiologic studies and small pilot trials have suggested that nonsteroidal anti-inflammatory drugs (NSAIDs) prevented or delayed progression in AD.²⁷ However, several large double-blind, placebo-controlled trials have indicated no significant reduction in risk for AD with NSAIDs and, rather, a significant increased risk for gastrointestinal symptoms, such as hemorrhage, and cardiovascular disease including stroke.^{28,29}

Head trauma has been suggested as a risk factor for AD, but studies have been muddled by wide differences in reported series in the criteria used for defining what constitutes significant previous head trauma history. Further, APOE $\epsilon 4$ patients have been demonstrated to recover less completely from head trauma, so a more prominent history of head trauma may be a pseudomarker for carrying the APOE $\epsilon 4$ polymorphism, which is a risk factor for AD.³⁰

More recently, a number of studies and trials have suggested the metabolic syndrome increases risk for AD.³¹ Specifically the main features of the metabolic syndrome; diabetes mellitus or insulin resistance, high cholesterol, hypertension, and obesity are all suggested risk factors for AD. Several prospective are investigating whether improving or treating these factors individually will reduce conversion of normal or MCI individuals to AD and/or delay progression of AD in subjects already affected. It remains to be determined whether these approaches: such as treating hypertension such as treating insulin resistance with glitazones, and statins to reduce cholesterol, are effective. In a related therapeutic approach, some recent studies have suggested

exercise may delay progressive brain atrophy in patients with AD.

CLINICAL DIAGNOSTIC CRITERIA FOR ALZHEIMER'S DISEASE

Criteria for the clinical diagnosis of AD have been developed and are widely used to diagnose this form of dementia. These are the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV)*³² and consensus criteria developed by the National Institute of Neurological and Communicative Disorders and Stroke and the Alzheimer's Disease and Related Disorders Association (NINCDS-ADRDA).³³

The DSM-IV criteria are more general, essentially requiring insidious and progressive memory and cognitive impairments where other potential causes have been excluded (Table 54-1).

NINCDS-ADRDA criteria for "definite AD" require clinical features for probable AD and autopsy confirmation. A diagnosis of "probable AD" requires deficits in two or more areas of cognition, including memory, that are progressively worsening, confirmed by clinical and neuropsychological evaluations, and not caused by either delirium or other brain or systemic illnesses. Onset is between 40 and 90 years of age (Table 54-2). The diagnosis is further supported by impaired function in activities of daily living (ADLs) and altered patterns of behavior and family history (particularly if supported by previous neuropathology). Other features include supportive laboratory results. A diagnosis of "possible AD" includes cases where there is either a single progressively more severe cognitive deficit, or a second brain or systemic cause for their dementia, or an atypical onset (early or with unusual symptoms or course [unusually rapid or stuttering]). Both DSM-IV and NINCDS-ADRDA criteria rely heavily on history and the neurologic examination, and recent evidence suggests that both sets of criteria exclude broad populations of patients

Table 54-1. DSM-IV Criteria for Dementia

<p>Multiple Cognitive Deficits Criteria</p> <p>Criterion A</p> <ul style="list-style-type: none"> • Memory impairment • One or more of the following: <ul style="list-style-type: none"> • Aphasia (language disturbance) • Apraxia (impaired motor activity) • Agnosia (impaired recognition) • Disturbed executive function (planning, organization, etc.) <p>Criterion B</p> <ul style="list-style-type: none"> • Cognitive deficits in criteria A1 and A2 each cause: <ul style="list-style-type: none"> • Impairment in social or occupational functioning • Are not due to a CNS disease • Are not due to a medical disorder • Do not occur solely during the course of delirium • Criterion C: Gradual and continued cognitive decline • Criterion D: Other systemic neurologic and psychiatric illnesses should be eliminated • Criterion E: AD should not be diagnosed in the presence of delirium

Criteria adapted from American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR)*, 4th ed. Washington DC: American Psychiatric Association; 2000.

in very early stages of the illness who arguably may be more likely to respond to future disease progression—delaying therapeutic approaches. These patients typically have isolated amnesia with minimal impairment in function in ADLs and are labeled as having mild cognitive impairment (MCI). However, there has been resistance to this entity largely related to lack of consensus regarding the defining criteria, by various regulatory authorities. These or similar more expansive criteria will likely facilitate not just research studies with diagnosis but clinical care for such patients in general practice.

Table 54-2. NINCDS-ADRDA Criteria for AD

<p>I. Criteria for the Clinical Diagnosis of Probable AD</p> <ul style="list-style-type: none"> • Dementia established by clinical examination and documented by the Mini-Mental State Test, Blessed Dementia Scale, or some similar exam, and confirmed by neuropsychological tests • Deficits in two or more areas of cognition • Progressive worsening of memory and other cognitive functions • No disturbance of consciousness • Onset between ages 40 and 90, most often after age 65 • Absence of systemic disorders or other brain diseases that could account for the dementia <p>II. Conditions That Support a Probable Alzheimer's Disease Diagnosis</p> <ul style="list-style-type: none"> • Progressive deterioration of specific cognitive functions such as language (aphasia), motor skills (apraxia), and perception (agnosia) • Impaired activities of daily living and altered patterns of behavior • Family history of similar disorders, particularly if confirmed neuropathologically • Laboratory results of: normal lumbar puncture as evaluated by standard techniques; normal pattern or nonspecific changes in EEG, such as increased slow-wave activity; and evidence of cerebral atrophy on CT with progression documented by serial observation <p>III. Other Clinical Features Consistent with the Diagnosis of Probable Alzheimer's Disease</p> <ul style="list-style-type: none"> • Plateaus in the course of the illness • Associated symptoms: depression, insomnia, incontinence, delusions, illusions, hallucinations, catastrophic verbal, emotional, or physical outbursts, sexual disorders, weight loss, other neurologic abnormalities present in some patients, especially with more advanced disease may include motor signs such as increased muscle tone, myoclonus, or gait disorders • Seizures in advanced disease and structural imaging study (CT or MRI) normal for age <p>IV. Features that Make the Diagnosis of Probable AD Uncertain or Unlikely</p> <ul style="list-style-type: none"> • Sudden, apoplectic onset • Focal neurologic findings such as hemiparesis, sensory loss, visual field deficits, and incoordination early in the course of the illness • Seizures or gait disturbances at the onset or very early in the course of the illness <p>V. Some Criteria for Possible AD</p> <ul style="list-style-type: none"> • Dementia syndrome, in the absence of other neurologic, psychiatric, or systemic disorders sufficient to cause dementia, and in presence of variations in onset, in the presentation, or in clinical course • Presence of second systemic or brain disorder sufficient to produce dementia, which is not considered to be the cause of the dementia • A single, gradually progressive severe cognitive deficit identified in the absence of other identifiable causes <p>VI. Criteria for Diagnosis of Definite Alzheimer's Disease</p> <ul style="list-style-type: none"> • The clinical criteria for probable Alzheimer's disease • Histopathologic evidence obtained from a biopsy or autopsy
--

Dubois et al³⁴ have proposed consensus criteria that define the earliest stage of AD as an isolated amnesic deficit, not requiring significant functional impairment in ADLs, but rather biomarker or other objective test results specifically supporting the diagnosis of AD; CSF with low amyloid β and high tau, abnormalities on PET; and mutations associated with autosomal dominant familial AD.

CLINICAL EVALUATION FOR ALZHEIMER'S DISEASE

Questioning a patient with Alzheimer's disease directly about his or her illness and past medical history may be either misleading or unproductive. When asked for their chief complaint, the patient may say nothing is wrong or discuss some other unrelated health problem. It is often necessary for a family member, caregiver, or friend with knowledge of the patient's general cognitive functioning and function in ADLs to confirm or give the history. Insidious onset of short-term memory problems is key for the diagnosis of AD. Patients often repeat themselves in conversation and forget appointments. Typically, they may read the newspaper and watch TV but remember little or nothing of what they have read or seen. Memory impairment becomes broader to include poor recall of past events as the illness worsens. A number of cognitive deficits beyond memory impairment differentiate AD from normal aging. Language deficits including inability to name family or friends and word finding difficulties in conversation may be present. This advances with decreased fluency as the illness progresses to a more severe stage with the patient eventually becoming mute.

Visuospatial impairments are common. An affected individual may get lost trying to find their car at the mall or go off route by many miles while driving from what should be a short trip near home. Important items such as a wallet, purse, checkbook, or keys may be mislaid in the home. Calculation difficulties are often present with the patient unable to figure a tip or balance his or her checkbook. Patients with executive functioning difficulties are unable to follow a recipe, plan trips, or manage their financial affairs. Dyspraxia may be present such that they cannot dress themselves or operate kitchen appliances.

Behavioral disturbances in AD occur in a large majority of patients as the illness progresses. Apathy typically occurs early in the illness causing marked loss of initiative and reduced interest in the surroundings. As many as 30% of patients in the early stages of AD will have significant depression, including loss of energy, appetite, or sleep disturbances such as insomnia.³⁵ However, insomnia in AD patients may also be caused by sleep apnea, myoclonus, or side effects of various medications. Other behavioral symptoms include anxiety, particularly when family members leave them at home alone or when they are forced to interact with larger groups of unfamiliar people. As AD progresses from moderate to severe stages, paranoia and delusions become more frequent. A common delusion is the belief that their spouse is having an affair with someone else or that neighbors, friends, or family are stealing from them. Misidentification and visual hallucinations may occur with a daughter or another individual thought to be their spouse or the patient may see other people in the house or just outside who are not really present. As AD progresses, agitation occurs eventually in up

to 75% of patients, with typical symptoms including verbal or physical aggression toward a family member, wandering, or repetitive motor symptoms such as pacing.^{36,37} Patients may develop disinhibition and inappropriate behaviors with examples being, off-color jokes in inappropriate venues, rough play with children, or sexual advances directed toward family members, including children, or even strangers.

The ideal history should document any cognitive deficits, impairment in ADLs, and behavioral abnormalities. Rate of progression over time should be globally assessed. Risk factors should be determined including previous cardiovascular disease or stroke, hypertension, lipid disorders, diabetes mellitus, head trauma, or family history of dementia.

NEUROLOGIC EXAMINATION

Both general physical and neurologic examinations are important to the evaluation of a dementia patients to look for signs that might suggest other causes of dementia, as well as to document any findings that may relate directly to AD. A mental status exam is needed to document presence of cognitive deficits supporting the dementia diagnosis and to begin staging the illness.

The differential diagnosis process for dementia still very much remains a diagnosis of exclusion. The focus is to exclude reversible causes of cognitive impairment and the other irreversible dementias. The physical examination provides a brief screen to exclude organ system problems as the source of the patient's cognitive impairment. The general neurologic examination may often be normal in the demented patient with AD, but the presence of focal deficits (e.g., visual field deficits, weakness, or spasticity in an arm or leg) suggests a vascular etiology for dementia. Older series have reported signs of Parkinson's disease such as rigidity, bradykinesia, and tremor, in as many as 10% to 30% of patients with AD. With recent inclusion of immunohistochemistry in neuropathologic studies in a large series of patients with previous history of dementia, and clinicopathologic correlation, it has become clear that many, if not most, of these patients have diffuse Lewy body disease (DLBD) or Parkinson's disease with dementia.

Gait or balance impairment may also indicate Binswanger's disease (a form of vascular dementia associated with multiple lacunar subcortical strokes), normal pressure hydrocephalus, or progressive supranuclear palsy. Continuing gait problems can also occur in more severe stages of AD leading to substantially increased risk for falls. Myoclonus in early-stage dementia is worrisome for Creutzfeldt-Jacob disease (CJD) or other prion diseases whereas it may be found later in the disease course in 5% to 10% of patients with AD. The list of neurologic findings that may suggest possible, if rarer, etiologies for a patient's dementia is quite lengthy. In general, clues from the history and physical examination guide any additional laboratory testing outside the standard dementia evaluation.

Mental status testing varies in its breadth and depth according to the preferences of the individual physician. In general, assessment should include level of alertness or attention, orientation (person, place, time), short-term and remote memory (remembering three words for 5 minutes and knowledge of their birth date and high school), language, visuospatial functioning (copying figures), calculation, and

executive functioning or judgment. The Mini-Mental State Examination (MMSE) is most widely used to screen for cognitive dysfunction to support the diagnosis of dementia and to stage the dementia (Table 54-3).³⁸ A significant limitation is that it does not assess executive function, a major feature of AD and other dementias. Also, education, as well as ethnicity, familiarity with the English language, and other factors, may influence MMSE scores. It is also relatively insensitive to measuring change in the dementia patient. It is widely familiar to physicians, but its future use may be limited as recently the copyright is being enforced and payment may be demanded for its use.

Clock drawing is a similarly useful very short screen for dementia.³⁹ It is easy for physicians to administer and score. Surprisingly, for such a simple test, at least a dozen different ways to score performance on clock drawing have been proposed, and all appear to be valid, correlating well with other tests assessing cognition in dementia.

LABORATORY STUDIES

It has been estimated that more than 95% of dementia in elderly persons is caused by neurodegenerative or ischemic diseases that are not reversible. The focus of laboratory evaluations has been to first and primarily identify the small minority of patients who have reversible causes for their dementia (Table 54-4).^{37,40} In reality, a potentially reversible cause may be identified in 25% to 40% of patients, but when the laboratory abnormality is corrected or an offending drug (anticholinergic, pain medication) is withdrawn, only transient mild improvement or stabilization in cognitive functioning occurs. The patient still has progressive dementia, most often AD. Nonetheless, any improvement in cognition or function in ADLs, even if limited or transient, is greatly appreciated by patients and their caregivers, and the benefits fully justify doing an evaluation for reversible conditions.

Table 54-3. Instruments Used to Monitor Response to Pharmacologic Therapy in Clinical Practice

Mini-Mental State Examination

- Global measure of cognition widely used by physicians and third-party caregivers
- Assesses orientation, registration, recall, language, and attention
- Uses a 30-point scale
- Requires approximately 5 to 10 minutes to complete
- Sensitivity 80% to 90% and specificity 80%
- Administered by psychometricians, nurses and physicians
- AD typically advances by 3 points per year

Clock Drawing

- Global measure of cognition widely used by physicians
- Multiple scoring systems with proven validity, sensitivity 59%, and specificity 90%
- Assesses in a single test multiple cognitive domains
- 1 to 2 minutes to complete
- Minimal training to administer

Geriatric Depression Scale

- Evaluates depressive symptoms in patients
- Requires 5 minutes to complete
- Very useful in assessing depression in both new patients and in follow-up
- Minimal training to administer
- East of administration is leading to rapid spread in its use

A second purpose of the laboratory evaluation is to aid differential diagnosis among the neurodegenerative and vascular dementias (AD, dementia with Lewy bodies or Parkinson's dementia, vascular dementia, frontotemporal dementias [FTDs]). Accurate diagnosis about the cause of dementia can guide counseling patients, families, and caregivers regarding course and prognosis. Accurate diagnosis of dementia is also important in guiding therapeutic choices. There is evidence from double-blind, placebo-controlled trials suggesting some efficacy for available drugs in all of the irreversible dementias mentioned above except FTD.

In evaluating for potentially reversible causes of dementia, space-occupying masses or other structural abnormalities in the brain may be identified by brain imaging with techniques such as computed tomography (CT) or magnetic resonance imaging (MRI). Most frequent abnormalities identified might include ischemic changes including strokes, normal pressure hydrocephalus, subdural hematomas and hygromas, tumors such as large meningiomas, and gliomas or brain metastases from unidentified primary tumors.

Selective frontal or temporal atrophy on MRI or CT may suggest FTD, and multiple large vessel strokes or smaller subcortical strokes may suggest vascular dementia. Discrimination of FTD from AD in individual patients may be difficult using clinical examination and CT or MRI. Functional imaging measuring blood flow or metabolism by single-photon emission computed tomography (SPECT) or positron emission tomography (PET) may be better able to discriminate FTD from AD and other forms of dementia.

With regard to reversible causes of dementia, metabolic abnormalities worsen cognitive deficits. Relatively minor deviations out of the normal range can exacerbate mental impairment in elderly individuals, particularly those with some other preexisting cause for these cognitive impairments or dementia. Metabolic and endocrine causes are all potentially reversible.

Hyperkalemia may occur in many patients taking diuretics for treatment of hypertension or with congestive heart failure, as well as in individuals taking steroids; hypernatremia may be found in patients with dehydration, which can occur in impaired elderly patients who are dependent on others for fluid intake; hyponatremia may occur in association with

Table 54-4. Laboratory Evaluation of Patients with Dementia

HIV testing	

Adjuvant Studies to Aid Diagnosis

- Other tests as indicated by history or physical or neurologic examinations
- Single photon emission computed tomography (SPECT)
- Positron emission tomography (PET)
- Lumbar puncture with cerebrospinal fluid for A β and tau levels

a variety of chronic illnesses or medications; hypocalcemia and hypercalcemia are found more rarely but also can affect cognitive functioning and should be screened for.

The most common reversible endocrine cause for dementia in older adults is hypothyroidism. Diabetes mellitus, which is increasing rapidly in the United States, is another cause that has both reversible and irreversible aspects. Unrecognized intermittent hyperglycemia or hypoglycemia may cause cognitive impairment, which is reversible. The longer-term effects of diabetes mellitus on vessel walls may cause subcortical ischemic vascular disease, directly causing vascular dementia and also being a risk factor for AD.

Chronic diseases of the major organ systems may all secondarily cause cognitive impairment. These chronic illnesses include acute and chronic pulmonary diseases such as asthma, chronic obstructive pulmonary disease and pulmonary fibrosis, liver diseases such as hepatitis and cirrhosis, cardiac diseases such as congestive heart failure and arrhythmias, chronic CNS infections (including tuberculosis, *Cryptococcus*, and other fungal infections), HIV, Creutzfeldt-Jacob disease, Whipple's disease, and syphilis. Most will have other symptoms or signs and lumbar puncture to obtain cerebrospinal fluid for testing is most often required for diagnosis. Elderly patients with urinary tract infections, as well as upper respiratory infections, may also have reversible cognitive impairments. Subclinical or partial seizures may mimic dementia, with intermittent worsening confusion or automatisms such as lip smacking suggesting the diagnosis.

Polypharmacy in older adults is arguably the most common reversible cause of cognitive impairment. A partial list of the drug categories that are the biggest offenders includes anticholinergics, antihypertensives, antidepressants, anti-anxiety drugs, antipsychotics, analgesics, and hypnotics. If suspected, use may be eliminated or the lowest dosage necessary to control symptoms should be used.

BEHAVIORAL SYMPTOMS IN ALZHEIMER'S DISEASE

Behavioral disturbances are common in AD and increase as the illness declines to the more severe stages. Dysfunctions in the cholinergic and glutaminergic systems are associated with cognitive impairment in AD, but with disease progression, abnormalities in multiple other neurotransmitter systems can be demonstrated that likely underlie the onset of behavioral or psychiatric symptoms.⁴¹ For example, aggressiveness has been associated with dysregulation in the γ -aminobutyric acid-ergic, serotonergic, and noradrenergic systems. Similarly depressive symptoms have been associated with loss of neurons in both the medium raphe nuclei and locus ceruleus and consequent depletion of serotonin and noradrenalin. Treatment approaches have been guided by these observations. Major therapeutic targets in patients with AD include agitation, depression, anxiety, and insomnia or disturbances in day-night sleep cycles. Treatment of these symptoms may be difficult and none of the drugs currently used to treat these symptoms is approved by the U.S. Food and Drug Administration for treating behavioral symptoms in AD.

Double-blind, placebo-controlled trials are limited, but available data suggest that substantial placebo effects occur with therapy of most of these symptoms and that many

commonly used drugs have modest real effects. Treatment of behavioral symptoms is of great importance to family members and caregivers because they are difficult to manage and are one of the principal factors for nursing home placement.

Aggressive or assaultive behaviors are relatively common in AD with roughly 20% of patients in the community and up to 50% of nursing home patients committing physical assaults. Verbal attacks are reported to occur in 50% of patients with AD. Hallucinations occur in as many as 30% of patients at home and in 50% of nursing home patients. Changes in the environment, such as being moved to a new locale, having a new caregiver, or simply as the result of disease progression, may precipitate all of the previously listed symptoms. A recent comparative study suggests limited efficacy for the most commonly used drugs for agitation.⁴² The atypical neuroleptics, despite recent evidence suggesting some increased risk for stroke with chronic use, are still most useful in patients with AD for treating agitation.^{43,44}

In the absence of approved drugs or a convincing clinical trials evidence base for treating patients with behavioral symptoms, the following general therapeutic approach should be followed.

Target symptoms for treatment should be identified before therapy begins. Typical symptoms include wandering, physical aggression, restlessness, agitation, pacing, screaming, disinhibition, delusions, hallucinations, misidentification, sleep disturbances, and very frequently depression.

Iatrogenic causes such as anticholinergic and pain medications should be excluded and infections and other new illnesses should be eliminated, and potential sources of pain in the patient eliminated and possible changes in his or her environment should be investigated. For the identified target symptoms, drug therapies should be started slowly and advance slowly. When the symptoms are controlled, periodic attempts should be made to wean the medications.

BIOLOGIC MARKERS OF DIAGNOSIS OF DISEASE PROGRESSION

No biomarkers are currently sensitive and specific enough to reliably establish the diagnosis of AD, but some have potential utility as adjuncts to the clinical evaluation. None of these surrogate disease markers have enough utility as of yet to be broadly used in clinical practice. Structural MRI is the most thoroughly validated of the potentially available surrogate markers. Progressive atrophy in the hippocampus and loss of whole brain volumes have had high correlation with progression of clinical symptoms.⁴⁵ This methodology is widely used as a secondary assessment to support efficacy claims for antidementia drugs in clinical trials (Figure 54-4). Serial MRIs may be more widely used clinically to assess disease progression if one of the investigational drugs currently under study delays disease progression. Both MRI spectroscopy and 18-fluorodeoxyglucose PET detect metabolism changes associated with AD (Figure 54-5), but lack of longitudinal data and high cost have limited their broad adoption.

An agent labeling amyloid, PIB, has been demonstrated to reliably label amyloid deposits in the brains of patients with AD (Figure 54-6). Unfortunately 10% to 20% of normal elderly by age 65 show PIB positivity, and the percentage of normals with significant PIB positivity progressively

increases to 50% for normal patients in their mid-80s.⁴⁶ However, in subjects with amnesic MCI, PIB positivity appears to predict earlier conversion to dementia, and absence of PIB positivity appears to be strong evidence against progression to AD.⁴⁷ Short half-life and the need for an outside cyclotron to produce the Carbon¹⁴-label of PIB has limited its use. Very similar amyloid-labeling compounds using radioactive fluorine, which has a longer half-life, may have broader future potential to aid clinical

Figure 54-4. MRI study with coronal view through the hippocampal region illustrating moderately severe medial temporal atrophy and milder global atrophy typical for Alzheimer's disease.

imaging in Alzheimer's disease; particularly if drugs in development that reduce amyloid in the brain become more widely available.

A β 1–42 protein levels in CSF from patients with AD are lower than in age-matched controls.⁴⁸ Similarly, tau protein levels and phospho-tau levels are significantly higher in AD than in normal elderly patients.⁴⁹ Unfortunately, abnormal A β and tau levels occur in other neurodegenerative diseases such as CJD and DLBD, and some overlap occurs with normal aging. Combining these two measures improves accuracy of diagnosis, but it is unclear that CSF A β and tau measurements improve specificity of clinical diagnosis enough to justify lumbar puncture in most patients. In general, biologic markers for AD and disease progression have

Figure 54-6. Agent labeling amyloid, PIB illustrating significant uptake in frontal and parietal regions.

Figure 54-5. Views from PET study using 18-fluorodeoxyglucose obtained in a patient with Alzheimer's disease. The image demonstrates decreased signal or metabolism in the posterior parietal regions as may characteristically be seen with this illness.

had limitations that have limited their adoption in clinical practice.⁵⁰ Ultimately, investigation of a number of markers in plasma and CSF in large prospective longitudinal studies, such as the Alzheimer's Disease Neuroimaging Initiative, may yield more sensitive and specific biologic markers for AD.

TREATMENT

Current therapies for AD treat either cognitive or behavioral symptoms but have not been shown to delay biologic progression of disease. The development of a therapy to delay or prevent onset of dementia and to delay disease progression remains an actively pursued but so far elusive goal. Currently available drugs for AD modestly improve some aspects of cognition and function in ADLs as well as less well-established beneficial effects on behavioral disturbances (Table 54-5). Significant benefits are seen only in a minority of patients, and stabilization and temporary reduction of symptomatic decline are the best results achieved in most others. Families and caregivers need to be cautioned against unrealistic expectations. Benefits always need to be weighed against adverse effects when deciding whether a drug dose should be increased or whether the antidementia medication should be continued at all.

Recognition that cholinergic deficiency, including progressive loss of cholinergic neurons in a brain region known to be involved in learning and memory, led to the development of the cholinesterase inhibitors. Tacrine, the first cholinesterase inhibitor successfully developed to treat AD, caused frequent liver toxicity, thus requiring frequent blood testing to monitor liver functions and had a very short half-life, which made four times per day dosing necessary, which was very difficult for AD patients and their caregivers to

comply with. It never was broadly used in clinical practice. Donepezil is a cholinesterase inhibitor more selective for acetylcholinesterase; rivastigmine inhibits both acetylcholinesterase and butyrylcholinesterase; and galantamine inhibits cholinesterase but also modulates acetylcholine effects on nicotinic receptors. The clinical significance of these differences in the cholinesterase inhibitor is unknown. Double-blind, placebo-controlled trials have demonstrated that donepezil, rivastigmine, and galantamine mildly improve cognition, function in ADLs, and behavior in some patients with mild to moderate-stage AD for periods of between 6 and 18 months.⁵⁶ Donepezil also has proven effective in treating patients with moderate- to severe-stage dementia (see Table 54-5).⁵⁷

When therapy is initiated, all cholinesterase inhibitors need to be titrated to decrease adverse effects and to achieve the maximum-tolerated dose to optimize benefits. If adverse effects occur, doses may be skipped or the dosage reduced until they abate or lessen, and higher dosages may again be tried at a later time. In general, the effects on cognition, function in ADLs, and behavior potentially may be accompanied by and weighed against adverse effects such as nausea, vomiting, and diarrhea, which also increase with dose. Finding the best balance between adverse and beneficial drug effects in the individual patient is the goal. If patients are intolerant of one cholinesterase inhibitor, they may tolerate another, so a trial of switching to an alternative medication sometimes is appropriate. Both the AD 2000 Collaborative Group study and the Alzheimer's Disease Cooperative Studies–Mild Cognitive Impairment Trial suggested that donepezil, and by implication the other cholinesterase inhibitors, may be less effective after 18 to 24 months.^{21,58} Neuropathologic studies, however, suggest that central cholinergic deficits in MCI may be less than in AD,⁵⁹ and the AD 2000 study design included periodic withdrawal, suggesting that the conclusion from each of these studies, that efficacy of cholinesterase inhibitor therapy waned after 18 to 24 months, may not be generalizable. Substantial open-label follow-up data are available for all of the cholinesterase inhibitors suggesting, but not proving, continued beneficial effects for 5 years or longer. However, these data are uncontrolled and biased by selective dropouts.

When to withdraw these drugs is a major concern. As a general principle, these drugs should be stopped when the patient is no longer benefiting from their use, but this may be difficult to assess in late-stage individuals. In severely affected patients, the drugs should be withdrawn when patients are no longer able to meaningfully interact with family or caregivers.

Memantine belongs to a second class of drugs that works by partially antagonizing glutamate at the NMDA receptor, which may improve symptoms in AD by two different mechanisms of action. First the regulation of glutamate effects improves signal transmission improving the efficiency of neurotransmission and presumably at a clinical level improves cognitive symptoms. Second, memantine may prevent excess calcium entrance into the neurons following glutamate stimulation, thus potentially having neuroprotective effects. In patients with moderate- to severe-stage disease, as demonstrated in previous clinical trials, memantine mildly improves cognitive deficits, function in ADLs, and behavior. Adverse clinical effects with memantine are fewer than with the cholinesterase inhibitors, and one large double-blind, placebo-controlled trial in AD patients on

Table 54-5. Clinical Trials Evidence for Drugs Approved for Treatment of Alzheimer's Disease

established donepezil suggested that there may be fewer rather than more side effects when memantine was added, as well as an additive symptomatic benefit. Trials in patients with milder-stage AD have demonstrated less consistent benefits. Memantine is currently not recommended for use in this population. With memantine, as with the cholinesterase inhibitors, symptomatic benefits may be difficult for caregivers to judge in some patients and so they should be counseled about realistic expectations regarding the potential magnitude of benefits with this therapy. As with the cholinesterase inhibitors, memantine should be continued until patients are judged to be no longer benefiting or until the patients have no meaningful personal interactions.

PREVIOUSLY ACCEPTED THERAPIES MAY BE INEFFECTIVE

Vitamin E was reported to delay functional deterioration, nursing home placement, and death by approximately 25% in moderate- to severe-stage AD in a large double-blind, placebo-controlled trial.⁶⁰ However, these results were obtained only after adjusting for group differences in cognitive functioning at baseline, and no cognitive benefits were seen in the group taking vitamin E. Recently, the vitamin E group in the Alzheimer's Disease Cooperative Study Group–Mild Cognitive Impairment study showed no benefit versus placebo,²¹ and other studies have also suggested risks concerning thrombosis with the 2000 U vitamin E dose used in the above studies. Vitamin E is no longer broadly recommended as a therapy for AD.

Similarly, several epidemiology studies have suggested that estrogens and nonsteroidal anti-inflammatory drug (NSAIDs) may delay the onset of AD.²⁷ However, several recent large double-blind, placebo-controlled studies have suggested both estrogens and NSAIDs used as preventatives in normal elderly individuals and in patients with AD may have greater risks than benefit.^{29,61–63}

MORE TARGETED THERAPEUTIC APPROACHES IN ALZHEIMER'S DISEASE THERAPY

Broad acceptance of the amyloid hypothesis as a target for therapy and the availability of transgenic animal models known to develop amyloid plaques has made reducing amyloid the major focus in developing drugs to delay disease progression. More detailed understanding of AD's metabolism has led to the development of β - and γ -secretase inhibitors that block the formation of A β from the amyloid precursor protein (APP) by interfering with the enzymes that slice it from the larger APP. Despite concerns regarding potentially an adverse side effect of γ -secretase inhibitors on notch signaling that may cause severe gastrointestinal toxicity⁶⁴ and concerns about the potential for β -secretase inhibition to adversely affect central or peripheral myelination,⁶⁵ both types of secretase inhibitors are in phase II or III AD therapeutic trials.

An entirely different approach, vaccination using the β -amyloid protein, has proved effective initially in reducing β -amyloid plaques in transgenic animals, and a similar vaccine has been tested in a large phase II trial.⁶⁶ This large vaccination study was suspended when several subjects developed

encephalitis.⁶⁹ Some evidence has suggested cell-mediated immunity may have been involved in these adverse reactions. However, autopsy in patients who later died showed apparent clearance of β -amyloid plaques from broad areas, particularly the frontal lobes of the cortex. Vaccinated patients were followed and clinically appeared to have less than expected clinical deterioration but greater cortical atrophy. The dichotomy between clinical and structural effects has yet to be adequately explained. However, several groups have resumed clinical trials in AD patients with more targeted approaches using revised protein targets and adjuvants monoclonal antibodies to A β have been developed that are being passively infused into AD patients. One of these A β antibodies recently was shown to reduce progression versus placebo over 1 year at low doses but to cause frequent vasogenic edema at higher doses.⁶⁸ Patients with the APOE4 genotype appear more likely to develop vasogenic edema at lower doses than those without this allele. It remains unclear, however, whether these newer vaccination or antibody infusion approaches will stabilize or reverse clinical symptoms of AD or rather these patients will continue to deteriorate despite reduced plaque formation and/or burden. If this proves true, other approaches, possibly focusing on the tau protein, will need to be pursued for developing future therapies.

ACKNOWLEDGMENT

KEY POINTS

Alzheimer's Disease

- The diagnosis of probable Alzheimer's disease is determined by a clinical process rather than a laboratory test.
- The major risk factors for Alzheimer's disease are older age, APOE4 genotype, and lifestyle (metabolic syndrome).
- It is unclear whether determination of APOE4 genotype in a patient with dementia improves diagnostic specificity enough to be clinically useful.
- Several different disease mechanisms associated with Alzheimer's disease have been identified that are targets for drug therapy.
- Symptomatic treatment with cholinesterase inhibitors is effective in patients with mild-, moderate-, and severe-stage Alzheimer's disease.
- Symptomatic treatment with memantine is effective in moderate- to severe-stage Alzheimer's disease and benefits are seen with memantine additive to cholinesterase inhibitors.
- Mutations associated with familial Alzheimer's disease have led to the creation of transgenic animals that have greatly facilitated therapeutic research.
- Amyloid-labeling agents using PET imaging research are being evaluated for their predictive, diagnostic, and risk factor utility regarding Alzheimer's disease.
- Behavioral symptoms in Alzheimer's disease are common, and most therapies are unapproved and at best marginally effective.
- Several promising treatments for Alzheimer's disease identified in epidemiology studies have failed in clinical trials.

Vascular Cognitive Impairment

Paige A. Moorhouse

Kenneth Rockwood

Vascular cognitive impairment (VCI) is a global diagnostic category applied to a heterogeneous group of cognitive disorders that share a presumed vascular cause. Note that it is an umbrella term, which includes several syndromes, and is not simply the vascular counterpart of mild cognitive impairment (MCI). Specifically, VCI includes vascular dementia (including poststroke and multi-infarct dementia), mixed primary neurodegenerative disease and vascular dementia, and cognitive impairment of vascular origin that does not meet dementia criteria (VCI-ND). VCI may be preventable, although the evidence for this is not as complete as it is for the prevention of stroke. Beyond prevention, specific treatment has shown limited efficacy. Updated clinical diagnostic criteria for VCI are needed, and clinical investigators now emphasize harmonized standards to study the clinical, neuropathologic, and neuroimaging manifestations of VCI in daily practice. This chapter builds on a recent review¹ to outline the evolution of the VCI construct, presents current thinking regarding clinical diagnosis and the supportive role of neuroimaging, and addresses the challenges that will shape future developments in this area.

HISTORICAL OVERVIEW

The conceptual prototype for VCI was “multi-infarct dementia” (MID),² itself an improvement over “senile dementia due to hardening of the arteries.”³ Like many prototypes, MID was constructed with inefficient tools: neuropsychological testing based on the Alzheimer’s disease paradigm and (initially) no or rudimentary neuroimaging. This construct defined MID as dementia arising as a consequence of multiple strokes and was said to account for 15% of dementias.⁴ As neuroimaging techniques evolved, the array of vascular pathologies outgrew the MID construct, so the vascular dementia (VaD) construct (of which MID became a subtype) was created to allow more flexibility in the size and distribution of neuroimaging abnormalities (from single strategic infarcts to leukoaraiosis) related to the diagnosis.^{5,6}

Like its forerunner, the VaD construct was soon outgrown due to at least three key developments. First, growing neuropathologic evidence indicated that most dementias have both neurodegenerative (most commonly Alzheimer disease [AD]) and vascular features⁷ and that these features appear to act synergistically.^{8,9} Second, existing diagnostic criteria all required that memory impairment be present to diagnose VaD and this was at odds with clinical experience.^{5,6,10,11} Finally, with improved clinical recognition of earlier stages of cognitive impairment and increasing emphasis on prevention, the VaD construct was not sensitive to the clinical phenotype of cognitive impairment of a presumed vascular cause that was not severe enough to meet the criteria for dementia. The VCI construct therefore includes a broader spectrum of clinical profiles. These range from individuals with cognitive impairment not dementia, individuals who meet the criteria for VaD (poststroke dementia, MID, etc.) and individuals in whom cognitive impairment shows mixed “primary” neurodegenerative (PND) and vascular features (mixed PND/VaD).¹²

The development of the VCI construct represents advances in how we understand cognitive impairment that is related to cerebrovascular disease. It recognizes that in addition to single strategic infarcts, multiple infarcts, and leukoaraiosis, there are other mechanisms of cerebrovascular disease, such as chronic hypoperfusion, which may account for the pattern of cognitive deficits (another old idea that has become modern again). It also affords greater attention to opportunities for primary and secondary prevention.¹³ The VCI construct also recognizes that more than one cause of dementia might exist in the same patient. Even so, the formulation of the VCI construct is not entirely settled. In consequence, the ongoing debate regarding the precision of the construct^{14,15} and the ever-changing terminology have posed significant challenges to ongoing research in the area. For example, estimates of incidence and prevalence of VCI rely on varied definitions. Similarly inclusion criteria for research studies vary according to the diagnostic criteria used and hamper meta-analyses and external validity. Incomplete agreement on terminology has also undermined development of standardized language and criteria for vascular lesions in neuropathology and neuroimaging.¹⁶

EPIDEMIOLOGY

VCI is common. Approximately one third of dementia cases show significant vascular pathology on autopsy,^{7,17} although this does not indicate the clinical relevance of such pathology. Depending on how cerebrovascular mechanisms are understood, VCI can be considered the most common form of cognitive impairment¹⁴ but it is most commonly referred to as the second most common form of cognitive impairment (after Alzheimer’s disease).

The novelty and the heterogeneity of the VCI construct (particularly the inclusion of those with VCI-ND) create challenges for descriptive epidemiology, much of which still relies on vascular dementia terminology. In the Canadian Study of Health and Aging, it was estimated that approximately 5% of people over the age of 65 had VCI, with 2.4% having VCI-ND, 0.9% having mixed dementia, and 1.5% having VaD.¹⁸ The incidence of vascular dementia ranges from 6 to 12 cases per 1000 over the age of 70 per year.¹⁹

SUBTYPES OF VCI

As argued elsewhere,¹ given the considerable heterogeneity within VCI, subgroup classification is necessary. Proposed subgroup schemata have distinguished subtypes on the basis of neuropathology, risk factors, and treatment response,²⁰ but in practice VCI is a clinical diagnosis, often supported by neuroimaging, therefore subgroups will be described here on the basis of their clinical presentation. Clinical subgroups include VCI-ND, mixed PND/VaD, and VaD. In this classification system, disorders originally included in the VaD construct, such as poststroke dementia, multi-infarct dementia, subcortical dementia, and leukoaraiosis remain in the VaD subtype. This system is not universally agreed upon.

Poststroke dementia has been proposed as separate from these subgroups but is limited as a standalone subgroup by the omission of poststroke VCI-ND^{21,22} and incomplete overlap of clinical and neuroimaging findings. Similarly, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL)²³ does not easily fit into this subgroup classification scheme but remains a relatively infrequent (albeit possibly underdiagnosed²⁴) cause of VCI.

The neuropathologic relationship between AD and VaD is incompletely understood, but their coexistence is well recognized²⁵ with mixed dementia emerging as one of the most common forms of dementia in neuropathologic studies.⁷ Neuropathologic features of vascular disease (atherosclerosis, endothelial proliferation, and neovascularization) have been described in those with AD since Alois Alzheimer's first case of AD,²⁵ but the two processes were conceptually distinguished from one another for most of the twentieth century on the basis of clinical and neuroimaging features.^{2,26} With the emergence of increasingly sensitive neuroimaging techniques and emphasis on earlier detection and prevention of cognitive impairment, the pendulum has swung back to embrace the interactions between vascular and neurodegenerative pathologies. Some have even considered AD to be a primary vascular disorder, but this has not been confirmed with epidemiologic, clinicopathologic, or animal model studies to date.¹⁶ Alternatively, structural changes in actin and deposition of beta amyloid in AD may lead to vascular reactivity and impaired cerebral autoregulation, thereby potentiating cerebral vessel damage.²⁷

What is well accepted is that vascular risk factors are associated with late-life cognitive impairment, including Alzheimer's disease (see Prevention and Treatment). In addition, it seems clear that when both neurodegenerative lesions and vascular ones are present, they interact synergistically, to the detriment of cognition. The Nun Study⁹ indicated an additive effect of vascular lesion burden and neurodegenerative pathology on cognitive impairment, but it may be that the interaction is dependent on lesion type,²⁸ location,²⁹ and dementia stage.¹⁶ Lesion thresholds have been discussed but remain controversial.²⁸ Infarction in the frontal subcortical tracts may be responsible for clinical presentation with neurodegenerative changes being incidental.³⁰

ETIOLOGY AND PATHOPHYSIOLOGY OF VCI

VCI comprises many heterogeneous syndromes, each with its own array of causes and clinical manifestations. A mechanistic approach to pathophysiology divides cognitive impairment associated with large vessel disease from small vessel disease (including subcortical ischemic vascular disease) and noninfarct ischemic changes. Neuropathologic lesions associated with VCI include large and small vessel infarcts, white matter changes, hemorrhage, gliosis, and in mixed dementia, neuropathologic changes of AD.³¹

Large vessel disease

Poststroke dementia is the clinical archetype for VCI associated with large vessel disease. Poststroke dementia (PSD) is defined as cognitive impairment from any cause following stroke that is significant enough to impact daily function.

The prevalence of PSD varies depending on diagnostic criteria used, age of the study population, and delay between stroke and cognitive evaluation³² but ranges from 14% to 32%, with incident poststroke dementia ranging from 20% at 3 months to 33% at 5 years.^{33,34} Poststroke cognitive impairment—that is, inclusion of cases in which cognitive impairment without dementia is diagnosed following stroke—may be even more common.^{35,36} In the Framingham study the rate of dementia in people with a history of stroke is approximately double that of the nonstroke population.³⁷

Risk factors for PSD may be patient related or stroke related. Vascular risk factors such as hypertension, diabetes, hyperlipidemia, and smoking have shown inconsistent association with PSD,^{35,36} whereas age, low education, and preexisting cognitive impairment or dependency have shown more consistent association.^{32,36,38} The relationship between preexisting cognitive impairment and the risk of poststroke dementia had been seen as robust, likely reflecting some combination of the effects of stroke, the effects of chronic ischemia, and the presence of preexisting neurodegenerative impairment. A report from the large and carefully conducted Rotterdam study has brought this into question, however.³⁹ It may be that the number of vascular risk factors is more important than any one individual factor in predicting PSD.³⁵ Neuroimaging features such as global cerebral atrophy and medial-temporal lobe atrophy are associated with a higher risk of PSD.⁴⁰ Although medial-temporal atrophy has been proposed as a marker of preexisting neurodegenerative disease in these cases,⁴¹ it is also present in VaD and in patients without preexisting clinical evidence of dementia.

Single strategic infarcts in the cortex (hippocampus, angular gyrus) or subcortex (thalamus, caudate, globus pallidus, basal forebrain, fornix, and genu of the internal capsule) can result in characteristic PSD cognitive syndromes. For example, angular gyrus infarction is associated with an acute onset of fluent dysphasia, visuospatial disorientation, agraphia, and memory loss that can be mistaken for AD.⁴² Large vessel disease seldom occurs in isolation, as neuroimaging evidence of small vessel disease is ubiquitous in the older population with varying degrees of clinical significance. Most often, cognitive impairment in association with vascular disease results from the cumulative effects of several cortical infarcts of varying size and number—the basis of cortical MID as described by Hachinski in 1974.² The infarcts of MID occur predominantly in the cortical and subcortical arterial territories and distal fields.

Small vessel disease

Small vessel disease includes leukoaraiosis, subcortical infarcts, and incomplete infarction. It is more common by far than large vessel disease⁴³ and may be the most common cause of VCI.^{44,45}

Leukoaraiosis describes diffuse, confluent white matter abnormalities (low density on computed tomography [CT] and hyperintense on T2-weighted magnetic resonance imaging [MRI] and FLAIR). Increasing sensitivity of MRI has resulted in less specificity and predictive validity of leukoaraiosis, which can now be detected in more than 90% of older people.⁴⁶ Just as the term *leukoaraiosis* does not presuppose pathology, white matter changes are not specific to infarcts but may also occur with leukodystrophies, metastases, and other inflammatory conditions.⁴⁷ Leukoaraiosis may

be present at varying degrees from small punctate hyperintensities to large confluent lesions. The major neuropathologic features found in leukoaraiosis in association with VCI include axonal loss, enlargement of perivascular spaces, gliosis, and myelin pallor.⁴⁷ Whether periventricular and deep white matter lesions are distinct in their etiologies, presentations, or rates of progression is not well understood.⁴⁸

The association between leukoaraiosis and cognitive and functional decline appears robust,⁴⁹ but the cognitive domains affected are not clearly established. The Framingham study indicates association between presence of leukoaraiosis and executive functions, new learning, and visual organization.⁵⁰ In general, confluent lesions appear to have a worse prognosis than punctate ones, but decline is more consistently related to measures of atrophy.³⁵ Visual and volumetric quantitative measurement scales for leukoaraiosis have been developed⁵¹ but are limited in their utility as outcome measures by ceiling effects.⁵²

Subcortical ischemic vascular disease

The term *subcortical ischemic vascular disease* (SIVD) was proposed to characterize a clinical profile of a dysexecutive syndrome, with no (or minimal) memory impairment, commonly accompanied by psychomotor slowing, which was seen in the presence of subcortical—including white matter—injury. Subcortical vascular injury occurs through small vessel infarct, ischemia or incomplete ischemia within the cerebral white matter, basal ganglia, and brain stem, especially the prefrontal subcortical circuit and the thalamocortical circuit. Lacunes are infarcts < 15 mm in diameter in the cortical white matter or in the corona radiata, internal capsule, centrum semiovale, thalamus, basal ganglia, or pons.⁴⁵

It is clear that lesions in the prefrontal subcortical circuit (including the prefrontal cortex, caudate, pallidum, and thalamus) or thalamocortical circuit may manifest as the "subcortical syndrome" as described previously. Commonly, however, the profile is accompanied by memory impairment that is more than "minimal."⁵³ In any case, these lesions are also associated with increased risk of stroke and dementia. Although it has been held that this profile is associated with more rapid cognitive decline even when controlling for other vascular risk factors, this view has been disputed.⁵⁴

Subcortical lesions are often associated with impairments of executive function,^{50,55,56} which is broadly defined as the ability to sequence, plan, organize, initiate, and shift between tasks. Even so, there are several distinct frontal lobe syndromes, so that to say a given patient has executive dysfunction is not always to give a precise account of what is wrong. Each of the major three frontal syndromes has been described in people with cerebral ischemia/infarction: dorso-lateral (executive function and impaired recall), orbitofrontal (behavioral and emotional changes), and anterior cingulate (abulia and akinetic mutism).⁵⁷ Clinically, however, mixed syndromes are common. The importance of executive dysfunction in VCI^{58–62} is unclear, but it is unlikely to be unique to VCI at any stage.^{30,63,64} Strong support for this contention comes from a recent prospective neuropsychological/autopsy-based study.⁶⁵

Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is a hereditary microangiopathy associated with mutation in the *Notch 3* gene on chromosome 19.²³ Clinical presentation consists of

migraine with aura, mood disturbance, recurrent subcortical strokes, and progressive cognitive decline.²⁴ Although a comparatively rare cause of VCI, it deserves special mention for two reasons. First, it is generally considered to be a model of pure VaD because generally onset occurs between the ages of 40 and 50, when comorbid AD pathology is rare. Second, the use of cholinesterase inhibitors in those with CADASIL has shown statistically significant improvement in some measures of executive function. This provides a basis for cholinergic therapy in VCI. Cholinergic mechanisms appear to play a critical role in cerebral perfusion.⁶⁶ The best diagnostic criteria for CADASIL are the NINDS-AIREN criteria for subcortical ischemic VaD.⁶⁷

Noninfarct ischemic changes and atrophy

Noninfarct ischemia is an integral part of the pathophysiology of VCI, affecting both clinical presentation and outcomes.⁶⁸ Diffusion tensor MRI techniques can detect abnormalities that extend beyond the visible borders of leukoaraiosis and that show more robust association with cognition than leukoaraiosis alone.⁶⁹ Ischemia also may contribute to mixed dementia by promoting the neuropathologic changes of AD. In animal models, ischemic changes in vascular endothelium increase amyloid precursor protein cleavage, promote tau phosphorylation, and inhibit clearance of extracellular amyloid.^{70–72} Hypoperfusive hypoxic changes are associated with concurrent AD neuropathology⁷³ and might explain poor outcomes in people with VCI who have no lesions on neuroimaging.⁷⁴

Gray matter atrophy may show stronger association with cognitive impairment than strategic infarcts and subcortical vascular disease.⁷⁵ Cortical atrophy predicts cognitive decline independent of vascular burden on neuroimaging.⁷⁶ In particular, medial-temporal atrophy (MTA) shows association with cognitive dysfunction (including executive dysfunction).⁶² MTA was initially thought to indicate underlying neurodegenerative pathology because of the predilection of amyloid plaques in the medial-temporal lobes of those with AD. However, MTA may also result from vascular pathology.⁶² Thalamic volume has also shown association with the degree of cognitive impairment.⁷⁷

Cerebral amyloid angiopathy

Cerebral amyloid angiopathy (CAA) is a heterogeneous group of sporadic and (more rarely) hereditary diseases in which amyloid proteins aggregate in the vessel walls of leptomeningeal and cortical arteries, arterioles, capillaries, and, less commonly, veins.⁷⁸ CAA is associated with a spectrum of clinical presentations including TIAs, stroke, seizures, migraine, and cognitive impairment and behavioral symptoms. Clinical presentations include lobar hemorrhage, subarachnoid hemorrhage, cortical infarction, and cognitive profiles similar to subcortical ischemic vascular disease. CAA is a prevalent finding in dementia with vascular and neurodegenerative pathology^{2,16} but is also found in clinically asymptomatic patients in autopsy studies.² T2-weighted MRI often reveals evidence of prior cerebral microhemorrhage, but its significance in a given patient with cognitive impairment is unclear and needs to be correlated with other clinical and imaging characteristics.⁷⁹ Positron emission tomography (PET) scans using Pittsburgh Compound B allows labeling of vascular and parenchymal amyloid. The number of cerebral

microbleeds has been shown to be an independent predictor of cognitive impairment and dementia.⁸⁰

DIAGNOSIS

Diagnostic criteria for VCI *writ large* are lacking. Current VaD include the National Institute of Neurological Disorders and Stroke Association Internationale Pour la Recherche et l'Enseignement en Neurosciences (NINDS-AIREN) criteria,⁶ the Alzheimer's Disease Diagnostic and Treatment Centers (ADDTC) criteria,⁵ the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (DSM-IV) criteria,¹⁰ and the International Classification of Diseases (ICD-10) criteria¹¹ (Table 55-1). These diagnostic criteria show low associations with each other, making comparisons difficult,⁸¹⁻⁸³ and do not include VCI-ND, which may account for up to half of people with VCI.^{81,84} Further, the timelines for temporal association have not been reflected by empirical data. In a Mayo Clinic population-based neuropathologic study in which 13% had "pure" VaD without major evidence of AD, requiring that dementia follow a known stroke resulted in high specificity but low sensitivity of autopsy-verified cases.⁸⁵ The recently developed Harmonization Standards are consensus recommendations from the NINDS and the Canadian Stroke Network (CSN)⁷¹ that aim to establish screening protocols and datasets for clinical practice and research.⁸⁶

Clinical evaluation

VCI is a clinical diagnosis. A detailed account from the patient and informant of the onset and progression of cognitive domains affected (such as memory, speed of thinking or acting, mood, and function), vascular risk factors (such as hypertension, hyperlipidemia, diabetes mellitus, alcohol or tobacco use, and physical activity), gait disturbance, and

urinary incontinence should be sought.^{47,86,87} History of atrial fibrillation, coronary artery bypass surgery or angioplasty stenting, angina, congestive heart failure, peripheral vascular disease, transient ischemic attacks or strokes, and endarterectomy is also important. Other elements of medical history including hypercoagulable states, migraine, and depression may also be helpful.⁸⁶ Physical examination should include blood pressure, pulse, body mass index (BMI), waist circumference, and examination of the cardiovascular system for evidence of arrhythmias or peripheral vascular disease, neurologic examination for focal neurologic signs, and assessment of gait initiation and speed.⁸⁸

Cognitive assessment

The pattern of cognitive deficit in VCI is as broad as the construct itself. Single strategic infarcts can have characteristic cognitive profiles, whereas subcortical lesions (and less commonly cortical lesions⁸⁹) are often associated with a cluster of features termed *the subcortical syndrome*, which includes abnormalities of information processing speed, executive function, and emotional lability that are not recognized by standard cognitive assessments such as the Mini-Mental State Examination (MMSE).⁹⁰ Screening with subsets of tests such as the five-word immediate and delayed recall, six-item orientation task, and phonemic fluency tests from the Montreal Cognitive Assessment (MoCA)⁹¹ is currently recommended⁸⁶ with administration of the entire MoCA, the Trail Making Test,⁸² or a semantic fluency test if time allows.⁸⁶ Although executive dysfunction has proven useful and sensitive for the evaluation and even prediction of disease progression, this is not specific to VCI.^{65,74} Even though clinicians who evaluate patients for VCI and for executive dysfunction more generally are justly skeptical about relying on the MMSE as a global screening measure of cognition, tests of executive function are not adequate, in isolation, for

Table 55-1. Comparison of Diagnostic Criteria for Vascular Dementia

Diagnostic Criteria	Requirements for Diagnosis	Criticism
DSM-IV ¹⁰	Course characterized by stepwise decline in cognition and function. Focal neurologic signs and symptoms or laboratory evidence of focal neurologic damage judged to be related to the clinical presentation.	Requires memory impairment as one of the cognitive domains affected. Definitions lack detail. No information regarding neuroimaging features. Does not include VCI-ND.
ADDTC ⁵ Criteria for ischemic vascular dementia	At least one infarct outside the cerebellum. Evidence of two or more strokes by history, neurologic signs, or neuroimaging. Or, in the case of a single stroke, a clear demonstration of a temporal relationship between the stroke and cognitive presentation.	Temporal relationship not defined. Requirement for neuroimaging evidence of stroke is too confined: small vessel disease including leukoaraiosis not included.
ICD-10 ¹¹	Patchy distribution of cognitive deficits and focal neurologic signs. Cerebrovascular disease must be judged to be etiologically related to the dementia.	Definitions lack detail. Does not include VCI-ND.
NINDS-AIREN ⁶	Cognitive decline in memory <i>and</i> two other cognitive domains severe enough to interfere with activities of daily living <i>and</i> Clinical and radiographic evidence of cerebrovascular disease <i>and</i> A relationship between neuroimaging and clinical presentation (onset of dementia within 3 months following a stroke or abrupt onset of cognitive impairment or fluctuating stepwise progression of cognitive decline.	Requirement for cognitive domains affected is less permissive compared with ADDTC criteria. Requirement for neuroimaging evidence of CVD is more strict. Does not include VCI-ND Temporal relationship with cerebrovascular event is strict.

evaluation of VCI.⁹² The problem appears to be both one of specificity; highly educated people with dementia, for example, might appear to have “memory sparing” on screening tests—and one of sensitivity—the sorts of behaviors that are troublesome failures of judgment are not always captured by the ability to draw a clock or to copy a motor sequence.

Neuropsychiatric profiles

Unsurprisingly, given how common injury to the prefrontal circuitry is, neuropsychiatric symptoms are common in people with VCI.⁹³ Depression is the most extensively studied affective syndrome in VCI.^{53,74} In addition, criteria for a so-called “vascular depression” have been proposed, but they have yet to be fully accepted.⁹⁴ As noted, distinct frontal lobe syndromes have been described in patients with VCI. A host of poststroke cognitive syndromes also are well known.³²

Neuropathology

Many researchers believe that neuropathology is the gold standard for a diagnosis of VCI, even though a considerable body of evidence appears to undermine its standard as a test “of 100% sensitivity and specificity.”^{7,9,17,95} This is because neuropathology (on autopsy) does not inform the relationship between vascular lesions and clinical presentation⁹⁶ nor has a neuropathologic threshold of cerebrovascular disease reliably distinguished between NCI and dementia.⁷ Instead, the role of neuropathology is to identify the type and extent of lesions present (especially those that are not visible with neuroimaging), as well as other coincident pathologies.¹⁶

Neuroimaging

Neuroimaging studies remain subordinate to clinical assessment; there are no pathognomonic neuroimaging features for VCI, and infarct location often does not correlate with the cognitive profile (Figure 55-1). At present, neuroimaging cannot reliably confirm the chronology of lesions or inform the relative contribution to the clinical presentation of neurodegenerative versus ischemic processes. Increasing recognition of the importance of incomplete infarction and hypoperfusion inform the understanding that VCI may be present in the absence of neuroimaging abnormalities because of incomplete infarction and hypoperfusion, and absence of neuroimaging lesions in those with VCI is associated with a particularly poor prognosis.⁷⁴ However, advances in neuroimaging technology, especially MRI-based techniques, have begun to allow improved understanding of the lesion type and location.

Clinically significant white matter disease is associated with loss of neuronal integrity leading to higher mean diffusivity and lower fractional anisotropy.⁹⁷ Diffusion tensor MRI studies (DTI) allow mapping of white matter fiber pathways (tractography), thereby enhancing the understanding of lesion location and volume in relation to clinical presentation.⁶⁹ DTI such as fractional anisotropy have been helpful in differentiating clinically significant leukoariosis (that associated with lower FA). Semiquantitative methods such as the Cholinergic Pathways Hyperintensities Scale (CHIPS scale) allow assessment of the degree to which cholinergic pathways are affected in those with mixed AD/leukoariosis

Figure 55-1. Clinical and neuroimaging profiles inform the clinical diagnosis of vascular cognitive impairment. VCI, vascular cognitive impairment; mix AD VaD, mixed neurodegenerative (AD); and vascular dementia (VaD).

pathology,⁹⁸ and this has been shown to correlate with response to anticholinergic medications.⁹⁹ MRI also allows more detailed assessment of leukoaraiosis, which has clinical importance. For example, individuals with punctate leukoaraiosis on MRI show a lower tendency toward progression over time compared with those who have confluent lesions, but this association is likely modulated by other factors such as atrophy.¹⁰⁰

The clinical importance of atrophy in VCI is increasingly recognized and may show a stronger association with disease progression and depressive symptoms than white matter change.⁸⁴ Medial temporal atrophy is emerging as an important correlate of cognitive dysfunction, including executive dysfunction.⁶²

Biomarkers

In addition to neuroimaging biomarkers, molecular biomarkers are indicators that may or may not be on the causal pathway of disease and correlate with disease process and progress. Biomarkers for VCI could aid in early detection, discrimination of neuropathology, estimation of prognosis, and monitoring of disease progression or treatment response. However, the presence of pathology (such as white matter hyperintensities) in normal individuals as well as the high prevalence of mixed dementia in VCI poses challenges for the development of biomarkers. Biomarkers cannot be expected to take the place of clinical diagnosis, and their contribution to our understanding of VCI requires significant empirical data and standardized measurement techniques.

To date, no single molecular biomarker has shown consistent discriminative ability in VCI, and it is more likely that profiles consisting of an array of biomarkers will be necessary. Candidate biomarkers include the cerebrospinal fluid (CSF) blood-brain albumin index (which is compromised in many types of dementia)¹⁰¹ and matrix metalloproteinases.^{102,103} Higher CSF concentrations of molecules found in normal myelin have been found in people with subcortical vessel disease compared to AD¹⁰⁴ and may be markers of demyelination.¹⁰⁵ CSF tau and phospho-tau are elevated in nonvascular dementias and may be useful as negative biomarkers.¹⁰⁶

DISEASE PROGRESSION

Within the VCI construct, the parallel condition to MCI is VCI-ND, although the term *vascular pre-dementia MCI* is sometimes used in the MCI literature rather than VCI-ND.¹⁰⁷ However, VCI-ND should not be used interchangeably with nonamnestic MCI because other types of MCI also show progression to VCI.^{108,109} Like MCI, VCI-ND may exist in a spectrum between normal cognition and VaD,⁶¹ but little is known about the progression of VCI-ND. VCI-ND does not always progress to dementia, and improvement is common.¹¹⁰ VCI-ND is common after stroke, but here too a substantial proportion of patients show cognitive improvement, especially those without evidence of prior frontal-subcortical involvement.¹¹¹ VCI-ND may show less progression than other subtypes of VCI,⁷⁴ but the presence of certain baseline features such as prior history of stroke and memory impairment coupled with functional impairment may indicate an increased risk of progression to incident dementia.^{59,112} Medial temporal atrophy and thalamic atrophy appear to be more important than white matter

hyperintensities in predicting cognitive impairment and dementia after stroke.¹¹³

Similar to VCI-ND, progression of poststroke dementia shows considerable variability, with up to one third of people having a change in their diagnostic category (NCI, CIND, dementia) within 1 year after stroke.¹¹⁴ Risk factors for progression and functional decline include age, previous cognitive impairment, polypharmacy, hypotension during acute stroke,¹¹⁵ depression,¹¹⁶ and medial temporal atrophy.^{61,113}

Most people with VCI show clinical progression that is readily detectable. Current cognitive and functional assessments such as the MMSE, Disability Assessment for Dementia (DAD), and the Functional Rating Scale (FRS) may be less responsive to deterioration in the severe stages of VCI.⁷⁴ Compared with AD, those with VCI may show more prominent progression of affective symptoms such as depression.⁷⁴

PREVENTION AND TREATMENT

Data on prevention of VCI through treatment of vascular risk factors had shown largely equivocal support for primary and secondary prevention, although this may be changing.¹¹⁷ In the Hypertension in the Very Elderly Trial–Cognitive Function Assessment study, patients assigned to indapamide +/- perindopril had a lower risk of developing dementia than those on placebo (33/1000 patient years versus 38/1000 patient years). Although this difference was not statistically significant, the trial was stopped early because of less all-cause mortality and stroke in the treatment arm. An accompanying editorial pointed out that this may be the best data available, given that it would no longer be ethical to conduct a placebo-controlled study of this question.¹¹⁸ The authors combined the data from their trial with others to show a net benefit for blood pressure dementia treatment on the prevention of dementia. In a secondary analysis of the Study on Cognition and Prognosis in the Elderly trial, patients treated with the angiotensin receptor blocker (ARB) candesartan showed a reduced risk of white matter hyperintensities,¹¹³ possibly related to blockage of AT1 and activation of AT2 receptors.¹¹⁹ Benefits of primary prevention of stroke or general cognitive decline through blood pressure lowering have not yet been shown in meta-analysis.¹⁰⁴ Additionally, one meta-analysis showed benefit of blood pressure lowering

KEY POINTS

Vascular Cognitive Impairment

- Vascular cognitive impairment (VCI) is an umbrella term that includes vascular dementia (including poststroke and multi-infarct dementia), mixed primary neurodegenerative disease and vascular dementia, and cognitive impairment of vascular origin that does not meet the criteria for dementia.
- The clinical diagnostic criteria for VCI are evolving.
- VCI is a clinical diagnosis, with neuroimaging and neuropathology having a supportive role.
- Treatment of VCI is often unsatisfactory. Cholinesterase inhibitors and N-methyl-D-aspartate (NMDA) antagonists have only limited evidence for use, although some of this may represent underrecognition of mixed dementia in Alzheimer disease trials.
- Preventive strategies for VCI include exercise and vascular risk factor control.

for some cognitive outcomes but detrimental effects for others.¹²⁰ Consideration of composite end points including cognition, stroke, macular degeneration, renal, and heart disease may make a more convincing case for primary prevention through blood pressure control.¹²¹

Diabetes has been associated with risk of stroke, cognitive decline and dementia in several population studies.^{122–124} A large-scale prospective study is now examining the effects of glycemic control on incident cognitive function and structural brain changes.¹²⁵ Hypercholesterolemia (especially in midlife)¹²⁶ is a well-recognized risk factor for stroke, and the Stroke Prevention by Aggressive Reduction in Cholesterol Levels (SPARCL) study found a reduction in recurrent stroke for those with a history of stroke or transient ischemic attack, treated with statins.¹²⁷ Individuals with poststroke dementia show a slow decline in the absence of further cerebrovascular disease.⁸⁹ Beyond controlling established vascular risk factors for stroke, prevention of VCI may be possible through physical activity,¹²⁸ but physical activity has not been associated with a decreased rate of progression of white matter changes on MRI.¹²⁹

The effects of treatment in VaD are modest. A meta-analysis concluded that only small benefits of uncertain clinical meaningfulness were available from cholinesterase inhibitors or memantine.¹³⁰ Although some patients experience clinical benefit, no clinical features predicting treatment response have been found. The case for cholinergic inhibition is mixed. On one hand, the use of cholinesterase inhibitors in those with CADASIL has shown statistically significant improvement in some measures of executive function, and cholinergic mechanisms appear to play a critical role in cerebral perfusion.⁶⁶ However, the studies that most persuasively assembled groups of “pure” VaD patients¹³¹ had small effect sizes, no dose response, limited evidence for convergence of treatment effects within and across trials, and no clear translation into what physicians might look for in usual care.¹³²

Frontotemporal Dementia

Kristel Sleepers

Christine Van Broeckhoven

Frontotemporal dementia (FTD) is the most frequent and well-recognized clinical presentation of frontotemporal lobar degeneration (FTLD). FTD typically presents with changes in personality, behavior, and social comportment and is associated with atrophy of the prefrontal and antero-temporal cortex. The other two clinical manifestations of FTLD, semantic dementia (SD) and progressive nonfluent aphasia (PNFA), mainly exhibit language dysfunction.¹ PNFA is characterized by dysfunction of expressive language and is associated with asymmetric atrophy of the left frontal and temporal cortices. On the other hand, the pattern of atrophy in SD is bilateral, affecting the middle and infero-temporal cortex, and language dysfunction mainly consists of impaired word comprehension. Notwithstanding clear distinctions, considerable clinical overlap exists between these disorders, likely reflecting the expanding distribution of pathologic changes in different brain regions.

Scientific progress in recent years has greatly improved the characterization of these disorders, most notably in terms of the dissimilar pathomechanisms that may underlie similar clinical phenotypes. The increasing understanding of this etiologic heterogeneity is causing a shift in perspective from one that focuses on differences in clinical manifestation to one that is based on distinct proteinopathies. This distinction will be crucial in the diagnosis and management of these diseases, as well as for development of biomarkers and a curative treatment where none currently exists.

ETIOLOGY

It is now more than a century ago since Arnold Pick, a Czechoslovakian neurologist and psychiatrist, first published a report on frontotemporal dementia, describing a 71-year-old man who developed dementia with sensory aphasia and behavioral symptoms.² Autopsy demonstrated severe atrophy of the frontotemporal lobes, swollen ("ballooned") achromatic neurons and argyrophilic inclusions within frontal neurons consisting of insoluble filaments of the microtubule associated protein tau, a protein crucial for intraneuronal transport and structural integrity of the cell. These tau-positive inclusions were later referred to as Pick bodies, and their presence was necessary for pathologists to come to a diagnosis of Pick's disease. Gradually, the eponym was taken over by clinicians to diagnose patients with a dementia syndrome with disinhibited behavior, even though at autopsy a substantial number of patients appeared not to have Pick bodies or even tau pathology. The importance of tau in FTLD was lent further support by the discovery that mutations in the gene encoding the microtubule associated protein tau (*MAPT*)³ caused an autosomal dominantly inherited form of FTLD. At present, 43 mutations in *MAPT* have been described in 127 families with FTLD or related disorders (<http://www.molgen.ua.ac.be/FTDMutations>). Yet abnormal aggregation of tau is not necessary for a clinical manifestation of FTLD. Over 50% of autopsies do not display a tauopathy but rather show ubiquitin immunoreactive neuronal inclusions that are tau negative.⁴ A majority

of these inclusions was recently shown to consist mainly of ubiquitinated, hyperphosphorylated TAR DNA-binding protein 43 (TDP-43),⁵ leading to the notion of TDP-43 proteinopathy as opposed to tauopathy. In recent years, mutations in three different genes have been found to give rise to tau-negative, ubiquitin-positive FTLD, progranulin (*PGRN*, also known as *GRN*),^{6,7} valosin-containing protein (*VCP*),⁸ and chromatin-modifying protein 2B (*CHMP2B*).⁹

Ever since the discovery of loss-of-function mutations in *PGRN* in autosomal dominant FTLD in 2006,^{6,7} the number of FTLD patients in whom a *PGRN* mutation is detected has risen dramatically (currently 57 different mutations in 160 unrelated patients), revealing that *PGRN* is at least as important as *MAPT* in the genetic etiology of FTLD (<http://www.molgen.ua.ac.be/FTDMutations>). Frequency estimates vary, depending on source population and ascertainment, but are around 5% in unselected groups of patients and up to 25% in patients with a positive family history.¹⁰ Progranulin is a widely expressed secreted precursor protein with functions ranging from cell growth to inflammatory response. Given the reduction in functional progranulin protein in loss-of-function mutation carriers, progranulin is postulated to have a role in neuronal survival or neuroinflammation as well. Mutations in *VCP* and *CHMP2B* are infrequent (<1%) causes of tau-negative FTLD. Mutations in *VCP* cause a rare autosomal dominant syndrome of inclusion body myopathy associated with Paget's disease of the bone and frontotemporal dementia (IBMPFD).⁸ Mutations in *CHMP2B* disrupt the endosomal secretory complex, because of accumulation of mutant protein on the surface of enlarged vesicular structures. Of interest, whereas both *PGRN* and *VCP* mutations are associated with TDP-43 positive inclusions, the inclusions observed in *CHMP2B* carriers are TDP-43 negative,⁴ suggesting another distinct pathomechanism (Table 56-1).

Not all patients with a positive family history can be explained by mutations in one of the genes. In a Belgian study, for example, 37% of the 43 patients with a positive family history is explained by mutations in *MAPT* (N = 2), *PGRN* (N = 11), *VCP* (N = 2) and *CHMP2B* (N = 1).¹¹ The contribution of these four genes to familial FTLD might be somewhat underestimated because more complex mutations, such as large deletions, duplications or mutations in distant regulatory elements, are not readily detected in standard mutation screening, although this is unlikely to fully explain the remaining portion of familial FTLD patients. Rather, other as yet unknown genes play a role in FTLD, but they are missed in genetic studies because of reduced penetrance. Genetic linkage of families with FTLD and amyotrophic lateral sclerosis (ALS) to a chromosomal region on chromosome 9 suggests at least one other gene involved in the etiology of FTLD.^{12,13} Further, extensive clinical heterogeneity can be observed in families with a known mutation in *MAPT* or *PGRN*, suggesting the existence of other genes modifying the clinical phenotype.^{14,15} A plausible candidate gene was *TARDBP*, encoding TDP-43, but no mutations have been found in FTLD patients.¹⁶ In contrast, mutations in *TARDBP* do appear to play a role in the etiology of ALS,

Table 56-1. Genes Involved in FTLD with Associated Clinical and Pathologic Phenotypes

Gene	Protein	Chromosome	Mutations (Families)*	Clinical Phenotype	Pathologic Phenotype
<i>MAPT</i>	Microtubule associated protein tau	17q21.31	43 (127)	FTLD	FTLD-tau
<i>PGRN</i>	Progranulin	17q21.31	57 (160)	FTLD	FTLD-U/TDP-43 +
<i>VCP</i>	Valosin containing protein	9p13.3	11 (25)	IBMPFD	FTLD-U/TDP-43 +
<i>CHMP2B</i>	Charged multivesicular body protein 2B	3p11.2	4 (4)	FTLD	FTLD-U/TDP-43 -

FTLD, frontotemporal lobar degeneration; IBMPFD, inclusion body myopathy associated with Paget disease of the bone and frontotemporal dementia; FTD-MND, frontotemporal dementia with motor neuron disease; TDP-43, TAR-DNA binding protein.

a disorder that has a similar TDP43-opathy as the majority of FTLD-U patients.^{17,18}

CLINICAL PRESENTATION

Of the clinical variants of FTLD, FTD is the most common, with an estimated frequency of 57% among FTLD patients. PNFA is estimated to occur in 24% and SD in 19% of all FTLD patients.¹⁹

FTD, sometimes referred to as frontal variant FTD or behavioral variant FTD, typically presents with an insidious change of personality and behavioral abnormalities, such as loss of social awareness, poor insight, and blunting of affect. Other prominent symptoms include disinhibition, antisocial behavior, poor impulse control, and stereotypical or ritualized behavior, such as foot tapping, or more complex behavioral routines, or repetitive use of a phrase.^{20,21} reflecting the topography of neurodegeneration. Behavioral symptoms seem to be most severe in patients with right-hemisphere involvement.²² Cognitive impairment may be less prominent initially and mainly involves working memory and executive function. Cognitive changes include impaired attention, abstraction, problem solving, planning and organization, and perseveration. Visuospatial skills are remarkably spared until late stages of the disease. Frequently, dietary changes are reported, such as cravings for sweets and gluttony, leading to weight gain in many patients. Apathy can be another prominent feature, often reflecting involvement of the medial frontal and anterior cingulate regions. Language changes may include echolalia, perseveration and eventually mutism.²¹ During the course of the disease, motor symptoms may develop such as parkinsonian signs (akinesia and rigidity; in ~14%) or symptoms of MND (4–17%).²³

SD most often presents with fluent aphasia. Communication is mainly impaired by difficulties in recognizing and understanding the meaning of words. Use of substitute words and semantic paraphasias is frequent in otherwise grammatically flawless speech.²⁴ Loss of word comprehension is part of a more widespread loss of semantic knowledge of faces and emotions, facts and objects. This puts additional strain on daily activities (e.g. by inability to recognize ordinary household objects).²⁰ SD patients often display disinhibited or compulsive behavior, which may be more prominent than in FTD.²⁰ Episodic memory is relatively spared, but memory for autobiographical events is often affected.

In contrast to SD, patients with PNFA present with decreased fluency of speech, whereas comprehension of single words is usually intact. Symptoms include word-finding difficulties, changes in pronunciation, grammatical errors, anomia, phonemic paraphasias, stuttering, and apraxia of speech.²⁰ Semantic and episodic memories are preserved. Awareness of language deficits may explain socially withdrawn behavior and depression. Changes in behavior tend to occur later in the disease, and numerous patients eventually develop corticobasal syndrome (CBS) or progressive supranuclear palsy (PSP).

Although FTLD may clearly present with one of the three disorders, in the natural course of the disease patients will invariably develop symptoms of the other FTLD syndromes. Moreover, overlap with symptoms of Parkinson's disease (PD), CBS, PSP, ALS, or Alzheimer's disease (AD) is not exceptional.²⁵ This may be due to progressive involvement of other brain regions in the disease process, but it also results from comorbidity, especially in elderly patients.

EPIDEMIOLOGY

FTD is the third most common cause of neurodegenerative dementia, after AD and dementia with Lewy bodies (DLB).⁴ FTD is mostly thought of as an early onset dementia, and indeed, the majority of patients develop symptoms before 65 years, with an estimated age-specific prevalence of 4 to 15 per 100,000 for people aged 45 to 65 years.^{23,26} Epidemiologic data on FTD in the elderly are sparse, but a population-based survey in the Netherlands suggested that almost 1 out of 4 patients have an onset after 65 years. Of those, over one third were older than 70 years when they developed first symptoms of FTD.²³ Even in families with a known pathogenic mutation, onset age can be highly variable and may range from the third to eighth decade. Onset age for patients with a mutation in *MAPT* tends to be younger (mean onset age 47.9 ± 10 years) than for patients carrying a *PGRN* mutation (mean onset age 60.6 ± 8.6 years), but both *MAPT* and *PGRN* mutation carriers may be asymptomatic until late in life.¹⁰ Disease duration is generally shorter than for other neurodegenerative diseases like AD²⁷ and is estimated to be on average 6 to 7 years but may be as long as 35 years.¹⁰ Concomitant symptoms of MND are associated with a shorter survival,²⁸ whereas a clinical phenotype of SD²⁷ or a *MAPT* mutation¹⁰ is associated with a longer survival. Variability is considerable, however, so prognosis

should not be based on absence or presence of any of these factors.

Although data on risk factors for FTLD are sparse, positive family history has long been recognized as a major risk factor for FTLD. About 40% of FTLD patients have a positive family history, and in 20% to 30% the mode of inheritance is autosomal dominant.¹⁰ Most likely, in some patients without a clear mode of inheritance, age-dependent or incomplete penetrance of a pathogenic mutation obscures a clear inheritance pattern, but other genetic factors probably exist (see also Etiology). First-degree relatives of patients with FTD have a 3.5 times increased risk of developing FTD.²⁹

DIAGNOSIS

It can be quite challenging to come to a clinical diagnosis of FTLD; diagnostic delay is estimated to be between 3 to 4 years.²⁸ Because of insidious changes in behavior and personality, patients are often initially referred to a psychiatrist. A neurologic examination, with emphasis on detailed cognitive and behavioral assessment, combined with neuropsychological testing and neuroimaging, provide the foundations for a clinical diagnosis of FTLD. It is important to exclude other (potentially reversible) causes of cognitive and behavioral deficits, such as normal pressure hydrocephalus, tumors, hypothyroidism, alcohol abuse, and large or small vessel disease.

Clinical criteria

In 1998, consensus clinical criteria were established to serve as a guideline in the diagnosis of FTD.¹ In an overall clinical profile dominated by change of character and social conduct, several core features are required to come to a diagnosis of FTD. These core features include an insidious onset and gradual progression of symptoms, early decline in social interpersonal behavior, early impairment in regulation of personal conduct, blunting of affect, and loss of insight. Supportive diagnostic features include behavioral disorders (decline in decorum, mental rigidity, distractibility, dietary changes, perseverative or stereotyped behavior, and utilization behavior), disorders of speech and language (economy of speech, stereotypy, echolalia, perseveration, and eventually mutism), and physical signs (most notably parkinsonism). Using these guidelines, a good diagnostic accuracy can be obtained, with sensitivity and specificity greater than 85%.²¹

For general physicians, a simpler set of criteria is available,³⁰ consisting of six items: early and progressive change in personality or language, impairment in social and occupational functioning, gradual and progressive course, exclusion of other causes, presence of deficits in the absence of delirium, and exclusion of psychiatric causes. Whereas sensitivity of these criteria will be high, specificity will be reduced, but they may serve well to expedite referral to specialized centers.²¹

Neuropsychological testing

Mini-Mental State Examination (MMSE)³¹ has limited use in diagnosing FTLD. In patients with the behavioral variant FTD, MMSE scores may be normal even when the patient already requires nursing home care.³² On the other hand, language may be impaired, hindering a proper MMSE test of patients with SD or PNFA.²⁰ But also other neuropsychological test results should be interpreted with caution, especially when only the (quantitative) test scores

are considered. Failure to perform on a neuropsychological test may have various reasons, which are not reflected in the overall score. Especially in FTD, behavioral abnormalities such as impulsive behavior and perseveration may affect test performance²¹ such that the neuropsychological test scores would not differentiate from other neurodegenerative disorders such as AD. However, when taking into account the qualitative errors during testing, diagnostic accuracy for FTD may increase from 71% to 96%.³³ A large meta-analysis of cognitive tests discriminating between AD and FTD showed that measures of orientation, memory, language, visuospatial function, and general cognitive ability discriminated best, but that overlap in test performance was still considerable, indicating that a differential diagnosis should not be based on neuropsychological tests alone.³⁴

Several more easily applicable clinical and behavioral assessment scales exist that are not (or less) burdensome to the patient, such as the Middelheim Frontality Score,³⁵ the Philadelphia Brief Assessment of Cognition,³⁶ or the Frontal Behavioral Inventory (for caregivers),³⁷ and that perform relatively well in distinguishing patients with FTLD from other neurodegenerative diseases.

Neuroimaging

Neuroimaging may further help in the differential diagnosis. The three clinical FTLD syndromes show different patterns of atrophy on structural MRI, which can also be distinguished from AD and other related disorders, such as PSP and CBS.²⁵ Further, other structural causes of behavioral abnormalities, such as tumors or small or large vessel disease, can be excluded. In the early stages of disease, MRI may show cortical volumina within normal limits. Functional neuroimaging with positron emission tomography or single photon emission computed tomography might already reveal a pattern of hypoperfusion in frontal or temporal lobes.³⁸ At present it is not clear if the underlying pathology (tau positive or not) can be distinguished based on existing neuroimaging techniques.³⁹ Large multicenter collaborations will likely address these issues in the near future.

Postmortem diagnosis

A definite diagnosis can only be established postmortem, unless a pathogenic mutation in one of the known genes has been found. It should be noted, however, that neuropathology does not always shed light on the underlying etiology. Rare instances are known of mutations in genes typically involved in one neurodegenerative disease to give rise to a different pathology. A mutation in presenilin 1 (*PSEN1*) (e.g., a gene usually involved in AD) has been found in a patient with a clinical phenotype of FTD and a pathologic diagnosis of Pick's disease.⁴⁰

Based on the most recent insights, renewed neuropathologic criteria for FTLD have been formulated⁴ distinguishing seven broad classes, including three distinct types of tauopathy, three types defined by the presence of tau-negative ubiquitin-immunoreactive (Ub-ir) inclusions, and one class lacking distinctive histology.

The three types of tauopathy are defined by the occurrence of specific tau isoforms in the intraneuronal inclusions. In adult brain, six isoforms of tau exist, three of which contain three microtubule-binding domains (3R), and the other three contain four binding domains (4R), at a 1:1 ratio. Different

mutations in *MAPT* may bring about changes in this ratio in both directions, leading to a predominance of either 3R or 4R or equal presence of both in the insoluble tau aggregates typical for tauopathy, but different isoform signatures are also found in absence of a *MAPT* mutation. When the 3R isoforms are predominantly hyperphosphorylated, the diagnosis most likely is FTLD with Pick bodies or *MAPT* mutation. Predominance of 4R isoforms points toward corticobasal degeneration, PSP, FTLD with a *MAPT* mutation, or less frequently, multisystem tauopathy or argyrophilic grain disease, dependent on clinicopathological correlations. FTLD with a *MAPT* mutation may also be the underlying diagnosis when both 3R and 4R isoforms are present, but presence of 3R and 4R isoforms may also indicate neurofibrillary tangle dementia (in absence of amyloid beta plaques) or AD.⁴

Four types of nontauopathies can be found, three of which are characterized by Ub-ir neuronal inclusions in the nucleus or cytoplasm. The presence of a TDP-43 proteinopathy (when the inclusions contain TDP-43) points toward FTLD with *PGRN* or *VCP* mutations. In absence of a known mutation, the diagnostic criteria propose a diagnosis of FTLD-U (where U stands for ubiquitin-positive) with or without MND. Diagnoses in this category will likely be subject to change when novel causes for TDP-43 proteinopathy are identified. FTLD-U, but without TDP-43 positive inclusions, is typical for FTLD caused by a *CHMP2B* mutation or may indicate basophilic inclusion body disease, but it could also include other as yet unknown disease causes. When alpha-internexin-positive inclusions are found in addition to FTLD-U, the most likely diagnosis is neuronal intermediate filament inclusion disease (NIFID).⁴

The seventh category, of frontotemporal neuronal loss and gliosis without any signature inclusions, currently is called dementia lacking distinctive histologic features (DLDH) but may in future years reveal a distinct phenotype. Of note, several cases of DLDH are now known, because of the use of immunohistochemistry and discovery of novel disease entities, to have FTLD-U.⁴ Immunohistochemistry of other inclusions such as amyloid beta, alpha synuclein will allow distinction from other neurodegenerative diseases, but overlap between different proteopathies is not infrequent, especially in elderly patients. It should further be noted that the density and distribution of protein aggregates do not always correlate well with the clinical symptoms.⁴

Genetic testing

The only way to obtain certainty regarding the underlying disease entity during life is when a mutation screening of the genes implicated in FTLD reveals a pathogenic mutation. *MAPT* and *PGRN* mutations are both found in approximately 5% of referred patients, whereas mutations in *CHMP2B* and *VCP* are rare. Moreover, *VCP* is associated with other clear clinical features, as part of IBMPFD, suggesting an initial screening in an FTLD patient should be targeted to *MAPT* and *PGRN*. In specialized genetic diagnostic centers genetic testing is available, for *MAPT* exons known to harbor mutations and for the coding regions of *PGRN*. No clinical distinctions exist that may point toward one specific gene, although it has been suggested that primary progressive aphasia (PPA) is frequent in *PGRN* mutation carriers.^{10,41} Moreover, *PGRN* mutations have, so far, not been found in FTLD with concomitant MND. *MAPT* mutations are highly penetrant, so arguably these need

not be screened for in sporadic patients,⁴² whereas *PGRN* mutations have been identified in sporadic patients as well.⁴³ A caveat here is that both mutations in *PGRN* and *MAPT* show considerable clinical heterogeneity, so the presence of ALS or PD may be misinterpreted when examining family history. Further, because of the high variability in onset age, an autosomal dominant pattern of inheritance may be obscured.

Genetic testing should always be paired with genetic counseling, as it does not only serve to give diagnostic certainty but also has a profound impact on family members, especially in the current absence of a targeted cure for tau-positive or tau-negative FTLD. Reduced penetrance complicates the interpretation of a positive test, incomplete knowledge of the causes of FTLD complicates the interpretation of a negative test, and it is possible that mutations of questionable pathogenic significance are found.

BIOMARKERS

The availability of biomarkers for FTLD is still limited, but development of proteinopathy-specific biomarkers will increasingly be important. Because tau has long been the only recognized protein to be involved in FTLD, focus in the development of biomarkers has been on tau. Commercial tests are available to measure levels of total tau, hyperphosphorylated tau, and amyloid beta simultaneously in cerebrospinal fluid, which may add to the differential diagnosis between AD, DLB and FTLD. Levels of total tau have been found to be lower in FTLD compared to AD,⁴⁴ but they have also been found to be higher or normal.³⁹ Levels of hyperphosphorylated tau appear to be increased in AD patients compared to FTLD and DLB. The level of tau has also been correlated with cortical volume of the right frontal and left ventral temporal brain regions.⁴⁴ The inconsistency of the results might be explained by the fact that until now, study populations of FTLD contained a large proportion of unrecognized FTLD-U patients, obscuring a correlation between CSF-tau levels and tau-positive FTLD. Sufficiently large studies correlating CSF tau levels with neuropathologic phenotype are unfortunately still lacking.

The discovery of *PGRN* loss-of-function mutations as an important cause of tau-negative FTLD,^{6,7} and the identification of TDP-43 as a major constituent of the characteristic inclusions in the majority of FTLD-U patients⁵ will likely allow antemortem distinction between tau-positive and tau-negative FTLD in the very near future. Because loss-of-function mutations in *PGRN* leads to a loss of functional *PGRN* protein, levels of circulating *PGRN* will probably be reduced in mutation carriers versus nonmutation carriers. Indeed, evidence exists that a reduction of *PGRN* because of a loss-of-function mutation is detectable in CSF⁴⁵ and serum⁴⁶ by means of Enzyme-linked immunosorbent assay (ELISA). Another group recently reported on an ELISA to measure TDP-43 in plasma.⁴⁷ Elevated plasma levels of TDP-43 were detected in 46% of FTLD patients, which is close to the expected frequency of FTLD-U. Unfortunately, correlation of plasma levels with TDP-43 pathology in the brain could not be assessed. Variability of TDP-43 levels was considerable, even in healthy individuals, suggesting the usefulness as predictor of disease may be limited.

The advent of biomarkers specific for these molecular entities will add to the ability to reliably diagnose the different

FTLD syndromes. Moreover, it will facilitate the development of etiologically based medication. Inclusion criteria for drug trials can be more stringent based on biomarker profiles, and the biomarkers can be used to monitor efficacy of treatment accurately. Once a preventive strategy becomes available, these biomarkers may even be measured as predictors of disease, to guarantee intervention in the preclinical stage of the disease.

TREATMENT AND STRATEGIES

Although currently no etiologically based curative treatment exists for FTD, treatment options exist to diminish the burdensome (behavioral) symptoms associated with the disease, to significantly improve patient care and quality of life. Both pharmacologic and nonpharmacologic symptomatic approaches exist. Strategies for symptomatic treatment of FTLT are derived from other disorders with behavioral disturbances, such as AD. Studies addressing the efficacy and safety of these symptomatic medications in FTLT are limited. Most evidence comes from case reports and open-label studies of small patient groups. The decision to prescribe any of these medications should be carefully considered for each patient, but especially in the elderly, in light of interaction with other medications and comorbidity.

Selective serotonin reuptake inhibitors (SSRIs: fluoxetine, fluvoxamine, sertraline and paroxetine) may counteract social abnormalities (such as depression, anxiety, disinhibition, impulsivity, and sexually inappropriate and stereotyped behavior), but they are also reported to suppress eating abnormalities (such as decreased satiety and food cravings).^{20,48} Although the use of SSRIs in FTLT is plausible given the association of these behavioral abnormalities changes in cortical serotonin levels,⁴⁸ the results of the few existing trials have been inconsistent.^{49,50}

Other behavioral features such as agitation and psychosis are often treated with neuroleptic medication, but the traditional neuroleptic agents have undesirable side effects, such as parkinsonism or somnolence, particularly in the older patient. Extrapyramidal side effects may be less pronounced when prescribing atypical antipsychotic drugs, but increased mortality during use of atypical antipsychotics was reported in the elderly.⁴⁸ On the other hand, a study specifically addressing this issue suggested these drugs are well tolerated by the elderly.⁵¹ Anticonvulsant drugs are sometimes given to treat aggression, but side effects (including confusion) limit their use in the elderly.⁵² No placebo-controlled trials exist.⁴⁸

With the availability of acetylcholinesterase inhibitors (rivastigmine, donepezil, galantamine) for symptomatic treatment of AD, these are also being examined in FTLT patients, even though the cholinergic system seems to be relatively unaffected in FTLT compared to AD.⁴⁸ Studies on the efficacy of cholinesterase inhibitors give inconsistent results.^{20,48} Overall, cholinesterase inhibitors appear not to have an effect on cognition. Memantine, a drug targeting the glutamatergic system in AD, has been tested in a trial; it resulted in no changes in behavior and a worsening of cognitive performance.⁵³

Behavioral symptoms tend to be more distressful early in the disease, also for those surrounding the patient. But as the pathologic process progresses, patients gradually display more apathy and less behavioral disturbances, allowing withdrawal of symptomatic treatment in advanced stages.²⁰

Like the pharmacologic treatments, the nonpharmacologic management of a patient should be tailored to his or her specific symptoms and should be adapted when needed along the course of the disease. Interventions may include structuring of the environment and the establishment of daily schedules to reduce the chance of agitation, controlled access to food for patients with food cravings, and help in planning and avoiding of complex multistep activities for patients with executive dysfunction.⁵²

When language dysfunction is prominent, focus should be on optimizing communication, for example, by speaking slowly in short sentences in case of impaired comprehension and by employing picture cards or computer-assisted devices in case of reduced fluency.⁵² Other nonpharmacologic approaches should be targeted to reduce physical discomfort, such as reducing the risk of falls, physical therapy, prevention of decubitus ulcers in bed-ridden patients, and prevention of aspiration pneumonia, especially in patients with gorging behavior.⁵² Special attention should also be given to caregivers of FTLT patients. The symptoms of FTLT (inappropriate behavior, agitation, and psychosis) may cause considerable distress for the caregiver and are unknown to many people, so community support for caregivers may fall short. Studies have shown that caregivers experienced most distress in the initial stages of the disease, especially when a patient was institutionalized after short dementia duration,⁵⁴ suggesting there may be adaptation over time.

Ultimately, management should be fitted to the underlying disease entity, because this will be the only possibility to cure the disease. Ideally, targeted therapy should be commenced in the early stages of disease, before the disease becomes clinically manifest, even allowing prevention of FTLT. The discovery of novel FTLT genes has not only been instrumental in identifying novel molecular targets for drug development, it also presents researchers with the possibility of developing biomarkers that will help in early detection. This in turn will allow more efficiently organized drug trials that are not confounded by etiologic heterogeneity.

KEY POINTS

Frontotemporal Dementia

- Main presenting symptoms of FTLT are changes in personality and behavior, or language dysfunction.
- Currently only symptomatic treatment exists, which may increase quality of life but can have adverse side effects, so their use in elderly patients should be carefully considered.
- FTLT has a strong genetic component, with two major genetic causes (*MAPT* and *PGRN*) and two rare genetic causes (*CHMP2B* and *VCP*) currently known.
- FTLT is a clinically, genetically, and pathologically heterogeneous disorder.
- Distinction of the different molecular entities (tauopathy, TDP43-opathy, or other) will increasingly be important when etiology-based medicine becomes available.
- Biomarkers specific for the different molecular entities are in early stages of development.

Functional Psychiatric Illness in Old Age

Cornelius Katona
Gill Livingston
Claudia Cooper

Older people may suffer a wide range of psychiatric difficulties in late life, and those who have a concurrent physical illness are particularly vulnerable. Although these conditions tend to be underdetected and undertreated, their outcome with appropriate management is often excellent. This chapter discusses in some detail the clinical presentation, epidemiology, management, and outcome of depression; the schizophrenia-like psychoses and delusional disorders; mania; the anxiety disorders; alcohol-related problems; and disorders of personality in old age, with briefer discussions of obsessive-compulsive disorder, somatoform disorders, and posttraumatic stress disorder.

DEPRESSION

By 2020, depression will be second only to heart disease as a contributor to global disability and a major public health problem in older people.¹ Despite this, depression is often missed, ignored, or not managed adequately, especially in this age group. Patients present needing help but with presenting complaints other than low mood. This is in part a consequence of widely held "agist" assumptions that depression is intrinsic to the aging process and that treatment is inappropriate, excessively risky, or unlikely to be effective. These assumptions are demonstrably untrue: the majority of older people are not clinically depressed (despite their increased risk of loss and of adversity); those that are respond as well to the range of pharmacologic and psychological treatment as do younger depressed patients.

Epidemiology

The prevalence of depression in older people varies widely depending on sample selection, instruments used, and "case-ness" criteria. The clinical features of depressive disorder may be complicated by its less than obvious presentation as well as by coexisting medical problems or cognitive impairment. Older subjects in the community appear to have a lower prevalence of *major* depression [as defined within the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) system] than their younger counterparts.² An early United Kingdom community study found a 10% prevalence for depression in community residents, but only 1.3% met criteria for major depression.³ In an Australian study,⁴ which included individuals living in both community and institutional settings, the rate for depressive episodes was 3.3% using ICD-10,⁵ compared to 11% using DSM-III-R criteria.⁶ Within DSM criteria, rates for dysthymia (chronic mild depression) are far from consistent; for example, in the U.S. Epidemiologic Catchment Area Study, the prevalence was 1% to 1.5% in those aged over 65,⁷ whereas in a Finnish study,⁸ the rate was 23%. More consistent results have been achieved using semistructured interviews and diagnostic algorithms.^{9,10} Studies using these instruments have found prevalences of 14.2% for moderate to severe depression in Tasmania,¹¹ 11.3% in Liverpool,¹² 16.2%

in New York City, and 19.5% in London.¹³ An inner London community-based study¹⁴ reported a 15.9% rate of depression and an annual new incidence rate of 3.8%.

In these studies, the overall depression prevalence rates for women were about 50% greater than for men, but for severe depression they were similar in male and female subjects. A comprehensive review¹⁵ reported an average prevalence of 13.5%. Rates for women and for people who were socioeconomically disadvantaged were consistently higher. Similarly, a review comparing nine European community studies¹⁶ found an overall prevalence of 12.3% (women 14.2%, men 8.6%).

The prevalence of depressive illness appears higher among older GP attenders, with reported rates as high as 31%,¹⁷ although others give a prevalence of about 15%.¹⁸ There is an established interrelationship between increased depression, physical disability, and more contact with services including GP attendance,^{14,19} suggesting that frequent attendance may be a "marker" of depression.

In the hospitalized elderly, the prevalence of depression is also high, with a reported range between 12% and 45%.^{20,21} Similarly, the prevalence of depressive disorders among elderly people in long-term institutional care is in excess of 20%.²²

Depression in old age may be complicated by underlying cerebral pathologies. Rates of depression of 20% to 30% are found in people with Alzheimer's disease.^{23,24} Studies that screen out individuals with cognitive impairment may miss cases of clinically significant depression, although such depression may be relatively likely to remit spontaneously.²⁵

Etiology

Demographic, social, and biologic factors have all been implicated in the etiology of depression in old age.

Gender and age

Most community studies find significantly higher rates for depression in women than in men—this is particularly clear in a recent meta-analysis.¹⁶ The relationship between depression and age itself within the elderly population is not clear-cut; some studies find depression to be more common in the very old,¹¹ whereas others find the reverse to be true.²⁶

Genetic susceptibility

Genetic factors are generally reported to be less important in elderly patients with depression than in their younger counterparts.²⁷ However, some studies have found a positive family history for depression in about one third of patients with first onset of depression after the age of 60.²⁸

Neurobiologic risk factors

In both depression and aging, there may be decreased non-adrenergic responsiveness with compensatory increases in postsynaptic receptor number. A positive correlation has

been noted between age and platelet α_2 adrenergic binding capacity in controls but not in subjects with depression.²⁹ Aging may enhance depression-associated changes in serotonergic responsiveness as evidenced by reduced platelet ³H-imipramine binding³⁰ and blunted prolactin responses to the 5HT precursor L-tryptophan.³¹ It has been hypothesized that cholesterol might be an important factor in the relationship between serotonergic dysfunction and depression, through alterations in synaptosomal membrane properties. However, a meta-analysis of the outcome of older patients participating in clinical trials of cholesterol-lowering agents revealed no significant associations between low cholesterol concentration and severity of depressive symptoms.³²

Imaging techniques have been widely used in the study of depression in old age. Abnormalities of the amygdala might predispose to depression with patients having a larger amygdala volume than controls. Increased activity of the amygdala combined with inadequate corticoregulation of its emotional output probably contributes to depressive symptoms.³³ Ventricular enlargement and ischemic changes are more frequently found in patients whose first onset of depression was after the age of 60.³⁴ Older patients with depression have lower regional cerebral blood flow (rCBF) than controls, particularly in the left hemisphere.³⁵ However, rCBF failed to correlate with severity of depressed mood. In another study, reduced anterior frontal and temporal blood flow, an increase in occipital flow,³⁶ and a reduction in whole brain glucose metabolic rate were associated with depression.

Physical health

Depression is more common in physically ill than in healthy older people. As physical illness and depression both often present with physical features (such as sleep disturbance, loss of appetite, and pain), then the use of screening tests that utilize biologic symptoms can lead to false positives. The prevalence range varies from 6% to 25% when diagnostic interviews validated among elderly people are used.^{37,38} The main risk factors for depression appear to be the severity of physical illness, the degree of disability, pain, coexisting cognitive impairment, and a positive past psychiatric history.

Although illness in general is a risk factor for depression, stroke and Parkinson's disease have been associated with a particularly high likelihood of developing depression. The 1-year prevalence of depression following a stroke is 20% to 50%, with an apparent peak within the first 6 months.³⁹ Reported relationships with lesion size and site in stroke have been inconsistent. Rates of 40% to 50% have been reported in people with Parkinson's disease.⁴⁰ Among people who have had a myocardial infarction or undergone cardiac catheterization, a quarter have major depression and a further quarter minor depression.³³ Physical disability seems to be particularly strongly associated with depression in institutional settings.²²

Depression in elderly medical patients frequently becomes chronic and in turn appears to have an adverse effect on the physical prognosis, especially in terms of likelihood of successful rehabilitation.⁴¹ In addition, older medical patients with depression consume more health care resources, have longer admissions, have a higher mortality, and are more likely to be transferred to residential care.⁴² However, medical staff members frequently

overlook depression in elderly medical patients, despite high rates of depressive symptomatology.⁴³ Its detection may be facilitated by simple screening tests such as the Geriatric Depression Scale (GDS).⁴⁴ The five-item version of the GDS has the best psychometric properties for use in medically ill people, with a sensitivity of 97% and specificity of 85%.⁴⁵ The following questions are included in the five-item GDS: "Are you basically satisfied with your life?" "Do you often get bored?" "Do you often feel helpless?" "Do you prefer to stay at home rather than going out and doing new things?" and "Do you feel pretty worthless the way you are now?" Positive answers for depression screening are no to the first question and yes to the other questions, with at least two positive answers denoting a screen positive result. The Patient Health Questionnaire Depression module (PHQ-9) is increasingly used in general practice as a depression screen, and it has also been validated in older people. This scale acts both as a brief self-reported diagnostic screen and as a measure of the severity of major depression.⁴⁶ Several studies support its validity, feasibility, and capacity to detect changes in depressive symptoms over time.

Personality and social factors

Those individuals with late-onset depressive illness appear to have more robust personalities than those with recurrent depression arising earlier.⁴⁷ Dependent, anxious, and avoidant personality traits have, however, been reported to be associated with late life depression.⁴⁸

Life events often precipitate depression in old age.⁴⁹ Several community studies have shown the importance of loss in the depressions of old age. Illness, chronic disability, social isolation, bereavement, and poverty are all correlates of depressive symptoms.^{50,51} The importance of physical illness has already been discussed. People who are separated, divorced, or widowed (and have therefore lost a partner) are more likely to have a depressive illness than those who are married or cohabiting.⁵² Similarly, depression is associated with recent deaths and accidents in near relatives.⁵³ Being a caregiver for someone with dementia or depression is associated with an increased risk of depression in the caregiver; this is particularly marked in women, in spouse-caregivers, where the premorbid relationship was poor, and where there are prominent behavioral problems such as aggression.^{54,55} A confidant may act as a buffer against such loss-related depression, particularly in women.⁵¹ The direction of causality is unclear as poor support may render persons liable to depression, or the depression may lead to the loss of support. Personality variables are likely to be important mediators.

Clinical features

Depression often presents in a less typical fashion in old age. This clearly has implications for the under- or misdiagnosis of depression in the elderly. Older patients tend to have an increase in somatic complaints, sleep disturbance (initial insomnia), and agitation.⁵³ There are two main symptom clusters: *affective suffering*, which included low mood, tearfulness and occasionally hopelessness, seeing the future as bleak, and the wish to die, and a *motivational cluster*, comprising loss of interest, poor concentration, and lack of enjoyment.⁵⁶ Depressed mood, guilt, anxiety,

and diurnal mood variation are more common in women than in men with depression.⁵⁷ People whose first episode of depression occurred in late life are less likely to display psychotic features and are also more likely to display cognitive impairment.⁵⁸

Depression and dementia

Cognitive impairment is frequently found in association with depression in older people. Its presence may be important not only in terms of hindering diagnosis but, more positively, as an etiologic and prognostic pointer and an element in a possible specific approach to the subtyping of depression in old age. Prominent cognitive dysfunction that initially reverses with successful antidepressant treatment is the essential clinical feature in the minority of elderly depressed patients with *depressive pseudodementia*.⁵⁹ Subtle cognitive impairment may, however, be present in a broad spectrum of the elderly depressed and may in any case not be as consistently reversible as had been thought.⁶⁰ Although depression is increased in those with dementia, the risk of depression is not related either to insight or to severity. It is, however, less common in those who take exercise.⁶¹

A recent thoughtful review suggests that there may be clinically distinct subtypes of depression within dementia. In particular, apathy may be prominent, as may executive dysfunction and disinhibition.⁶² Physically aggressive behavior in people with dementia may in particular be depression driven. Apathy may also be an important presenting feature.

The evolution of cognitive and depressive symptoms in people in whom these coexist is not always straightforward.⁶³ Lack of motivation increased sharply with decreasing cognitive function, and increasing disability may be associated with deterioration in both mood and motivation symptoms. This depression-executive dysfunction syndrome has retardation, reduced interest, limited insight, and poor self-care as predominant features. The closely related concept of *vascular depression* is characterized clinically by apathy, psychomotor retardation, loss of verbal fluency, and generalized cognitive impairment with radiologic evidence of cerebrovascular disease and high rates of progression full-blown dementia.³³

The detection of depression in people with severe dementia is difficult. People find it difficult as dementia progresses to articulate emotional distress or remember their symptom pattern. There are, however, rating scales specifically designed to detect depression in subjects with dementia; the best of these is probably the Cornell Scale.⁶⁴

The Geriatric Depression Scale⁴⁵ is sensitive and specific in hospital settings, is quick to administer, and is highly acceptable to patients.

The management of depression in old age

The management of depression in physically ill elderly patients is essentially the same as for depression in general. Antidepressant and psychological therapy are equally effective in older and younger adults,³³ although in pharmacotherapy, medical comorbidities, and the possibility of adverse consequences or interactions between antidepressants and other drug treatments must be considered carefully.

Certain drugs are associated with depression. These include propranolol, beta-blockers, antiparkinson drugs,

cimetidine, clonidine, estrogens and progesterone, tamoxifen, and dextropropoxyphene. Depression is also associated with malignant and cerebrovascular disease, myocardial infarction, thyroid, parathyroid, and adrenal endocrine disturbance.³³ Removal of depression-causing medication and treatment of illnesses associated with depression may improve mood. Antidepressants should be given at adequate doses for a minimum of 4 weeks before concluding they are ineffective and changing to a different class. If response is poor, consider whether the patient is adhering to the treatment and increase to a higher dose.³³

A recent Cochrane review found 29 trials of antidepressant therapy in people aged 55 and over; selective serotonin reuptake inhibitors (SSRIs) and tricyclic antidepressants were equally efficacious, although tricyclics were associated with more withdrawals because of side effects.⁶⁵ Patients with depression may make different decisions about life-sustaining therapy after their depression is treated, so wherever possible such decisions should be postponed until they have recovered. Serotonin-norepinephrine reuptake inhibitors (SNRIs) (venlafaxine and duloxetine) have also been demonstrated to be effective treatment for depression in older people.^{66,67}

Depression in old age frequently fails to respond to initial treatment. Pharmacologic strategies for treatment-resistant depression may be useful despite the toxicity risk. Nortriptyline, lithium, and bupropion were found to be useful additive treatments where an SSRI is the initial treatment.³³ People with dementia are at an increased risk of developing depression. In people with Alzheimer's disease, the findings from controlled trials of antidepressants (reviewed by Lyketsos et al)⁶⁸ are inconsistent, though sertraline was efficacious in a recent RCT.⁶⁹

Antidepressant prescribing for depressed older people appears to have increased in recent years, perhaps because of the perceivably superior safety profile of SSRIs.⁷⁰ Pathologic crying, or more rarely pathologic laughing, may develop poststroke in 7% to 48.5% of stroke survivors, and there is evidence that SSRIs can be efficacious in reducing symptoms within days of commencing therapy [Number Needed to Treat 1.5 (NNT 1.5)].⁷¹

The safety profile of electroconvulsive therapy (ECT) in older patients with depression is very good.⁷² A wide spectrum of clinical responses has been demonstrated, including reduction of anxiety symptoms. A meta-analysis of published studies revealed 62% recovery and 21% substantial improvement rates.⁷³ Although much of the evidence base for ECT is from studies of predominantly younger adults, reanalysis of these studies indicates that ECT is at least as effective in adults aged 60 and older and may positively influence outcome.⁷⁴ Unilateral electrode placement appears as effective as bilateral in older patients, but there is clearer evidence that unilateral electrode placement is associated with fewer memory-related side effects in this age group.⁷⁵ A study comparing an SSRI (paroxetine) to ECT in resistant depression in elderly has reported a dramatic difference in the results, with a low response rate of 28% in the paroxetine group compared to 71% in the ECT group.⁷⁶

Psychological treatments are underused in old age. This is partly because their availability is often limited. There is also a misconception that older people lack the psychological flexibility to benefit from psychotherapeutic interventions.⁷⁷

Elderly people appear to respond particularly well to cognitive therapy for depression; this is effective both in an individual setting and (more economically) in groups. The focus is often on real or threatened losses (bereavement, physical health, financial security) and on fears of impending death. Brief, highly focused cognitive-behavioral therapies such as problem-solving therapy are being advocated increasingly for older people, including those with some degree of cognitive dysfunction,⁷⁸ and they may be effective when used in people at high risk to prevent as well as treat depression in old age.⁷⁹ Another brief talking therapy, interpersonal psychotherapy, has also been shown to be effective in older people.⁸⁰

Community and primary care studies suggest that only a small minority of older patients with depression receive treatment. A community study found that only 13% of subjects with depression were being treated with antidepressants; at follow-up, the figure remained virtually the same at 14%.¹⁴ Similarly, only 10% of patients with depression identified from consecutive primary care attenders were receiving treatment for depression.¹⁷ However, their general practitioners were aware of depression in 95% of cases. This suggests that GPs may conceptualize depression in old age as a legitimate and unavoidable consequence of aging and associated adversity, which is recognizable but not seen as treatable. Collaborative care has emerged as a helpful approach toward integrating primary and secondary care teams and combining the use of a range of treatment modalities. Tailored collaborative care was associated with substantial benefits (compared with treatment as usual) in terms of improvement in depressive symptoms, better physical functioning, and an enhanced quality of life.⁸¹

Suicide and depression in old age

Suicide in old age is almost twice as common in North American older people than in the rest of the population⁸²; similarly, suicide rates in most countries are highest in the elderly.⁸³ In the United Kingdom, the rate in those over 65 years is approximately three times that in the 15-to-24-year age group. Older people are more likely to die in a suicide attempt than younger people, and in men, the rate continues to rise into the ninth decade. Deaths are usually by overdose, but men more frequently use violent means (hanging, firearms, etc.).⁸⁴ Suicide is much more closely associated with depression in older than in younger subjects, and the best predictor of suicidality is the current severity of depression. The increased rate of suicide in those experiencing physical ill health is mediated by depression.⁸⁵ Other factors associated with suicide in old age include bereavement, substance misuse, increasing social isolation, deteriorating physical health, and pain.

Attempted suicide closely resembles completed suicide in the elderly.^{85,86} Psychiatric illness, particularly depression, is prominent in most cases. Minor depression and personality dysfunction are associated with suicide attempts of relatively low intent and higher levels of psychosocial stresses. Hopelessness persisting after remission of other depressive symptoms is associated with suicide attempts and completed suicide.⁸⁷

The close association between depression and deliberate self-harm in old age carries a clear message that all such behavior in older patients should be taken seriously with

particular attention to the exclusion or treatment of underlying depressive illness.

The prognosis of depression in old age

Treatment is generally as effective for older adults as for younger ones if depression is recognized and treated,³³ although patients often have recurrences. The mortality rate is considerably higher in elderly patients with depression than in age- and sex-matched controls.⁸⁸ Although this in large part reflects preexisting health problems that are significantly more common in depressed patients, they have a worse outcome than those with the same degree of physical illness who are not depressed.

The prognostic significance of cognitive impairment within elderly depressed patients remains unclear. However, in patients presenting with "pseudodementia," not only do computed tomography (CT) scan abnormalities seem to be significantly more common but this subgroup of patients has a poorer prognosis and 40% of them develop dementia within 3 years of follow-up.⁸⁹

In older people with depression, physical illness, cognitive impairment, and severe depressive symptoms rather than social factors are markers of a less optimistic prognosis.⁹⁰ Family problems including psychiatric symptoms in the spouse or adult child and poor physical health also adversely influence prognosis.⁹¹ Chronic health problems and acute new physical illness predict poor outcome, with the combination of depressive symptoms and physical disability together initiating a spiraling decline in physical and psychological health.

Continuing treatment appears to have a protective effect against relapse. This has been shown most clearly for maintenance antidepressant drugs,⁹² but the efficacy of supportive group psychotherapy has also been shown.⁹³

LATE LIFE PSYCHOSIS

The onset of schizophrenia-like psychotic illness later in life not due to an organic or affective disorder has been referred to as *paraphrenia*, *late paraphrenia*, and *late-onset schizophrenia*. In 2000, the International Late-Onset Schizophrenia Group defined the terms *late-onset schizophrenia* and *very late-onset schizophrenia* for schizophrenia-like illnesses with onsets between age 40 and 60 and after age 60, respectively. The term *late-onset schizophrenia* is used to describe these conditions within this chapter. More circumscribed delusional disorders also occur in late life; these are referred to later as *late life delusional disorders*. In addition, the challenges posed by patients with long-standing psychotic illness (usually schizophrenia) who "graduate" to old age are also considered within this section.

Late-onset schizophrenia

The original concept of late-onset schizophrenia referred to the first onset of persecutory delusions and associated hallucinations after the age of 60 years in the absence of an affective or organic psychosis.⁹⁴ It may thus be viewed as schizophrenia or a schizophrenia-like illness in old age.

Epidemiology

Although the incidence of schizophrenia is highest in people aged 16 to 25, there is a second peak in incidence in those aged ≥ 65 .⁹⁵ The prevalence of nonaffective psychosis

in people aged ≥ 65 years has been reported as 2.3% in women and 1.7% in men.⁹⁶ Data from GP practices regarding patients with treated schizophrenia (1997–1998) indicate that prevalence peaks in women in the 65-to-74 age group compared with the 45-to-54 age group in men, reflecting the higher prevalence of late-onset schizophrenia in women. The incidence of late-onset schizophrenia has been reported at 12.6 per 100,000 population per year.⁹⁷ Incidence is positively correlated with age, with first admission data suggesting an increase of 11% for every 5-year increase in age.⁹⁸ In the United Kingdom, African-Caribbean older people are more likely than white British older people to be in contact with services for a new diagnosis of psychosis.⁹⁹ Prevalence of late-onset schizophrenia is likely to be underestimated by community surveys and treatment data as those affected are far less likely than the rest of the population to cooperate with survey investigators and often refuse treatment. They may only be treated compulsorily and in the context of particularly severe behavioral disturbance or when the illness affects their physical health.

Etiology

About 10% of the relatives of patients developing schizophrenia in middle age also have the disease; this is similar to the proportion for patients with early-onset schizophrenia.¹⁰⁰ In family studies of late-onset schizophrenia, however, the rate of schizophrenia in first-degree relatives is much lower.¹⁰¹ Standardized instruments were not used in the late-onset schizophrenia studies, however, so the data are not directly comparable to those from fully operationalized family studies of younger subjects.

The influence of personality, social, and environmental factors in association with genetic predisposition is clearly complex.¹⁰² Patients with late-onset schizophrenia are often socially isolated and live alone.¹⁰³ They are more likely to have paranoid or schizoid premorbid personalities that are characterized by suspicion, sensitivity to setback and disappointment, and preoccupation with what others may think about them.¹⁰⁴ Their isolation is often longstanding and may well be secondary to personality traits. They are predominantly unmarried women without close family or personal attachments. Those who do marry often end up divorced or separated. However, premorbid educational, occupational, and psychosocial functioning is less impaired in late-onset than early-onset schizophrenia.¹⁰⁴ Fertility seems markedly reduced. This social isolation, which is often increased by sensory isolation and retirement in older people, creates an environment allowing the individual to become preoccupied with his or her own internal world.

In terms of sensory impairment, there is a confirmed association between deafness and very-late-onset schizophrenia in particular.¹⁰⁴ Many of those patients have conductive hearing loss contracted in early life to such a degree as to impair social interaction resulting in “social deafness.”¹⁰⁵ Visual impairment may be present but is probably no more common than in normal elderly people.⁹⁴ Patients with late-onset schizophrenia have been found to come from the lower social classes or socioeconomic groups¹⁰³; this may result from social deterioration secondary to the disease, as also occurs in younger people with schizophrenia.

Presentation and clinical features

Patients often come to the attention of services because they complain to the police and neighbors with bizarre accusations over a period of time or because of neighborly concern triggered by extreme self-neglect. On mental state assessment, there are no qualitative differences between the positive symptoms of early-onset schizophrenia and of late-onset schizophrenia. The clinical presentation of late-onset schizophrenia is quite varied. Patients are in clear consciousness. Usually their affective state is normal although occasionally a secondary depressive mood is found. The history may be difficult to elicit from patients with late-onset schizophrenia who tend to be distrustful and hostile.

Delusions are central. Persecutory delusions are particularly common. Sexual themes are common in women. The patient may accuse a man or men of entering her bed at night and molesting her sexually. Delusions of influence and passivity phenomena are frequently reported.¹⁰⁶ Patients may describe their bodies as being controlled, or complain that some power affects them and they are made to do things against their will. Thought insertion, withdrawal, and broadcasting are, however, fairly rare, and formal thought disorder is almost nonexistent.

Hallucinations are frequently experienced.¹⁰³ Those with late-onset schizophrenia experience a great number of different types of hallucinations. Auditory hallucinations are the most common and usually have an accusatory and/or insulting content. The voices speak in the second or the third person with “running commentary” occasionally encountered. Hallucinations of bodily sensation are also found. Patients complain of being vibrated, raped, or forced to have sexual intercourse. Olfactory hallucinations often relating to poisonous gas are encountered. Visual hallucinations are rare in late-onset schizophrenia and if present should raise the strong suspicion of an underlying organic state. Comorbid depression and suicidal ideation are common.

It is not only social and sensory isolation that may make people vulnerable to psychosis but also a more vulnerable brain. Their cognitive function is often mildly impaired at initial presentation, to a much lesser degree than found in dementia, but significantly more than in psychiatrically healthy age-matched controls.¹⁰⁵ Decline is usually slowly progressive, with only a small group of patients entering the dementia range at 3-year follow-up.

Studies of older adults with psychosis have found lower quality of life to be associated with depression, positive and negative symptoms, cognitive deficits, physical disorders, and poorer perceived health, as well as social factors including loneliness and financial strain.¹⁰⁷

Brain imaging studies

Structural neuroimaging findings in later onset illness are similar to those found in patients with early onset schizophrenia. A representative computed tomography (CT) study has reported increased mean ventricle to brain ratio with cortical sulcal appearances remaining within normal limits.¹⁰⁵ Single-photon emission computed tomography (SPECT) studies have found reduced rCBF in late-onset psychotic patients compared to controls, which also appear similar to those found in early onset schizophrenia.¹⁰⁸ Magnetic resonance imaging (MRI) has demonstrated

increased periventricular hyperintensities and thalamic signal hyperintensities in late-onset schizophrenia, which have led to the suggestion that cerebrovascular disease may be significant in the pathogenesis of the condition,^{109,110} although these findings have not been consistently replicated¹¹¹ and may have reflected the overrepresentation of individuals with cerebrovascular disease risk factors.

A number of studies using PET have shown increased basal ganglia dopamine D2 receptors in late-onset schizophrenia.¹¹⁴ However, these findings have not been consistently replicated, particularly in drug-naïve subjects, suggesting that some of the differences initially reported may have reflected treatment rather than disease-induced receptor alteration.

Neuropsychological testing

Patients with late-onset schizophrenia have been shown to perform less well on the Mental Test Score and Digit Copying Test than age-matched controls. Deficiencies have also been shown on full-scale IQ tests, tests of frontal lobe function, and verbal memory tasks.¹⁰⁵ The presence of brain abnormalities was not associated with particularly low neuropsychological test scores. When patients with late life schizophrenia are compared to those with young onset disease, they have less neuropsychological deficits in abstraction and cognitive flexibility but more global impairment.

Assessment, treatment, and course

The initial management of late late-onset schizophrenia involves evaluation and engagement.¹⁰³ Patients should be assessed at home (rather than in a clinic) both because they are unlikely to comply with outpatient appointments and because their psychopathology may be strongly triggered by cues within their normal environment and less obvious away from it. It is also not surprising on this basis that hospital admission commonly results in an apparent complete remission followed by relapse on return home. Health workers may initially find it difficult to gain access to the home of a patient with late-onset schizophrenia. Once initial access is gained, patients often engage and are willing to discuss their delusional beliefs.

Late-onset schizophrenia may run a chronic course,¹¹² but recent studies have shown remission rates with treatment of 48% to 60%. Attempts at treatment should begin in the community wherever possible, with hospital admission reserved for patients with particularly severe or dangerous behavioral disturbance or poor self-care. Medication, psychosocial intervention, and ECT have all been reported to produce temporary remission. Adequate antipsychotic treatment produces improvement in psychotic symptoms but not much improvement to the patient's pretreatment level of social functioning. Dosages are much lower than those used in younger patients with schizophrenia; people with late-onset schizophrenia are often very sensitive to extrapyramidal side effects.¹¹³ Patients do better in terms of side effects, efficacy, and negative symptoms with atypical antipsychotics, but risperidone and olanzapine are relatively contraindicated in those with cardiovascular morbidity or diabetes. Patients are often not adherent to medication, particularly as they usually live alone and do not have any insight into treatment necessity. Even when compliance is assured, many patients with late-onset schizophrenia remain psychotic, although they may be less distressed by their symptoms and

less disturbed in their behavior.^{114,115} Community psychiatric nurses are most likely to ensure a favorable response. There is conflicting evidence regarding whether depot medication improves adherence.⁹⁹

An attempt should be made to correct remediable physical or environmental contributory factors, particularly through alleviating sensory or social isolation. A flexible approach is required, and patients' characteristic insistence on remaining isolated (as they have often been for much of their lives) must be respected. Patients' importuning requests for rehousing should be resisted if they are secondary to delusional beliefs; although if symptoms improve or even abate in a new home setting this is usually only a temporary respite. Old "tormentors" reemerge, and new ones may be acquired. Antipsychotic medication is a vital component of the total therapeutic package but is far from the whole answer; improvisation and ingenuity in engaging these patients and then retaining them in long-term follow-up is crucial to maintain both compliance and an optimal level of social functioning and to reduce risk of symptomatic relapse.

Late-life delusional (paranoid) disorder

It has been estimated that 4% of a community-living elderly population experience some persecutory delusions.¹¹⁶ Such beliefs are commonly associated with a neuropsychiatric disorder. A primary delusional disorder is present when there is evidence of persistent, nonbizarre delusions that are not attributable to another psychiatric disorder or any organic cause.¹¹⁷ Delusional disorder refers to persistent delusions without evidence of schizophrenia, schizophreniform, or mood disorders. Hallucinations are not prominent. There is no evidence of organic dysfunction. The distinction between such disorders and late-onset schizophrenia reflects the relative absence of schizophrenia-like features other than delusions in the late-life delusional group. Delusional disorder occurs in middle as well as late life. Men tend to be affected earlier than women (40 to 49 years versus 60 to 69 years).

Pathogenesis and etiology

An increased prevalence of schizophrenia has been observed in families of patients with late-life delusional disorder.¹¹⁸ Individuals with avoidant, paranoid, or schizoid personality disorders may be more susceptible to developing a delusional disorder. There is an association between hearing loss and delusional disorder in the elderly.¹¹⁹ Immigration or low socioeconomic status may also predispose individuals to delusional disorder.¹²⁰ There is an increased frequency of women, immigrants, or children of immigrants with somatic delusions diagnosed as part of a delusional disorder. There may be a possible association of early life trauma and the failure to reproduce progeny with the development of delusions in later life.¹²¹

Management and outcome

The optimal approach encompasses drug treatment, psychotherapy, and environmental change.¹²² Antipsychotics may be effective in decreasing the intensity of the delusions, but (as in late-onset schizophrenia) nonadherence is a common problem and allocation of a community mental health worker may be important if the person is willing to engage with services. Intramuscular depot neuroleptics may be preferable. Antidepressant drugs and ECT have been used with

variable success in delusional patients, particularly those with coexistent depressive symptoms. The provision of alternative explanations for patients' delusional beliefs may be a useful psychotherapeutic approach. There are few outcome data available, but the overall outcome is often poor.¹¹⁷

Graduates

The term *graduates* is used to refer to patients with long-standing mental illness who have "graduated" to elderly status.¹²³ Many graduates entered a mental hospital when relatively young and remained in institutional care for much of their lives, only returning to the community to live independently or in group homes when the large psychiatric hospitals closed in the 1990s.

The largest subgroup is composed of graduates who have schizophrenia. Most of the remainder have primary diagnoses of affective psychoses, learning disability, or personality disorder. Disability in the graduate population is varied. Some patients may require total nursing care, whereas others remain physically fit and relatively competent in daily living skills. Many have some degree of cognitive impairment. There are associations between negative symptoms (social withdrawal, slowness, underactivity, poverty of speech, lack of interest, and poor self-care), cognitive deficit, and structural brain abnormality. This highlights the issue of the long-term cognitive effects of schizophrenic illness. Some of the deficits of chronic schizophrenia are probably integral to the illness process and may manifest at a relatively early stage in the evolution of the illness over time. In addition, increasing social disability may be secondary to the deleterious effects of institutional care on the capacity to return to independent living. It has been suggested that in some patients a phenomenon of "burnout" in schizophrenia (an amelioration of positive symptoms after the age of 55) may occur, but this is still disputed.¹²⁴ The lowered prevalence of positive symptoms in this group may be due to reduced exposure to the stresses and strains of everyday life rather than either the effects of medication or the natural history of schizophrenia.

Patients with schizophrenia have high rates of obesity, hypertension, diabetes, cigarette smoking—and therefore cardiovascular and respiratory disease—compared to the nonschizophrenic population, and consequent to this and higher rates of suicide their life expectancy is reduced by 20%.¹²⁵ Among those living in institutional settings, there is a high prevalence of physical disability and handicap. This increases with age but is not confined to elderly patients or those with the longest duration of stay. The presence of neurologic abnormalities referred to as "soft" neurologic signs—including disorders of posture and tone, motor performance, inappropriate activity, abnormal movements, automatic movements, and speech production—seem to be intrinsic to the schizophrenic process and cannot be attributed to hospitalization, physical treatment, or undiagnosed neurologic illness.¹²⁶

The care of graduate patients encompasses elements of good practice within old age psychiatry, psychiatric rehabilitation, and medicine of the elderly.¹²³ The needs of graduates are very different from those of patients with severe dementia, and they should not be cared for in the same settings. Patients' skills should be identified and

cultivated as part of a rehabilitative process, in the context of working toward an improved quality of life by improving the physical and social environment. Residential options in the community are varied and should be determined by the individual's present and likely future physical and mental health needs. Medication regimens often need review, and many patients benefit from cautious reduction or withdrawal of antipsychotic drugs that have often been prescribed in substantial amounts over the years.

MANIA

Epidemiology

A recent community 35-year incidence survey in the United Kingdom found that the incidence of mania peaks in early adult life, with a tenth of new onset cases of mania occurring above the age of 60.¹²⁷ This contrasts with studies based on psychiatric admission data, which suggested a stable incidence rate across age bands. Bipolar affective disorder is not uncommon in the elderly; prevalence rates range from 0.1% to 0.4%. However, it accounts for 5% of patients admitted to geropsychiatric inpatient units.¹²⁸

Older patients with mania typically had their first manic episode in their mid- to late 50s.¹²⁹ People with mania of earlier onset are underrepresented in these hospitalized samples; possible explanations for this include effective treatment with lithium, burnout after many years, and higher mortality rates among younger patients with bipolar disorder. In about half of elderly patients with mania, the first episode of mental illness is depression,¹³⁰ with many years of latency before mania becomes manifest.

Clinical features

Many of the clinical features of mania are similar to those found in younger patients, but dramatic physical overactivity, violence, criminal behavior, infectious euphoria, and grandiosity are less common.¹³¹ Clinical experience suggests that mixed mood states are more commonly found in older subjects, but this has not been substantiated in a controlled study.¹³² Adverse life events, particularly episodes of illness, more commonly appeared to precipitate mania in older subjects. Subjective confusion or perplexity is relatively prominent in the elderly. First episode mania in very late life with no previous psychiatric history is often associated with comorbid neurologic disorder.

Secondary mania

This concept refers to an episode of mania causally associated with medical illness, exogenous substances, and organic cerebral dysfunction.¹³¹ First-onset mania in old age should be considered to have an underlying organic cause until proven otherwise. The frequent presence of some degree of nonprogressive cognitive impairment in secondary mania reflects its heterogeneous etiology. Even if no acute cause is discovered, there is still a greater prevalence of coexisting neurologic illness. Stroke is the most characteristic precipitant of secondary mania, and long-standing cerebrovascular disease is also overrepresented, with white matter hyperintensities often found on MRI scanning. Family history and prior psychiatric disturbance are uncommon in secondary mania.

The treatment of mania in old age

The drug treatment of elderly people with mania is similar to that in younger patients. However, drug doses will generally be smaller. Neuroleptics are the mainstay of acute treatment. In secondary mania, treatment is also directed at the underlying medical cause. First-line prophylactic treatment is with lithium, although the risks of neurotoxicity are higher, even at relatively low serum lithium levels. The acute antimanic effect may also be useful in older people. The anticonvulsants carbamazepine, sodium divalproate, and atypical antipsychotics are increasingly widely used for their mood-stabilizing effects, but few data have been reported in older people with mania. Olanzapine and risperidone are contraindicated in people with dementia because of increased risk of stroke. Family involvement is important in ongoing management. The risk of marital and family breakup is high. The range of skills available within a multidisciplinary team is often needed to deal with the complexities of managing bipolar disorder in old age.

Outcome

The acute and long-term outcome is similar to that in younger patients. Mania with first onset in old age may, however, have a poorer prognosis than mania recurring in old age, perhaps because of the greater likelihood of comorbid physical disease or cognitive impairment.¹³²

ANXIETY DISORDERS

Epidemiology

Several studies have examined the prevalence of anxiety disorders in community-based populations.^{133–135} The prevalence rates for phobias range between less than 1% to 11.7%; for generalized anxiety, the range is between 1.4% and 7.1%. The variability in these findings probably reflects the use in some of specific case-finding instruments designed for older people and also whether a hierarchical approach is used in which those who have depression are not counted as anxious. Anxiety is frequently comorbid with depression. There is consensus that panic disorder is extremely rare in old age.

Specific groups of people may be likely to become anxious as they are in stressful situations and these include carers and the physically ill. As well as changing the situation (which is not always possible), psychological strategies such as the use of appropriate coping strategies may be helpful. Cognitive-behavioral treatment (CBT) and other psychological treatments are first line, although the only randomized controlled trial comparing antidepressants (sertraline) to CBT showed that sertraline had a larger effect size (0.94 versus 0.42 at 3 months) for all anxiety disorders.¹³⁶

Phobic disorders

Phobic disorders consist of persistent or recurrent irrational fear of an object, activity, or situation that results in the compelling desire to avoid the phobic stimulus.¹³⁷ In old age they are associated with higher rates of medical and of other psychiatric morbidity but are frequently found in the absence of other psychiatric disorder.¹³³ Agoraphobia is often triggered by the traumatic experience or acute physical ill health.¹³⁷

The longitudinal course of phobic disorders in old age is unclear. Individuals with one phobia may develop another. Fear of crime is particularly common in old age, leading to fear of going out and to nighttime fearfulness. Social phobias in old age have usually developed earlier in life and persisted; they tend to be chronic and unremitting.¹³⁸ Comorbidity with agoraphobia, specific phobia, depression, and alcohol abuse is common.¹³⁹ Older people rarely seek treatment but change their life to accommodate their avoidance. Anxiolytics provide only symptomatic relief and are best avoided because of their dependency potential.¹³⁷

Generalized anxiety disorder

Generalized anxiety disorder consists of generalized, persistent anxiety, with motor tension, autonomic symptoms, apprehensiveness, and hypervigilance.¹⁴⁰ It usually runs a chronic course.¹³⁹ It is hard to diagnose in the elderly because of its high degree of comorbidity with depression. Coexistent medical conditions can complicate the situation. Benzodiazepines have been the mainstay of treatment, but dependence and adverse effects should limit their use to very short-term management only. Antidepressants may be useful, and cognitive-behavioral strategies may be effective.

Panic disorder

Panic disorder is characterized by recurrent attacks of panic, with sudden, discrete periods of intense fear accompanied by severe somatic anxiety symptoms, usually lasting for 1 to 10 minutes. The disorder usually runs a chronic course¹⁴¹ but may remit spontaneously or become less disabling secondary to reduced rates of social interaction in old age. It may, albeit rarely, occur de novo in older people.¹⁴² Panic disorder with onset earlier in life is associated with depression,¹⁴³ alcohol abuse,¹⁴⁴ increased suicide risk,¹⁴⁵ and higher cardiovascular morbidity.¹⁴⁶ Panic disorder becomes less rare as people age. Part of the explanation for the low prevalence in the elderly may be that sufferers may not survive into old age. Physical limitations in daily activities as well as the presence of other psychiatric disorders (major depression and social phobia) are significantly associated with panic disorder.¹⁴⁷ Antidepressants are the pharmacologic antipanic agents of choice with SSRIs increasingly used in preference to tricyclics.¹³⁹ Benzodiazepines are efficacious for symptom control but can only be used very short term because of undesirable side effects and dependence. Cognitive-behavioral therapy is often effective. Long-term outcome is improved by combination drug and cognitive-behavioral approach.

Posttraumatic stress disorder and bereavement

Posttraumatic stress disorder (PTSD) occurs in response to a catastrophic event. Symptoms usually start after a month but always within 6 months. Traumatic events in old age can trigger similar PTSD reactions to those occurring in younger victims.¹³⁹ PTSD is still present in some aging survivors of combat and can arise again when a person ages and becomes vulnerable again. In one study of Holocaust survivors in older age, experience of more severe trauma, use of immature defense mechanisms, and higher neuroticism were associated with significant PTSD

and psychological morbidity.¹⁴⁸ The intensity of the physiologic response to the original trauma may be the most significant predictor of a poor outcome. Further stressful life events can slow recovery, which may also be hindered by drug and alcohol abuse, which may themselves be triggered by PTSD.¹⁴⁹ Busuttill¹⁵⁰ provided an overview of treatment in older people. Treatment outcome studies are lacking in older people. Therefore, treatment follows the principles used in younger adults. These include medications and psychotherapy separately or in combination. Stabilization using medication first may be indicated. Useful medications for treating PTSD include antidepressants. SSRIs are usually first line, which help for reexperiencing and hyperarousal. Psychotherapeutic interventions include behavioral, cognitive, cognitive-behavioral therapies and eye movement desensitization and reprocessing (EMDR). Several trials have demonstrated highly significant reductions in PTSD symptomatology.

Bereavement is, sadly, an all-too-common experience for older people. Although depressive symptoms are common in the weeks immediately after bereavement, this is normal and most people experience a gradual diminution of these symptoms without developing a full-blown depressive illness. Persistence and severity of symptoms are what differentiates depression and normal grieving following bereavement. Postbereavement depression is most strongly associated with a past history of depression. Surprisingly, only weak statistical associations are found with quality of the relationship with the lost partner or with level of postbereavement social support.¹⁵¹

Obsessive-compulsive disorder

Obsessions are intrusive thoughts, images, or impulses that are unpleasant, consciously resisted, which the patient is aware arise from his or her own mind. A compulsion is a behavior that causes anxiety when resisted and is usually repeated and recognized as purposeless. The diagnosis is only made when the problem interferes with normal functioning. Obsessive-compulsive disorder (OCD) has a prevalence rate of 1.5% in older people.¹³⁴ The onset is usually earlier in life, with persistence into old age.¹³⁹ OCD is often resistant to treatment, but the use of serotonin enhancers (clomipramine, SSRIs) and cognitive-behavioral techniques has improved the outlook.¹⁵² In the elderly, it is important to bear in mind that obsessive-compulsive phenomena frequently occur within a primary depressive illness, and the development of obsessional orderliness may indicate the onset of dementia or an affective disorder.¹⁵³

SOMATOFORM DISORDERS

Somatoform disorders are those in which physical symptoms occur in the absence of any or sufficient organic pathology to account for them and include conversion disorder, somatization disorder, pain disorder, and hypochondriasis. They are not due to malingering or fabricated symptoms and the patient experiences the symptoms presented. Psychological contributory factors can usually be identified.

Although somatoform disorders—in particular syndromes of chronic fatigue, irritable bowel syndrome, and fibromyalgia—have received considerable attention recently

in psychiatry and relevant consumer groups, this has not been true for older people, and health practitioners are less likely to recognize these disorders.¹⁵⁴ This may be because somatoform disorders present differently in older people; this has significant implications for their measurement and validation in older people. For example, such disorders are masked by physical comorbidity, and practitioners may be more likely to perceive associated mental distress as appropriate in older people.¹⁵⁴ Somatizing presentations are common among older primary care attendees.¹⁵⁵ Older people often develop exaggerated bodily complaints in the context of physical illness. Physically ill patients may also present with generalized anxiety or panic symptoms. The common medical disorders producing anxiety symptoms are endocrine, cardiovascular, pulmonary, and neurologic conditions. A thorough history should help to establish the temporal relationship of psychiatric symptomatology and the onset of medical illness.

Although the onset of somatoform disorder is usually in early life and runs a chronic course, somatizing patients avoid psychiatrists in youth and adulthood and so not uncommonly present to them for the first time in old age.¹⁵³ The epidemiologic catchment area studies from the United States suggest the prevalence is the same and rare (0.1%) throughout adult life when the disorder is defined as having 12 or more unexplained medical symptoms. Rates of persistent fatigue are also similar across age groups and occur in more than a quarter of adults of all ages.¹⁵⁴ Such patients usually have clear symptoms of depression or anxiety; their bodily complaints tend to be restricted to one or two body organs or systems. They are preoccupied with the possibility of serious physical illness. They demand investigation rather than treatment. In contrast, hypochondriacal preoccupation presenting for the first time in old age is unlikely to be secondary to anxiety and depression. Hypochondriasis is a persistent, unrealistic preoccupation with the possibility of having at least one serious disease in which normal sensations and appearances are often misinterpreted as abnormal and signs of disease, and the patient cannot accept reassurances of doctors. Elderly patients only rarely present with conversion reactions (e.g., paralysis) or dissociative amnesia in response to stressful experience. Treatment of associated psychiatric conditions may lead to improvement in somatic attributions.¹⁵⁵ There have been no specific trials in older people, but cognitive approaches are effective among younger patients¹⁵⁶ and so may also be helpful in older people.

ALCOHOL

The average alcohol intake of older people is less than that of younger adults. Fewer drink regularly,¹⁵⁷ and abstinence is more common.¹⁵⁸ Social and psychological factors may contribute to a decrease in alcohol intake with age, including reduced social opportunities and financial constraints. Moderate drinking rather than abstinence seems to be better in terms of mortality and cognition.^{159,160} Older people are, however, more vulnerable to the effects of alcohol because of physiologic changes and the increased presence of pathologic processes. Despite the general downward trend, drinking is an important contributor to mental and physical ill health in some old people.¹⁶¹

Epidemiology and etiology

Studies in the United States suggest that the prevalence of abusive or dependent drinking is about 5% in the population aged 65 years and over, with a male preponderance of about 4:1.¹⁶² A British community study reported a 1% prevalence of problem drinking.¹⁶³ In the hospital setting, elderly patients who abuse alcohol are concentrated in general medical settings; one study¹⁶⁴ identified 14% of elderly emergency admissions as having current alcohol abuse. Cultural, ethnic, and socioeconomic factors; differences between countries; and regional variation may influence drinking behavior and related problems resulting in variable prevalence.

The rates of alcohol abuse in the elderly are related to the levels of consumption by the community as a whole.¹⁶⁵ The surveys, which are cross-sectional, do not take into account that drinking less may be a cohort rather than an age effect, whereby those who are currently older may always have had a relatively low intake. New cohorts of older people may drink more than those who started drinking in the 1920s.¹⁶⁶ Psychiatric disorder and personality attributes predispose to alcohol abuse. In particular, those older people with a late onset of alcohol abuse tend to have a past history of harmless drinking patterns, with consumption increased in the context of depression, bereavement, lack of social support, or deteriorating physical health.^{161,167} Elderly people with insomnia or chronic pain, those previously dependent on alcohol, and those with current depression or dementia seem particularly vulnerable to developing alcohol-related problems in old age.¹⁶⁸ Persisting social problems perpetuate the cycle of loneliness and further drinking.¹⁶⁵

Clinical features

The diagnosis of alcohol abuse may be difficult because the presentation may be masked, unsuspected, or atypical.¹⁶⁹ In a general medical setting the prevalence is higher and the index of suspicion should be raised.¹⁷⁰ In particular, alcohol abuse should be suspected in the assessment of otherwise unexplained falls. Alcohol abuse may present with a wide range of neuropsychiatric complications.¹⁵⁷ Patients can present with cognitive impairment, problems related to mixed intoxication with drugs, or unrecognized withdrawal states. Alcohol abuse is also associated with functional psychiatric disorder, particularly depression.¹⁷¹ Up to one third of elderly persons who break the law either abuse alcohol or are dependent on it.¹⁷² They are often under the influence of alcohol when the crime is committed.

There is little information regarding the clinical course and prognosis. Light to moderate use of alcohol is associated with a decreased mortality in the elderly. The benign course of "normal" drinking seems very different, however, from that of the problem drinkers in old age, who often present when brain damage or social breakdown supervenes. A past history of alcohol-related problems is associated with both depression and dementia in later life. Depression and anxiety are major comorbid diagnoses.

Management

Alcohol abuse in older people is probably often undetected,¹⁷³ particularly in patients presenting with medical conditions. Screening at-risk groups¹⁶⁸ may identify

individuals at risk of alcohol abuse. Screening instruments used for younger people are probably of limited value in the elderly; a review by Beresford¹⁶² presents one such screening test designed for older people, the Michigan Alcoholism Screening Test—Geriatric Version, although this has yet to be extensively validated.

When an individual is recognized as having an alcohol-related problem, several services may need to be involved. Home visits are often invaluable in the initial assessment.¹⁷⁴ Hospital admission may be needed to break the drinking routine, reduce risks associated with acute alcohol withdrawal,¹⁷⁵ and allow for full physical and psychiatric assessment. Alcohol withdrawal symptoms become more severe with age, and detoxification is more likely to be complicated by intercurrent illness. Withdrawal seizures occur within 24 hours if at all. Tremor, tachycardia, hypertension, anxiety, nausea, and insomnia are prominent features of the alcohol withdrawal syndrome in old age. The patient should be nursed in a calm, well-lit environment. Shorter acting benzodiazepines are preferred for sedation. The dosage for older patients undergoing detoxification should begin at about one third of that used for a fit younger person and should then be titrated against the clinical response.

A long-term management plan needs to be formulated with either abstinence or controlled drinking as a goal. Older people respond better to social intervention than to intensive confrontation. Alcohol is often an occupation, and drinkers' social contact may be entirely with other drinkers. Thus, part of the plan has to involve consideration of where and how someone who wishes to be an ex-drinker will spend the day. Amelioration of social stresses, group socialization, family work, medical treatment, and management of depression are all part of the approach needed. Cognitive therapy, sometimes delivered through alcohol services, is often used. Those who wish to continue to drink and are eating little will often take thiamine and this may help protect them from Korsakov's syndrome. Disulfiram is not recommended in older people because of increasing medical risks involved with ingesting alcohol while taking the drug.¹⁷⁶

PERSONALITY DISORDERS IN OLD AGE

Personality disorders are generally recognizable by adolescence or earlier and continue throughout most of adult life, although they become less obvious in middle or old age and as in younger people the diagnosis is only applicable to those who have long-standing dysfunction from the beginning of their adult life.¹⁷⁷ Some lifelong obsessive or schizoid personality traits may worsen in old age, possibly as a result of experiencing increasing stress and adversity or as a way of adapting to losses in old age¹⁷⁸ and may present for the first time possibly as a person who has interpersonal difficulties becomes dependent on others. Global well-being, life satisfaction, and capacity to cope with illness and loss in old age are also critically influenced by personality and its adaptation to old age.¹⁷⁹ Personality traits may be critical in adapting to the adverse life events all too often encountered by older people.

Epidemiology

An individual's personality is essentially stable over time.¹⁷⁹ Introversion has, however, been shown to increase with age,¹⁸⁰ whereas extraversion, neuroticism, and openness to experience decrease.¹⁸¹ Older people tend to have higher scores on scales for orderliness, social conformity, and emotional stability and lower scores for activity and energy.¹⁸² A decline in sociopathy and criminality has been documented.¹⁸³ Few large-scale studies of personality disorder in old age have been performed. An early epidemiologic survey³ reported a prevalence of 3.6% to 10.6% for personality disorders in people aged 65 years and older. More recent surveys of older community-living individuals using standardized diagnostic schedules have found lifetime prevalence rates for personality disorders ranging between 2.1% and 18%; a more recent meta-analysis reported an overall prevalence of 10% of those over 50 years old.^{184,185} The mental health of older male prisoners is reported to be worse than that of younger prisoners, with 45% having a psychiatric illness with a prevalence of personality disorders of 30%.¹⁸⁶

Comorbidity

People with personality disorders are vulnerable to other psychiatric illnesses as there is a particular association between personality disorders and affective illness, although the first episodes of depression or anxiety disorders usually occur before old age. People with late-onset schizophrenia often have premorbid schizoid or paranoid traits.

Senile self-neglect (Diogenes syndrome)

Patients with this syndrome (also known as senile self-neglect or senile squalor syndrome) often present to units for medicine of the elderly. There is usually gross self and domestic neglect, often with hoarding and social withdrawal. Although the most common diagnosis is dementia, others are depressed, have a paranoid psychosis, or abuse alcohol. Rarely patients have an obsessional disorder. Several studies have reported that about a third to a half have no psychiatric illness and tend to have higher than average intelligence.¹⁸⁷ For others, the syndrome can be understood as an expression of abnormal personality traits, in reaction to stress and loneliness or as the end stage of long-standing reclusiveness. It may be, however, as some authors have suggested, that frontal lobe degeneration or obsessive compulsive disorder tends to be present if those patients are investigated thoroughly, although this is usually difficult as patients are uncooperative.¹⁸⁸ The clinical picture is of very gross self-neglect. Most people live alone but a number of cases of folie à deux have been reported. The prognosis of such cases is not good. Compulsory hospitalization is difficult to accomplish, and mortality is high; apparently successful rehabilitation is usually followed by relapse.¹⁸⁹ Daycare might maintain an individual, but some form of institutional care usually becomes necessary. The recent Mental Capacity Act may prove helpful.

Outcome of personality disorder in old age

Clinical experience suggests that patients with personality disorders do not cause as much trouble for themselves, their families, and health care professionals by the time they reach

old age.¹⁷⁷ Formal long-term follow-up studies are, however, sparse. Immature personality disorders including antisocial, impulsive, histrionic, dependent, and narcissistic usually improve with time. Mature personality disorders, including anancastic, paranoid, schizoid, and schizotypal, tend to persist into later life. Deterioration may become evident in the obsessive-compulsive patient as increased rigidity, in the paranoid patient as more suspiciousness and isolation, and in the schizotypal/schizoid patient as more social withdrawal and anxiety.

Patients with borderline personality tend to improve (or not survive) as they age and thus rarely present in older age. Good global outcome in such patients is associated with high intelligence, attractiveness, artistic talent, and coexisting obsessive-compulsive traits.¹⁹⁰ The highly subjective "likeability" seems also to confer good prognosis. Poor outcome is associated with a history of parental brutality, impulsivity, poor premorbid functioning, and coexistent schizotypal/antisocial personality disorder.¹⁹¹

In patients with antisocial personality disorder, there is a tendency toward spontaneous remission so that these individuals are rarely encountered over the age of 60.¹⁷⁷ Patients with schizotypal and schizoid personality disorder rarely seek treatment, so little is reported on their long-term outcome but the outlook is probably poor.¹⁹² There is also little information on the outcome of histrionic, narcissistic, obsessive-compulsive, and depressive personality disorders.¹⁷⁷

KEY POINTS

Functional Psychiatric Illness in Old Age

- By 2020, depression will be second only to heart disease as a contributor to global disability and a major public health problem in older people.
- The management of depression in physically ill elderly patients is essentially the same as for depression in general. Antidepressant and psychological therapy are equally effective in older and younger adults, although there is a need for increased caution with medication because of medical comorbidities and the greater possibility of adverse effects and drug interactions.
- Occasionally the age onset of schizophrenia is over 60. New psychotic symptoms in older people are more often due to delirium, dementia, or depression.
- The initial approach to late-life paranoid illnesses encompasses drug treatment and managing sensory impairment and isolation. Olanzapine and risperidone are contraindicated in people with dementia because of increased risk of stroke.
- A tenth of new onset cases of mania occur in individuals above the age of 60. The drug treatment of elderly people with mania is similar to that prescribed for younger patients.
- Bereavement is a common experience for older people. Although depressive symptoms are prevalent in the weeks immediately after, this is normal and most people experience a gradual diminution of these symptoms. Postbereavement depression is most strongly associated with a past history of depression and should be suspected if symptoms are severe or persist.

Management of personality disorder in old age

There has been little formal study of treatment approaches to personality disorders in old age.¹⁷⁷ The management of coexisting psychiatric illness is as discussed previously, and many of the traits are less expressed in behavior when these are treated. The psychotherapeutic treatment of elderly patients may be unpromising for individuals with long-standing personality disorders who may have particular difficulty in resolving a lifetime of failed relationships and missed opportunities. Cognitive analytic therapy, which

is about interpersonal understanding rather than using an illness model, is a therapy used to search for the meaning behind symptoms and offers a narrative reconstruction of an individual's life story.¹⁹³ It is used to generate a written reformulation and diagrams and has been used to help older people with narcissistic and borderline traits.¹⁹³ The use of medication in old age personality disorders has not been formally studied.

The Older Adult with Intellectual Disability

John M. Starr

DEFINITIONS AND ETIOLOGY

Intellectual disability (ID) is the current term used to describe what in the United Kingdom has been known as *learning disability* and in the United States as *mental retardation*. In Australia, the 1986 Victorian Act of Parliament, which established the basis on which services to people with intellectual disabilities or significant delay in their development are provided, defines intellectual disability as follows:

Intellectual disability in relation to a person over the age of five years means a significant subaverage general intellectual functioning existing concurrently with deficits in adaptive behaviour and manifested during the developmental period.

(INTELLECTUALLY DISABLED PERSONS SERVICES ACT, 1986)

The threshold at which general intellectual functioning is considered "subaverage" is often fixed at an IQ of 70, two standard deviations below the mean IQ. Controversially, in 1992 the American Association on Intellectual and Developmental Disabilities (AAIDD) loosened this threshold to include people with IQs in the range of 70 to 75. The AAIDD also required 2 out of 10 areas of adaptive functioning to be assessed to have deficits. This definition was adapted by the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (DSM-IV). In 2002, the AAIDD reinstated the IQ 70 threshold and required deficits in conceptual, social, and practical adaptive skills to be present. These changes in definition have implications for epidemiologic data collection, but the key concept of ID remains. An IQ of less than 70 is necessary, but this in itself is inadequate for the diagnosis to be made. There has to be evidence of both a developmental disorder, that is onset during childhood, and deficits in adaptive behavior for the diagnosis to be made.

Further classification of ID can be made within the broad definition. The Diagnostic Criteria for Psychiatric Disorders for Use with Adults with Learning [Intellectual] Disabilities (DC-LD)¹ describes a person with ID's mental health in terms of ID severity, ID etiology, and related mental disorders (developmental disorders, psychiatric illness, personality disorders, problem behaviors, and other disorders). Severity is grouped according to IQ as 50-69 mild ID, 35-49 moderate, 20-34 severe, and less than 20 profound. The Swedish model of ID classification developed by Kylen² is often helpful in clinical situations where IQ is not known:

- Severe: Communication is based on simple nonverbal signs, no verbal communication, no concept of time or space. Equivalent to IQ <10.
- Moderate: Limited verbal skills. Limited understanding of local space. Can structure thoughts in relation to individual experiences. Equivalent to IQ 10 to 40.

- Mild: Basic literacy and mathematical skills present. Can rearrange, structure, and perform concrete cognitive operations. Equivalent to IQ 41 to 70.

In addition, the DC-LD includes appendices that relate to medical factors influencing health status and contact with health services. The latter are highly relevant because developmental disorders that affect the brain, giving rise to ID, often affect other body systems also.

The etiology of ID is frequently unknown in older adults, but it can be considered along conventional lines of external causes (infection, injury, poisoning), internal disorders (endocrine, metabolic), perinatal insults, and congenital conditions (chromosomal abnormalities, gene mutations). The latter are of particular relevance to the health of older adults with ID, as specific syndromes are associated with risk of particular physical disorders and diseases. Common syndromes seen in older adults include Down syndrome (DS), Angelman syndrome, fragile X syndrome, Klinefelter syndrome, Turner syndrome, and Williams syndrome. [Table 58-1](#) provides a brief description of these syndromes. It is worth noting that, given the preceding definition of ID, by no means does everyone with one of these syndromes fulfill the diagnostic criteria for ID; this is particularly true of women with Turner syndrome who have a tendency for nonverbal cognitive deficits but are often of average intelligence.

Just as there is a considerable overlap between congenital syndromes, such as DS and ID, there is a similar overlap between ID and autism. The diagnosis of autism depends on (1) abnormal social development, (2) communication deficits, and (3) restricted and repetitive interests and behavior. Around three quarters of people with autism have a nonverbal IQ less than 70 and hence also fulfill diagnostic criteria for ID; but in autism, social and communication skills are worse than expected for any given nonverbal IQ.

EPIDEMIOLOGY OF INTELLECTUAL DISABILITY AND AGING

Prevalence

In 2001, the World Health Organization reported the following:

The prevalence figures [of ID] vary considerably because of the varying criteria and methods used in the surveys, as well as differences in the age range of the samples. The overall prevalence of mental retardation is believed to be between 1% and 3%, with the rate for moderate, severe and profound retardation being 0.3%.³

Extrapolating these figures to the United Kingdom provides estimates of around 175,800 people with moderate-to-profound

Table 58-1. Characteristics of Common Syndromes Associated with Intellectual Disability

The phenotypic features are "typical" and may not be evident in all people with the syndrome. Similarly, many phenotypic features are found in unaffected individuals.		
Syndrome Name	Chromosomal Abnormality	Phenotypic Appearance
Angelman syndrome	15q11-q13 in the maternally contributed chromosome (cf Prader-Willi has same deletion in paternal chromosome); a few cases are due to paternal chromosome 15 disomy and a few are due to putative single gene mutation on chromosome 15	Microcephaly, ataxic gait, strabismus, scoliosis
Down syndrome (DS)	Vast majority trisomy of chromosome 21; a few have trisomy 21 mosaicism. Small proportion translocation of chromosome 21	Flat facial profile, epicanthic fold, relative hyperglossia, single palmar crease
Fragile X syndrome	X-linked, semi-dominant disorder with reduced penetrance. Number of fragile sites on X-chromosome identified, two important for ID around X27.3.	Broad forehead with long face, large ears, strabismus, high arched palate, macro-orchidism, scoliosis, joint hyperextensibility
Klinefelter syndrome	XXY and XXY mosaicism with variants XXXY or XYY	Taller than average, microorchidism, youthful appearance, gynecomastia
Turner syndrome	XO, partial deletion of second X chromosome, XO mosaicism	Short stature, premature ovarian failure, high arched palate, low set ears, webbed neck, strabismus, cubitus valgus, scoliosis, short fourth metacarpals
Williams syndrome	Deletion of <i>CLIP2</i> , <i>GTF2I</i> , <i>GTF2IRD1</i> , <i>LIMK1</i> , and other genes from chromosome 7	'Elfin features' of upturned nose, widely spaced eyes, wide mouth with full lips, small chin, high levels of empathy and anxiety

ID with mild ID ranging from 586,000 to 1,465,000.⁴ For Finland, the equivalent estimates are 15,300, 51,000 and 127,500 respectively. Population-based surveys in Finland have estimated moderate-to-profound ID prevalence at no more than 0.2% and overall ID prevalence at just over 1%.⁴ The situation is similar for the United Kingdom.⁴ Notably, Finnish prevalence rates estimated from national registers is a little lower at 0.7%, perhaps indicating that not all people with ID are known to Finnish health or social services.⁵ Within overall prevalence figures there is considerable variation by age. In the Finnish national register survey, the rates were 0.53% for individuals 0 to 15 years of age, 0.70% for those 16 to 39 years, 0.92% for those 40 to 64 years, and 0.38% for those 65 years and older.⁵ Variation in Finland between age groups was attributed to changes in incidence, mortality, diagnostic practices, and benefit provision. Changes in diagnostic practices have been discussed in the previous section and benefit provision is specific to Finland, but changes in ID incidence and mortality have been tracked across the world.

Incidence

Estimation of ID incidence is problematic given that ID is, by definition, a developmental disorder and thus there is no single point at which it is recognized. In view of this reality, Down syndrome is often used as a proxy because it is the largest single cause of ID. However, its use as a proxy is far from ideal because risk is clearly associated with maternal age and prenatal screening has been widely introduced. [Table 58-2](#) summarizes secular trends in DS incidence from various countries. Overall DS incidence appears to have been rising before the introduction of prenatal screening. This resulted in a decrease that is projected to be offset by increasing mean maternal age. Overall, there seems little to indicate a great change in ID incidence and numbers of people with ID may track the overall birth rates in different countries.

Mortality

Mortality has had the greatest impact on ID prevalence, especially in older age groups. In 1900, a child with DS would expect to survive to around 9 years of age. In the United States, the median age at death increased from 25 years in

Table 58-2. Secular Trends in Down Syndrome Incidence

Study	Country	Dates	Incidence Changes (per 10,000 Live Births)
Krivchenia et al. <i>Am J Epidemiol</i> 1993;137:815-28	United States	1970-1989	Increase in all groups except urban white population where incidence decreased due to terminations of pregnancy; 11.7 average over whole period
Carothers et al. <i>J Med Genet</i> 1999;36:386-93	Scotland	1990-1994	Decrease from 10.8 to 7.7
Merrick J. <i>Down Syndrome Res Practice</i> 2001; 6:128-30	Israel	1964-1997	Decrease from 24.3 to 10, but unchanged when terminations of pregnancy included
Verloes et al. <i>Eur J Hum Genet</i> 2001;9:1-4	Belgium	1984-1998	Decrease following, but not fully explained by, prenatal screening from 12.6 to 6.2 live births
Nazer et al. <i>Rev Med Chile</i> 2006;134:1549-57	Chile	1972-2005	Increase, 3.36 average over whole period

1983 to 49 years in 1997.⁶ The improvement is likely to reflect improved socioeconomic circumstances, improved correction of congenital cardiac abnormalities, and perhaps changing attitudes to treating people with ID. There is little difference in life expectancy for people with DS compared with other causes of ID.⁷ Identification of common causes of death in people with ID is made difficult by poor death certificate completion. For example, many people in the United States had either ID or DS listed as a primary cause of death, which is inappropriate.⁷ However, as the ID population ages, the causes of death are thought to resemble those in the general population more and more closely. Those with mild ID survive

longer, and there is some equivalence to this observation in the general population where people with low IQs within the normal range suffer premature mortality largely attributable to cardiovascular disease.⁸ Current trends suggest that people with ID can expect to survive to 60 to 65 years and an increasing proportion will survive beyond this age.

BIOLOGIC AGING IN ID: SYNDROMIC AND NONSYNDROMIC

Even with recent improvements, life expectancy of people with ID is considerably less than that of the non-ID population. This raises the question as to whether ID is associated with accelerated biologic aging. The measurement of biologic age usually depends on identifying suitable biomarkers of aging. Criteria for such biomarkers have been proposed⁹:

1. They must reflect some basic biologic process of aging rather than disease.
2. They must have high cross-species reproducibility.
3. They must change independently of chronologic time.
4. They must be obtainable antemortem.
5. They must be measurable over a short period compared to the life span of the organism.

One such biomarker is telomere length.¹⁰ There is a paucity of data on telomere length in ID in general, but there is evidence for telomere shortening in DS¹¹ although this appears to be downstream from cellular redox status¹² as is also likely in the general population.¹³ In cri-du-chat syndrome, there is often a deletion of the short arm of chromosome 5 where the telomerase reverse transcriptase (*hTERT*) gene is localized (5p15.33). Reconstitution of telomerase activity by ectopic expression of *hTERT* extends telomere length, increases population doublings, and prevents the end-to-end fusion of chromosomes.¹⁴ It may thus be one element contributing to the syndrome's phenotypic features. Whether this is the case or not, accelerated telomere shortening occurs with aging in this syndrome.¹⁵ At least a further 5% of ID is attributable to similar subtelomeric deletions or copy number variations,¹⁶ and these too may influence telomere length. Telomere length is thus a potentially useful index of accelerated biologic aging in ID,

but whether it contributes to aging itself or is only a correlate remains unclear. Moreover, telomere shortening is subject to syndrome-specific effects. Beyond the cellular level, various physiologic biomarkers are also affected in ID. Physiologic variables are long recognized as indices of biologic age.¹⁷ The limited data available indicate that people with DS had accelerated biologic aging, but that people with nonsyndromic ID do not.^{18,19} In summary, the evidence suggests that syndromic biologic aging dominates over any accelerated biologic aging that might be associated with ID in general and that different ID syndromes are likely to have different aging profiles depending on the specific genetic changes underlying them.

AGE-RELATED DISEASE: SYNDROMIC AND NONSYNDROMIC PATTERNS

People with ID exhibit considerable morbidity. A study of 346 people aged 20 to 50 years in North Sydney found they had a mean 2.5 major problems and 2.9 minor problems each with 42% of these undiagnosed before the study and, of the 58% already known, only 49% were being managed adequately.²⁰ A study of 1371 adults aged 40 years and over in New York State found that increased age was associated with higher prevalence of cardiovascular disease, cancer, respiratory disease, musculoskeletal disorders, infections, and visual and hearing impairments; gastrointestinal disease was not associated with age but with being male, more severe ID, cerebral palsy, and obesity.²¹ Compared with the non-ID population, there was less cardiovascular disease and musculoskeletal disease, except osteoarthritis, and people with DS did not have solid neoplasias. However, these data may reflect underdiagnosis and lifestyle factors such as the low rate of cigarette smoking among people with ID. A similar age-related pattern of disease was found in Southern Holland.²² The pattern may change as fewer people with ID live in institutions: there is evidence from the United Kingdom that poor diet, reduced physical activity, and obesity risk factors are greater in women with ID who are more able and independent.²³ In addition to the general tendency for high levels of morbidity, which is associated with both age and degree of ID severity, specific syndromes carry their own particular risks (Table 58-3). The

Table 58-3. Common Adult Medical Problems in Various ID Syndromes

Syndrome	Cardiovascular Problems	Neurologic Problems	Sensory Problems	Other Problems
Angelman	Septal defects, valvular disease	Seizures common, ataxia, absence of speech	Otitis media	Respiratory infections, obesity
Down	Septal defects, valvular disease	Seizures in around 10%, Alzheimer-type dementia	Cataracts, hearing loss	Osteoporosis, hypothyroidism, blood dyscrasias, atlantoaxial instability
Fragile X Myotonic dystrophy	Septal defects, valvular disease	Seizures may occur Myotonia with muscle weakness	Cataracts, coloboma	Joint instability, hernias
Rubinstein-Taybi	Septal defects, valvular disease	Seizures may occur	Cataracts, optic nerve abnormalities, hearing loss	Renal abnormalities (absent/extra kidneys, etc.), cryptorchidism
Smith-Lemli-Opitz	Septal defects, valvular disease		Visual and hearing loss	Low cholesterol levels, multiple organ abnormalities
Smith-Magenis	Septal defects, valvular disease, hypertension	Sleep disturbance, self-injury, aggression, peripheral neuropathy	Hyperacusis, wax buildup	Multiple organ abnormalities, hypothyroidism, immunoglobulin deficiency
Williams	Septal defects, valvular disease, hypertension	Cerebrovascular disease		Multiple organ abnormalities, hoarse voice, hypothyroidism, constipation

most common syndrome in older adults with ID is DS, and discussion of the various problems in people with DS can provide a general approach to such problems in other syndromes.

Down syndrome: effects on systems

CARDIOVASCULAR: LATE EFFECTS OF CONGENITAL HEART DISEASE AND HYPERLIPIDEMIA

Congenital heart disease is common in many ID syndromes as multiple genes contribute to its etiology; DS is a common cause of ID-associated congenital heart disease. Nowadays there is no reason why children with DS and congenital heart defects should not have surgical correction.²⁴ Complications of uncorrected congenital heart disease, such as Eisenmenger's syndrome and infective endocarditis, are thus becoming rare. In addition, persistent atrial septal defects are associated with increased risk of cerebral embolic events. However, many people with DS are not under regular follow-up once they become adults and may continue to have problems with arrhythmias. In particular, right bundle branch block is not uncommon after surgery. This is usually of no relevance until some form of left bundle branch block occurs when progression to complete heart block becomes more likely. There may also be residual hypoxemia because of persisting right-to-left shunts. Again this generally is of no consequence until some extra stress to the system occurs such as a general anesthetic. Some residual shunts may also be associated with a degree of pulmonary hypertension. Lifestyle factors and associated obesity put adults with DS at increased risk of hyperlipidemia. It is unclear how much impact this has on cardiovascular disease risk in this population, but there is evidence for a deleterious effect on cognition (see the next section).

NEUROLOGIC: DEMENTIA, EPILEPSY, VISION, AND HEARING LOSS

Dementia is three to four times more prevalent among adults with ID than the similarly aged general population.²⁵ The prevalence in DS is substantially higher. Forty percent of those over 50 years acquire an Alzheimer-type dementia with the typical neuropathologic features present in nearly everyone by the age of 40 years.²⁶ Dementia incidence over 50 is 18%,²⁷ indicating the very short survival once the condition is diagnosed. Despite similar neuropathologic features, clinical manifestation of dementia often differs in DS with frontal lobe symptoms, such as deficits in executive functioning characterized by planning problems, personality changes, and development of problem behaviors, being present at an early stage. It is natural to attribute any such changes to the onset of a dementing illness in DS because dementia is so common, but other conditions, even something as simple as constipation, may also present with similarly atypical symptoms. A full health assessment, paying attention to physical factors, is therefore necessary. Epilepsy is common in ID, including DS, and may signal the onset of dementia in older adults, and this may be especially the case for late-onset myoclonic epilepsy. People with more severe ID are at increased risk of seizures. Seizures are usually controllable with monotherapy. In other syndromes, seizures can be far more difficult to control.

Visual problems in DS may be associated with development; around 60% of children require glasses, for instance. People with DS have a flat nasal bridge and this can result in their glasses slipping. Strabismus is also common. In later life, cataracts are highly prevalent, nearly 30% in those aged

65 and older.²⁸ Hearing impairment is also common and, like visual impairment, may date from childhood. This may result from a buildup of earwax, but hearing aids are often needed for both conductive and sensorineural deficits.

GASTROINTESTINAL: DENTITION, GASTROESOPHAGEAL REFLUX, AND CONSTIPATION

Although not associated with either aging or mortality, gastrointestinal complaints are frequent in DS. In the general population, dental status is an index of socioeconomic status and so poor dentition may reflect this in DS where conventional socioeconomic measures are often unhelpful. It may also reflect both severity of ID, affecting oral hygiene, and age. Chronic gingivitis and especially periodontitis is highly prevalent in DS and is associated with cardiovascular disease, respiratory disease, and diabetes. Gingival hyperplasia is sometimes found in people who are taking phenytoin for epilepsy. Obesity is common in DS and is associated with gastroesophageal reflux disease (GERD) and cholelithiasis. A Dutch study of 77 adults with ID aged 60 years or over found 9% had GERD, 10% symptomatic cholelithiasis, and 57% had chronic constipation; the latter was far more common in those with mild ID compared to moderate or severe ID.²⁹ Only the minority of adults with GERD complained of typical symptoms; most presented with insomnia or behavioral changes.

ENDOCRINOLOGY: HYPOTHYROIDISM, TESTOSTERONE, AND ESTROGEN DEFICIENCY

Around one quarter of people with DS develop hypothyroidism, many in childhood or early adulthood. Other forms of endocrine failure are also more common. Women with DS are twice as likely to experience an early menopause as the general population³⁰ with a median age around 46 years. Those women who experience menopause earlier were also at increased risk of developing dementia at a younger age.³¹ This may reflect some general biologic aging phenomenon or be associated with a specific lack of estrogen. It is unclear whether age at menopause relates to IQ, as is the situation in the general population.³² Men with DS tend to have elevated follicle-stimulating hormone (FSH) and luteinizing hormone (LH) with low testosterone levels. There is a lack of trials of testosterone replacement therapy in men with DS, so it is unclear whether testing gonadal hormone levels is useful.

MUSCULOSKELETAL SYSTEM: ARTHRITIS, METABOLIC BONE DISEASE

Osteoarthritis is common in DS and, like other conditions, may be associated with obesity. Osteoporosis is also common and may, in part, relate to hypothyroidism and gonadal hormone failure. In people with ID, in general ages 40 to 60 years, and who were community residents, 21% had osteoporosis and 34% osteopenia.³³ People with DS appear to benefit from vitamin D and calcium treatment as much as the general population.³⁴

DERMATOLOGY: ECZEMA, ACNE, AND DISEASES OF THE SCALP

Eczeema, acne, and yeast-associated folliculitis are all common in DS. The latter may reflect some subtle deficiency of cellular immunity as also reflected by increased prevalence of fungal infections of the nails.³⁵ There is evidence of altered T-cell function, especially in older men with DS.³⁶ An immune etiology may also underpin the increased incidence of alopecia

as suggested by the high prevalence of autoimmune thyroid disease. Adults with DS may have low neutrophil counts with a tendency of lymphocyte counts also to be on the low side.³⁵

ASSESSMENT OF THE HEALTH OF OLDER ADULTS WITH ID

The preceding sections indicate that older people with ID have an increased disease load and usually suffer from multiple pathologies. Disease load increases with ID severity; hence it particularly affects those people with more communication problems. Partly for this reason, the disease often goes undetected. When assessing the health of someone with ID it is worth recalling the North Sydney experience where half of the major medical problems were unknown and of the half that were already known, half were inadequately managed.

The multidisciplinary setting of assessment

People with ID are usually at the center of a complex support system. It is usually worth taking time to elucidate this together with identifying all the health and social care professionals involved, as this often provides useful information. Typical professional contacts might include social work, clinical psychology, speech and language therapy, community nurses, psychiatrists with an interest in ID, occupational therapists, audiology services, community dentistry, and so on. In some countries, there may be a formal legal representative of the person with ID; for example, in Scotland a welfare guardian may have been appointed under the Adults with Incapacity Act. Although information gathering is important, such information may not always be reliable. For example, when 589 adults with ID were being discharged from a large Scottish institution, the nurses who had been looking after them thought 49% of the adults had perfect vision, whereas an actual ophthalmologic assessment showed that only 0.8% did.³⁷ Similarly, the nurses thought 74% of the adults had perfect hearing, whereas an audiologic assessment found this was the case for only 11%.

Brief physical health screening tools

A number of brief physical health screening tools have been developed. These are often designed to be administered by nurses. They are usually based on making medical diagnoses and are not designed to assess atypical presentation of disease. Wilson and Haire provided the prototype for this kind of assessment, largely by applying methods of examination used in the non-ID population, which, like other studies, noted the large number of health problems that had been undetected prior to screening.³⁸ These assessments were originally designed to detect threats to health. For example, routine physical examination of the chest is performed because respiratory infection is a major cause of death in people with intellectual disabilities.^{39–41} However, even in the general population chest examination⁴² has poor sensitivity and specificity. The same can be said for many aspects of routine physical examination, such as abdominal examination⁴³ and musculoskeletal examination.⁴⁴ In addition, older adults with ID do not always find conventional medical examinations easy to tolerate. It may be difficult to explain the relevance of various elements, such as chest percussion, and there may have been experiences of physical or sexual abuse, recall of which is cued by a physical examination. Screening tools are

therefore best used to provide a checklist for information gathering as a background for fuller assessment.

User-led physical health assessments

One way to find a workable way to assess the health of older people with ID is to find out what they consider to be health and what kinds of assessment they find acceptable. The comprehensive health assessment program (CHAP) is one such example developed in Australia and validated by randomized control trial with its acceptability to participants assessed.^{45,46} The CHAP is, itself, a development from the Cardiff health check that was also subject to a randomized controlled trial⁴⁷; its validation is thus reassuring as to the validity of caregiver-answered items, because other assessments have found caregiver responses to be unreliable as noted previously. Although acceptable to people with ID, the CHAP was not designed to align with their particular priorities for health. This alignment is essential because at present people with ID feel that the partnership between them and their doctor is far from equal.⁴⁸ Moreover government policies are beginning to require this as, for example, NHS Scotland directives, which recommended attention to these "critical factors":

- Component parts of the health screen which must be relevant to the particular health needs of persons with learning disabilities (rather than the general population).
- The acceptability of the health screen to persons with learning disabilities and their caregivers.⁴⁹

When older adults are asked about their understanding of health three key themes emerge:

1. Being able to do things and participate in activities
2. Nutrition
3. Hygiene/self-care⁵⁰

Moreover, their concept of health is much closer to the World Health Organization's definition in that it incorporates aspects of well-being beyond the mere absence of disease.⁵¹ Appropriate health assessments need to capture these positive aspects, therefore, by asking questions related to the key health themes in addition to the standard medical checklists designed to identify disease. Similarly, examination needs to incorporate measures germane to the health themes rather than merely aiming to identify disease. Unsurprisingly, adults with ID welcome such aspects of assessment,⁵⁰ and several have been validated in this population. Figure 58-1 provides a template user-led health assessment that includes independently validated items that are both generally acceptable and feasible.⁵² In practice it takes an average of 20 to 30 minutes to complete, and this tends to be a little quicker in those with more severe ID who find some of the items very difficult (e.g., peak flow). Indeed, it is sensible to note the severity of ID in conjunction with the assessment and, where this is unknown, use the Swedish classification developed by Kylen (discussed earlier). The assessment provides a good baseline against which changes in health status can be assessed. To work out foot size to which shoe size can be compared, the chart in Table 58-4 can be used by measuring foot length (draw a line on a piece of paper at the heel and toes); allow one half size either way. It is not uncommon for older adults with ID to have shoes larger than their measured size because their feet are often disproportionately wide.

Medical information		Townsend disability scale

Mental health assessment

Assessing mental health may fall to specialists in the psychiatry of ID. However, it is useful for physicians to be able to diagnose delirium and dementia in older adults with ID. The principles of diagnosing delirium in people with ID are no different from those in the general population. The ICD-10 diagnostic criteria are made up of the following: (1) impairment of consciousness and attention, (2) global disturbance of cognition, (3) psychomotor disturbance, (4) sleep/wake cycle disturbance, and (5) emotional disturbance. Generally the diagnosis applies to symptom duration of less than 6 months. The challenge is being able to make the diagnosis in people with severe or profound ID where there is usually a background disturbance of all five criteria. Here a fluctuating course can be a helpful indicator of the presence of delirium. Similarly, psychomotor disturbance, unexplained hypo- or hyperactivity is also a useful pointer. Emotional disturbance is likely to be expressed nonverbally by changes in behavior.

Similarly, the diagnosis of dementia in people with ID can also require considerable clinical skill. Often decline in function or change in behavior can be useful signs. Change in new learning ability and the presence of repetitive questioning can be helpful pointers in the history. The key diagnostic criterion is demonstrating cognitive decline from baseline, and this usually requires two detailed clinical psychology assessments. Several assessment tools are available; one that spans the general and ID population is the Severe Impairment Battery.⁵³ Having demonstrated cognitive decline, a hierarchical approach can be adopted to determine etiology.²⁵ This comprises considering (1) physical illness, (2) effects of medication, (3) sensory loss, (4) environmental change or life events, and (5) mental illness.²⁵ This is not to say that the diagnosis of dementia cannot be made in the presence of any of these five possible contributors to cognitive decline; indeed, not infrequently such potential contributors coexist with dementia. Nevertheless, it is generally worthwhile addressing reversible causes of cognitive decline (e.g., sensory loss) where possible. As noted earlier, behavioral changes may predate any clinically evident cognitive decline.

COMMUNICATION

The General Medical Council's *Tomorrow's Doctors*⁵⁴ lists 14 basic duties of a doctor, the first 8 of which are especially pertinent when caring for older adults with ID:

- Make the care of your patient your first concern.
- Treat every patient politely and considerately.
- Respect patients' dignity and privacy.
- Listen to patients and respect their views.
- Give patients information in a way they can understand.
- Respect the rights of patients to be fully involved in decisions about their care.
- Keep your professional knowledge and skills up to date.
- Recognize the limits of your professional competence.

Caregivers and other members of the multidisciplinary team, such as nurses and speech language therapists, can be particularly helpful if you feel you are reaching the limits of your own professional competence in communicating with people with ID. Most older adults with ID will lie in the mild end of the spectrum and thus be able to communicate verbally. It is important to take account of any sensory loss, which is common, and to provide an appropriate environment to facilitate communication. Plenty of time should be available. It is good practice to keep sentences short with just one idea per sentence and to use plain language. Conditional sentences are best avoided. It is also helpful to use concrete rather than abstract terms, supporting this with nonverbal aids whenever possible. If you are drawing a body part, remember to put this in context of the external human figure. Pictures of sunrises or beds may help with eliciting duration of symptoms. Just as with other communication, it is sensible to check what has been understood by asking people with ID to explain things in their own words. Various organizations produce easy-to-read information on common health topics, which can be helpful. For example, the Royal College of Psychiatrists has produced a "Books Beyond Words" series.

HEALTH PROMOTION

Health promotion is predicated on having appropriate health targets. Typically targets aim for equity with the non-ID population based on evidence for effective interventions⁵⁵ and cover these areas:

- Dental health
- Hearing and vision
- Nutrition and growth
- Prevention and treatment of chronic constipation
- Epilepsy review

- Thyroid screening
- Identification and treatment of mental health problems
- GERD and *H. pylori* eradication
- Osteoporosis
- Medication review
- Vaccination
- Provision of exercise opportunities
- Regular physical assessment and review
- Breast and cervical cancer screening

In addition to these general recommendations, there may be syndrome-specific actions to be considered. User-led concepts of health (functional ability and participation, nutrition, self-care, and hygiene) are likely to be useful in structuring health promotion for older adults with ID. Communication is key to good health promotion. For example, if a health promotion campaign endorses a negative stereotype of obesity, people with ID may identify with the stereotype and feel unhealthy as a consequence. It would be preferable to deliver a clear positive message about healthy eating and exercise instead. Perhaps the most important task of health promotion is to communicate with caregivers and any social or health care professionals involved in the care of an older adult with ID the importance of enhancing functional abilities, participation, and self-care.

KEY POINTS

The Older Adult with Intellectual Disability

- There is a rapid increase in the number of adults with intellectual disability surviving into old age.
- Diagnosis requires an IQ <70 together with both evidence of a developmental disorder and deficits in adaptive behavior.
- Severity of intellectual disability can be estimated according to verbal skills.
- Health status is influenced by the degree of intellectual severity and specific syndromic associations.
- Older adults with intellectual disability envisage health in terms of (1) being able to do things and participate in activities, (2) nutrition, (3) hygiene/self-care.
- User-led health assessments are feasible and relate closely to conventional health outcomes.
- Dementia is common in older adults with intellectual disability. Diagnosis is aided by a hierarchical approach considering (1) physical illness, (2) effects of medication, (3) sensory loss, (4) environmental change or life events, and (5) mental illness.

INTRODUCTION

Epilepsy is a common cause of morbidity and mortality. Epilepsy is not thought of as a disease of old age in the same way as cerebrovascular or neurodegenerative conditions, probably because of the presence of other comorbidities and complex etiologic factors and a less visible socioeconomic burden compared to adults of working age. Epilepsy in the elderly presents greater diagnostic difficulty than in the young. Management considerations include the presence of concomitant disease, altered drug handling, polypharmacy, social isolation, and lack of access to specialist investigation or treatment.

Epileptic seizures are typically brief and transitory. They cause disability because of the unpredictable nature of attacks, the risk of injury they bring, and the neurologic impairment from repeated seizures and adverse effects of treatment.¹ Driving is restricted, and there is social embarrassment, stigma, and impact on employment.²⁻⁴ Fundamental questions regarding the neurobiology of epilepsy, reasons for its development, what makes a seizure start and stop, and the variable responses to treatments remain unanswered.

Epilepsy in the elderly needs special consideration.⁵ The older person presenting with attacks that might be epilepsy can present a considerable clinical challenge.⁶ Diagnosis rests on the history of events obtained from the patient and a reliable witness. There are rarely clinical signs that can be elicited in clinic to support the diagnosis, and tests can be normal or show nonspecific abnormalities that catch the unwary. The differential diagnosis of collapse or altered consciousness in the elderly is wide. A previous diagnosis of epilepsy made earlier in life, either as a child or an adult, should not be assumed to explain new or ongoing attacks and the term *known epileptic* should be avoided.

Older people with a diagnosis of epilepsy can be considered as falling into four groups:

1. Those with new onset seizures in late life
2. Those with an established diagnosis of epilepsy with seizures persisting or recurring in late life
3. Those with new onset attacks in late life that have been misdiagnosed as epilepsy
4. Those with an established diagnosis of epilepsy with new or ongoing attacks that are not due to epilepsy

DEFINITION

An epileptic seizure is the clinical manifestation of an abnormal synchronous neuronal discharge. Epilepsy is defined as a tendency to recurrent epileptic seizures. A diagnosis of epilepsy is not appropriate after a single event.⁷ In the elderly, the likelihood of further seizures after a first is more likely as a result of a higher incidence of seizures resulting from a structural brain lesion.⁸⁻¹⁰ The ability to predict the individual who will develop epilepsy after a first seizure still remains insufficient to warrant the label or treatment.

EPIDEMIOLOGY

Epilepsy is the third most common neurologic condition in old age after dementia and stroke.¹¹ The incidence is two to three times higher than that seen in childhood.⁶ A community study, the United Kingdom General Practice Survey of Epilepsy and Epileptic Seizures, found that 24% of newly diagnosed cases of definite epilepsy occurred in patients over 60 years old.^{9,12} A significant rise in incidence with increasing age has been confirmed by a number of studies, from an overall incidence of 50/100,000 to 70 to 80 per 100,000 in the over 60s and 160 per 100,000 in the over 80s¹³⁻¹⁸ (Figure 59-1). The prevalence of epilepsy is generally taken as between 5 and 10 cases per 1000 persons, with a lifetime prevalence of 2% to 5%.¹⁹ Rates are dependent on case ascertainment and agreement on definitions used, for example, definite active epilepsy (ongoing seizures) versus those on treatment.²⁰

In light of these figures, there would appear to be relative under provision in specialist care for the elderly with epilepsy, in research and in treatment trials. The reasons are unclear, whether they relate to a lesser perceived impact on lifestyle compared to younger patients with epilepsy or that associated or unrelated comorbidities leave epilepsy low down on a list of other medical conditions.²¹

CLASSIFICATION

Epilepsy classification is often thought of as complex and hard to follow. This need not be the case if the principles behind the classification are understood. The current classification of epilepsy was developed by the Commission on Classification and Terminology of the International League against Epilepsy (ILAE).

There are two parallel schemes, one for epileptic seizures²² and another for epilepsy syndromes.²³

There are a number of areas of confusion in classification encountered in the nonspecialist setting. Typically these arise from the use of outdated terminology or failing to distinguish between terms intended to describe seizure types and those intended to designate epilepsy syndromes or some etiologic substrate. Accurate syndromic classification helps direct treatment decisions and inform on prognosis. Classification is also important for epidemiologic studies and service needs assessments. Furthermore, rigorous attempts at classification benefit the whole diagnostic process and reduce or identify previous epilepsy misdiagnoses. A good understanding of epilepsy syndromes that present in childhood or early adult life remain useful when dealing with elderly patients in that seizures risk can persist throughout life, patients may carry a diagnostic label that may not be correct, and questions regarding the continuation of long-standing medication may be raised.

Epilepsy is not a specific disease but a heterogeneous group of disorders manifesting the neuroanatomic and pathophysiologic substrate causing the seizures.

The latest proposals from the ILAE suggest five parts or "axes," organized in a hierarchical fashion allowing the

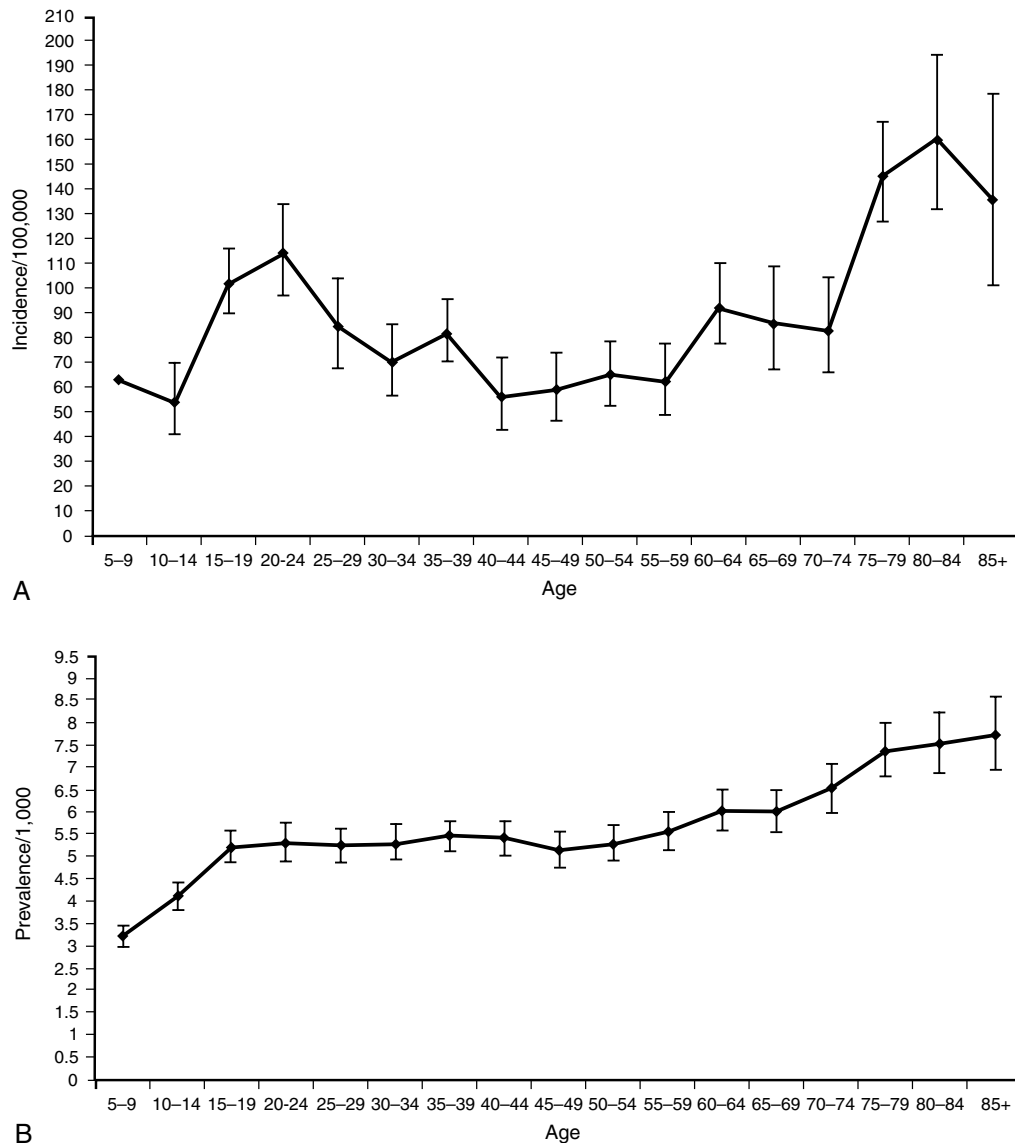

Figure 59-1. A, Age-specific incidence of treated epilepsy per 100,000 persons. B, Age-specific prevalence of treated epilepsy per 1000 persons. (From Wallace H, Shorvon S, Tallis R. Age-specific incidence and prevalence rates of treated epilepsy in an unselected population of 2,052,922 and age-specific fertility rates of women with epilepsy. *Lancet* 1998;352:19–26, with permission.)

integration of available and new information. The five axes are as follows:

- Axis 1: Ictal phenomenology. Describing in detail the ictal event (Table 59-1).
- Axis 2: Seizure type. Localization within the brain and precipitating stimuli for reflex seizures should be specified when appropriate.
- Axis 3: Syndrome. With the understanding that a syndromic diagnosis may not always be possible.
- Axis 4: Etiology. This includes a specific disease, genetic defects, or pathologic substrates causing seizures.
- Axis 5: Impairment. This optional but often useful additional diagnostic parameter can be derived from an impairment classification adapted from the World Health

Organization International Classification of Disease (WHO ICD10).

It remains to be seen whether this five axis scheme will be widely adopted and other axes have already been proposed.²⁴ The long-running debate of how best to classify epilepsy continues.²⁵

Shortcomings of the classification scheme

Changing lists of descriptive entities inevitably cause confusion. A simplified system based on etiology rather than descriptive terminology is suggested by some, particularly with advances in imaging and genetics.²⁶ Perhaps the main shortcomings of the ILAE classification schemes are its poor dissemination among nonepilepsy specialist health care professionals. Revisions in the classification scheme and the

Table 59-1. ILAE Task Force Seizure Classification

Generalized Seizures	
•	Tonic-clonic seizures (includes variations beginning with a clonic or myoclonic phase)
•	Clonic seizures
•	Without tonic features
•	With tonic features
•	Typical absence seizures
•	Atypical absence seizures
•	Myoclonic absence seizures
•	Tonic seizures
•	Spasms
•	Myoclonic seizures
•	Massive bilateral myoclonus
•	Eyelid myoclonia
•	Without absences
•	With absences
•	Myoclonic atonic seizures
•	Negative myoclonus
•	Atonic seizures
•	Reflex seizures in generalized epilepsy syndromes
•	Seizures of the posterior neocortex
•	Neocortical temporal lobe seizures
Focal Seizures	
•	Focal sensory seizures
•	With elementary sensory symptoms (e.g., occipital and parietal lobe seizures)
•	With experiential sensory symptoms (e.g., temporo parieto occipital junction seizures)
•	Focal motor seizures
•	With elementary clonic motor signs
•	With asymmetrical tonic motor seizures (e.g., supplementary motor seizures)
•	With typical (temporal lobe) automatisms (e.g., mesial temporal lobe seizures)
•	With hyperkinetic automatisms
•	With focal negative myoclonus
•	With inhibitory motor seizures
•	Gelastic seizures
•	Hemiclonic seizures
•	Secondary generalized seizures
•	Reflex seizures in focal epilepsy syndromes

rationale behind them tend to be published in specialist journals and as such remain relatively inaccessible to the nonepilepsy specialist. Given that epilepsy is so commonly encountered, this is one area that should be addressed.

The terms *grand mal* and *petit mal* are still commonly heard. Although they may provide a vague reference to a seizure type, they give little indication of the true seizure semiology, the possible pathophysiology, or even a secure diagnosis. Patients may use the term *grand mal* to refer to either a complex partial seizure or a generalized tonic clonic seizure. Similarly, *petit mal* can be used to refer to any brief alteration of consciousness, without further appropriate history to attempt to define the event further.

Despite the shortcomings in epilepsy classification, those involved in the care of patients with epilepsy or episodes that might be attributed to epilepsy should familiarize themselves with the current scheme and in particular the principles behind it.

EPILEPTIC SEIZURES

The international classification of epileptic seizures (ICES) was developed by a panel of international experts examining video recordings of clinical and electroencephalographic

seizures.²² As such it is based on a consensus of opinions. Table 59-1 shows the current recommended classification of epileptic seizures. By design, the categories are descriptive. The first level of this system distinguishes between generalized seizures, a seizure whose initial semiology indicates, or is consistent with, involvement of entire cerebral hemispheres, and focal onset seizures, a seizure whose initial semiology indicates, or is consistent with, initial activation of only part of one cerebral hemisphere.

Generalized seizures

Generalized seizures are divided into absence, myoclonic, tonic, clonic, or tonic-clonic events. Absence seizures can be divided into typical absence and atypical absences. Typical absences are seen in idiopathic generalized epilepsy (discussed later). They occur in childhood onset syndromes but can persist into old age. Typical absence seizures of childhood used to be referred to as *petit mal*; however, this term should now be considered obsolete. They consist of an alteration of consciousness, occasionally there is associated eye flickering but other motor manifestations are rare; attacks are brief, usually less than 30 seconds. Characteristic electroencephalography (EEG) findings are of generalized spike wave discharges of 3 to 5 Hz. Myoclonic jerks are brief muscular jerks affecting limbs and less commonly trunk. The term *myoclonic jerk* comes under the heading of generalized seizures; however, myoclonic jerks do occur in focal epilepsy, affecting one limb or side; strictly following the ILAE scheme would classify these as focal motor seizures.

Focal seizures

Focal seizures are separated into motor, somatosensory or special sensory, autonomic, and psychic. The term *localization related*, previously proposed for focal seizures, is cumbersome and not widely adopted; the terms *focal* or *partial* remain in more common use. For the past few decades, focal seizures have been separated into simple partial seizures (consciousness is preserved, with maintained awareness) or complex partial seizures (consciousness is lost). The preservation or loss of consciousness is very relevant in the clinical setting, indicating a level of impairment caused by seizures. A seizure aura, often taken to be the warning before a seizure, is a simple partial seizure that may immediately precede a complex partial seizure or secondary generalization. Auras can occur in isolation (i.e., a simple partial seizure). Auras are typically short lived—over a few seconds to minutes but rarely longer.

TEMPORAL LOBE SEIZURES

Temporal lobe seizures are perhaps the most familiar of all focal seizure types. Seizures either arise from mesial temporal structures, part of the limbic system (e.g., the hippocampus), or from the temporal neocortex. Symptoms at onset include epigastric discomfort, "butterflies" or a rising sensation, abnormal taste, experiential phenomena such as *déjà vu*, and psychic features, fear, or euphoria; these symptoms are usually short lived of a few seconds to minutes and can occur in isolation without progression to loss of awareness of secondary generalization. Patients will often recall these initial symptoms as seizure auras. A complex partial seizure of temporal origin will typically manifest with orofacial automatism—lip smacking or repeated swallowing. This is an extremely useful piece of history from a witness and specific inquiry is helpful. In addition, there

may be limb automatisms and typically there is dystonic posturing. Patients typically feel tired with the need to sleep after an attack.

FRONTAL LOBE SEIZURES

Frontal lobe seizures vary greatly because of the size of the frontal lobe and widespread functions it subserves. The semiology of frontal lobe seizures depends on the origin and spread of the epileptogenic focus.²⁷ The frontal lobe contains the primary motor cortex, supplementary motor cortex, prefrontal cortex, and limbic and paralimbic cortices.

In general, frontal lobe seizures manifest with prominent motor manifestations. There may be forced head version or forced eye deviation. Limb involvement can include tonic, clonic, or postural movements or bilateral vigorous motor automatisms—for example, bicycling. Sometimes bizarre motor movements are seen; occasionally patients can retain consciousness even with jerking in all four limbs; these features can lead to an incorrect diagnosis of nonepileptic seizures. A “Jacksonian march” refers to a march or spread of the focal motor seizure in a predictable and sequential manner from a distal limb to proximal areas or from leg to arm. The term *Todd paresis* refers to a transient hemiparesis that can last a day or more occurring after a secondary generalized focal motor seizure.

OCCIPITAL SEIZURES

Occipital onset seizures manifest as would be expected with visual phenomena. Typically these are vivid or formed hallucinations. They are distinct from migraine aura in that colors are vivid and they evolve over seconds rather than the several minutes of a migraine aura. They may involve flashing balls of light or revolving bright colors. Other manifestations include well-formed hallucinations, again these are short lived of seconds to minutes and may evolve to secondary generalized seizures.

PARIETAL SEIZURES

Parietal lobe seizures are rare. For a review see reference.²⁸ The parietal lobes are involved in the processing and integration of sensory and visual information. Stereotyped episodes that involve pain, numbness and tingling, heat, or pressure sensations suggest parietal lobe seizures.

EPILEPSY SYNDROMES

The international classification of epilepsy syndromes and epilepsies (ICEES)²³ supplements the ICES. Some epilepsy categories represent pure disease entities, whereas others represent a spectrum of clinical forms (e.g., idiopathic generalized epilepsy).

The dichotomy between generalized and focal is retained in the syndrome classification. The next classification level takes into account known or suspected etiology: symptomatic, with a known underlying cause; idiopathic, occurring without known underlying disease. Two further categories are recognized, one of epilepsies and epilepsy syndromes where categorization into focal or generalized is not possible because of a lack of clearly distinguishing features often the case with nocturnal seizures, and another for seizures associated with a specific situation, fever, drugs, and metabolic disturbance (i.e., provoked seizures).

Idiopathic generalized epilepsy

Idiopathic generalized epilepsy (IGE) is characterized by one or more of the following seizure types: typical absences, myoclonic jerks, and generalized tonic-clonic seizures (GTCS); interictal and ictal generalized spike or polyspike; and wave on EEG. Further syndromic subclassification of IGE is made on the prevalence of the different seizure types and EEG features. Some propose the inclusion of age of onset and diurnal seizure patterns. The main subgroups seen in adults with epilepsy are as follows:

- Juvenile myoclonic epilepsy (JME)
- Juvenile absence epilepsy (JAE)
- Epilepsy with generalized tonic clonic seizures on awakening (EGTC)

It remains debated whether different clinical manifestations represent different ends of a biologic continuum or a group of distinct syndromes.²⁹ The typical onset age of IGE is childhood or in early adult life; however, a later onset form is recognized,^{30,31} and there are case reports of classical IGE presenting for the first time in the elderly.^{32,33}

The term *idiopathic* refers to a disorder unto itself, *sui generis* (i.e., without other neurologic abnormality) and *not* etiology unknown. The risk of seizures in IGE usually continues into old age. A late presentation of absence status in four patients over age 60 with a prior diagnosis of IGE and absence seizures that resolved in their second decade has been reported.³⁴ Response to appropriate antiepileptic drug treatment is good in most, but not all. One study of epilepsy patients with IGE over age 60 found a small subgroup who experience an exacerbation of seizures in old age.³⁵

Idiopathic focal epilepsy

The idiopathic focal epilepsies are restricted to childhood and rarely if at all persist into adult life. They are mentioned here for completeness. They are typically benign. It would be highly unusual and probably indicate an incorrect diagnosis if seizures persist into late life.

Symptomatic epilepsy

Focal symptomatic epilepsy is the predominant cause of new onset seizures in the elderly.^{21,36} Symptomatic epilepsy means a cause is known. In the absence of an imaging abnormality, a history of prior brain injury—for example, from intracranial infection (meningitis or encephalitis) or trauma—can be sufficient to attribute a cause to new onset seizures. The term *remote symptomatic* is used for patients developing seizures some years after a significant brain injury, in contrast to acute symptomatic, where epilepsy is a presentation of new brain dysfunction.

Probably symptomatic (cryptogenic) epilepsy

The term *cryptogenic* was used to classify those with epilepsy of unknown etiology. The ILAE now recommends the term *probably symptomatic*. With advances in brain imaging, the proportion of patients in this group is falling. Younger adults with normal magnetic resonance imaging (MRI) and refractory epilepsy remain a significant health burden. In the elderly, the likelihood of MRI abnormalities is high, particularly leukoaraiosis.³⁷ The relationship of such abnormalities

to epilepsy and why some develop seizures and other not remains unclear.³⁸

MAKING THE DIAGNOSIS

Epilepsy can present with disparate manifestations. Similarly, a number of other conditions present with features that may be mistaken for epileptic seizures. The key feature in epilepsy is that episodes are typically stereotyped, unchanged over a long period of time, and usually short lived. The following episodic manifestations occurring in isolation or in combination can be caused by epilepsy:

- Loss of awareness or consciousness
- Generalized convulsive movements
- Drop attacks
- Focal movements—jerks, posturing, semipurposeful movements, rarely thrashing, bicycling or motor agitation
- Sensory episodes—tingling, pain, burning
- Vocalization—formed speech, incomprehensible words, screams, or laughter
- Psychic experiences
- Episodic phenomena from sleep
- Prolonged confusion or fugue state

The importance of a careful history in making a diagnosis of epilepsy cannot be overstated. This should include a description of events from the patient and crucially a firsthand witness description. Overreliance on a secondhand statement of “it looked like a fit” is likely to lead to misdiagnoses. There is no single test to make a diagnosis of epilepsy, and time taken by an experienced clinician in taking a careful history cannot be circumvented. In each case, an account of the circumstances, time of day, situation, prodrome or warning, detailed account the attack, its semiology and duration, the rate and nature of recovery, and associated symptoms or signs—for example, headache or confusion—are needed.

Direct questions about the attack itself and other previous attacks are helpful but care should be taken not to lead the history, and these questions are best left until the patient and witness have given a free account of the event or events in question. Useful features that are worth inquiring about directly if not first offered include head or eye deviation, the nature of limb movements, posturing, jerks, or automatisms, and whether movements are rhythmic or synchronous and how they evolve over time. Asking a witness about repeated swallowing or lip smacking can be revealing. Any changes of color, breathing pattern, or sweating need to be ascertained along with an account of the recovery period, its duration, and any subsequent symptoms such as headache, confusion, or altered behavior. It is always useful to ask about possible prior attacks that the patient may not associate with the current event—for example, a patient presenting after his or her first generalized tonic clonic seizure may not make the link between previously experienced simple partial seizures. Classically tongue biting and incontinence were thought to strongly indicate an epileptic seizure. This is not always the case. Urinary incontinence can occur during syncope. Injury to the tip of the tongue can occur in syncope, although if the sides of the tongue or inner cheek are severely bitten then this usually indicates that a generalized tonic clonic seizure has taken place.³⁹

The past medical history should include inquiries about previous history of head injury or intracranial infection, and cardiac history. Family history, medication history, and social history are important as in any other presentation. Specific inquiry should go into living arrangements, driving, occupation, and hobbies or pastimes.

DIFFERENTIAL DIAGNOSIS

The two main differential diagnoses of epileptic seizures to consider are syncope and psychogenic or nonepileptic attacks. Manifestations of both epileptic seizures and syncope may differ in the elderly compared to the young, making diagnosis difficult or increasing misdiagnosis. Other more rare conditions leading to blackouts or altered consciousness to consider are hypoglycemia, other metabolic disorders, structural abnormalities at the skull base affecting the brain stem, and lesions affecting cerebrospinal fluid circulation. Transient cerebral ischemia or transient ischemic attacks (TIAs) are usually easily separated from epileptic events by their frequency and time course. They rarely present with loss of consciousness, and TIAs are typically less frequent and do not remain stereotyped over long periods of time. One exception are focal “seizures” affecting the hand seen in critical cortical ischemia; this is described in more detail later in this chapter.

Syncope

Syncope is the most common cause of episodes of loss of awareness. Syncope is covered in greater detail in Chapter 46. Aspects of an attack should not be taken in isolation and given undue emphasis, as elements of epileptic seizures can occur in syncope. Key features of syncopal episodes versus epileptic seizures are the precipitating factors, warning symptoms, a brief loss of consciousness, and rapid recovery, although there can be greater variation in older people (see Table 59-2). Features that may mimic seizures include head turning, automatisms and urinary incontinence, and relatively minor tongue biting.⁴⁰ Injury can occur from a syncopal fall, although this is less common as people tend to crumple to the floor rather than experience the stiff fall of an epileptic seizure.

In cardiac syncope, attacks occur without warning; there is abrupt unprovoked collapse with brief unconsciousness and rapid recovery. The attacks are not situational, and there is less often a prodrome than in vasovagal syncope. Cardiac syncope should be strongly suspected in those with a history of structural heart disease, previous myocardial infarction, rheumatic fever, or heart murmur.

Psychogenic attacks

Episodes that outwardly appear similar to epileptic seizures but are not caused by ictal electrical discharges in the brain are referred to by a number of terms: nonepileptic attacks (NEA), nonepileptic seizure (NES), psychogenic nonepileptic attacks or seizures (PNEA) or (PNES), or the less favored pseudoseizures.⁴¹ The prevalence of PNEA appears less in the elderly, although no studies have looked at ascertainment or reporting bias. In a study of video-EEG monitoring in the elderly (>60), PNEA was diagnosed in 10 of 34 patients who had recoded events during the monitoring period;⁴² this series came from 71 patients over 60 years of age who had

Table 59-2. Features that Help Distinguish Syncope from Epileptic Seizures

Features	USUAL DIFFERENCE		
	Faints	Fits	Modification in Older Patients
Posture	Usually occur in the upright position	Not position dependent	Faints in older people are not always position dependent because they are often the result of significant, position-independent pathology
Onset	Gradual	Sudden	Loss of consciousness may be quite abrupt in syncope in an older person; complex partial seizures may have a gradual onset
Injury	Rare	More common	A syncopal attack may be associated with significant soft tissue or bony injury in an older person
Incontinence	Rare	Common	An individual prone to incontinence may be wet during a faint; partial seizures will not usually be associated with incontinence
Recovery	Rapid	Slow	A fit may take the form of a brief (temporal lobe) absence; a faint associated with a serious arrhythmia may be prolonged
Postevent confusion	Little	Marked	A prolonged hypoxic episode as the result of a faint may be associated with prolonged postevent confusion
Frequency	Usually infrequent with a clear precipitating cause	May be frequent and usually without precipitating cause	Faints associated with cardiac arrhythmias, low cardiac output, postural hypotension, or carotid sinus sensitivity may be frequent

undergone video EEG monitoring out of a total of 440 over a 7-year period. Another study⁴³ found a diagnosis of PNEA was made 7 of 16 patients over 60 years of age undergoing video-EEG monitoring, this from a total of 834 admitted for long-term video-EEG monitoring. Further study of long-term video EEG monitoring over an 8-year period identified 39 patients over the age of 60 who were admitted for evaluation, 13 of whom were diagnosed with PNEA on the basis of video EEG.⁴⁴ Nevertheless PNEA remains an important differential diagnosis in the elderly, particularly when apparent medically refractory epilepsy is encountered.⁴⁵

PNEA probably arises as a result of patients responding to psychosocial stress with unexplained somatic symptoms that come to medical attention,⁴⁶ and PNEA is associated with a number of distinct pathologic personality profiles that could be used to tailor therapy.⁴⁷ Somatoform disorders, anxiety disorders, mood disorders, and reinforced behavior pattern are all features associated with PNEA. In one study, a subgroup of elderly patients were described who had PNEA that presented over the age of 55; they were more likely to be male and more likely to have a history of traumatic experience related to ill health.⁴⁸ Suspicion of PNEA should be raised where there are unusual features to attacks, associated physical or mental ill health, adverse social circumstances, or bereavement before presentation. Confidently securing a diagnosis of PNEA usually requires long-term video-EEG monitoring, an investigation that would appear to be of limited access to the elderly population in most centers.

The Cochrane database review in 2007 found insufficient evidence to recommend specific treatments for PNEA and stressed the need for randomized trials to assess treatment interventions.⁴⁹ One of the first aims of treatment once a diagnosis is made should be to reduce unnecessary medical interventions or hospital admissions.

Transient epileptic amnesia

Transient epileptic amnesia (TEA) has been used to describe recurrent episodes of transient amnesia in the absence of overt seizures.⁵⁰ TEA needs to be distinguished from transient global amnesia (TGA) (discussed later). In TEA, there

is evidence for a diagnosis of epilepsy based on one or more of EEG abnormalities, co-occurrence of other clinical features of epilepsy (for example, automatisms or olfactory hallucinations), and clear-cut response to antiepileptic medications.⁵¹ Other features include interictal memory disturbance manifest by accelerated forgetting, remote autobiographic amnesia (i.e., patients demonstrate a patchy but dense loss of memories for important personal events from the remote past), and topographical amnesia (i.e., patients have difficulty navigating their way around new or familiar routes).^{52,53} It is not clear whether episodes of TEA represent ongoing ictal activity or a postictal phenomenon. Whether TEA is a sufficient diagnostic entity to be regarded as a distinct syndrome⁵⁰ or another manifestation of temporal lobe seizures in the elderly remains to be seen.

Transient global amnesia

Transient global amnesia (TGA) is a condition of transient loss of memory function that has been described for over 40 years.^{54,55} It is most common in middle to late life. Episodes of TGA have a characteristic presentation. There is usually, but not always, a history of provoking factors; these can include one or more of the following: vigorous exercise, acute emotional stress, or change in temperature. During an attack, patients appear mildly agitated and repeatedly question or engage in searching behavior. Attacks typically last several hours, but less than 24 hours. During an attack, patients retain self-awareness and long-term memory and can perform familiar task or navigate a familiar environment but appear unable to lay down any new memories and appear amnesic of all recent events during the attack. Once an attack is over, patients regain some memory around the event but remain amnesic for the central period of the episode. Attacks are usually isolated, but there is a 6% recurrence rate. The clinical presentation is usually so characteristic that once seen it is not easily mistaken for epilepsy. There is no evidence to support an epileptic etiology or transient arterial ischemic events.⁵⁶ A popular hypothesis is that of venous congestion in bilateral temporal lobes as a result of internal jugular vein valve insufficiency and sudden rises in intrathoracic pressure.⁵⁷

If attacks are recurrent, have associated features (e.g., automatisms), and symptoms of memory impairment outside an attack, the diagnosis of transient epileptic amnesia should be considered.

Psychogenic amnesia

Psychogenic amnesia or dissociative fugue is rare and typically triggered by stressful or adverse life events. Careful clinical evaluation may reveal inconsistencies in the presentation that alert the practitioner to a conversion disorder. Features include extensive loss of autobiographic memories, including self-identity, in the context of preserved new learning and absence of repetitive questioning, and the ability to continue normal activities of daily living.

Parasomnias

Parasomnias are disorders that manifest around or during sleep. They are sometimes mistaken for epileptic seizures. The classification of parasomnias is changing as new information emerges.⁵⁸ They include REM parasomnias and periodic limb movements. An accurate history is usually sufficient to distinguish these from epilepsy, and occasionally video monitoring can be helpful.

Transient ischemic attacks

TIA symptoms tend to be negative (i.e., a loss of function). Epileptic seizures invariably produce positive symptoms. One rare exception is that of apparent focal motor seizures caused by critical cortical ischemia from carotid artery stenosis, or shaking limb TIA (SLTIA) (Figure 59-2). First described in 1962,⁵⁹ a handful of cases of SLTIA are reported in the literature.^{60–62} Events involve shaking of usually the upper limb that does not spread to the face. Episodes can be short lived or prolonged. They are typically provoked by maneuvers that appear to decrease cerebral perfusion, such as rising from a bed or a chair, or hyperextending the neck. Shaking does not respond to antiepileptic medication or benzodiazepines. The EEG during attacks is normal. The abnormal movements respond to measures that restore adequate cerebral perfusion (i.e., carotid endarterectomy or correcting relative hypotension). Single photon emission tomography studies (SPECT) support the hypothesis that SLTIAs are due to hypoperfusion rather than recurrent thromboembolic events.⁶³

OTHER CONSIDERATIONS

Convulsive status epilepticus

Convulsive status epilepticus (CSE) is defined as ≥ 30 minutes of either continuous seizure activity or consecutive seizures without regaining consciousness between them. CSE has a bimodal distribution with highest rates in infants and the elderly. It is associated with a significant morbidity and mortality. Increasing age and underlying etiology are predictors of higher mortality.^{64–66} Acute or remote stroke is a common cause of status epilepticus (SE) in the elderly.^{67,68}

CSE is a medical emergency. Treatment algorithms for CSE are the same for the elderly as for younger adults.⁶⁹ There may be local variation on treatment algorithms, but general principles are similar. Those treating medical patients in the acute setting should familiarize themselves

Figure 59-2. A CT angiogram in a 79-year-old patient with recurrent episodes of right arm shaking, worse on standing; shows occlusion of the left internal carotid artery.

with local guidelines. Initially, general resuscitation measures are required; drug treatment should start as soon as the diagnosis is suspected with intravenous benzodiazepines; care should be taken to avoid respiratory depression, particularly in the elderly. If there is no response to intravenous benzodiazepines, the next drug of choice is usually phenytoin, given as an infusion, with an initial loading dose. If there is a failure to respond to phenytoin, sedation with an anesthetic agent is necessary. Concurrent EEG monitoring is essential, in conjunction with a search for an underlying cause. Sedation is usually maintained for at least 24 hours while therapeutic levels of an anticonvulsant are instigated.

Nonconvulsive status epilepticus

Nonconvulsive status epilepticus (NCSE) is relatively common, making up a third of all cases with SE. It increases in incidence with age.⁷⁰ In the elderly it is also more difficult to diagnose, presenting as an acute or subacute prolonged confusional state. The presentation can be subtle. A high index of suspicion is required, and EEG essential to make the diagnosis.⁷¹ In the absence of coma, aggressive treatment should be avoided. A prospective study of 25 elderly patients with NCSE found that treatment with intravenous benzodiazepines was associated with an increased risk of death, and admission to the intensive care unit prolonged hospital stays without improving the outcome.⁷² NCSE should be considered in those who suffer neurologic deterioration after a stroke or subarachnoid hemorrhage.^{73,74} NCSE is an EEG diagnosis. EEG criteria for NCSE continue to be developed.⁷⁵

Sudden unexplained death in epilepsy (SUDEP)

Sudden unexplained death in epilepsy (SUDEP) is a term used when sudden death occurs in someone with epilepsy with no obvious cause of death found at postmortem.⁷⁶ It accounts for 7% to 17% of epilepsy deaths.⁷⁷ It seems likely that either cardiac or respiratory arrest in the context of a generalized tonic clonic seizure causes SUDEP, with the etiology being patient and seizure dependent.⁷⁷

Risk factors for SUDEP include the presence of generalized tonic clonic seizures, being alone in bed during a seizure, severe epilepsy, structural brain lesion, and younger onset of epilepsy and young age.⁷⁸ Reporting bias might explain the last two factors. Sudden death in the elderly is not necessarily an unusual occurrence. By definition SUDEP requires that no other cause of death is found at postmortem. Attributing sudden death in the elderly to SUDEP is unlikely in the presence of other comorbidities, whereas sudden death in the otherwise healthy young with epilepsy is a matter that generates the fullest investigation. It is not known whether the same mechanisms for SUDEP operate across all age groups, with the elderly equally susceptible, or that the elderly are somehow immune from this condition. How to measure its occurrence in the elderly may prove difficult.

ETIOLOGY

Cerebrovascular disease

Cerebrovascular disease is the most common cause for epilepsy in the elderly;⁷⁹ it accounts for 30% to 50% of epilepsy cases in the elderly³⁶ and 75% of symptomatic epilepsies. Poststroke seizures and epilepsy are considered as early, occurring within 2 weeks of stroke, or late, occurring after 2 weeks. A large study of 6044 hospital admissions with acute stroke found 3.1% had epileptic seizures within 24 hours of the stroke and 8.4% had seizures within the first 24 hours after subarachnoid hemorrhage (SAH) or intracerebral hemorrhage (ICH).⁸⁰ In the United Kingdom national general practice study of epilepsy and epileptic seizures (NGPSE), the standard mortality ratio was highest for those with epilepsy and cerebrovascular disease.⁸¹

Cortical involvement of infarct is predilection for developing seizures, and there may be an association with the site of infarction and development of epilepsy.⁸² In a large multicenter study, a worse outcome and increased in-hospital complication rate was associated with prophylactic antiepileptic drug use after SAH.⁸³ Patients who suffer status epilepticus (SE) of cerebrovascular etiology were found to have twice the risk of death at 6 months than patients with stroke and not SE,⁸⁴ although the independent effect of SE on mortality after stroke is controversial.⁸⁵

Cerebral tumors

The elderly patient with new onset seizures should have cerebral imaging to exclude a structural cause (see [Figure 59-3](#)). Benign tumors (e.g., meningiomas) can also present with epilepsy. Surgery for these tumors depends on their location and the age of the patient. Typically, meningiomas are indolent; however, they can be slow growing and there is a small risk of malignant transformation of benign meningiomas that favors surgery in younger patients with peripheral

lesions. Epilepsy from malignant tumors is rarely seen in the specialist setting, although seizures can be particularly refractory to treatment.

Neurodegenerative disease

Alzheimer's disease is associated with a six-fold increase in unprovoked seizures.⁸⁶ The history of seizures in these cases invariably needs to be form the caregiver. A further study found that 21% of a patients developed seizures after a diagnosis of dementia of Alzheimer type.⁸⁷

Other causes

Any structural, inflammatory, immune, or vascular intracerebral process can lead to epileptic seizures. Other causes include trauma; intracranial infection, in particular herpes simplex encephalitis and pneumococcal meningitis; subdural hematoma, paraneoplastic syndromes; limbic encephalitis; and malformations of cortical development (see [Figure 59-3](#)).

Provoked seizures

One or even more provoked seizures do not require a diagnosis of epilepsy. Provoked seizures can be caused by metabolic or toxic disturbance. It is important to recognize provoked seizures, as these typically do not warrant treatment with antiepileptic drugs and driving eligibility may vary.

INVESTIGATION

In the elderly, routine hematology, biochemistry, plasma glucose, calcium, and liver function should be checked. The mainstay of investigation includes the ECG, EEG, and neuroimaging. Particular attention should be paid to the effect of "normal" aging on brain imaging and neurophysiology. This includes atrophy on computed tomography (CT), atrophy and nonspecific white matter change on MRI, and EEG slowing.

Electrocardiography

Electrocardiography (ECG) is a simple, quick, inexpensive, and noninvasive test. It should be performed in all patients presenting for the first time with an episode of loss of consciousness, even if the history is strongly suggestive of an epileptic seizure. The ECG should be examined in detail for evidence of conduction abnormalities.⁸⁸ More advanced investigation for cardiac or vasovagal syncope should also be considered depending on the history (see [Chapter 46](#)).

Electroencephalography

The EEG should be used judiciously. It is a primary tool in the investigation of epilepsy. Nevertheless, the diagnosis of epilepsy remains a clinical one with EEG playing a supporting role. It is not appropriate as a screening tool or means of excluding epilepsy in those with suspected syncope.⁸⁹ The indiscriminate use of the EEG and its reporting and can lead to an overdiagnosis of epilepsy.⁹⁰ The interpretation of EEG requires a skilled neurophysiologist. Nonspecific findings can catch the unwary ([Figure 59-4](#)). The gold standard for classifying seizure is simultaneous video-EEG monitoring. Facilities for this monitoring are rarely available in the elderly care setting.

Figure 59-3. Causes of epilepsy. A, CT head showing a subdural hematoma in a 68-year-old woman presenting with focal motor seizures affecting her left hand. B, Gadolinium enhanced T1-weighted axial MRI showing right temporal meningioma presenting with simple partial seizures in a 60-year-old woman.

Figure 59-4. EEG features. A, Left temporal slow activity, a nonspecific feature. B, Right temporal sharp waves in 78-year-old man supporting a diagnosis of complex partial seizures. C, Focal spikes in a teenager with Benign epilepsy with centrotemporal spikes. D, Generalized spike wave activity in a young adult with IGE, an unequivocal "epileptiform" discharge.

Long-term video-EEG is useful tool in the investigation of epilepsy in all ages.^{91–94} It is primarily used for the following indications:

- Diagnostic clarification of epilepsy versus nonepileptic attacks
- Localization of seizure onset (of practical utility only in younger patients being considered for epilepsy surgery)
- Determination of seizure frequency in suspected partial or nocturnal seizures

It is notable that in published series on the utility of video-EEG on the elderly from large epilepsy centers, patients over the age of 60 make up only 2% to 17% of adult admissions to the monitoring units.^{92–95}

Neuroimaging

The two standard neuroimaging modalities used in epilepsy are computerized tomography (CT) and magnetic resonance imaging (MRI). All cases of new onset seizures in adults

should have brain imaging to exclude a structural lesion. The choice of CT or MRI rests on the cost and practicalities of each technique versus the expected yield leading to a change in management.

CT involves the reconstruction of X-rays taken in multiple planes to produce an image, and as such involves a radiation dose. Modern CT scanners are quick and brain images are acquired within a matter of minutes. The CT bore is relatively open and only the head needs enter. CT is therefore most appropriate in the acute or emergency setting, particularly if the patient is unwell and needs close monitoring, and for patients with claustrophobia or who have difficulty lying flat. CT is superior to MRI for identifying intracranial hemorrhage and for identifying areas of calcification. MRI involves the subject lying in a strong magnetic field with superimposed time-varying magnetic field gradients. It takes longer to administer an MRI than a CT, typically 10 to 20 minutes for a full series of brain images. The subject needs to lie still for the duration of the scan as images are degraded by even

a small amount of motion. The scanner bore is relatively narrow and long; patients enter the bore head first, and it covers most of the patient's body. Patients with claustrophobia or those unable to lie flat will not tolerate MRI. The advantage of MRI over CT is its much higher image resolution and tissue contrast, hence the ability to detect subtle abnormalities that might cause epilepsy; this is perhaps of more relevance in young adults with medically refractory seizures being considered for epilepsy surgery. Surgical resection of a benign lesion to treat epilepsy is rarely advantageous in the elderly, and the pursuit of subtle benign lesions causing epilepsy is unlikely to alter management in the elderly.

ANTIEPILEPTIC DRUG THERAPY

To the nonspecialist, there can be a bewildering array of new drugs to treat epilepsy. Twelve antiepileptic drugs (AEDs) have been developed and licensed worldwide since 1989. By convention, drugs that were available before this time are known as standard AEDs and those that became available after 1990 are called new AEDs. A number of further AEDs are in various stages of the development pipeline, some well advanced in phase 3 trials⁹⁶ and likely to add to the ever-growing list. Studies of AEDs in the elderly, however, are scant,³⁶ and those that exist tend to concentrate on the young elderly (aged 65 to 74).⁹⁷ Benefits and side effects tend to be extrapolated from studies in younger patients. Key points to consider when prescribing AEDs in the elderly are increased risk of side effects; drug-drug interactions; and altered protein binding, hepatic metabolism, and renal clearance; also, a careful review of already prescribed drugs is needed. When commencing a new AED, a low starting dose and slow titration are recommended.

Standard AEDs are acetazolamide, carbamazepine, clobazam, clonazepam, ethosuximide, valproic acid, phenobarbital, phenytoin, and primidone. The new AEDs are gabapentin, felbamate, lamotrigine, levetiracetam, oxcarbazepine, pregabalin, rufinamide, tiagabine, topiramate, vigabatrin, and zonisamide. Of these, felbamate and vigabatrin should not be used because of the risk of severe adverse effects, namely, potentially fatal liver failure or aplastic anemia with felbamate and retinal damage with irreversible visual field constriction with vigabatrin. These adverse effects were not recognized until a few years following the drugs' widespread use and highlight the need for postmarketing surveillance and adverse reaction reporting in all new drugs. Standard and new AEDs commonly used in adults are summarized in [Table 59-3](#).

The currently recommended first-line AEDs are valproic acid for generalized epilepsy and carbamazepine or lamotrigine for focal epilepsy. For many elderly patients, phenytoin still forms the mainstay of treatment.^{98,99} Some elderly patients with lifelong epilepsy may still be taking phenobarbital or primidone; it is not appropriate to change these for newer AEDs in patients who are stable.

The new AEDs are typically licensed as add-on therapy after randomized trials against placebo. Direct head-to-head comparisons of standard and new AEDs are lacking. Recent efforts to address this imbalance include the U.K. study of the Standard and New Antiepileptic drugs (SANAD) study, comparing sodium valproate against new AEDs in generalized seizures and carbamazepine against new AEDs in focal

epilepsies. Valproic acid was found to be most effective in IGE,¹⁰⁰ whereas lamotrigine was favored over carbamazepine for focal epilepsies.¹⁰¹ The trial did not include a number of later but now important AEDs—levetiracetam, zonisamide, and pregabalin—and further ongoing studies are needed.

A large multicenter study comparing lamotrigine, gabapentin, and carbamazepine in 593 elderly patients with newly diagnosed epilepsy found lower adverse events in those randomized to lamotrigine or gabapentin compared to carbamazepine, without significant difference in seizure-free rates at 12 months.¹⁰² A subsequent study comparing lamotrigine and sustained release carbamazepine in 185 patients over the age of 65 did not find a significant difference between lamotrigine and carbamazepine, but there was a trend toward greater efficacy with carbamazepine and lower adverse effects with lamotrigine.¹⁰³ A smaller study found similar efficacy but better tolerability of lamotrigine over carbamazepine in poststroke epilepsy,¹⁰⁴ and another study found switching to lamotrigine was associated with an improvement on the side-effect profile.¹⁰⁵

Adverse effects

All AEDs have side effects. These can be dose dependent or idiosyncratic. Dose-dependent side effects can be minimized by using a low starting dose with slow titration. Idiosyncratic side effects cannot be minimized, and usually necessitate rapid drug withdrawal. Idiosyncratic side effects include rash, blood dyscrasias, bone marrow impairment, liver failure, and Stevens-Johnson syndrome.

Dose-dependent side effects most commonly affect the central nervous system (CNS). They typically include dizziness; drowsiness; lack of energy or weakness; unsteadiness or incoordination; mood disturbance that includes depression, hostility, anger and irritability, and nervousness; cognitive effects that include confusion, difficulty concentrating or paying attention, abnormal thinking, speech or language problems; and difficulty falling asleep or staying asleep. Gastrointestinal side effects include nausea, abdominal pain, and diarrhea. Side effects can include frequency or urgency of micturition and effects on sexual function. Dose-dependent side effects are typically worsened by polytherapy,¹⁰⁶ and the lowest dose of AED that controls seizures should be the aim. Taking more than three AEDs in combination is rarely helpful, and those on several AEDs should have medication rationalized as best as possible.

Patients should be cautioned specifically regarding common or potentially serious side effects (see [Table 59-3](#)). It is helpful if patients have a rapid access point or contact number for advice should side effects develop so that drugs are not either stopped suddenly or continued with potentially harmful consequences. Some side effects occur when starting or raising the dose of an AED, but these wear off after a few days. Recurrent or unpleasant side effects need to be identified and addressed early.

Long-term adverse effects include osteoporosis. Osteoporosis is more common in women taking AEDs. Measuring calcium and vitamin D levels in women taking enzyme-inducing AEDs every 2 to 5 years and bone densitometry can be used to assess the risk of osteoporosis. Vitamin D and calcium supplementation can be taken in an attempt to correct any deficiencies. Bone fracture rates in epilepsy are two

Table 59-3. Main Antiepileptic Drugs Used for Epilepsy in the Elderly and Their Key Features

	Putative Mode of Action	Metabolism and Kinetics	Usual Starting and (Daily Maintenance Dose)	Adverse Events	Key Points
Carbamazepine* (1963)	Sodium channel inhibition	Hepatic metabolism; active metabolite	100–200 mg (400–1800 mg)	Idiosyncratic rash	First line for focal seizures can worsen MJ and absences in IGE Wide drug interaction including warfarin and other AEDs
Clobazam	GABA augmentation	Hepatic metabolism; active metabolite	10 mg (10–30 mg)	Rarely idiosyncratic rash	More commonly used as short-term adjunct
Clonazepam	GABA augmentation	Hepatic metabolism	0.5 mg (1–6 mg)	Rarely idiosyncratic rash	More commonly used as short term adjunct
Gabapentin (1993)	Calcium channel modulation	Not metabolized, urinary excretion unchanged	300 mg (1800–3600 mg)	Weight gain	Can worsen MJ and absences in IGE impaired cognition at higher doses
Lamotrigine (1991)	Sodium channel inhibition	50% protein bound, hepatic metabolism	25 mg (100–400 mg)	Idiosyncratic rash Rarely Stevens Johnson Syndrome	First line for focal seizures. Rapidly withdraw if rash occurs
Levetiracetam (1999)	Synaptic vesicle protein modulation	Urinary excretion	250 mg (750–3000 mg)	Tiredness, mood disturbance	Mood disturbance includes irritability, short temper
Phenobarbital* (1912)	GABA augmentation	Hepatic metabolism; 25% excreted unchanged	30 mg (30–180 mg)	Drowsiness, mood change, osteomalacia	Rarely initiated today; if withdrawal considered, needs to be slow
Pregabalin (2004)	Calcium channel modulation	Hepatic metabolism (saturation kinetics) 90% protein bound	50 mg (100–600 mg)	Drowsiness Weight gain	Can worsen MJ and absences in IGE dose-dependent side effects
Primidone* (1952)	GABA augmentation	Hepatic metabolism	125 mg (500–1500 mg)	Idiosyncratic rash	Rarely initiated; if withdrawal considered, needs to be slow
Oxcarbazepine* (1990)	Sodium-channel inhibition	Hepatic metabolism	150–300 mg (900–2400 mg)	Idiosyncratic rash; hyponatremia	Similar structure to carbamazepine
Tiagabine (1996)	GABA augmentation	Hepatic metabolism	5 mg (30–45 mg)	Increased seizures; nonconvulsive status	
Topiramate* (1995)	Glutamate reduction; sodium-channel modulation; calcium-channel modification	Mostly hepatic metabolism, with renal excretion	25 mg (75–200 mg)	Weight loss; kidney stones; impaired cognition; word finding difficulty	Dose-dependent side effects
Valproic acid (1968)	GABA augmentation	Hepatic metabolism; active metabolites	200 mg (400–2000 mg)	Rare hepatotoxicity or encephalopathy	First line for generalized seizures
Zonisamide (1990)	Calcium channel inhibition	Urinary excretion	50–100 mg (200–600 mg)	Idiosyncratic rash	Newly licensed in United Kingdom

*Induces hepatic enzymes and therefore affect plasma levels of other drugs undergoing hepatic metabolism (e.g., warfarin).

to three times that for the general population,¹⁰⁷ and screening for bone health in epilepsy is recommended.¹⁰⁸

Drug-drug interactions

Drugs that undergo hepatic metabolism are altered by hepatic enzyme-inducing AEDs (see Table 59-3). Those with the least risk for interactions are levetiracetam, gabapentin, and pregabalin,¹⁰⁹ although it remains to be seen how this translates in clinical practice. Enzyme-inducing AEDs should be considered carefully in patients already on medication, all prescribed drugs should be reviewed, and warfarin can be a particular concern.

There is a long-held belief that antidepressants lower the seizure threshold and are proconvulsant. There is in fact little evidence to support this view.¹¹⁰ Depression is common in patients with epilepsy and where present should be treated appropriately. The risk of seizures is dose dependent, and

new antidepressants particularly at low doses are considered safe in most cases. Antidepressants least likely to affect AED levels are citalopram, escitalopram, venlafaxine, duloxetine, and mirtazapine.¹¹¹

Therapeutic plasma monitoring

With the exception being phenytoin, monitoring plasma drug levels is generally not helpful in managing AED therapy. Laboratory reference ranges are of little value in dose adjustments, which should be done according to clinical response and dose-related side effects. A cross-sectional study of 92 nursing home residents in the United States found lower serum carbamazepine doses and concentrations than those used for young adults. The daily dose was significantly lower for the oldest age group (>85),¹¹² supporting this view. A recent review suggests situations in which therapeutic drug monitoring can be helpful.¹⁹

Withdrawing AEDs

Should AEDs be withdrawn in patients with elderly-onset seizures that have been seizure free for a period of time? What about those who have taken AEDs most of their lives with seizure freedom entering old age? Studies that address drug withdrawal have been done in a younger population.^{113,114} Conditions that lead to an increased risk of relapse after drug withdrawal include focal epilepsy, generalized tonic clonic seizures, the presence of cerebral pathology, and an abnormal EEG. Many of these conditions apply to the elderly with new onset seizures. The severity and frequency of seizures and the patient's view on taking medication can influence decisions to withdraw AEDs. It is difficult to extrapolate recurrence risk from population studies to the individual presenting in clinic.

Worthy of special note is the older person who has been on lifelong treatment with phenobarbital or primidone. Both are barbiturates and very difficult to withdraw without potential dangerous recurrence of seizures. If withdrawal of one of these agents is being considered, then it should be with the advice of a specialist and the drug slowly titrated down over many months—for instance, 10% of the initial daily dose every 6 weeks.

THE IMPACT OF EPILEPSY

Epilepsy is a chronic disease. It is associated with stigma and public misconceptions. There is no single test to confirm or refute a diagnosis of epilepsy, and misdiagnosis is a problem. Comprehensive and systematic investigation on the impact of epilepsy are lacking; however, a number of issues are well characterized. A questionnaire-based survey in a small number of elderly patients with epilepsy found their main concerns to be the impact on driving and transportation and concerns about medication side effects.¹¹⁵ Other concerns included personal safety, social embarrassment, employment, and memory loss (Table 59-4).

In a study of more than 1000 adults with epilepsy in the United States and comparison with the U.S. Census Bureau, respondents received less education, were less likely to be employed or married, and came from lower-income households.¹¹⁶ Uncertainty and fear of having a seizure were listed as the worst things about having epilepsy. Lifestyle, school, driving, and employment limits were also listed as major problems, and when asked to rank a list of problems, cognitive impairment was ranked highest. A study using a health-related, quality-of-life questionnaire in the elderly found lower scores in those with epilepsy compared to those without. AED side effects and depression were felt to be the main reasons,¹¹⁷ whereas another study concluded that fear of even infrequent seizures could affect quality of life in the elderly.⁴ Cognitive impairment is a major concern and is higher in those on more than one antiepileptic drug.^{118,119}

For patients with epilepsy, motor vehicle licensing is usually restricted until a defined seizure-free interval has passed.¹²⁰ This varies from country to country. Medical practitioners need to be familiar with their own licensing authority regulations.¹²¹

Beyond driving restrictions, a commonsense approach should be taken to further restrictions on activity. Day-to-day activities should otherwise not be limited. Patients with

severe or frequent seizures may develop a fear of public places or of being left alone. The physician should be mindful of this reaction.

SERVICES FOR PATIENTS WITH EPILEPSY

Elderly patients with epilepsy or presenting with blackouts should be seen by a specialist with an interest in the condition. Not all elderly patients will have access to specialist services. Syncope is the main differential diagnosis, and all physicians, not only epilepsy specialists and geriatricians, who treat patients with blackout should be aware of different presentations. An epilepsy service should work closely with cardiologists as well as with representative of the investigative specialties, neuroradiology and neurophysiology. One area that appears lacking is access to video-EEG. Epilepsy nurse specialists have not only taken some of the roles in long-term follow-up but also fill an important role in information giving and rapid access to specialist advice.^{122–125} The role of a wider multidisciplinary team dedicated to epilepsy, which includes input on all aspects of social care (such as social and occupational services), has not been well characterized.

AREAS FOR RESEARCH

Raymond Tallis wrote in the last edition of this book, "The observation made in previous editions of this textbook that geriatric epileptology is a relatively underdeveloped and under-researched field remains true. The outstanding research agenda is substantially the same."

There remains much to be learned about how and why seizures start and stop. Research in this area is predominantly in the young, usually those undergoing detailed investigation for epilepsy surgery, and in animal experimentation. Are there differences in seizure mechanisms in the elderly? Why is there such a disparity between idiopathic generalized epilepsy and symptomatic epilepsy across the extremes of age? How common is misdiagnosis? How common is PNEA? It is easily missed without an index of suspicion and access to appropriate investigation.

Do seizures have more adverse physical effects in old people, or is the converse true? Is there such a thing as SUDEP in the elderly? How frequent are fractures and other significant injuries? What cognitive impairments are associated with repeated seizures? Is this cause or effect? The main themes of many social epilepsy review articles are women with epilepsy, pregnancy, driving, and lifestyle issues. What are the information needs of the older person with epilepsy?

When to use AEDs

Should one treat a single unprovoked tonic-clonic seizure in old age or wait for two or more seizures? The ongoing MESS study referred to earlier should help. What are the chances of recurrence where there is no overt cause? How easy are seizures to control in old age? More prospective studies are needed to answer these questions.

The role of the newer generation of AEDs

What is the place of the new generation of anticonvulsants in the de novo treatment of elderly-onset seizures? Studies addressing these questions should focus not simply on the traditional end points such as seizure control. The importance of newer AEDs may lie more in reducing subtle adverse effects on gait and mobility than in improved seizure control, especially as "minor" effects of this sort may, in a frail elderly person, translate into significant dysfunction.

The organization of epilepsy services

How best should we provide a service for elderly people with seizures? What are the elements of an optimal overall comprehensive service? Who should provide it? How should

we evaluate it? If we had answers to these questions, our management of seizures in old age would be considerably better than it is now.

KEY POINTS

Epilepsy

- The most important step in the management of a person with suspected seizures is to determine whether or not the events are indeed epileptic fits.
- All adult patients with new onset or suspected seizures should have a brain scan.
- About 80% of people with elderly-onset seizures will be controlled with the first-choice drug. Drug-drug interactions are an important consideration in older people.
- The management of established epilepsy goes far beyond drug treatment. Key elements are reassurance, education, information, and support.
- Aside from phenytoin treatment, anticonvulsant blood level monitoring is not routinely indicated and for most antiepileptic drugs.
- Elderly patients with seizures require an initial specialist assessment and should have access to continuing specialist services, in line with recommendations for younger people.

INTRODUCTION

Headache remains the commonest neurologic disorder worldwide, yet only since the late 1980s has research, clinical diagnosis and management, and interest in the field been stimulated by the publication of *The International Classification of Headache Disorders*, the first edition (1988) and the second edition (2004).¹ Improved diagnostic criteria has led to better quality studies and more robust data from clinical trials, and it has engendered a more rigorous approach to headache diagnosis in the clinic, with inevitable improvements in management. Although this has obviously benefited the sufferers of headache, most published data are from younger cohorts, and few clinical trials recruit older people. This is pertinent as the populations of the developed world age, increasing the strain on the national health economy. In 1980, the World Health Organization (WHO) European demographic returns indicated that the proportion of the European Union population over 65 years of age was 13.22%, a figure that had increased to 16.47% by 2005 with every likelihood that this trend will increase.

Few epidemiologic studies have been carried out to estimate the size of the headache problem. In 1 year in the United States, 70% of the general population had a headache, 5% of whom sought medical attention.² Less is known about the frequency of headache in the elderly population, although in a large population-based study carried out in East Boston,³ some 17% of patients over 65 years of age reported frequent headache, with 53% of women and 36% of men reporting headache in the previous year. Headache prevalence in the elderly age group ranged from 5% to 50%.^{4,5} Overall, headache appears to be less frequently reported in the elderly population,⁶ and shows a decline with age.^{3,7} Most studies agree that the prevalence of primary headache syndromes declines with increasing age.⁷⁻¹⁰ One obvious limitation of these studies is that none is longitudinal and so may not differentiate an effect of aging from cohort or period effects. In addition, elderly patients may be less complaining, or the emergence of other more serious problems may have suppressed reporting of a benign symptom such as headache.

In elderly people headache is more likely to represent organic pathology.¹¹ A clinic-based retrospective case record study¹² concluded that, although it was less likely that elderly people would attend a hospital outpatients clinic for diagnosis of headache, there was a 10-fold increase in the likelihood of finding organic pathology. Recruitment bias is a problem in these studies. Nevertheless it is likely that headache is a more serious complaint from the elderly patient.

A large lifetime prevalence study¹³ utilizing a population-based questionnaire found that although migraine and tension-type headache appeared to decrease with increasing age, chronic tension headache has significantly higher prevalence rates in the elderly population. Medication overuse remains an important factor in the etiology of chronic daily headache in the elderly, especially in patients who have been subject to frequent migraine headache.¹⁴

The author concludes that headache remains an extremely common condition of elderly people; much of it has benign

origin, but more care needs to be taken with older patients to rule out underlying pathology, especially when they present for the first time.

PRIMARY HEADACHE DISORDERS

Migraine

Migraine is an episodic disorder that is diagnosed from the history, commonly starts around puberty, but may start at any age.¹⁵ Epidemiologic studies are difficult to carry out and are dogged by numerous problems.¹⁶ Only 5% of migraineurs consult specialists,¹⁷ so clinic-based studies will suffer from referral bias. It is clear that a significant proportion of the burden of migraine headache is undiagnosed and untreated, more so in the elderly. A number of population-based studies have been carried out.^{9,17-28}

Rasmussen et al²⁶ did not find a decrease in migraine prevalence with increasing age, in contrast to the findings of Stewart et al²⁴ who also showed that it is uncommon for migraine to start in a person's later years.⁹ The female preponderance of migraineurs persists in this age group.¹⁷ Migraine headaches tend to improve with increasing age.²⁹

Symptoms and diagnosis of migraine

Migraine is classified into two main forms, migraine with aura (formerly "classic migraine") and migraine without aura (formerly "common migraine"), based on criteria of the International Headache Society.¹ Other varieties of migraine include ophthalmoplegic, retinal, basilar, and familial hemiplegic, complications of migraine such as migrainous infarction (a neurologic deficit not reversible in 7 days) and status migrainosus (an attack of headache or aura lasting more than 72 hours). Migraine aura can exist without headache, and the same patient may at different times experience headache with aura, headache without aura, or aura without headache.^{30,31}

To diagnose migraine without aura, five attacks are needed, each lasting 4 to 72 hours and having two of the following four characteristics: unilateral location, pulsating quality, moderate or severe intensity, and aggravation by routine physical activity. In addition, the attacks must have at least one of the following: nausea or vomiting or photophobia and phonophobia. Migraine without aura is more common than migraine with aura and is usually more disabling.

Migraine with aura is diagnosed when there have been at least two attacks with any three of the following features:

- One or more fully reversible aura symptoms
- Aura developing over more than 4 minutes
- Aura lasting less than 60 minutes
- Headache following aura with a free interval of less than 60 minutes

A simpler working definition for the clinical diagnosis of migraine was proposed by Solomon and Lipton.³² A positive diagnosis could be made on any two of the following four symptoms:

- Unilateral headache
- Pulsating quality
- Nausea
- Photophobia and phonophobia

A similar headache must have occurred in the past and structural disease excluded. Migraine attacks may generally be divided into five phases: the prodrome (hours or days before the headache), the aura (migraine with aura), the headache, the headache termination, and the post-drome phase.³⁰ Symptoms of the prodrome may include mental, neurologic, or general (constitutional, autonomic) symptoms. Individuals may experience depression, euphoria, irritability, restlessness, mental slowness, hyperactivity, and drowsiness. General symptoms may include a feeling of coldness, sluggishness, thirst, anorexia, diarrhea, constipation, fluid retention, and food cravings. Photophobia and phonophobia may also occur.

The aura is a group of neurologic symptoms that precedes or accompanies the attack. They may be visual, sensory, or motor and may also cause language or brainstem disturbance. Headache usually occurs within 60 minutes of the end of the aura,¹ but it may begin with the aura. Most patients may have more than one type of aura and progress from one type to another in subsequent attacks. Common visual symptoms are the positive phenomena such as hemianopic photopsia (flashes of light) and teichopsia or fortification spectra. Scotomata may follow. Complex visual distortions and hallucinations are reported but are more common in younger people.³³ Somatosensory phenomena, typically paresthesias with anatomic march of symptoms, may occur and motor disturbance may result in hemiparesis. Aphasia has also been reported.^{7,34} Migraine aura symptoms may therefore be characterized by both positive and negative symptoms. Acephalgic migraine is an entity characterized by the neurologic dysfunction of the aura but without headache. This is strictly a diagnosis of exclusion especially in elderly people. These so-called migraine accompaniments may occur for the first time in the older age group^{35,36} and can be easily confused with transient ischemic attacks (TIAs) except in the most classic of cases. Migraine with aura and acephalgic migraine can both be confused with TIAs, and vice versa. Headache occurred with 36% of TIAs in one series³⁷ and is more common in vertebrobasilar ischemia.^{38,39} Migrainous aura in the elderly person presents a particularly difficult diagnostic dilemma. Transient hemiparetic or hemisensory symptoms occurring in elderly people for the first time should be assumed to be vascular (i.e., TIA) in etiology until proved otherwise. Alternating hemisensory/paretic symptoms are more likely to be migrainous but still could have an embolic cause. Investigation including carotid Doppler studies and echocardiography will be necessary to manage potentially treatable embolic sources. Visual disturbance is more likely to be helpful as fortification spectra and colored zigzag lines are unlikely to occur in straightforward TIAs and are almost always migrainous in origin. Migraine with aura may occur for the first time in the elderly person, although in general new onset migraine in the older age group is unusual^{12,40} and may reflect the development of vascular change. It is often helpful in these cases to elicit a previous history of common migraine earlier in life.

The headache of migraine is typically throbbing in nature and exacerbated by exercise.⁴¹ The pain may be unilateral in 60% of cases but bilateral at the outset in up to 40%.⁷ Unilateral headache may later become bilateral during the attack. The intensity is moderate to severe and pain may radiate down the neck to the shoulder. Some 40% of migraineurs report short-lived jabs of pain lasting seconds and having a needle-like quality, the so-called "ice-pick" pains.⁴²

The common accompanying symptoms of nausea and vomiting may make it difficult for the patient to take oral medication. There is usually photophobia and phonophobia; many patients retire to a dark and quiet room for rest. Constitutional, mood, and mental changes are universal,⁷ and the patient is usually left feeling lethargic for a period after the attack.

Basilar migraine is a variant characterized by brain stem dysfunction such as ataxia, dysarthria, diplopia, vertigo, nausea and vomiting, and alteration in cognition and consciousness. Headache is invariable. In the elderly person these symptoms should be assumed to be of vascular origin until proven otherwise.

Ophthalmoplegic migraine is rare and can be confused with the presentation of Berry aneurysm. Attacks of migraine-like pain occur around the eye with oculomotor nerve dysfunction and dilation of the pupil. The ophthalmoplegia may last from hours to months. The differential diagnosis includes orbital inflammatory disease and diabetic mononeuropathy.

Migraine attacks may vary in frequency from a few a year to several a week. Trigger factors include certain foods, red wine,⁴³ hormone replacement treatment in postmenopausal women,⁴⁴ irregular meals, and a change in sleep habit.⁴⁵ Environmental triggers include flickering lights, noise, rapidly altering visual stimuli, and even certain types of weather. Head injury and stress may lead to migraine attacks.

TREATMENT OF MIGRAINE

Once the diagnosis has been established, reassuring the patient may suffice. Any obvious precipitating cause such as diet, lack of sleep, or environmental factors should be discussed. Relaxation therapy may be helpful, but special diets have little place in management.

Pharmacotherapy includes treatment of the acute attack and consideration of prophylactic therapy. It should be remembered that changing biology in the elderly will influence response to medication.⁴⁶ Thus, gastric emptying slows, delaying absorption of medication; hepatic blood flow is reduced and so is glomerular filtration rate, affecting drug metabolism, usually leading to increased half life. In general, therefore, pharmacotherapy should be started with caution in the elderly who are often taking medications for other comorbidities. Acute treatment should be started by the patient at the outset of an attack and is best limited to simple soluble analgesics such as paracetamol or aspirin (Table 60-1). Combination analgesics such as co-proxamol should be avoided, if possible, because of side effects and risk of medication overuse leading to so-called transformed migraine. For a more severe headache, nonsteroidal anti-inflammatory drugs are used.⁴⁷ Ibuprofen (200 mg three times daily) may be obtained in the United Kingdom without prescription, or naproxen (250 mg t.d.s.) by prescription,

Table 60-1. Drugs for Use in the Treatment of Migraine*

Migraine Attack Treatments	Migraine Prophylaxis
Soluble aspirin	Propranolol and other β -blockers
Soluble paracetamol	Tricyclic antidepressants
Antiemetics such as domperidone	Pizotifen
Suppositories	Topiramate
Nonsteroidal anti-inflammatory drugs	Calcium channel antagonists
Sumatriptan (subcutaneous or oral)	Methysergide
Other triptans	Sodium valproate
Medihaler ergotamine and other ergotamine preparations	
Combination analgesia	

*Care must be taken with possible interactions with preexistent treatments and conditions such as asthma (if β -blockers are to be prescribed). The table lists medication in order of preference.

or diclofenac (75 mg twice-daily). This group of drugs should be administered with caution in the elderly population because of the increased risk of gastrointestinal hemorrhage, especially when there is a past history of peptic ulceration^{48,49} or renal insufficiency.

For moderate to severe migraine not responding to simple analgesia, sumatriptan can be tried. The initial dose is 50 mg orally and can be increased to 100 mg if there is no response. Subcutaneous self-administration is the preferred route when there is significant nausea or vomiting. Sumatriptan is a 5HT₁ agonist and is thought to act as a selective cerebral vasoconstrictor. Up to 80% of patients obtain relief from headache within 2 hours after an injection⁵⁰ and up to 65% after a tablet dose.⁵¹ The advantage is that the drug may be administered at any point during an attack and repeated if necessary. Flushing, tingling in the neck and head, and chest tightness can occur in up to 5% of patients.⁵² Because sumatriptan may cause coronary vasoconstriction, it is contraindicated in patients with ischemic heart disease or uncontrolled hypertension. Special care in the elderly person is required because the loss of subcutaneous fat may lead to intramuscular injection and more rapid absorption. A recent study failed to demonstrate increased risk of stroke, myocardial infarction, cardiovascular death, ischemic heart disease, and overall mortality in the elderly.⁵³ Pharmacotherapy should be combined with rest and sleep. A number of newer triptans have been licensed for use in migraine treatment and may be selected for the individual patient.⁵⁴

Ergotamine preparations are best reserved for occasional (>1 month interval) severe headaches. They are potent vasoconstrictors and are best avoided in patients with a history of vaso-occlusive disease, peripheral vascular disease, or hypertension, and those receiving β -blockers or with a history of Raynaud's phenomenon. Patients should be strongly encouraged to avoid overuse of these drugs, because this can lead to resistant medication-misuse headache. Admission for drug withdrawal may be required when this occurs.

The accompanying symptoms of nausea and vomiting are often as disabling as the headache and require treatment in their own right. Metoclopramide is the most commonly used antiemetic, and by promoting gastric emptying, it aids absorption of coadministered medication. It can cause extrapyramidal side effects, especially in the elderly person.

Domperidone is less likely to cause this problem as it does not cross the blood-brain barrier but does not aid gastric emptying.

Prophylactic therapy is indicated when there is severe recurrent headache causing disruption to daily life—as a guide, more than two severe headaches per month. Various drugs are used including β -blockers, antidepressants, serotonin antagonists, calcium-channel blockers, and occasionally anticonvulsants. Treatment is started at a low dose and built to maintenance. Possible side effects should be discussed and the regimen kept as simple as possible as many patients in this age group are likely to have coexistent medication. Patients should be weaned from therapy every 4 to 6 months.

Of the β -blockers, propranolol, metoprolol, and atenolol have all been shown to be effective in up to 60% to 80% of patients producing a greater than 50% reduction in attack frequency.^{55,56} Atenolol (50 to 100 mg daily) has a better side-effect profile than propranolol (20 to 160 mg daily). Patients may complain of fatigue, dizziness, nightmares, and cold extremities. Care should be taken when there is peripheral vascular disease and in combination with ergotamine.

The tricyclic antidepressants have been used in migraine prophylaxis, although the evidence for their efficacy is largely based on anecdotal reports or uncontrolled trials. Their effect in headache may be independent of their antidepressant effect.^{55,57} Amitriptyline is most commonly used, although fluoxetine has fewer anticholinergic side effects and causes less weight gain.⁵⁸ Paroxetine may be a suitable alternative where anxiety is a factor.⁵⁹ Because of their common side effect of drowsiness, the tricyclics are administered at the lowest effective dose at bedtime and slowly increased as necessary. Elderly people are more vulnerable to the muscarinic side effects. The typical starting dose for amitriptyline should be 10 mg, increasing to 150 mg if needed.⁶⁰

Sodium valproate (0.6 to 2.5 g daily) is well tolerated and there is clinical trial evidence of efficacy.⁶¹ Side effects of valproate include tremor, ataxia, and less commonly an extrapyramidal syndrome. Topiramate now has a license for use in migraine prophylaxis; the use of anticonvulsants for migraine prophylaxis has been reviewed recently.⁶²

Calcium-channel antagonists are not licensed for migraine prophylaxis in the United Kingdom but have been shown to be of benefit.⁵⁵ The mechanism of action of these compounds in migraine is uncertain and side effects are common, including edema, flushing, dizziness, and not infrequently an initial increase in headache frequency. Improvement of headache may require several weeks of treatment.⁶³

Of the serotonin antagonists, the two most commonly prescribed are pizotifen and methysergide. Pizotifen is a 5HT₂ antagonist that is usually commenced in a dose of 0.5 mg at night and increased in stepwise manner to a dose of 4.5 mg. It has mild antidepressant activity but unfortunately stimulates appetite and leads to weight gain if diet is not controlled. It can produce beneficial effects in 40% to 79% of patients.⁶⁴ Methysergide is also a 5HT₂ antagonist with some affinity for the 5HT₁ receptor. It is effective prophylaxis in up to 60% of migraineurs, possibly with better results in those with migraine with aura.⁶⁵ Side effects are common and include myalgia, weight gain, nausea, and hallucinations (especially after the first dose). The complication of retroperitoneal, endocardial, and pulmonary fibrosis

is rare and prevented by stopping treatment for 3 to 4 weeks every 4 to 6 months. The starting dose is 1 mg at night but may be increased to 6 mg daily in divided dosage.

Feverfew (*Tenacetum parthenium*) is a herbal remedy long used for headache treatment. It has limited effect, and the side effects include mouth ulceration and loss of taste.^{66,67}

Tension headache

Tension-type headache may be broadly classified into infrequent episodic tension-type headache, frequent episodic tension-type headache (at least 10 episodes occurring between 1 and 15 days a month), and chronic tension-type headache (headache occurring on more than 15 days per month).¹ The clinical features include the following:

- Pressing/tightening (nonpulsating) quality
- Mild or moderate intensity
- Bilateral location
- No aggravation on walking up or down stairs or similar routine physical activity

There should *not* be photophobia and phonophobia, although either alone is permitted within the definition. Patients should *not* experience nausea or vomiting (although the International Headache Society (IHS) criteria allow for nausea but not vomiting in the diagnosis of chronic tension-type headache).

In both types of headache, there may be pericranial muscle tenderness with or without increased electromyographic activity, although this does not assume that muscle tension is the cause of the headache.⁶⁸ In all age groups, tension-type headache is the most common form of headache, peaking in the 30s and 40s.⁶⁹ Chronic tension-type headache is more common in the older age groups than episodic tension-type headache, and only 5% of patients with chronic tension-type headache report onset after the age of 60 years.⁷⁰ Within all age groups, tension headache remains most common in females with a 1-year period prevalence of 27.1% in females and 25.6% in males in one large telephone-based study.^{26,69}

The pain of tension-type headache is usually described as a constant ache, which is infrequently pulsatile. Patients may describe a tight band about the head or a sensation of wearing a tight cap. There may be associated stiffness of the neck and upper back; in contrast to migraine, the pain is usually of lesser intensity. Scalp tenderness may lead to avoidance of hair brushing. This symptom is also recorded in migraineurs, and it may persist for some days after the headache has subsided.⁷¹

The headache may be unilateral or bilateral, commonly occipital or frontal, but may involve any site. It can be relieved by changing position.

Patients with episodic tension headache may experience pericranial muscle tenderness with palpable nodules.⁷² Depression, anxiety, and other psychological factors are important in the pathogenesis of tension headache, although not infrequently patients may initially deny any role.

Depression is common in the community at large, and in an average family practice in the United Kingdom it is the fourth most commonly diagnosed disorder.⁷³ The headache associated with depression can have features described for tension-type headache, and the headaches are often present for years or even throughout the patient's life. The headache is typically diurnal, usually worse in the morning and

in the evening. There may be identifiable emotional, physical, and psychic complaints. These problems merit attention in their own right, especially in the elderly person when organic pathology is more likely anyway. The presence of severe depression in elderly people may be easily overlooked. Other headaches associated with depression can be described more bizarrely with almost a delusional tone. Such headaches may indicate a serious psychiatric disorder and should lead to urgent psychiatric referral.

Treatment includes reassurance, simple analgesia as abortive treatment for the acute attack, and treatment of any psychopathology that may be present. Simple analgesia such as paracetamol should be used for acute attacks of pain. Non-steroidals are more likely to be associated with side effects in the elderly such as gastric erosions and renal and hepatic complications.⁷⁴ Frequent episodic tension-type headache and chronic tension-type headache may require the use of prophylaxis—tricyclics such as amitriptyline remain the most useful drugs, especially when there is sleep disorder. The latter is especially useful when sleep disturbance is a prominent symptom.⁷⁵ Fluoxetine (20 mg daily) is less sedating. Paroxetine (10 mg daily) may be helpful where there are additional anxiety symptoms. Monoamine oxidase inhibitors should be avoided if possible. Psychiatric help may be appropriate, although patients often initially reject this suggestion. Relaxation therapy and biofeedback may also have a role.

The mixed headache syndrome—migraine and tension-type headache in the same patient—usually responds to treatment with tricyclic antidepressants with the addition of analgesia for acute episodes. There are no specific data on the prognosis of tension-type headache in the elderly, although there is a tendency for improvement with increasing age.⁷⁶ It is important to continually bear in mind that secondary headache is more common in the older patient and that careful evaluation of the history and examination and a lower threshold for investigation should be applied in the elderly presenting with apparent nonspecific headache.

Chronic daily headache

The syndrome of chronic daily headache (CDH) accounts for 40% of patients seen in headache clinics⁷⁷ and worldwide is estimated to affect 3% to 5% of the population.⁷⁸ Only 5% reported their chronic headache as starting after 60 years of age.⁷⁰ Chronic daily headache is defined as 15 or more headache days a month for 3 months or more.

There are several subtypes of CDH (Table 60-2), with chronic migraine presenting five times more commonly than chronic tension-type headache to the specialist headache clinic.⁷⁹ The features of tension-type headache are discussed elsewhere in this section. Medication overuse is probably the third most common form of chronic headache after chronic tension-type headache and chronic migraine and is thought to affect up to 1% of the world population.^{80,81} The free availability of analgesics containing caffeine, codeine, barbiturates, and tranquilizers over the counter has been implicated as one cause of this syndrome.^{82,83} The management of this syndrome can be particularly challenging and hinges on the discontinuation of analgesic overuse, the possibility of going "cold turkey," and the use of suitable alternatives for weaning and prophylaxis.⁸⁴ In a proportion of patients the headache may revert to its original episodic form, but in the remainder the avoidance of analgesic overuse will

require the initiation of prophylaxis.⁸⁵ Suitable prophylactic treatment such as amitriptyline in an initial dose of 10 mg at night increased to 75 mg as tolerated is effective, with improvement seen at 2 to 14 days. The drug should be continued at an effective dose for 6 months and then withdrawn slowly over 3 months. Caution should be exercised in those with glaucoma and prostatism. Anticonvulsant drugs used in migraine prophylaxis may be effective, and sodium valproate, gabapentin, and more recently topiramate have been used with favorable results.^{86,87} Patient and physician education is especially important in prevention and management of this difficult headache syndrome.

Episodic migraine may evolve into CDH. In one study, 489 of 630 patients (78%) with CDH had a clear preceding history of episodic migraine.⁸⁸ This so-called transformed migraine may be caused by excessive use of opioid and simple analgesics, barbiturates, ergot compounds, caffeine, and frequent use of triptans. Headaches are often more severe on waking owing to a drug-free withdrawal period overnight effectively causing rebound. Hemicrania continua is side-locked headache that often has autonomic symptoms and shows an exquisite response to indomethacin.^{89,90}

The differential diagnosis includes headaches arising from the neck, temporal arteritis, mass lesions, and visual acuity problems. Because tension-type headache is often associated with depression, sleep disorder, and situational life events, especially in the elderly population, the treatment of CDH must include behavioral, psychological, and social aspects.

Cluster headache

This condition, although most common in young adults, may have its onset in the seventh decade.^{91,92} The International Headache Society classification divides the condition into episodic and chronic cluster headache, the latter being more common in the elderly population.⁹³ A review of the literature suggests a lifetime prevalence of 124 per 100,000,⁹⁴ with a higher male preponderance in the young but more females over 60 years affected than males.⁹⁵

Cluster headache is characterized by bouts of severe pain often described as "boring." The pain is constant, and patients walk around trying to find relief—in contrast to those with migraine who lie quietly. The pain is often centered around one eye, and there may be ipsilateral lacrimation, nasal stuffiness, and rhinorrhea. There is usually conjunctival injection, and there may be an associated ptosis, meiosis, and eyelid edema. The pain may spread to the whole side of the face. Bouts of pain occur one to three times per day with alarm-clock regularity, commonly an hour or so after going to sleep, and last from 15 minutes to a few hours (with a usual duration of 45 to 90 minutes). The headache may start and end abruptly, and in a few patients there may

be interictal discomfort.⁹⁶ The cluster period typically lasts for 1 to 2 months and then subsides. During the cluster attacks, alcohol is a potent precipitant, usually setting off an attack within an hour of ingestion, as are vasodilator drugs such as nitrates. The chronic form continues without remission often for many years.

Treatment is symptomatic. Oxygen at 100% is useful in the casualty department and can be given at home. It is important that a high flow valve is used with a nonrebreather mask capable of delivering 7 to 10 liters per minute. More practically, sumatriptan by subcutaneous injection is the drug of choice for acute attacks.⁹⁷ Nasal sumatriptan may be used but appears to be less effective.⁹⁸ Preventive treatments may be considered in terms of short-term measures and longer duration treatment for those with a more chronic course to their clusters. Steroids (prednisolone 1 mg/kg daily for a week and reducing by 10 mg a week) may shorten a cluster period, but relapse often occurs and so they may be used with other forms of prophylaxis.⁹⁹ Verapamil is the drug of choice for all forms of cluster headache prophylaxis¹⁰⁰ and compares favorably with lithium,¹⁰¹ particularly in view of the plethora of potential neuropsychiatric side effects of the latter. Doses of verapamil range from 240 mg to 960 mg twice daily in divided dose. As this drug may cause heart block, a baseline electrocardiogram (ECG) should be taken, an initial dose of 80 mg three times daily commenced, and then every 10 days or so the dose should be increased in 80 mg increments until attacks are suppressed or side effects prevent further titration. An ECG should be done after each increment. Sodium valproate may be tried in resistant cases.¹⁰² Lithium carbonate given in standard psychiatric doses (600 to 1200 mg) and monitored accordingly is useful in *chronic* cluster, but less so in episodic cluster headache.

Rarely, surgical intervention is attempted. Percutaneous radiofrequency trigeminal gangliorhizolysis or posterior fossa trigeminal sensory rhizolysis have been performed but are of unproven benefit. Operation can cause a reduction in facial sensation and corneal hypoesthesia with increased risk of corneal ulceration.¹⁰³

Cluster headache is an underdiagnosed cause of recurrent paroxysmal cranial pain in the elderly population. It may not have the usual classic features in this age group. Treatment may need to be given empirically when there is doubt.

Chronic paroxysmal hemicrania (Sjaastad headache), a rare variant of cluster headache, differs in the brevity (3 to 45 minutes) and frequency (up to 40 times a day) of the attacks. The invariable response to indomethacin now forms part of the diagnostic criteria.¹⁰⁴

FACIAL NEURALGIAS

Trigeminal neuralgia

DIAGNOSIS

Trigeminal neuralgia is diagnosed clinically. It rarely begins before the age of 30 years,^{105,106} has a prevalence of 0.1 to 0.2 per 1000 and an incidence of up to 20/100,000/year after the age of 60 years, and the female-to-male ratio is 3:2.¹⁰⁷ The symptoms are pathognomonic. The pain is periodic, of high intensity, and lancinating, lasting from 20 to 30 seconds followed by a period of relief lasting a few seconds to a minute, which may be followed by further paroxysms of pain. The pain usually commences in the maxillary and

mandibular divisions of the trigeminal nerve, and in fewer than 5% of cases it begins in the ophthalmic division. In some 10% to 15% of cases, all the divisions are involved and the symptoms may be bilateral in 3% to 5%.⁹⁶ Apart from the quality and characteristic site of pain, the patient can usually identify trigger factors such as brushing the teeth, washing the face, shaving, biting, chewing, or even a gust of cold wind on the face. Avoidance behavior is common.

The pain may occur daily for weeks or months followed by remission of varying periods. Unfortunately there is a tendency for the disorder to deteriorate, with increased frequency of attacks increasingly resistant to treatment. Clinical examination should be normal, and any loss of facial sensation should be promptly investigated, preferably with gadolinium-enhanced magnetic resonance imaging (MRI) of the brain and trigeminal system, to rule out a compressive lesion of the nerve.

ETIOLOGY

The presence of chronic irritation of the roots of the trigeminal nerve has been demonstrated to cause neuralgia, and it is believed that in the majority of patients, demyelination of the proximal nerve roots is causative. The proximal nerve roots lie within central nervous system (CNS) nerve tissue, which extends several millimeters from the surface of the pons. Animal laboratory data, however, are more consistent with a central mechanism mediated by the loss of segmental inhibition within the spinal trigeminal sensory nucleus. To reconcile these observations, Fromm et al¹⁰⁸ proposed that spontaneous peripheral activity from the irritated nerve, in the presence of the failure of the normal central inhibitory mechanisms, may cause paroxysmal bursts of neuronal activity within the trigeminal nucleus and its thalamic relays, perceived as neuralgia by the patient. This has been likened to a form of "sensory reflex epilepsy."¹⁰⁹ Some evidence for the peripheral component of this hypothesis comes from the common finding of vascular loops (arterial or venous) in association with the nerve root in a majority of symptomatic patients.^{110,111} Other compressive pathology should be considered including schwannoma, lymphoma, meningioma, and a variety of other tumors and infiltrative lesions. Pathologic specimens reveal focal demyelination within the proximal, CNS part of the root. It is proposed that ephaptic transmission of spontaneously generated ectopic impulses results in symptoms.¹¹² Because vessels tend to become more ectatic with age, this may explain why the condition is more common in the elderly population.

TREATMENT

The treatment of this condition is initially medical.^{113–115} Occasionally the symptoms are so severe that hospital admission is required to control symptoms and prevent a downward spiral of increasing pain, dehydration, and depression. This is particularly the case for the elderly and infirm individual.

A recent review confirmed that carbamazepine remains the first choice drug, and pain relief is usually obtained within 4 to 24 hours.¹¹⁶ The initial dose of 100 mg three times daily is increased every 48 hours in a stepwise manner until symptom relief or side effects occur. Patients should be warned of the potential for drowsiness, rash, and unsteadiness. A baseline full blood count is recommended because leukopenia does occur commonly and agranulocytosis

rarely; treatment should be stopped immediately if the latter occurs. Although carbamazepine is usually effective at blood levels of 25 to 50 mg/L, the dose can be titrated to the maximum tolerated in resistant cases. Therapy should be maintained until the patient has been free of pain for at least 4 weeks, after which slow reduction of dose by decrements of 100 mg of carbamazepine each week may allow for complete withdrawal of the drug. For patients who experience limited efficacy or side effects, oxcarbazepine should be tried.

If adequate pain relief is not obtained with standard doses of carbamazepine, a second drug such as baclofen (10 mg three times daily up to 1.03 mg/kg daily) can be added. This may aggravate drowsiness. Alternatively, phenytoin, clonazepam, or sodium valproate can be added. Polypharmacy should be avoided if possible because of additional side effects and problems with compliance.

Surgical intervention should be considered if medical treatment fails. Up to 50% of patients may eventually require some form of surgical treatment. There are two main options, rhizotomy or microvascular decompression.

Radiofrequency rhizotomy or alternatively glycerol rhizolysis is relatively safe and simple. Patients require only light anesthesia, and the procedure is carried out under radiographic screening control. Selective root lesioning is achieved if a stimulating electrode is employed, and this reduces the side effects (discussed later). Acute pain relief can be accomplished in over 90% of patients, and this can be maintained in the long term with repeated treatments if necessary.¹¹⁷ Glycerol injection into Meckel's cave acts as a neurotoxin.

The main side effect is sensory loss (usually less with glycerol injection). Corneal hypoesthesia is a problem and may result in ulceration. Rarely there may be masseter weakness. Both forms of treatment have about 90% success, and the patient can be discharged home within 24 hours. Unfortunately, the reported recurrence rates are about 25%. In a study comparing glycerol rhizolysis and posterior fossa exploration, freedom from pain at 5 years was 59% and 68%, respectively.¹¹⁸

Microvascular decompression involves major neurosurgery with a posterior fossa approach. This procedure was pioneered by Jannetta.¹¹⁹ If a blood vessel is found in close association with the trigeminal root or deforming it, it is mobilized and a small sponge of polyvinyl chloride interposed between the nerve and the vessel. This procedure is generally well tolerated by elderly patients who are otherwise medically fit for surgery. Recurrence rates of up to 24% at 30 months after the procedure were reported in one study.¹²⁰ Overall the recurrence of pain after any surgical procedure was 19% with a minimum 5-year follow-up, with microvascular decompression providing the greatest relief and patient satisfaction.¹²¹

Glossopharyngeal neuralgia

This syndrome has the same symptom characteristics as trigeminal neuralgia but the pain is felt in the region of the tonsil and ear. Trigger factors include swallowing, coughing, and talking, and the distribution of the pain is in the sensory territory of the glossopharyngeal nerve and the auricular and pharyngeal branches of the vagus nerve. Rarely the patient may become unconscious during an attack because of asystole.³³ Neurologic examination is normal unless the

syndrome is secondary to pathology such as neoplasm, infection, or inflammatory disease.

Treatment is the same as for trigeminal neuralgia with carbamazepine and other drugs. The medical treatment of this condition is less successful than in the case of trigeminal neuralgia and surgery is more often undertaken.¹²² If there is no improvement, microvascular dissection of the intracranial section of the glossopharyngeal nerve and upper two rootlets of the vagus can be undertaken.^{123,124}

Postherpetic neuralgia

Postherpetic neuralgia occurs following 10% of attacks of shingles, but this figure rises to 50% in the over-60 age group.¹²⁵ The most common site is the ophthalmic division of the trigeminal nerve. The virus has a predilection for the trigeminal (23% of cases¹²⁶) and upper cervical ganglia, and in the acute stages the herpetic eruption is seen in the appropriate distribution. The Ramsay Hunt syndrome is due to herpetic infection of the facial nerve. Excruciating pain may precede the eruption of vesicles by 1 to 3 days. The latter are seen over the external auditory meatus and mastoid process and may occur with edema and redness of the ear, making examination difficult. Occasionally, other cranial nerves may be affected with involvement of the trigeminal nerve, leading to loss of sensation on the face and numbness of the palate occurring when the 9th nerve is affected. A careful search for vesicles around the ear and in the mouth will make the diagnosis clear. There may also be involvement of the 4th, 6th, and oculomotor nerves,¹²⁷ with the possibility of long-term paralysis.

The syndrome of postherpetic neuralgia is characterized by a constant burning or aching pain with occasional stabbing components and occurs following healing of the rash. It may take several weeks or months to emerge. There is sensory loss over the affected area, and invariably allodynia develops.

Treatment is symptomatic.¹²⁸ Antiviral therapy such as acyclovir was shown to provide marginal evidence for reduction of pain incidence at 1 to 3 months following zoster onset. Famciclovir reduced the duration of the neuralgia but not its incidence, as did valacyclovir. Steroids had no effect on postherpetic neuralgia.^{129,130} Amitriptyline taken at the onset may reduce the incidence of postherpetic neuralgia, but more trials need to be undertaken.¹²⁹ Acyclovir (800 mg five times daily) may be prescribed if the rash is extensive or if there is a threat to eyesight. Opiate analgesia may be required. Once neuralgia is established, amitriptyline is of proven benefit,^{131,132} and carbamazepine may help to control the stabbing component of the pain. Relief of pain may be gained in up to 80% of cases. Nortriptyline and desimipramine may be better tolerated, causing less sedation, the former has been shown to be as effective as amitriptyline.¹³³ Transcutaneous electrical nerve stimulation (TENS) may sometimes be useful. Topical capsaicin cream has had variable success.^{134,135} Both gabapentin and pregabalin are licensed for the treatment of this condition,^{136,137} which is notoriously difficult to treat, but presently there is no role for surgery.

ATYPICAL FACIAL PAIN

More correctly defined as idiopathic persistent facial pain, this syndrome is rare in the elderly population. It is characterized by a continuous, chronic head or facial pain that does

not follow dermatomal boundaries or conform to any of the known patterns of headache or cranial neuralgia. The diagnosis can be made only after the exclusion of organic pathology, including dental and sinus disease.¹³⁸ Many patients are believed to be depressed³⁷ and receive tricyclic antidepressants, generally with a good result.¹³⁹ Lance and Goadsby⁹⁶ have proposed an organic basis to this syndrome. However, tricyclics remain the treatment of choice, together with the judicious use of baclofen. Occasionally the pain may have a throbbing vascular nature, and when intermittent it is worth considering a diagnosis of facial or "lower half" migraine.¹⁴⁰ In this case, a trial of a β -blocker or sumatriptan may be useful.

HEADACHE ARISING FROM THE NECK

Cervical spondylosis, affecting the neck vertebrae, has a strong association with aging.¹⁴¹ Degenerative changes lead to a loss of intervertebral height with narrowing of the central canal and the intervertebral foramina. Spondylotic changes may compress cervical nerves or the spinal cord to produce a syndrome of cervical spondyloradiculopathy with or without myelopathy. Symptomatic cervical spondylosis is more common in men than in women and produces symptoms typically in the fifth and sixth decades. Neck pain and headache may result, and although most of the population over the age of 40 years has radiologic changes consistent with cervical spondylosis without symptoms, in those with symptomatic disease (brachialgia or myelopathy), 40% reported headache as a chief symptom and 25% reported it as a major symptom.¹⁴² The mechanism of cervicogenic headache remains uncertain and is hotly debated.¹⁴³ It may be defined as headache arising from the structures of the neck, is unilateral, and may be exacerbated by neck movement. It is proposed that the convergence of sensory afferents from cervical structures with descending trigeminal pathways in the upper cervical segments of the spinal cord allow for bidirectional referral of pain between the neck and trigeminal receptive fields of the face and head.¹⁴⁴ However, overall cervical spondylosis is an uncommon cause of headache.

The head pain resulting from cervical degenerative disease is frequently occipital in distribution but may radiate to the vertex or even the frontal area. The greater occipital nerve (C2) provides much of the sensory input from the back of the head, and irritation of this nerve typically causes occipital headache. The pain is usually described as constant, not throbbing, and of moderate intensity. Associated muscle tenderness, perhaps secondary to spasm, may be present, and this may make differentiation from tension headache difficult. It is disputed whether the cervical spine itself gives rise to headache per se, but headache may arise as a secondary phenomenon because of muscle spasm in the neck.¹⁴¹ Movements of the cervical spine may aggravate the headache, and examination will reveal reduced range of movement and suboccipital tenderness with muscle spasm.

Treatment is usually conservative with nonsteroidal drugs or simple analgesics. Cervical collars are of uncertain worth and anyway should be combined with referral to a physiotherapist for neck exercises. Surgery is considered when there is myelopathy or radiculopathy, especially when it is progressive.

Lesions of the bones of the upper cervical spine and base of skull can give rise to occipital ache by pressure on the

cervical nerves. Myeloma, osteomyelitis, metastatic tumor, and erosive inflammatory disease such as rheumatoid arthritis may all cause headache and neurologic deficit. Paget's disease can cause basilar invagination with traction on the upper cervical nerves and or hydrocephalus, both of which may result in headache.¹⁴² A plain skull x-ray will usually rule out these possibilities if suspected.

SINUS DISEASE AND DENTAL DISEASE

Head and facial pain may be referred from the cranial sinuses. Experiments have shown that inflammation of the sinus lining is rarely painful,¹⁴⁵ but that pain arises from inflammation of the ducts and ostia of the sinuses or inflammation of the nasal turbinates.³³ Disease of the frontal sinuses causes ache localized over these sinuses; that of the antrum is usually referred to the maxillary region and into the zygomatic or temporal areas. Headache associated with sphenoidal and ethmoidal disease is mainly felt behind the eyes and over the vertex of the skull. Sinus headache is frequently overdiagnosed in the primary care setting, and many patients satisfy criteria for tension-type headache and migraine.¹⁴⁶ A sensible approach is to carefully elicit a history of symptoms compatible with nasal *acute* sinus inflammation (purulent nasal discharge, local pain over the relevant sinus) in addition to headache. Chronic sinusitis rarely causes headache.

The pain of sinus disease is usually deep-seated and dull, aching, and nonpulsatile. Adopting a recumbent position may relieve the headache of sinus disease, so these headaches are less prominent at night than during the day. Pain may be exacerbated by shaking the head or adopting a head-down position. Coughing or straining also exacerbates the pain by raising intracranial venous pressure.

The treatment of sinusitis is symptomatic with decongestants and analgesia, but unremitting pain may indicate a more sinister cause and merits further investigation.

Dental disease is referred to the distribution of the trigeminal nerve. In general, upper jaw disease is referred to the maxillary division and lower jaw disease to the mandibular division. The etiology of such pain is usually obvious, but continued facial pain may merit referral to a maxillofacial surgeon. Examination of the patient with facial pain includes assessment of the teeth and a search for tooth sensitivity with percussion.

VASCULAR DISORDERS AND HEADACHE

Giant cell arteritis

(See also Chapter 72)

This condition is rare below the age of 50 years, with incidence rising 10-fold between the sixth and ninth decades. The reported incidence of the condition has risen in recent decades, possibly because of raised awareness. Population-based studies suggest that up to 40% to 60% of patients have polymyalgia rheumatica in addition to giant cell arteritis.¹⁴⁷ The female-to-male ratio is approximately 4:1, and the prevalence varies from 7 per 100,000 in 50-year-olds to 70 per 100,000 in octogenarians.¹⁴⁸ The reported rates are highest in Scandinavian countries and lower in Mediterranean and Asian countries, and there is an association of HLA-DRB1*04.¹⁴⁹ Headache is the most common symptom (85% at some point in the disease).¹⁵⁰ It is usually severe, *persistent*,

may throb, and disturbs sleep. The pain is usually bitemporal but may be unilateral, frontal, or generalized. Scalp tenderness is common, and patients may avoid grooming the hair. Jaw claudication (facial pain when chewing) is virtually pathognomonic of this condition and may affect up to half of patients,¹⁵¹ and infarction of the tongue can follow. Vascular claudication may affect the arms and even the muscles of deglutition. Patients may report a number of constitutional symptoms such as fatigue and malaise, lethargy, anorexia, and a low-grade fever. Weight loss and sweating are common.

Sudden visual loss may affect up to 20% of cases and is an early manifestation.^{152,153} This is a result of ischemia of the posterior ciliary arteries (and less commonly ischemia of the retinal artery) and secondary ischemic optic neuropathy, or infarction of the choroid. Patients may complain of nonpainful amaurosis fugax, a shade covering the eye, sudden total visual loss, or transient diplopia. Left untreated, the second eye usually becomes affected within 1 to 2 weeks. Interestingly, patients with optic complications had lower clinical and laboratory markers of inflammation, were less likely to be anemic, and were more likely to be HLA-DRB1*04 positive.¹⁵⁴ Patients who have other ischemic complications were more likely to experience retinal ischemia.

Giant cell arteritis affects the proximal aorta and its extracranial arteries (i.e., large and medium-sized muscular arteries with a prominent internal elastic membrane and vasa vasorum). The inflammation is most severe at the junction of the intima and media of vessels, disrupting the elastic lamina. Intracranial vessels do not have a lamina, so intracranial inflammation is rarely seen.¹⁵⁵ The affected vessels become nodular, tortuous, and swollen. The superficial temporal artery may become palpable, tender, and pulseless. There is medial necrosis with formation of granulomatous tissue and invasion of lymphocytes and giant cells. Often there is thrombosis of the lumen.

Although temporal artery biopsy remains the gold standard, unfortunately the pathology is not continuous, and "skip lesions" mean that there is a good chance that a temporal artery biopsy will be negative. A minimum biopsy length of 1 cm can help to minimize the risk of false negatives.¹⁵⁶ Although a biopsy is desirable, treatment should not be delayed in clinically suspicious cases; biopsy specimens may show changes even 2 weeks after initiation of steroid treatment.¹⁵⁷

The sedimentation rate is a vital diagnostic test but can be normal in up to 10% of cases.¹⁵⁸⁻¹⁶⁰ C-reactive protein is believed to be a more sensitive indicator of disease activity in giant cell arteritis, although ESR remains the time-honored marker.¹⁶¹ Nonspecific abnormalities include a mild normochromic normocytic anemia and leukocytosis. Plasma fibrinogen levels are elevated, as are other acute-phase proteins. Liver function tests are often abnormal, with an elevated alkaline phosphatase and elevated transaminases. An elevated creatine phosphokinase does not occur and should lead to a search for an alternative diagnosis.

If clinical suspicion is high, the patient should be commenced on high-dose corticosteroids immediately because failure to act may cost the patient loss of vision. Prednisolone (60 to 80 mg) is given usually with rapid clinical effect. Failure of the symptoms to respond within 24 to 48 hours should lead to review of the diagnosis. This high dose is

maintained for 2 to 4 weeks and then tapered gradually (by a maximum of 10% of the total daily dose every 2 weeks) depending on the sedimentation rate and the patient's symptoms. Alternate day steroid regimens are associated with a higher treatment failure rate and should be avoided.¹⁶² The addition of nonsteroidal anti-inflammatory drugs (NSAIDs) can reduce minor recurrent symptoms.¹⁶³ Patients will need treatment for many months and most for several years; relapse is most common in the first year after stopping steroids, especially when the dose is reduced to 5 to 10 mg daily.^{164,165} After stopping treatment, the patient's sedimentation rate and symptoms should be monitored for at least 6 months to a year in case of relapse. Visual loss because of a relapse is unusual after a lengthy course of steroids. Osteoporosis prophylaxis may be necessary. There is some evidence from retrospective studies that combining low-dose aspirin with steroid therapy (where there is no contraindication, and with a proton-pump inhibitor) may lower the risk of ischemic complications, even though thromboembolic occlusion is not thought to be the cause.^{166,167}

Any elderly person with malaise, arthralgia, depression, and vague headache should be considered a possible case until proven otherwise.

Cerebrovascular disease and hypertension

Headache is a common accompaniment to cerebrovascular disease^{168,169} and may occur before, during, or after transient ischemic attack or stroke. The pain is often throbbing in nature and exacerbated with effort. Usually it is lateralized to the side of ischemia. It occurs most frequently when there is parenchymal hemorrhage (57%) but also with TIAs (36%), thromboembolic infarct (29%), and lacunar infarction (17%). It appeared that posterior circulation events (44%) were more frequently associated with headache than anterior circulation events (31%).¹⁷⁰ This study was before the computed tomography (CT) era, so it may be that hemorrhagic strokes were included in the data. A more recent study, however, reached similar conclusions.¹⁷¹

Headache does not occur more frequently in the hypertensive than in the normotensive general population unless it is of extreme degree or associated with rapid rises of blood pressure, as in pheochromocytoma.¹⁷² Occasionally, however, migraine has undoubtedly been aggravated by the occurrence of hypertension.

Carotid and vertebral artery dissection

Extracranial arterial dissection is a more common cause of stroke and headache in younger persons, but it remains a cause of headache and cerebrovascular ischemia in the elderly. The anterior circulation is more commonly affected.¹⁷³ Carotid artery dissection and occlusion give rise to ipsilateral pain involving the face and forehead and occasionally the neck. The pain is described as burning or throbbing but can be sudden and stabbing and may be mistaken for subarachnoid hemorrhage (discussed later). A Horner's syndrome may be present ipsilateral to the involved artery, with contralateral neurologic signs. Occasionally there are no associated neurologic signs.

Vertebral artery dissection is associated with neck and occipital pain¹⁷⁴ and may occur more commonly than is thought in patients diagnosed with so-called vertebrobasilar insufficiency. The occipital headache associated with this

form of dissection is almost always associated with neurologic deficits from the brain stem. The treatment of arterial dissection remains controversial as there is yet no solid evidence base to favor either antiplatelet or anticoagulant treatment, and in the elderly the risks of treatment are more prescient.¹⁷⁵

Subarachnoid hemorrhage

Intracerebral aneurysms are usually silent except when aneurysms cause compression of neural structures to produce focal signs and headache or when they rupture. The sudden, severe catastrophic headache of subarachnoid hemorrhage is easily diagnosed, and in the elderly patient the prognosis is usually poor.¹⁷⁶ Patients with thunderclap headache should be investigated for the possibility of aneurysmal bleed. An early CT scan should be undertaken; if that is negative, a lumbar puncture delayed to 12 hours after the ictus should be undertaken to exclude xanthochromia. Elderly patients respond potentially well to endovascular treatment.^{177,178}

Chronic subdural hemorrhage

This condition usually presents in an insidious manner and a history of head trauma may be absent or forgotten. The history may be one of fluctuating awareness, headache, memory disturbance, gait and balance problems, focal weakness, and a host of other nonspecific symptoms. Coagulopathy, particularly with a background of excessive alcohol consumption, is a well-recognized predisposing factor. Particular attention to the possibility of this diagnosis should be paid to those taking anticoagulants and, to a lesser extent, antiplatelet drugs. Brain imaging, either CT or MRI, is undertaken, and large symptomatic hematomas are usually evacuated, but smaller hematomas may be left and the patient's neurologic state monitored clinically. The resolution of the hematoma is reviewed by serial scans.

Headache associated with trauma

Between 9% and 14% of those admitted to head injury units are over 65 years of age, and this group has the worst prognosis.¹⁷⁹ Headache after injury, sometimes apparently trivial, is a common complaint, but persistence of headache usually indicates a psychogenic component. CT brain scan should be reserved for those with focal signs or fluctuating consciousness. Simple analgesia should be used, but resistant headache may require psychological management and the use of psychotropic drugs.

INTRACRANIAL TUMORS

(See also Chapter 55)

Although headache is present in 60% of those with an intracranial tumor,¹⁸⁰ it has to be reported as the sole presenting symptom in only 8% to 20% of patients of all age groups,^{181,182} and only 10% of elderly patients had headache in one series.¹⁸³ In a retrospective study from a large neurosurgical cohort of patients with primary and secondary headache, only 2% had headache without any other symptoms.¹⁸⁰ As in most age groups, the most common intracranial mass lesions in the elderly population are secondary tumors. Some tumors may grow to a large size in the elderly before symptoms and signs are evident; this is attributed to the increased space within the cranium secondary to cerebral atrophy. The mechanism

of headache in brain tumors is thought to be due to rises in intracranial pressure.

The typical features of raised intracranial pressure are the same in the elderly population as in all age groups: morning headache, vomiting, visual obscurations, or gradual visual loss. Coughing, straining, or bending forward may exacerbate the headache. There may be incontinence, gait disturbance, and cognitive decline. Papilledema is often absent. Stretching of pain-sensitive structures such as the dura may cause persistent focal headache; only infratentorial tumors seemed to be more likely to cause localized headache (occipital headache). Most supratentorial parenchymal tumors tend to produce poorly localized headache and not infrequently can mimic primary headache such as tension headache and migraine. Indeed, headache was more likely to be present with tumor if there was a history of preexisting headache (e.g., tension-type headache).¹⁸⁰ Thus, further investigation including a brain scan may be indicated in an elderly patient whenever there is recent onset of head pain syndrome or a change in pattern of preexistent headache.¹⁸⁴ Headache persisting for more than 6 months is unlikely to have a structural cause. However, rarely, pituitary tumors, which distort the sella turcica, can cause long-term headache, which is often deep-seated and retro-orbital.

The most common benign primary brain tumors are meningiomas, which are usually operable with good result in the otherwise fit elderly patient where there is headache or other symptoms and signs referable to the tumor. Asymptomatic meningiomas can be managed conservatively if monitored regularly.

LOW-PRESSURE HEADACHE SYNDROME

Orthostatic headache is most commonly seen after lumbar puncture, but the syndrome of spontaneous cerebrospinal fluid (CSF) leak and low-pressure headache is well recognized if often clinically overlooked. It may be a cause of chronic daily headache, especially when the initial orthostatic headache pattern has either evolved or been forgotten. It is less common in the elderly population^{185–191} and may be associated with a variety of symptoms, including pain or stiffness of the neck, nausea, emesis, change in hearing, visual blurring, interscapular pain, and occasionally facial numbness or weakness and upper limb radicular symptoms.¹⁹² The most common site of the leak is in the spine around the point at which the spinal nerve roots pierce the dura, usually in the thoracic and cervicothoracic regions. Magnetic resonance imaging (MRI) may show diffuse pachymeningeal enhancement; subdural and epidural collections may be seen. The management is conservative in the first instance; rarely, blood patches may be required to provide relief.

DRUG-INDUCED HEADACHE

Drugs causing headache

A large number of the drugs prescribed for elderly people cause headache (Table 60-3). The pain is usually described as involving the whole head, but it may be occipital or frontal.

Medication-misuse headache

Medication overuse headache is the third most common form of headache worldwide after tension-type headache and migraine, affecting up to 1% of the world's population

Table 60-3. Drugs That Can Cause Headache

Calcium-channel blockers	Nitrates
Indomethacin	Dipyridamole
Lithium	Corticosteroids
Hydralazine	Sympathomimetics
Monoamine oxidase inhibitors	Cimetidine
Ranitidine	Theophyllines

and accounting for 5% to 10% of patients attending headache clinics.^{193–195} The overuse of analgesics—particularly codeine-containing compounds and ergotamine—can lead to the development of chronic refractory headache, which then increases dependence on medication. Patients with initially intermittent migraine or tension-type headache may develop chronic daily headache because of analgesic abuse. These patients have higher depression scores, and attempted discontinuation leads to withdrawal symptoms and a refractoriness to prophylactic treatments.¹⁹⁶ Side effects of the medication are also more likely—such as ergotism, analgesic nephropathy, and gastrointestinal problems. Patients with migraine and tension-type headache who take analgesics for other conditions such as arthritis are more likely to develop rebound headache.¹⁹⁷

The only option is to stop the analgesics, although this almost inevitably precipitates a temporary worsening of the headaches. Prevention of the syndrome in the first place should involve patient and physician education.⁸³ Patients with severe headache may need to be admitted for drug withdrawal and given temporary cover with opiates and steroids along with instigation of antidepressant therapy and consideration of migraine prophylaxis.^{198,199}

HEADACHE AND THE EYE

The eye and orbit derive a rich innervation from the first division of the trigeminal nerve, and these structures are common causes of pain around the eye and of headache.²⁰⁰

In the elderly population, glaucoma can be an important cause of eye pain and headache. Although the condition may be acute or chronic, it is the acute closed-angle glaucoma that causes sudden onset of severe constant pain, centered on the affected eye. This may spread to give a generalized headache, and there are visual symptoms such as colored haloes in the visual field and misting of vision. There may be photophobia and nausea or vomiting. Patients may be diagnosed as suffering from subarachnoid hemorrhage unless the history or signs of eye disease are discovered. Clinically there is limbic injection, corneal edema (hazy appearance), and the globe will be hard and tender to palpation. This condition is an emergency that requires immediate referral to an ophthalmic casualty department for further treatment. Opiate analgesia will be necessary.

Proptosis, ophthalmoplegia, and pain can be caused by orbital pseudotumor.^{201,202} Often there is an elevated sedimentation rate and a rapid response to high-dose corticosteroids. The differential diagnosis includes dysthyroid eye disease, or orbital neoplasia (secondary spread from, for example, melanoma). Superior orbital fissuritis (Tolosa-Hunt syndrome)²⁰³ is one end of the spectrum of orbital inflammatory disease. MRI of the skull or CT of the skull

should differentiate between these conditions, but often the response to steroids aids the diagnosis.^{204–206}

Painful oculomotor paresis with retro-orbital pain is usually due to one of two main pathologies. If the pupil is fixed and dilated, then a surgical cause is likely, with aneurysm of the posterior communicating artery being the most common cause. If the pupil reacts to light, then the cause is likely to be nonsurgical and diabetes is the most likely cause. Angiography may still be necessary to rule out aneurysm even if the blood sugar is elevated.

Anterior uveitis and posterior uveitis are also causes of eye pain and visual disturbance. There may be evidence of coexistent systemic pathology, and the presence of local ocular changes help aid the diagnosis. Refractive disorders (so-called eye strain) rarely cause headache. Orbital pain may arise from entrapment of the greater occipital nerve as it emerges from between the occiput and first cervical vertebra. Pain usually starts in the occipital region and radiates forward to the eye, although it may be isolated to the orbit. Treatment is symptomatic and should include physiotherapy, appropriate use of analgesia, and limited use of a soft collar.

MISCELLANEOUS CAUSES OF HEAD PAIN

The hypnic headache syndrome was first described by Raskin²⁰⁷ and reviewed by Evers and Goadsby.²⁰⁸ It is an uncommon form of headache occurring only in the elderly population. Headaches wake the patient from sleep at a regular time each night. The headaches are usually ill defined, may have a pulsating quality, and may occur several times a month. They may last from half an hour to a few hours and recur the same night. There are no associated autonomic symptoms. Diagnostic criteria have been proposed.²⁰⁸ Polysomnography has shown that this is a REM sleep disorder. This disorder is rarely associated with secondary pathology,²⁰⁹ but the differential diagnosis includes mass lesions, temporal arteritis, and cluster headache, although the latter is characterized by additional autonomic features. Lithium carbonate has the best efficacy but is limited by its pronounced side effects in the elderly.²⁰⁸ Caffeine, flunarizine, and indomethacin may also be useful, as so may low-dose topiramate.²¹⁰

The *exploding head syndrome*²¹¹ is another benign cause of disturbance experienced more commonly by elderly people but that may affect any age group.²¹² It is not a pain or headache but a loud noise occurring in sleep or drowsiness and waking the patient. It may occur for a short period of weeks or months on an infrequent basis or recur irregularly. The noise is deep in the center or back of the head and causes fear in the patient. Some may describe momentary difficulty in breathing, tachycardia, or sweating. There are no sequelae, and usually patients do not have a preceding illness or history of neurologic disease. The etiology of the condition is unknown, and it is almost certainly underreported. Reassurance is usually all that is required. There is a limited report of successful use of clomipramine in three cases.²¹³

About a third of patients with Parkinson's disease report occipital headache, usually dull in nature. The cause of this is not clear, and it is not associated with nuchal rigidity.²¹⁴ Amitriptyline in low doses may be effective.²¹⁵

Infections, whether bacterial or viral, may be associated with headache. Chronic meningitis may cause headache and be associated with gait disorder secondary to hydrocephalus. Multiple cranial nerve involvement may be associated with basal meningeal involvement as seen in carcinomatous meningitis, tuberculosis, and sarcoidosis. Systemic metabolic causes of headache include hypoglycemia of less than 2.2 mmol/L, renal dialysis, hypercalcemia, and severe anemia.²¹⁶ Carbon monoxide poisoning from poorly ventilated gas appliances may be an insidious cause of chronic headache and nonspecific symptoms.^{217,218} Sleep-disordered breathing may be associated with headache, commonly on waking.

Headaches associated with sleep may arise because of a medical comorbidity such as obstructive sleep apnea syndrome and can be evaluated with an appropriate history from a sleeping partner and polysomnography.^{219,220} Primary headache disorders such as migraine, cluster headache and chronic paroxysmal hemicrania may also cause sleep-related headache and headache on waking, but a careful history will identify these and exclude complicating factors such as medication overuse and mood disorder. Such conditions are easily treated with appropriate medication.²²¹

THE DIAGNOSTIC APPROACH TO HEADACHE

As in any branch of medicine, the diagnosis rests heavily on the history of the complaint and use of appropriate investigations after a thorough physical examination. The duration of symptoms and their mode of onset together with the tempo of their development provide valuable diagnostic clues. Quality of headache is a less useful feature, but patients should be asked about position and intensity together with radiation of the pain and the presence of exacerbating and relieving factors. A complete drug history should be obtained, and appraisal of the patient's mood, sleep, and vegetative functions are helpful for discerning the impact of the illness and possible psychological background.

Although the vast majority of headaches in all age groups are benign, in the elderly population the risk of organic pathology is increased.¹² The diversity of symptoms of temporal arteritis can often lead to a delay in diagnosis. Chronic malaise, myalgia, and arthralgia are frequently seen in giant cell arteritis but easily dismissed as nonspecific symptoms and resulting from the aging process. Severe pain of sudden onset, pain that is persistent and progressively worsening with time, early morning headache with vomiting, and exacerbation by coughing, straining, and bending forward all suggest underlying organic disease. Migraine can be identified when there is a long history or classic symptoms, but complicated migraine may be difficult to differentiate from TIAs³⁵ and complete investigation is warranted. This is particularly because migrainous accompaniments are more common in the older age group. The presence of other symptoms such as drowsiness, confusion, and memory loss will raise the index of suspicion. Other worrying symptoms include progressive visual disturbance, weakness, clumsiness, and loss of balance. It is important to realize that the cranial neuralgias are not associated in their simple form with neurologic deficits and have a strict definition for a positive diagnosis. The description of bands of pain or a tight cap on the head is more likely to result from muscle tension as seen

in a tension-type headache or disease of the neck, but it can be a symptom of a more serious disease. Injury to the head may precede the formation of a subdural hematoma, which is more likely with coagulopathy or chronic alcohol abuse. Brachialgia together with myelopathy should point to the neck as the source of headache.

A normal neurologic examination will often help rule out serious underlying disease and avoid unnecessary investigations. A lower threshold for investigation should apply in the case of the elderly patient complaining of headache.

Summary of Management Algorithm Headache

Indications for Investigation

New headache with:

- Abnormal neurologic signs
- A history suggesting raised intracranial pressure
- Impairment of memory
- Impairment of consciousness
- Worsening pain which may disturb sleep
- Headache on waking and associated with vomiting

Apparent "late-onset" migraine

Atypical facial pain

- Migraine

Avoid easily identified triggers

Bedrest

Analgesia

- Paracetamol or aspirin
- NSAIDs (beware peptic and renal side effects)
- Triptans for moderate to severe headache
- Antiemetics if required
- Prophylaxis
- β -blockers
- Tricyclic antidepressants
- Topiramate/valproate
- Serotonin antagonists (e.g., pizotifen)
- Tension-type headache

Reassurance after careful clinical assessment.

Simple analgesia.

Address possible psychological issues.

Treat depression if identified (tricyclics useful).

Question relaxation therapy and biofeedback.

Avoid chronic analgesic use, which can lead to the syndrome of chronic daily headache.

- Trigeminal neuralgia

This is diagnosed only on strict criteria.

Carbamazepine is still first line treatment.

Alternatives include baclofen, phenytoin, sodium valproate, clonazepam, gabapentin, and lamotrigine.

Up to 50% of patients may require surgical treatment.

- Postherpetic neuralgia

Up to 50% of elderly patients may develop this syndrome.

Amitriptyline and carbamazepine are both of proven benefit.

Gabapentin and pregabalin are licensed to treat this condition.

- Giant cell arteritis

This medical emergency requires swift initiation of steroids.

Jaw claudication is virtually pathognomonic.

Constitutional symptoms are common.

In up to 10% of cases, the sedimentation rate may be normal.

KEY POINTS

Headache and Facial Pain

- Headache is a common problem in the whole population. However, it is less often reported by elderly people in whom there is a decline in prevalence, although the symptom is more likely to represent serious pathology.
- Management of the common primary headache conditions is the same as for younger patients. Elderly people are more likely to have comorbidity that may limit their ability to tolerate medication or side effects resulting from drug interactions.
- A careful history of analgesic use, including proprietary analgesics, should be elicited in patients presenting with a chronic daily headache syndrome, as medication-overuse headache is common.
- Giant cell arteritis is a medical emergency and should be treated without delay if suspected.

Stroke: Epidemiology and Pathology

Amanda G. Thrift
Velandai K. Srikanth

STROKE EPIDEMIOLOGY

The World Health Organization (WHO) defined stroke as “rapidly developing clinical signs of focal disturbance of cerebral function lasting more than 24 hours (unless interrupted by surgery or death) with no apparent cause other than of vascular origin.” The major types of stroke are ischemic stroke (caused by a cerebral vessel occlusion) and hemorrhagic stroke (caused by bleeding from the cerebral vessel). Stroke epidemiology is concerned with the study of patterns and risk factors associated with stroke. This is important because it enables one to determine efficient strategies for stroke prevention. It also enables one to make predictions about the future burden of stroke. This can then be used for planning of future health care requirements.

In the following sections, we summarize the current knowledge about the epidemiology of stroke. In particular, we have focused on the burden of stroke including mortality, incidence, and prevalence, as well as known risk factors and prevention strategies. The pathology underlying strokes is briefly described.

Burden of stroke

From a population level, the burden of stroke can be measured in three different ways, each method having advantages and limitations (Table 61-1). Stroke mortality figures usually include all individuals with stroke recorded as the primary cause of death on their death certificates. Systematic and long-term collection of these data allows assessment of trends over time and comparisons between countries. Mortality figures are subject to some limitations including imprecision in death certification and incomplete assessment of the overall burden of stroke; between 45% and 60% of people with stroke survive beyond 5 years.¹⁻³ Prevalence studies can be used to assess burden in stroke survivors. Using methods such as door-to-door surveys, one can estimate the impact of stroke on survivors and assists with the planning of community health care resources.

Carefully conducted stroke incidence studies provide the best source of information on the burden of stroke at an individual and societal level. These allow a better understanding of the empirical relation between incidence, mortality, and survival. For example, changes in stroke mortality may be attributable to changes in stroke incidence, case-fatality, or a combination of both. Comparison between two identically conducted stroke incidence studies will help to determine where the changes have occurred. Worldwide, few of these studies have been conducted, largely because of the expense and labor-intensive nature in undertaking them using the strict “ideal” criteria for stroke incidence studies.⁴⁻⁷ Because of this restraint, most of the incidence studies conducted using these criteria have been undertaken in developed countries.

It is estimated that more than 55 million people worldwide are survivors of stroke,⁸ and more than half of these

individuals are expected to have some form of stroke-related disability. This burden is likely to increase rapidly in the coming years, largely because of the increasing life expectancy.⁹ This is because there is a strong positive relationship between age and stroke incidence.

Stroke mortality

There is some disagreement about whether stroke is the second or third most common cause of death worldwide. According to WHO, stroke is the second most common single cause of death in the world after ischemic heart disease.¹⁰ However, if all cancers were grouped together, they would occupy second place. Regardless of the ranking, in 2002 an estimated 5.5 million deaths from stroke occurred worldwide; these deaths comprising approximately 9.7% of all deaths.¹⁰ Approximately one third of these deaths occurred in developed countries; the remainder occurring in developing countries. The large number of stroke deaths occurring in developing countries is largely attributable to their large population (approximately 3.5-fold that of the population in developed countries). This is despite the fact that the mortality rate (number of deaths per 100,000 population per year) is lesser in developing countries (76.7/100,000/year) than in developed ones (130.5/100,000/year).^{10,11}

The best data about changes in stroke mortality come from developed countries. Stroke mortality declined in many of these nations between the 1960s and the early 1990s,¹² although there was evidence of a leveling off of this decline in the 5-year period to 1994.¹²⁻¹⁴ Countries with the lowest mortality rates, such as the United States, Canada, Switzerland, France, and Australia, tended to have the steepest declines. In contrast, in all countries that previously belonged to the former Soviet Union, stroke mortality increased among both men and women.¹² These differences in geographic variations are likely to reflect an influence of environmental factors on mortality. An example is the particularly large increase in mortality rate observed in the countries of the former Soviet Union during the 1990s, this being

Table 61-1. Methods for Assessing Stroke Burden

Method	Advantages	Limitations
Mortality	Allows study of time trends Allows comparisons between regions	Imprecision in death certification Only part of the overall burden
Prevalence	Assists in study of impact of stroke in survivors Enables health care resources planning for survivors	Time-consuming and expensive Only part of the overall burden
Incidence	Allows study of relation between incidence, prevalence, and mortality	Expensive Labor-intensive

a time of great political upheaval and economic uncertainty in this region.¹²

Changes in stroke mortality may reflect changes in incidence, case-fatality, or a combination of the two. In their analysis of time trend data from the World Health Organization Monitoring Trends and Determinants in Cardiovascular Disease (WHO MONICA) project, Sarti and colleagues provide preliminary evidence that case-fatality may underlie the observed changes in mortality.¹⁵ They reported that in countries with increasing mortality from stroke, the increase was almost entirely attributable to an increase in case-fatality, whereas in countries where stroke mortality was declining, approximately two thirds were explained by a reduced case-fatality, the remainder being attributable to reduced stroke occurrence.¹⁵ This analysis was limited to people aged 35 to 64 years, so it may not necessarily reflect what occurs among those in older age groups.

Stroke prevalence

A number of well-designed stroke prevalence studies have been conducted around the world. Stroke prevalence (per 100,000 population standardized to the world population aged more than 65 years) appears least in rural South Africa (1539/100,000), the United States (4536/100,000), and New Zealand (4872/100,000), whereas greater prevalence was evident in L'Aquila (Italy; 6812/100,000), Newcastle (United Kingdom; > 7000/100,000), and Singapore (7337/100,000).^{16–19} Interestingly in Singapore, prevalence rates among Malays (5396/100,000) appeared less than those of Chinese (7829/100,000) or Indian (6,871/100,000) descent, although this was not statistically different.¹⁹ Importantly, about half of these survivors of stroke are likely to require assistance in everyday activities. This places a great burden on family caregivers of stroke survivors and the health care system. Because a decline in case-fatality has been reported to account for two thirds of the decline in mortality in those countries where mortality is declining,¹⁵ prevalence must be increasing. This increase in prevalence will result in an increase in the burden of stroke to those communities affected.

INCIDENCE OF STROKE AND STROKE SUBTYPES

Most incidence studies of stroke that have been conducted according to "ideal" criteria have been undertaken in developed nations, largely coming from Europe, Australia, and the Americas,^{16,20–29} with Barbados being the only exception.³⁰ After adjusting to a common standard to eliminate variation attributable to demographic differences, there do appear to be some regional differences. When comparing incidence rates between regions, adjusted to the European population aged 45 to 84 years, the lowest incidence rates occurred in Dijon (238 per 100,000 population per year), whereas the greatest were in Russia (626/100,000/year) and the Ukraine (938/100,000/year).^{31–33} The remaining studies exhibited similar incidence rates. There is a lack of studies from regions such as Africa and Asia.

Longitudinal trends in stroke incidence can be examined when ideal incidence studies have been repeated over successive time points using the same methods. Upon examination of these data, stroke incidence has declined significantly over the past few decades, particularly in the 1970s and

1980s,^{25,34–39} with some notable exceptions in Denmark, the United States, and Estonia.^{40–42}

HETEROGENEITY OF STROKE

Stroke is a heterogeneous condition with three main subtypes each with differing incidence rates, risk factors, and outcomes. The most common, ischemic stroke (IS), accounts for between 63% to 84% of all strokes.¹⁶ Depending on the study region, intracerebral hemorrhage (ICH) accounts for between 7% and 20% of all strokes, whereas subarachnoid hemorrhage (SAH) accounts for between 1% and 13% of all strokes.¹⁶ The proportion of strokes that are hemorrhagic appear to be greater in nonwhite populations and among those living in developing countries compared with white populations in developed countries.^{23,43–45} This suggests that there may be differences in risk factor prevalence or indeed genetic differences between white and nonwhite populations. Within the category of ischemic stroke, there are further subtypes that are based on clinical signs or have a mechanistic basis.^{46,47} The most robust classification system for use in population-based epidemiologic studies is a system based on clinical findings devised by the investigators of the Oxfordshire Community Stroke Project.⁴⁷ The advantage of this classification system is that it is based on clinical findings, and there is no need to rely on expensive investigations that may be unavailable in some regions.

COSTS OF STROKE

On a societal level, stroke is responsible for a significant portion of formal health care costs; globally approximately 2% to 4% of total health care costs are attributable to stroke. The cost of stroke has been estimated by using a variety of "bottom up" and "top down" approaches in a number of Western countries. Using a bottom-up approach, the estimated 12-month cost of stroke in Australia in 1997 was US\$420 million.⁴⁸ Acute hospitalization (28%) and inpatient rehabilitation (27%) comprised the majority of these costs. The average cost per case was US\$14,361 during the first 12 months and US\$33,658 over a lifetime, with overall lifetime costs being greater for ischemic stroke than for ICH.^{48,49} With the expected increase in overall number of strokes, there is likely to be increased strain on health care systems.

There are also significant economic costs attributable to informal caregiving. Dewey et al⁵⁰ undertook an economic analysis to determine the total 12-month costs associated with informal care for first-ever strokes. They estimated that the total costs of informal care for first-ever strokes comprised between 4% and 7% of total stroke-related costs during the first year and between 14% and 23% of costs over a lifetime. This demonstrates the considerable burden placed on the families of people with stroke.

Risk factors for stroke

During the last half of the past century, a large number of major stroke risk factors were identified. These risk factors, and protective factors, may be modifiable or non-modifiable (Table 61-2). There are some indications that the stroke risk factor profile in developing nations is not the same as in developed nations.⁵¹ With this in mind, the following discussion relates to risk factors in developed nations.

Table 61-2. Risk Factors for Ischemic Stroke

Nonmodifiable Risk Factors	Modifiable Individual Risk Factors	
	Known	Possible
Age	Hypertension	Physical inactivity
Gender	Smoking	Obesity
Heart disease	Diabetes	Dietary factors
Family history	Atrial fibrillation	Oral contraceptive use
Ethnicity	Hypercholesterolemia	Lack of hormone replacement therapy
Socioeconomic status	Prior transient ischemic attack or stroke	Infection
	Heavy alcohol consumption	Stress
	Prothrombotic factors	Air pollution
	Hyperhomocysteinemia	Depression
	C-reactive protein (inflammation)	Subclinical atherosclerosis

NONMODIFIABLE RISK FACTORS

Nonmodifiable risk factors are those that cannot be altered by intervention. These include factors such as advancing age, male gender, ethnicity, socioeconomic status, family history and genetic conditions. Age is strongly associated with stroke incidence, with incidence rising from between 10 to 30 per 100,000 person-years aged less than 45, to 1200 to 2000 per 100,000 person-years in those aged 75 to 84 years.¹⁶ Within each age group, stroke incidence is greater among men than women.^{20,52} In the older age groups, however, the overall number of strokes is often greater in women than men simply because of the larger number of women surviving to these ages. People living in more disadvantaged regions have been reported to have a greater incidence of stroke. Those living in the most disadvantaged areas of Melbourne, Australia, had incidence rates of stroke that were almost double (366/100,000/year) that of those living in the least disadvantaged areas (200/100,000/year).⁵³ Similar differences have been seen in other parts of the world, including Sweden⁵⁴ and the United Kingdom,^{55,56} although in some studies it is unclear whether differences are attributable to ethnicity rather than socioeconomic status.

MODIFIABLE RISK FACTORS

Modifiable risk factors are those factors that can be altered through either treatment or by changes in behavior. By reducing the prevalence of these risk factors, it is therefore possible to reduce the incidence or reoccurrence of the disease. Such established and modifiable risk factors include hypertension, smoking, diabetes, and atrial fibrillation. There are also other less well-established risk factors and protective factors including alcohol consumption, regular exercise, obesity, oral contraception, hormone replacement, and illicit drug use. It is possible that such risk factors interact with each other in many different ways in contributing to the risk of stroke rather than being independent of each other. Such interactions may be different between different age groups.

Hypertension, a condition that is highly prevalent with increasing age, is one of the most clearly recognized and probably the most important risk factor for stroke at a population level. In a meta-analysis of about 13,000 strokes in 450,000 people, prospective cohorts undertaken to assess

the influence of diastolic blood pressure on the risk of stroke, the authors showed that for each 10 mm Hg increase in diastolic blood pressure the risk of stroke increased almost two fold with a relative risk of 1.84 (95% confidence interval [CI] 1.80–1.90).⁵⁷ In the same collaborative study, the strength of the association between usual blood pressure and risk of death from stroke was shown to decline to some extent with increasing age. However, stroke is so much more common in old age than in middle age that the absolute annual difference in stroke death associated with a given difference in blood pressure increases with increasing age. Atrial fibrillation is associated with a high stroke risk and accounts for a major part of the population-attributable risk of stroke, particularly in older age. In the Framingham study, the risk attributable to atrial fibrillation increased significantly from 1.5% for those aged 50 to 59 years to 23.5% for those aged 80 to 89 years.⁵⁸ Diabetes mellitus may be responsible for up to 20% of the population-attributable risk fraction in the developed world.⁵⁸ However, it is uncertain whether the risk attributable to diabetes mellitus or other factors such as dyslipidemia changes significantly with increasing age.

Numerous studies have been undertaken to assess the association between smoking and stroke.⁵⁹ Evidence for an association between smoking and the risk of stroke is strengthened by the demonstration of a positive dose-response relationship. In addition, smoking cessation is associated with a reduced risk of stroke when compared with current smoking. In the Honolulu Heart Program, smokers who continued to smoke at the sixth year of follow-up were at an increased risk of stroke, whereas those who had ceased smoking at the sixth year of follow-up showed a reduced risk of stroke.⁶⁰ This provides some further support that smokers can reduce their risk of ischemic stroke after ceasing smoking.

People at high risk of stroke often have multiple risk factors. This is important because some risk factors interact, resulting in greatly increased risk of stroke. Important interactions have been shown to occur between transient ischemic attacks and age, hypertension and age, and cigarette smoking and age; all risk factors have shown a declining risk of stroke with increasing age. An interaction has also been observed between atrial fibrillation, hypertension, and age: hypertension potentiated the risk of stroke among those with intermittent atrial fibrillation, and this declined with age.⁶¹ People with hypertension who also smoke have also shown a potentiation in the risk of stroke.⁶²

The increasing burden of stroke

Current projections support the notion of a large increase in the future number of strokes occurring in both developed and developing countries. In Australia, it is estimated that the number of stroke occurring in Australia will more than double over the next 25 years, even assuming that incidence remains the same.⁶³ In developed countries, this increase is largely attributable to an aging population. In developing countries, the population is also aging; however, an epidemiologic transition is also occurring.⁶⁴ With an increased availability of clean water, food, shelter, and medical care, life expectancy increased from 41.2 years in 1951–1961 to 61.4 years in 1991–1996.⁶⁵ Thus, more individuals are now reaching ages where stroke more commonly occurs. In parallel, there is rapid industrialization and urbanization, which has resulted in significant dietary changes and increases in

Table 61-3. Relative Population Impact of Treating Selected Risk Factors for Ischemic Stroke

Risk Factor	Prevalence	Relative Risk (range)	Relative Impact
Hypertension	~ 20% men ~ 15% women	2.5–8.0	High
Atrial fibrillation:			
aged ≥ 40 years	~ 2.0%	2.0–6.0	High in older age groups with additional risk factors
aged ≥ 65 years	~ 5.0%		
men aged ≥ 75 years	~ 10%		
women aged ≥ 75 years	~ 6.0%		
Smoking	~ 25% men ~ 20% women	1.5–6.0	High
Hypercholesterolemia*	~ 15% men ~ 15% women	1.5	Low
Diabetes	~ 5%	1.5–4.0	Low
Heavy alcohol consumption†	~ 2.5%	2.0–2.5	Low

*Hypercholesterolemia is defined as a plasma cholesterol level of ≥ 6.5 mmol/liter.

†Heavy alcohol consumption is defined as drinking on average ≥ 5 standard drinks per day.

smoking prevalence.^{66–69} Diets containing more meat and dairy products, processed grains, and added sugar are associated with increases in blood pressure, serum cholesterol levels, and body weight. Combined, these factors are likely to result in increases in stroke incidence in the future.

Prevention of stroke

If the impending increase in burden of stroke is to be minimized, or even reduced, prevention strategies must be improved considerably. The main aim of primary and secondary prevention strategies for stroke is to reduce stroke incidence and recurrence. The effectiveness of prevention strategies is influenced by three important characteristics of each risk factor for stroke: whether the risk factor is modifiable, the strength of the association, and the prevalence of the risk factor in the population. The strength of the association is indicated by the relative risk or odds ratio of the exposure variable. Higher relative risks indicate stronger associations. The prevalence of a risk factor is the proportion of people within the population in whom the factor is present. The more common the risk factor within the population, the greater is its prevalence. Together, the relative risk and prevalence give an indication of how useful these factors are as targets for prevention strategies (Table 61-3).

Declines in stroke incidence and mortality have largely been attributed to improvements in the primary prevention of stroke. Both the introduction of blood pressure lowering agents with increasing efficacy and improvement in living standards provide plausible explanations for these declines. The Oxford Vascular Study investigators reported significant decreases in systolic and diastolic blood pressure, cholesterol levels, and prevalence of smoking during the 20-year interval in which incidence rates of stroke were seen to decline by 29%.²⁵ More modest declines in incidence among more recent studies may reflect the fact that other risk factors, such as an aging population, obesity, and diabetes mellitus, may be on the rise despite aggressive approaches to reducing hypertension, hypercholesterolemia, and smoking.³⁹

Mass approach

The mass or population approach to prevention involves changing risk factors at a population level. This may involve media and education campaigns to alter risky behaviors on a population basis, or it may involve the use of government

legislation. This approach may result in an overall small reduction in the risk factor on an individual basis, but it may have a significant impact on the whole population.

Reducing blood pressure levels within the population is an important strategy for reducing stroke risk. This could be achieved by a number of means including reducing salt intake and promoting exercise. It is estimated that people consume on average approximately two to three times more salt than is recommended.⁷⁰ Reducing salt intake by half would reduce blood pressure in both hypertensive and normotensive individuals⁷¹ and is also estimated to reduce stroke incidence by 22%⁷² and stroke mortality by up to 25%.⁷³ Eighty percent of the salt we consume is hidden within processed foods, thus reducing the amount of salt added to food during manufacture would have an enormous public health impact.⁷⁴ A reduction in only 20% of the salt content of processed foods could lead to a significant drop in blood pressure levels in the population. Encouraging governments to legislate such changes within the food industry remains a major barrier. Other cost-effective population-wide prevention strategies may be tobacco and alcohol control via increased taxation and the regulation of accessibility, and promotion of healthy diets and exercise. Because geriatricians, more than many other specialties, are used to taking a population perspective and to patient advocacy, they—and their specialty societies—may find a role in advocating for changes in food processing or better city and building design to come easily.

High-risk approach

The high-risk individual approach involves identifying people at high risk of stroke and either introducing treatment strategies or minimizing risky behaviors. People may be identified through mass screening campaigns or through opportunistic screening during other health consultations. People could be encouraged to cease smoking, introduce exercise, or reduce alcohol or fat intake. Risk factors could also be modified in high-risk individuals by treatment with medications, such as antihypertensive agents to reduce blood pressure levels or use of lipid lowering drugs to reduce cholesterol levels.

In a meta-analysis conducted by the Blood Pressure Lowering Treatment Trialists' Collaboration, people treated with antihypertensive medication had a 28% to 38% lower

incidence of stroke, depending on the medication used.⁷⁵ Although improvements have been made in the identification and treatment of hypertension, significant improvements in both of these areas still need to be made, particularly in developing regions.⁷⁶

Another high-risk approach is to target people who have already had a stroke, as these individuals are at increased risk of stroke recurrence. Among those who survive an initial stroke, up to 20% suffer another event within 5 years.⁷⁷ Controlling hypertension can reduce the incidence of recurrent stroke by up to 28%.⁷⁸ Furthermore, this reduction in risk has been observed in both normotensive and hypertensive individuals with stroke.⁷⁹ Other prevention strategies that have demonstrated effectiveness in those with a previous stroke include the use of antiplatelet agents, such as aspirin, dipyridamole, ticlopidine, or clopidogrel, and the use of anticoagulants in people with atrial fibrillation.

COMBINED APPROACH TO PREVENTION

To maximize the prevention of stroke, a combined approach to prevention should be used. This includes population and high-risk primary prevention approaches, as well as targeting those who have already had a stroke (secondary stroke prevention). The high-risk approach may involve screening patients for particular risk factors opportunistically and then providing treatment for those individuals at high risk. To complement this strategy, the population approach should also be utilized. This might be achieved by educating people via mass media campaigns or by government legislation.

PATHOLOGIC MECHANISMS UNDERLYING STROKE

Ischemic stroke

CEREBRAL VESSEL OCCLUSION

Atherosclerosis is by far the most common cause of cerebral infarction caused by large and medium vessel disease and is mediated by thrombotic and embolic complications. Atherosclerosis is an almost universal feature of large and medium-sized arteries in elderly people and is most severe in the aortic arch and at points of bifurcation (e.g., carotid bifurcation) and confluence (e.g., basilar artery). At least in large extracranial vessels, thrombus tends to complicate the ruptured or eroded "unstable" atherosclerotic plaque.⁸⁰ Such plaques are characterized by a large necrotic core covered by a thin, inflamed fibrous cap similar to coronary arterial plaque.⁸¹ Exposure of the thrombogenic plaque core causes activation of platelets and triggering of the coagulation cascade. The resulting thrombus either occludes the vessel in situ or, more commonly, probably dislodges as embolus and occludes a distal smaller vessel. Rupture of unstable plaques appears to be less common in intracranial vessels, where atherosclerosis may more commonly mediate stroke by low-flow effects or by acting as luminal narrowings at which emboli impact. On occasion, intracranial or extracranial vessel occlusion may occur as a result of dissection of the lumen, the most commonly seen sites being the vertebral and the carotid arteries.

Small, deep (lacunar) infarcts are likely to be due to two important causes.⁸² The first is small vessel arteriolosclerosis, and the second is a complex destructive lesion of small

arteries ("lipohyalinosis") characterized in the acute phase by fibrinoid necrosis and a healed phase characterized by loss of wall architecture, collagenous sclerosis, and mural foam cells.⁸² The pathogenesis of lipohyalinosis is uncertain, but it may be linked to inherited and acquired disorders of small vessel tone.⁸³

Ischemic strokes crossing arterial boundaries may occur because of cerebral venous sinus thromboses. Cerebral veins and venous sinuses may become thrombosed when a variety of constitutive and acquired factors, both local and systemic, promote hypercoagulability or venous stasis.⁸⁴ However, in many cases the pathogenesis is uncertain.

CONSEQUENCES OF VESSEL OCCLUSION

The size, shape, and location of occlusive arterial infarcts conform more or less to individual arterial supply zones, variations dependent on interindividual differences in vascular anatomy, adequacy of collaterals, preexisting vascular disease, and other factors. Hemorrhagic transformation of initially pale ischemic infarcts is relatively common following lysis, either spontaneous or therapeutic, of thromboemboli.⁸⁵ Bleeding may be severe enough to mimic a primary intracerebral hemorrhage.⁸⁶ The distribution of infarction in global cerebral circulatory insufficiency is diverse but commonly involves spinal as well as cerebral arterial border zones and selectively vulnerable brain regions such as the CA1 zone of the hippocampus, neocortical layers 3, 5, and 6, cerebellar Purkinje cells, and basal ganglia.^{86,87} Venous infarcts characteristically do not conform to arterial supply zones and are often accompanied by subarachnoid and intracerebral hemorrhage and massive brain swelling.

Irrespective of size or location, brain infarcts are areas of ischemic coagulative necrosis of all cellular elements, ultimately becoming fluid-filled cavities.⁸⁸ Temporary or less severe ischemia may produce areas of so-called incomplete infarction,⁸⁹ characterized by death of only the most vulnerable cells, in particular neurons, representing perhaps a neuropathologic substrate of transient ischemic attacks.⁹⁰ The ultimate fate of affected brain depends not only on the severity and duration of ischemia but also on how selectively vulnerable is the region and its component neurons and on the degree and duration of reperfusion ("delayed neuronal death").⁹¹ In humans, cerebral blood flow must fall from an average normal value of about 50 mL 100 g⁻¹ min⁻¹ to 18 to 20 mL 100 g⁻¹ min⁻¹ before neurons become electrically silent and to 8–9 mL 100 g⁻¹ min⁻¹ before neuronal ion pumps fail.⁹² The marginal zone of brain around the doomed ischemic core has cerebral blood flow levels between these thresholds of synaptic transmission and membrane failure. This "penumbra," nonfunctional yet viable, is the focus of potential therapeutic salvage.⁹³ Better understanding of the cascade of ischemic neuronal damage⁹⁴ may yet provide effective stroke therapy targets, and it is increasingly speculated that the future of stroke treatment lies in rapidly instituted combination therapy with thrombolytic, neuroprotective, and ultimately perhaps regenerative/trophic agents.

Hemorrhagic stroke

CAUSES OF VESSEL RUPTURE

The most common type of hemorrhagic stroke remains the classic spontaneous "hypertensive" hemorrhage, characteristically in basal ganglia, thalamus, lobar white matter,

cerebellum, and pons, in approximate descending order of frequency.⁹⁵ Their pathogenesis has been difficult to study, but circumstantial evidence points to the same, or closely related, lesion as that causing lacunar infarction³¹ with which it colocalizes and shares a common risk factor profile. Thus, a destructive lesion characterized by fibrinoid necrosis and associated with hypertension is considered by many to be the underlying vascular lesion in most cases.⁹⁶ In elderly people, an increasingly recognized form of spontaneous brain hemorrhage is due to cerebral amyloid angiopathy, in which bleeds are classically lobar, superficial, and multiple.⁹⁷ The mechanism of amyloid-related bleeds, their relation to classic "hypertensive" bleeds, and the contribution of amyloid angiopathy to cognitive decline in Alzheimer's disease are ill understood.

The most common cause of isolated, spontaneous subarachnoid hemorrhage is rupture of a berry aneurysm, about 85% of which in adults occur at proximal arterial bifurcations on the anterior circle of Willis.⁹⁸ Their pathogenesis is

disputed but appears to involve acquired degenerative tunica media defects at arterial branch points, sometimes in genetically predisposed individuals.

CONSEQUENCES OF VESSEL RUPTURE

Intracerebral hemorrhage is more often acutely fatal than ischemic stroke, largely because of its mass effect and the consequent potential for raised intracranial pressure and reduced cerebral perfusion. Hematomas, however, tend to dissect and separate brain tissue, with relatively less direct parenchymal damage. Therefore, should the patient survive and the hematoma be cleared by phagocytic cells to leave a blood-stained slit-like cavity, the prognosis for recovery may potentially be better than that for cerebral infarcts of similar size and location.

Stroke: Clinical Presentation, Management and Organization of Services

Velandai K. Srikanth

Thanh G. Phan

INTRODUCTION

Stroke is the most common clinical manifestation of disease of cerebral blood vessels and thus falls under the broad category of *cerebrovascular disease*. Transient ischemic attacks (TIA) are harbingers of a particular type of stroke known as ischemic stroke. Other common subclinical manifestations of cerebrovascular disease include cerebral white matter lesions (WML) and "silent" brain infarcts. This chapter will primarily focus on stroke and TIA, with some emphasis on WML and silent infarcts, the management of which are uncertain at the present time.

Stroke and TIA are the leading cause of acute neurologic admissions to hospitals throughout the world, and tend to predominantly affect older people. The seriousness of stroke is underlined by the fact that it is the second leading single cause of death worldwide.¹ Approximately a third of stroke patients die within the first 6 months, and approximately 60% by 5 years after stroke.² Stroke also ranks as the sixth most important cause of disability among survivors.³ With aging populations, it has been estimated that stroke will rank as the fourth most important cause of disability in the western world by the year 2030.³ Older people are at greater risk of accumulating other age-related diseases and consequently greater frailty.⁴ The impact of a stroke on such people with preexisting disability can be particularly devastating, often leading to a move from their home environment to residential care facilities.

Stroke is also an expensive disease in monetary and societal terms. In Australia, during the year 1997, the average cost per stroke patient was estimated as A\$18,956 during the first 12 months and A\$44,428 over a lifetime.⁵ Overall, the most important categories of cost during the first year were acute hospitalization A\$154 million, inpatient rehabilitation A\$150 million, and nursing home care A\$63 million.⁵ There are also significant costs for caregivers of stroke patients, with much of the informal care provided by family members leading to loss of earnings, family time, or leisure time.⁶ Although it is ideal to prevent strokes from occurring in the first place, it is equally important to adopt a cohesive and multidisciplinary approach toward clinical management and rehabilitation of stroke patient to minimize long-term stroke-related disability. Although stroke care has been regarded by many physicians with a sense of pessimism in the past, there have been remarkable advances in the last decade that have led to significant improvements in stroke care and measurable reductions in mortality and disability. The advent of multidisciplinary Stroke Care Units (SCUs) and more specific treatments based largely on evidence from randomized controlled trials have led to an exciting transformation in the attitude of physicians and the general medical community toward stroke management.

DEFINITIONS

Stroke - The World Health Organization (WHO) defined stroke as "rapidly developing clinical signs of focal disturbance of cerebral function lasting more than 24 hours (unless interrupted by surgery or death) with no apparent cause other than of vascular origin."⁷ The emphasis of this definition is on the *focal nature* of the clinical signs, implying that stroke is a disease causing focal brain injury, and the *acute onset* which is identified by the patient's ability to specifically describe what he or she may have been doing when the first symptoms occurred. This definition excludes cases of primary cerebral tumor, cerebral metastases, subdural hematoma, postseizure paralysis, and brain trauma. Although it is a predominantly clinical definition, it still holds validity in the current era of medical imaging because of the differences in the temporal and clinical presentations of other differential diagnoses mentioned earlier. For example, the time of onset of symptoms in patients with brain tumor may be difficult to pin down compared with stroke, and other conditions such as subdural hematoma and postictal paralysis are usually associated with a history of injury or seizures. However, brain imaging has assumed an important role in excluding other diagnoses, determining whether a hemorrhagic stroke may have occurred, and more recently is also of interest in trying to establish the occurrence of infarction in patients with suspected TIA.

Transient Ischemic Attack (TIA) - TIA refers to the transient occurrence of symptoms of ischemic stroke. The classic definition for a TIA differs from that for stroke primarily in the duration of symptoms. By this definition, TIA is considered as a diagnosis if there is a focal disturbance of cerebral function of sudden onset, lasting less than 24 hours and with no apparent cause other than of vascular origin. This emphasis on the 24-hour criterion evolved in the 1950s, was adopted at the Fourth Princeton Conference in 1965,⁸ and reinforced by the National Institutes of Health (NIH) in 1975.⁹ However, the majority of data at the time, and even at present, indicate that symptoms of TIA last less than an hour in most patients.¹⁰ Therefore it is now being increasingly considered that the 24-hour cutoff is out of date. Moreover, changes of infarction have been detected on MRI in a significant proportion of patients with suspected TIA.^{11,12} These issues have led to further debate on whether the definition of TIA should be altered to incorporate changing views on the typical duration of symptoms and imaging findings.¹⁰ At this point, the traditional definition of TIA remains widely in use and is important particularly in the context of epidemiologic studies of TIA that require standard definitions to compare incidence or prevalence rates over time and between populations. Older terms such as reversible ischemic neurologic deficit (RIND) and cerebral infarction with transient symptoms (CITS) have been discarded because they do not assist any further in disease phenotyping, understanding mechanisms,

or clinical management. The presence of symptoms such as faintness, dizziness, confusion, or falls is highly unlikely to be because of a TIA unless they are accompanied by focal neurologic symptoms.¹³ Transient global amnesia (TGA), a self-limited anterograde memory loss, is often mistaken to be a TIA. However, there is little evidence to suggest that it has a vascular mechanism.¹⁴ Similarly the occurrence of transient isolated neurologic symptoms, such as double vision, vertigo, or dysphagia, are more likely to be due to nonvascular causes. Acute delirium is unlikely to last only a few hours and is almost always not secondary to a TIA, although it can be an uncommon presentation of stroke.

Cerebral White Matter Lesions - These are radiologically defined and are visible as hyperintensities (bright signals) seen on T2 or fluid attenuated inversion recovery (FLAIR) sequences of MRI scans.¹⁵ They are seen to some degree in most people over the age of 65 years¹⁶ and are often considered to be "subclinical" manifestations of chronic occlusive disease affecting small cerebral blood vessels, although they can be nonspecific. Although chronic arterial hypertension is a consistent risk factor,¹⁷ the histopathology of WML is heterogeneous, showing a number of changes, including ischemia, demyelination, and chronic inflammation.¹⁸

Silent Brain Infarcts - These are small areas of typical infarction that are detected radiologically as areas of reduced intensity on T2 or FLAIR sequences of MRI in the absence of obvious acute stroke symptoms.¹⁹ They are detected in the subcortical regions of the brain in about 20% of healthy elderly and up to 50% in selected clinical samples.¹⁹ They increase in prevalence with age and are also associated with risk factors for small vessel disease, such as hypertension, smoking, hypercholesterolemia, and diabetes mellitus.¹⁹

STROKE TYPES

Strokes are either ischemic or hemorrhagic, with each having different pathophysiologic mechanisms and treatments. Approximately 80% of all strokes are ischemic, caused by

an acute occlusion of a cerebral blood vessel. Increasing age, history of TIA or stroke, hypertension, atrial fibrillation, cigarette smoking, diabetes mellitus, and hypercholesterolemia are important risk factors for ischemic stroke.¹ The mechanisms of arterial occlusion are predominantly those of artery-to-artery embolism and cardioembolism, rather than in situ vessel thrombosis. Hemorrhagic strokes (primary intracerebral hemorrhage [PICH]) occur in approximately 15% of all cases and most often result from chronic hypertensive small vessel disease, leading to vessel wall lipohyalinosis, microaneurysm formation, and rupture, and less commonly in relation to other conditions such as amyloid angiopathy.²⁰ Subarachnoid hemorrhage (SAH) is also classified as a type of stroke within the WHO definition, occurring in about 5% of all strokes and caused by the rupture of larger saccular intracerebral aneurysms within the subarachnoid space. Cigarette smoking, hypertension, female gender, and heavy alcohol intake have been identified as important risk factors for SAH, and these may interact with genetic susceptibility to aneurysm formation and rupture.^{21,22}

The distinction between ischemic and hemorrhagic stroke is important as their treatments are quite different (Figure 62-1). For example, thrombolysis is an acute treatment for ischemic stroke, but contraindicated for hemorrhagic stroke for obvious risks of worsening the hemorrhage. Computed tomography (CT) or MRI are both established methods for effectively excluding hemorrhagic stroke in the acute setting.²³

Ischemic stroke subtypes

The classification of ischemic strokes into further subtypes has been driven by the needs of observational epidemiologic studies and clinical trials in stroke. The most commonly used classification in observational epidemiology is the Oxfordshire Community Stroke Project Classification (OCSP).²⁴ In clinical trials and in situations that require an understanding of the mechanisms underlying

Figure 62-1. Hemorrhagic infarct and not primary intracerebral hemorrhage. 83 year old female had resolving right hemiparesis but residual right hemianesthesia (A). Twelve hours later she redeveloped right hemiparesis with obscuration of the left lentiform nucleus (solid arrow in B). Her blood pressure was elevated at 230/120 mm Hg. She deteriorated overnight with the final CT performed 24 hours (C) after admission, looking indistinguishable from a primary intracerebral hemorrhage.

the stroke, the most commonly used criteria for classification are the Trial of Org 10172 in Acute Stroke Treatment (TOAST) criteria.²⁵

Oxfordshire Community Project Classification (OCSF)
According to the OCSF classification, ischemic strokes are classified as one of four subtypes by their clinical presentation: Total Anterior Circulation Infarcts (TACI), Partial Anterior Circulation Infarcts (PACI), Posterior Circulation Infarcts (POCI), and Lacunar Infarcts (LACI) (Table 62-1). In a recent population-based study of stroke incidence, the annual incidence rates per 100,000 persons adjusted to the "world" population were 11 (95% confidence interval or CI, 4–18) for TACI, 25 (95% CI, 15–35) for PACI, 17 (95% CI, 9–25) for POCI, and 18 (95% CI, 10–26) for LACI. It is important to note that the OCSF classification is a syndromic classification based on the constellation of clinical signs and symptoms at stroke onset. Although this type of classification may be useful in studying risk factors and

outcomes, or assigning prognosis, it does not allow a definitive understanding of the actual mechanism underlying the stroke in an individual patient without further investigations.

TACI usually involves a major portion of the carotid artery territory and may occur as a result of occlusion of the internal carotid artery or proximal stem of the middle cerebral artery (MCA), with or without involvement of the anterior cerebral artery (ACA). Given the extensive nature of infarction, TACI is associated with a very high case-fatality (approximately 35% die within the first 28 days).²⁶ Survivors of TACI are usually left with severe generalized neurologic deficits attributable to the affected hemisphere, consequent immobility, and high levels of disability or handicap.^{26,27} PACI probably occurs as a result of occlusion of more distal branches of the MCA and is associated with a lesser degree of, but nonetheless significant, neurologic impairment including higher cortical deficits. PACI carries the highest rate of early stroke recurrence among the OCSF subtypes (approximately 17% in the first year),²⁶ necessitating a comprehensive assessment and management of modifiable risk factors. POCI refers to ischemic strokes occurring in the vertebrobasilar artery territory and generally has an intermediate level of case-fatality, lower than TACI but higher than LACI.²⁶ LACI refers to the different presentations of ischemic strokes with mainly motor or sensory deficits in the absence of signs and symptoms attributable to the cerebral cortex or the posterior circulation. They are generally milder and have a relatively good prognosis compared with the other OCSF subtypes.²⁶ Although it is assumed that LACI occurs because of the occlusion of small deep cerebral blood vessels, this cannot be definitively ascertained without further investigation.

Trial of Org 10172 in Acute Stroke Treatment (TOAST) Criteria - This is a classification of subtypes using a combination of clinical features and results of ancillary diagnostic studies, and is extremely important for use in trials of stroke treatment or prevention. "Possible" and "probable" diagnoses can be made based on the physician's certainty of diagnosis based on all available clinical information. Apart from use in trials, it allows the clinician to focus on disease mechanisms underlying the stroke and therefore a better framework for clinical decision-making for treatment. The TOAST classification was first developed in 1993 as part of a clinical trial and denotes five categories of ischemic stroke: (1) large-artery atherosclerosis, (2) cardioembolism, (3) small-vessel occlusion, (4) stroke of other determined cause, and (5) stroke of undetermined cause.²⁵ These were developed using available diagnostic and clinical information at the time, and given the limitations of these diagnostic tests, may have led to many cases placed in the category of undetermined cause. A more recent adaptation is the SSS-TOAST (Stop Stroke Study-TOAST), which takes into account recent advances in diagnostic technologies, particularly neuroimaging and cardiac imaging, to further specify the level of confidence (evident, probable, and possible) for assigning ischemic stroke subtype.²⁸ This classification scheme also allows for the possibility that there may be more than one mechanism involved in causing the stroke. The SSS-TOAST criteria can now even be applied in a web-based algorithm allowing for standardization in multicenter studies of stroke.²⁹

Table 62-1. Oxfordshire Community Stroke Project Classification (OCSF)

Total Anterior Circulation Infarct (TACI)

- Unilateral motor deficit of at least two areas of the face, arm, and leg
- Homonymous hemianopia
- Higher cerebral dysfunction (for example, aphasia, neglect, dyscalculia, visuospatial disorder)
- If the conscious level was impaired and formal testing of higher cerebral function or the visual fields was not possible, a deficit is assumed

Partial Anterior Circulation Infarct (PACI)

One of:

- Any two of the features listed above for TACI
- Higher cerebral dysfunction alone
- Motor and/or sensory deficit more restricted than those classified as LACI (for example, confined to one limb, or to face and hand but not to whole arm)

Posterior Circulation Infarct (POCI)

One or more of:

- Bilateral motor or sensory signs not secondary to brainstem compression by a large supratentorial lesion
- Cerebellar signs, unless accompanied by ipsilateral motor deficit (see ataxic hemiparesis)
- Unequivocal diplopia with or without external ocular muscle palsy
- Crossed signs, for example, left facial and right limb weakness
- Hemianopia, alone or with any of the four items above
- Ipsilateral cranial nerve palsy with contralateral motor and sensory deficit

Lacunar Infarction (LACI)

Pure Motor Stroke (PMS)

- Unilateral, pure motor deficit
- Clearly involving two of three areas (face, arm and leg)
- With the whole of any limb being involved

Pure Sensory Stroke (PSS)

- Unilateral purely sensory symptoms (± signs)
- Clearly involving two of three areas (face, arm, and leg)
- With the whole of any limb being involved

Ataxic Hemiparesis (AH)

- Ipsilateral cerebellar and corticospinal tract signs
- With or without dysarthria
- In the absence of higher cerebral dysfunction or a visual field defect

Sensory-Motor Stroke (SMS)

- PMS and PSS combined (i.e., unilateral motor and sensory signs and symptoms)
- In the absence of higher cerebral dysfunction or a visual field defect

CLINICAL PRESENTATION

The patterns of clinical presentations for stroke vary and cannot be exhaustively dealt with in this chapter alone. For a detailed examination of this topic, readers are referred to the authoritative text titled "Stroke Syndromes," edited by Bogousslavsky and Caplan.³⁰ However, in the following section, the most commonly encountered clinical features associated with stroke will be presented.

Stroke

Clinical presentations of ischemic stroke, PICH and TIA, can most often be ascribed to specific brain locations that are affected. Stroke and TIA, being part of the same clinical spectrum of disease, have very similar presentations except for the transient nature of symptoms in the latter. It is also unusual to have a TIA with purely sensory symptoms. The most commonly encountered clinical manifestations of stroke are as below:

1. Motor weakness - Hemiparesis or other motor weakness is the most common presenting abnormality in stroke, usually seen in more than 80% of patients.³¹ This is possibly because of the large extent of the corticospinal pathways in the brain making it susceptible to the effects of stroke almost anywhere in the brain. Motor weakness leads to obvious difficulty in mobility and consequent disability. Apart from the predictable nature of large superficial MCA stroke, there is not a strong correlation between the location of stroke and severity of motor weakness.³² Hemiparesis uniformly affecting the upper and lower limbs is the most frequently encountered motor deficit in about two thirds of cases, followed much less frequently by monoparesis, paraparesis, or quadriparesis.³¹ The pattern of weakness may provide clues toward the topography of the stroke, although recent advances in MR imaging provide this information with far greater accuracy. Weakness of the face, arm, and leg usually indicates the involvement of the MCA territory, whereas predominant weakness of the lower limb is commonly seen in cases of anterior cerebral artery stroke. On occasion, proximal posterior cerebral artery occlusion can produce a pattern of weakness combined with deficits in higher cortical function that mimics MCA infarction.³³ The presence of a pure motor hemiparesis involving face, arm, and leg in the absence of cortical signs is the most common manifestation of lacunar infarction, resulting from a deep penetrating artery occlusion in the internal capsule or the base of the pons.³⁰ Care has to be taken to differentiate between true motor weakness and other deficits that may mimic weakness; for example, an apraxia of movement may be mistaken for motor weakness. Apraxia refers to a higher cortical disorder of initiation of movement in the absence of motor weakness, either for whole limb movement or more skilled movement. Motor weakness of the articulatory apparatus or the muscles involved in chewing and swallowing may lead to dysarthria and swallowing difficulties.
2. Sensory dysfunction - More than 60% of stroke patients admitted to the hospital suffer some form of tactile sensory impairment, and smaller proportions either suffer loss of proprioception or cortical sensory impairment.³⁴ The true prevalence of sensory abnormalities after stroke may well be underestimated given the usual laxity in sensory examination and the lack of sensitive clinical tools for detecting abnormalities. Protopathic sensory loss (involving peripheral perception of pain, temperature, vibration) may lead to problems with daily function, such as when coming into contact with hot and cold temperatures and using utensils or instruments, and also with mobility in case of significant proprioceptive loss. Severe sensory loss may lead to a difficulty in performing complex tasks in the affected limb causing a "pseudoparesis," and on occasion result in motor incoordination or involuntary movements. Strokes involving the brain stem (medulla, pons, midbrain), the thalamus and occasionally thalamocortical radiation may all lead to varying degrees of impairment in touch, pain, temperature, and vibration. The exact location of the stroke will dictate the modalities that are impaired and the pattern of co-occurrence of other neurologic deficits. Examples of cortical sensory impairments include loss of discrimination sense, difficulty in localizing touch and pain (topagnosia), failure to recognize numbers or letters drawn on the skin (graphesthesia), and failure to recognize texture, size, or shape of objects by palpation (astereognosis). These signs are usually seen with parietal cortical strokes in the MCA territory in combination with other features, such as hemiparesis, hemianopia, aphasia, or hemineglect. Sensory abnormalities may be associated with poststroke pain syndromes, which can be very debilitating to the patient. Poststroke pain may occur in up to 10% of stroke patients and usually has a delayed onset.³⁵ The symptoms are variable and may include burning, aching, lacerating, and cold sensations among others. Dysesthesia and allodynia are also commonly present. The pathophysiology underlying central poststroke pain is poorly understood.
3. Higher cortical dysfunction - There are several types of cortical dysfunction that can occur after stroke depending on the location of the lesion. The cortical deficits that have the most important adverse impact on stroke outcome are dysphasia (usually dominant hemisphere stroke) and hemineglect (usually right hemisphere stroke). Language is served by several sites in the brain that are part of a network, and hence disruption of this network at any site may produce several types of language deficits. Broca's aphasia (also termed expressive aphasia or motor aphasia) is most commonly caused by strokes involving the left frontal opercular and central cortex, with or without involvement of the subcortical striatocapsular region. It is characterized by effortful speech, word-finding difficulty, phonemic errors, and agrammatism, but with relatively preserved comprehension. Global aphasia refers to severe impairment of motor

speech and comprehension and is usually a consequence of a major left MCA stroke. Verbal apraxia (also termed as pure motor aphasia) is characterized by an inability to position the articulation apparatus to produce words because of a loss of programming of skilled motor movements, and is commonly seen in conjunction with Broca's aphasia. Transcortical aphasia is a disorder of spontaneous speech but with preserved repetition and comprehension, generally because of stroke involving the dominant mesial frontal cortex or the supplementary speech area. Sensory aphasia with relatively fluent speech but poor language comprehension is usually associated with strokes involving the superior temporal lobe and includes Wernicke's aphasia and conduction aphasia, among others.

Hemineglect is characterized by a reduction in attention to stimuli and events on one side of the body. This is usually seen in right hemisphere stroke, although it can be seen in varying degrees in up to 20% of left hemisphere strokes.³⁶ Hemineglect may affect visual, auditory, and somatosensory perceptual systems. Clinically, it can be detected using tests of cancellation or copying, simultaneous sensory testing or dichotic listening, or from clinical observation of the fact that the patient may ignore stimuli arising from the affected side, not eat food on the plate on the affected side, or ignore personal hygiene on the affected side. The presence of significant hemineglect is associated with greater dependence in function³⁷ and hence requires significant effort in rehabilitation. Other perceptual disorders associated with hemispherical strokes include impaired topographical recognition (disorientation to previously known surroundings), visual agnosia (impaired recognition of visual material in the presence of normal acuity), prosopagnosia (inability to recognize previously known faces), anosognosia (lack of concern for deficits on affected side), and occasionally auditory or visual hallucinations.

4. Visual dysfunction and eye movements - Visual symptoms may arise from lesions affecting the visual pathway anywhere from the retina to the occipital cortex. Retinal or ophthalmic artery occlusion occurs because of embolism from the carotid system and may lead to monocular blindness. When monocular visual loss is acute and transient, then it represents a TIA, warranting urgent investigation of the carotid circulation to identify and treat internal carotid artery stenosis that may be the source of the embolus. Visual field defects are a common visual manifestation that occurs as a result of stroke affecting the optic radiation fibers, leading to either hemianopia or quadrantanopia depending on the site of the lesion and the extent of damage to the optic radiation. Middle cerebral artery and posterior cerebral artery strokes can lead to visual field defects, the former affecting the parietal and occipital optic radiation and the latter the more distal occipital radiation fibers. Strokes affecting the striate cortex may lead to visual agnosia, color perception defects in addition to visual field defects.

Less commonly, bilateral striate cortex infarction may lead to complete cortical blindness that may be distinguished from ocular disease by the presence of normal papillary light response and fundus examination. Some patients with cortical blindness may deny their visual problems and claim normal vision, and this has been termed Anton's syndrome. A further common feature in stroke is visual hemineglect (also termed as visual inattention) in which the patient may fail to attend to visual stimuli on the side of the body contralateral to the stroke lesion. Detection of visual neglect can be clinically extremely difficult in the presence of a hemianopia. Ocular movement abnormalities are commonly seen in stroke affecting the brainstem, but also less commonly seen with cerebellar and cerebral lesions. Diplopia is usually associated with eye movement abnormality and can be quite disabling. The importance of detection and characterizing visual deficits in stroke patients is of extreme importance, given their potential impact on daily life and complex activities such as driving.

5. Posterior fossa syndromes - Vertigo, or a disordered perception of motion of either the patient or the environment, can be caused by strokes involving the vertebrobasilar circulation and is often accompanied by nystagmus. Ataxia of the trunk or limbs may be caused by strokes affecting the cerebellum and adjacent brainstem. Ataxic hemiparesis is a condition that is characterized by the presence of mild hemiparesis and ipsilateral limb ataxia without sensory loss. It may be caused by stroke involving the base of pons, crus cerebri, thalamus, or internal capsule by affecting projection fibers in the corticopontocerebellar or the dentate-thalamic pathways. Several auditory symptoms may also be associated with brainstem strokes including hearing loss, hyperacusis, tinnitus, and auditory hallucinations. Sudden stroke-related hearing loss is uncommon and usually occurs in conjunction with other brainstem signs. However, it has been described on occasion in patients with vertigo and nausea without additional brainstem signs.³⁸
6. Neurocognitive syndromes - Stroke is very commonly associated with alteration in cognitive status at acute presentation and in the medium to long term.³⁹ About 25% of stroke patients have an acute confusional state.⁴⁰ It is important to exclude other causes of acute confusion in the hospitalized stroke patient, such as infection, hypoxia, or alterations in biochemical profile. Close to 50% of survivors have some form of cognitive impairment at 3 months after stroke.⁴¹ Stroke is strongly associated with a twofold increase in the risk of dementia after stroke, with the presence of prestroke cognitive decline explaining a large proportion of these cases.⁴² This suggests that the majority of cases of dementia diagnosed after stroke are likely to be due to a combination of stroke-related cognitive impairment and preexisting neurodegenerative disease such as Alzheimer's disease. In most cases of stroke-related cognitive impairment, the deficit may be explained

by the location of the lesion. For example, medial temporal or left thalamic strokes are strategically placed to cause memory impairments by disrupting the limbic pathways.⁴³ Thalamic and caudate strokes can produce several other cognitive deficits in addition to memory impairment, such as reduced problem-solving capacity and attention. Frontal lobe strokes may lead to several cognitive sequelae, such as lack of initiation, apathy, and poor planning. Such strategic cognitive syndromes may be associated with some improvement with time, but many patients are left with some residual cognitive deficits. In many situations, however, stroke patients suffer nonspecific reductions in attentional capacity and working memory, representing a more widespread disorder of fundamental cognitive abilities irrespective of the location of the lesion. Much of the cognitive burden associated with strokes may go unrecognized, particularly in those with so-called "silent" brain infarcts (SBI) that usually are not associated with the classic motor or sensory symptoms seen in the average stroke patient. Care must be taken to look for cognitive loss in people with SBI. SBI may have important effects on future cognitive outcome, particularly in increasing the risk of incident dementia.¹⁹ Up to 30% of patients may also suffer from depressed mood in the medium to long term after stroke,⁴⁴ with disability and history of depression being important predictors of long-term depression.⁴⁵ Patients with frontal or temporal lobe involvement may also display emotional outbursts (poststroke emotionalism). Such nonspecific neurocognitive syndromes may impact significantly with their functional status and quality of life irrespective of physical recovery.⁴⁶ Cognitive and mood examination is therefore extremely important in stroke patients to allow clear plans to be made for rehabilitation or supported care, more so in the very elderly who are at higher risk of other causes of cognitive impairment.

Apart from the manifestations mentioned above, stroke may less commonly have other clinical presentations. These include extrapyramidal features such as tremor, hemiballismus or dystonia (due to lesions affecting the basal ganglia), seizures, and disorders of wakefulness and sleep.

7. Incontinence - Urinary and fecal incontinence are common and disabling effects of stroke. The prevalence of urinary incontinence among survivors of stroke has been shown to range from 36%⁴⁷ to 83%⁴⁸ within the first 3 months. The incidence of urinary incontinence has been reported to be 29/1000 persons per month in a hospital-based sample of post-acute stroke patients.⁴⁹ Increasing stroke severity is a predictor of the presence of incontinence independent of age. Incontinence may be a direct consequence of loss of neurogenic control or because of functional incapacitation secondary to immobility or cognitive loss. Urinary incontinence is a marker for increased mortality after stroke and overall poor outcome among survivors. Fecal incontinence is also common after stroke. In a community-based postal survey, 5%

of stroke survivors reported major fecal incontinence, with 4.3% reporting fecal and urinary incontinence and 0.8% reporting isolated fecal incontinence.⁵⁰

Effects of cerebral white matter lesions

Cerebral white matter lesions (WML) have been linked to cognitive and noncognitive effects. Most commonly, they are associated with reductions in fundamental cognitive abilities, such as attention, speed of processing, and executive function, presumably secondary to the disconnection of white matter association tracts that enable brain networks.^{51,52} They have also been associated with poorer gait and balance because of a general disruption of motor control.⁵³ It is likely that these effects may be clinically most evident when there are very large volumes of WML in the brain, as may have been found in very early descriptions of Binswanger's disease⁵⁴ characterized by abnormal gait, dementia, incontinence, and motor deficits.

INVESTIGATIONS

Brain imaging

DIAGNOSIS OF HEMORRHAGE

Computed tomography (CT) should be performed to exclude intracranial hemorrhage. On rare occasions, a subdural hematoma may have transient symptoms mimicking a TIA. Hemorrhage in the basal ganglia and pons suggests that hypertension may be the likely cause, whereas hemorrhage in cortical (lobar) locations suggests the possibility of amyloid angiopathy as the primary causal mechanism. In some cases, primary intracerebral hemorrhage and hemorrhagic infarcts are indistinguishable on CT unless a series of CT scans have been obtained to record the evolution of hemorrhage into the infarct (see [Figure 62-1](#)).

RECOGNITION OF ISCHEMIC CHANGES ON CT

It was only recently recognized that early ischemic changes are present in the first 6 hours in approximately a half to three quarters of patients with MCA territory infarction.⁵⁵ Significant early ischemic changes include parenchymal hypoattenuation and diffuse swelling of the hemisphere.⁵⁶ The definition of parenchymal hypoattenuation is a decrease in tissue density below that of white matter but greater than that of cerebrospinal fluid. This definition excludes old cerebral infarction in which the tissue density is similar to that of cerebrospinal fluid. Lacunar strokes resulting from small vessel disease are not easily seen in the first 24 hours after stroke.

MRI FINDINGS IN STROKE

Signal change on MRI diffusion-weighted imaging (DWI) reflecting altered water diffusion can reveal abnormalities within minutes of ischemia in the majority of patients with ischemic stroke.⁵⁷ This change is seen earlier than on conventional MR imaging sequences such as T2-weighted images. The bright signal change on DWI becomes less bright after 10 days.⁵⁸ Hemorrhage on the other hand contains paramagnetic material and has a dark signal on T2-weighted images. The evolution of MR signal changes in intracerebral hemorrhage is quite complex and the reader is referred to the excellent description by Atlas and Thulborn.⁵⁹

In older people, focal areas of signal loss on gradient echo (GE) MR imaging pathologically represent focal hemosiderin deposition associated with previous hemorrhagic events. These are usually cerebral microhemorrhages and have been found in patients with previous ischemic stroke, intracerebral hemorrhage (ICH), cerebral amyloid angiopathy (CAA), and cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL). In patients with CAA, such microhemorrhages may predict the risk of recurrent lobar ICH.⁶⁰

EVALUATING TISSUE AT RISK

Stroke pathophysiology can now be inferred from dynamic scanning by tracking a bolus of intravenous contrast with sequential acquisition of CT or MR images (Figure 62-2). These CT or MR perfusion images enable analysis of cerebral perfusion deficit. For MR images, the salvageable tissue is represented by the difference of the poorly perfused region and the region of restricted diffusion (infarct core).⁶¹ For CT scan, the infarct core is represented by the most poorly perfused region on CT perfusion images. These dynamic scanning methods are being tested as guides to therapy in trials of thrombolysis therapy beyond 3 hours after stroke onset.⁶²

Diagnosis of stroke mechanism

EXTRACRANIAL ARTERY ULTRASOUND

Ultrasound is traditionally performed to screen for carotid artery atherosclerosis. It can provide evidence of vertebral artery disease as well. There are a few caveats to interpreting ultrasound results: firstly, the result is dependent on the operator; secondly, assignment of degree of carotid artery stenosis is to a large extent dependent on the velocity of flowing blood in that artery. Consequently, a critically narrow artery on one side may lead to compensatory elevation of velocity in the contralateral artery leading to erroneous misclassification of the contralateral artery as critically stenosed; thirdly, ultrasound assignment of carotid artery stenosis as moderate (50% to 70% stenosis) can either mean that the artery is 50% to 70% stenosed or greater than 70% stenosed; finally, near occlusion on ultrasound can mean near occlusion, complete occlusion, or critical stenosis. A rule of thumb is that when the ultrasound suggests more than 50% stenosis and the patient is fit for carotid endarterectomy, a second test such as CT angiography or contrast enhanced MR angiography may be necessary to clarify the exact degree and nature of the stenosis.

CT ANGIOGRAPHY

CT angiography is performed by rapid injection of contrast bolus and acquiring the images during the arterial phase of contrast arrival in the brain. CT angiography can provide coverage from the aortic arch to the circle of Willis. This method has excellent correlation with digital subtraction angiography⁶³ and together with MR angiography has largely replaced the latter for investigating carotid artery disease.

MR ANGIOGRAPHY

MR angiography techniques are divided into those designated as "bright blood" and "black blood" techniques depending on the signal intensity of blood. In bright blood techniques, voxels within a blood vessel have bright signal. Hence, very slowly moving parts (very tight stenosis) or stationary parts

(occluded) of the blood vessel will experience a loss of signal. Hence this "time of flight" MRA sequence cannot reliably distinguish between complete occlusion or a critically stenosed carotid artery. Phase contrast MR angiogram, on the other hand, provides information on direction of flow and velocity of flowing blood in that vessel and is more often used for research purposes. Contrast-enhanced MR angiography (CEMRA) is performed by fast injection of an intravascular contrast agent (gadolinium) and acquiring images during the arterial phase of contrast arrival. Unlike the time of flight MRA, this method relies on contrast with the lumen to depict the arterial lumen size and thus provide similar findings as digital subtraction angiography. Like CT angiography, this method has largely replaced digital subtraction angiography for investigation of carotid artery disease.^{63,64}

STROKE PATTERNS

The stroke patterns on CT and MR images can also be used to infer stroke mechanism. DWI-MRI has been advocated to be better than CT because it may reveal smaller strokes not seen on CT images.⁶⁵ A small deep lacunar infarct may indicate the presence of small vessel disease. Bilateral hemispheric (MCA) strokes imply cardiac embolism or artery-to-artery embolism from an aortic arch atheroma. However, bilateral anterior cerebral artery strokes may occur in the absence of a central embolic source. In this situation, the mechanism may be due to distal artery-to-artery embolism to a single proximal anterior cerebral artery that gives rise to the two distal anterior cerebral arteries (an anatomic variant). This situation can also occur in the case of bilateral thalamic infarction because of occlusion of the artery of Percheron, a solitary arterial trunk that arises from one of the proximal segments of a posterior cerebral artery, and on occasion supplies both thalami.⁶⁶ Strokes involving both posterior cerebral arteries may be due to artery-to-artery embolism from a vertebrobasilar source and do not necessarily indicate a cardiac mechanism.

ECHOCARDIOGRAPHY

Echocardiography can assist in clarifying the mechanism of ischemic stroke. However, the routine use of echocardiography for determining stroke mechanism is controversial. It is rare to find an abnormality on echocardiography that would lead to anticoagulation in patients with a normal electrocardiogram and cardiovascular examination. The need for routine echocardiography in ischemic stroke needs to be supported by strong evidence for a benefit from therapy, namely prophylactic anticoagulation. At present, there is level I evidence that anticoagulation prevents stroke in patients with atrial fibrillation.⁶⁷ There is no evidence at present to support routine anticoagulation for stroke prophylaxis in people with sinus rhythm even among high-risk patients with heart failure.⁶⁸ This lack of level I evidence may have been the reason why the current stroke guidelines have not emphasized the role of echocardiography in stroke. Routine echocardiography may lead to the chance finding of patent foramen ovale or valvular strand, which may further confuse clinical decisions, as the evidence is lacking for anticoagulation or surgical therapy in such situations.^{69,70} On the other hand, echocardiography may prove to be useful in detecting aortic arch atheroma. Complex aortic arch atheroma confers a fourfold increased risk

Figure 62-2. CT imaging revealing salvageable tissue in acute ischemic stroke. An 84-year-old man had acute left MCA occlusion resulting in aphasia and dense right hemiparesis while playing golf. This man was known to have AF and not on warfarin. The acute CT scan (A) showed the hyperdense MCA sign, which corresponded with CT angiography (D) evidence of left MCA occlusion. There is obscuration of the lentiform nucleus and edema in the left frontal cortex (B and C). The CT perfusion pictures (E and F) showed that the striatocapsular region was likely to be infarcted, whereas the surrounding area was at risk of infarction. He was treated with tissue plasminogen activator and the CT scans performed (G–I) 2 days later showed infarction of **only** the left striatocapsular region.

of stroke.⁷¹ Although emboli from aortic arch atheroma do not strictly originate from the heart, the stroke syndromes they cause are similar. Transesophageal echocardiography is superior to transthoracic echocardiography for the detection of aortic arch atheroma.⁷² However, there is no

evidence at this time whether warfarin may be more useful than routine antiplatelet therapy in patients with arch atheroma as the predominant mechanism, reducing the urgency to pursue this stroke mechanism at the present time.⁷¹

Blood tests for the diagnosis of stroke risk factors

SERUM CHOLESTEROL

Measuring fasting serum cholesterol has taken on greater importance with the recent success of statins in secondary stroke prevention.⁷³ When measuring serum cholesterol, it is important to realize that the levels dip acutely after stroke and return to "true" value approximately 12 weeks after stroke onset.⁷⁴ Consequently, a "normal" result within 1 week of stroke may represent a falsely low result.

SERUM GLUCOSE

Measurement of fasting glucose is essential to exclude diabetes mellitus, which can often surface as a diagnosis after stroke. To avoid the confounding of results by acute phase hyperglycemia, it is often advisable to conduct definitive testing with fasting glucose or glucose tolerance testing a few weeks after stroke.

INFLAMMATORY MARKERS

Erythrocyte sedimentation rate (ESR) and high sensitivity C-reactive protein (CRP) can be performed to examine the possibility of temporal arteritis or subacute bacterial endocarditis as unusual causes of stroke. Recently, high-sensitivity C-reactive protein has been recognized as a marker of stroke prognosis and active atherosclerotic disease.⁷⁵

ANTIPHOSPHOLIPID ANTIBODY SYNDROME

The relationship between antiphospholipid antibody and stroke is not as straightforward as previously thought since this antibody has a high prevalence in people above the age of 40.⁷⁶ It is recognized that this antibody is a marker of increased risk of stroke, peripheral vascular disease, and ischemic heart disease.^{76,77} It is often difficult to ascribe a causal role for the antibody in contributing to the stroke mechanism in an individual patient. It appears that identifying the presence of antiphospholipid antibody in stroke patients may not assist in deciding whether to treat with antiplatelet agents or anticoagulants. Patients with this antibody do reasonably well when treated with aspirin, whereas those treated with warfarin have a similar reduction in stroke risk, but with a potentially higher risk of intracranial hemorrhage.⁷⁸ Routine testing for this antibody is generally not recommended.

THROMBOTIC RISK FACTORS

The contribution of hypercoagulable states to arterial occlusion in ischemic stroke is controversial despite its recognized role in causing cerebral venous thrombosis.⁷⁹ Coagulation abnormalities have been described in stroke patients, but often concurrently with other well-established causes of stroke.⁸⁰ In elderly patients, a full blood count can be helpful to exclude rare cases of thrombocytopenia or polycythemia rubra vera. It is unlikely that a search for other rare causes of stroke would be useful in elderly patients in the absence of clinical pointers.

Management of stroke patients

ACUTE TREATMENT OF ISCHEMIC STROKE

Acute stroke treatments may involve either stroke-specific therapies or more general treatments aimed at optimizing the overall medical state. Three specific interventions

have been shown to be effective in randomized trials for the acute treatment of ischemic stroke. These include antiplatelet agents,⁸¹ tissue plasminogen activator (tPA),^{82,83} and organized stroke units.⁸⁴ The latter is particularly important because it provides the framework for ensuring appropriate overall management of a patient. Recently, there have been limited data on the usefulness of decompressive hemicraniectomy in patients with malignant MCA infarction.⁸⁵ The role of other medications (such as antihypertensive drugs and statins) in the acute phase of ischemic stroke is uncertain and remains to be clarified. Neuroprotective agents have largely failed to show benefits in acute stroke therapy.

ORGANIZED STROKE UNIT CARE

The implementation of organized stroke units has been the most important advance in acute stroke management. A collaboration of stroke unit trial lists demonstrated that organized stroke units result in long-term reductions in the odds of death (14%), death or institutionalized care (18%), and death and dependency (18%) regardless of age, sex, or stroke severity.^{86,87} This translates to having to treat approximately 25 patients (number need to treat [NNT]) to prevent one from dying or being dependent. Outcomes were also found to be better in patients admitted to a discrete ward under the care of a dedicated multidisciplinary team, compared with a roving stroke service visiting patients on general medical wards.⁸⁸ Furthermore, there were no indications that stroke unit care resulted in longer hospital length of stay.^{86,87} It has been proposed that stroke units work by reducing secondary complications of stroke and reducing disability through the use of a dedicated team of nurses and allied health members and implementation of stroke protocols. The consistent characteristics of effective stroke units appear to be (1) a comprehensive approach to medical problems, impairments, and disabilities, (2) active and careful management of physiologic abnormalities, (3) early mobilization, (4) skilled nursing care, (5) early setting of rehabilitation plans, and (6) early assessment and planning of discharge needs with involvement of caregivers.⁸⁹ Appropriate fluid and nutritional support in the acute phase with either intravenous fluids or nasogastric feeding are also important in those with significant dysphagia and risk of aspiration. The use of percutaneous endoscopic gastrostomy (PEG) in the acute phase is generally not recommended because it is associated with an increased risk of death or poor outcome at 6 months.⁹⁰ The early detection and treatment of pyrexia and infectious complications is a major contributor to the effectiveness of stroke unit care.⁹¹ A protocol driven approach in stroke units may also enable the standard use of low-molecular weight heparin to prevent venous thromboembolism, with recent evidence supporting their superiority in ischemic stroke patients compared with standard unfractionated heparin.⁹² Nursing care should incorporate avoidance of pressure areas, urinary catheters, and bed rest because these contribute significantly to the development of complications, such as sepsis and deep venous thromboses. Blood pressure reduction should be generally avoided in the acute phase (except in selected situations, such as before thrombolysis or in people with hemorrhagic strokes and mass effect) because of concerns about interfering with cerebral autoregulation,

and if performed should be done cautiously and in well-monitored situations. A very important component of stroke unit care is the conduct of regular (weekly) formal multidisciplinary meetings that serve as forums for the entire team to discuss various aspects of individual patient care and set early plans for rehabilitation and discharge.⁸⁹ Among the established acute stroke therapies, it has been estimated that stroke unit care has the greatest ability to prevent disability or death (approximately 50 patients for every 1000 strokes) compared with aspirin (4 patients per 1000) and tPA (6 per 1000).⁹³

ANTIPLATELET THERAPY

The International Stroke Trial (IST) and Chinese Aspirin Stroke Trial (CAST) clearly demonstrated the efficacy of aspirin (160 to 300 mg) as an acute stroke therapy for ischemic stroke,^{81,94} with approximately 80 people (NNT) needing treatment to prevent one from dying or being dependent. In both studies, heparin was not found to be superior to aspirin. There have been several trials of the efficacy of low molecular weight heparin in acute ischemic stroke, with none showing superiority over aspirin but with increased risk of intracranial hemorrhage.⁹⁵ The benefit of aspirin in the acute phase of stroke is relatively small, with about four patients saved from death or disability per 1000 treated. However, it is an inexpensive therapy, is widely available, and should be used in acute ischemic stroke treatment in the absence of a significant contraindication.

THROMBOLYSIS FOR ACUTE ISCHEMIC STROKE

Until recently, stroke therapy had largely been confined to secondary ischemic stroke prevention and rehabilitation because reversal of neurologic deficit and salvage of ischemic tissue was thought not possible. The introduction of recombinant tissue plasminogen activator (tPA) has led to new found optimism for reversing the neurologic deficit because of ischemic stroke.^{82,83} It is postulated that the mechanism of action of tPA is lysis of the thrombus/embolus leading to recanalization of the arterial lumen and salvage of the ischemic brain tissue. In a pivotal randomized controlled trial (the NINDS trial), tPA given within 3 hours of symptom onset led to a 12% increase in the number of patients discharged home with no neurologic deficit.⁸² Approximately 18 patients (NNT) will need to be treated with tPA to prevent one from dying or being dependent. These results were duplicated in a large phase IV study involving 6483 patients treated with tPA across Europe.⁹⁶ There have been several smaller phase IV studies examining the safety of thrombolysis in patients over the age of 80.⁹⁷ With the advent of tPA, there have been significant efforts to enable more patients to have access to the therapy, with improved ambulance response and emergency department triaging being important to reduce the "door-to-needle time" and allow treatment to be given within the 3-hour time window. The most important adverse effect of tPA is symptomatic intracerebral hemorrhage in about 6% of cases. The risk of symptomatic intracerebral hemorrhage rises with age, high blood pressure, and very severe neurologic deficits.¹ Although there have been concerns regarding an increased risk of bleeding in older people, the majority of available data indicate that the benefit is

also seen in the older patient with ischemic stroke who meets the strict inclusion criteria used in the NINDS trial.⁸² However, there are some important caveats to using tPA in elderly patients. Those patients with extensive cerebral white matter lesions on CT scan are more likely to develop thrombolysis-related intracranial hemorrhage.⁹⁸ The presence of a significant preexisting dementia or extreme frailty (particularly in those already living in high-level residential care) may be a cause for concern and be relative contraindications to thrombolysis. At this point, there is insufficient evidence to support the use of tPA when the 3-hour time window has passed.

EMERGING TREATMENTS

Decompressive hemicraniectomy may be considered in the occasional patient who has a rapidly declining neurologic state and a large MCA infarct with mass-effect (malignant infarction), with a pooled analysis from three trials that indicate a benefit in survival but not necessarily a large reduction in disability, with the majority of survivors having a modified Rankin score of 4 indicating severe disability.⁸⁵ There are several other approaches that are being studied to improve the acute treatment of ischemic stroke. These include ways to extend the time window for thrombolysis, using transcranial ultrasound to assist in clot lysis during thrombolysis, acute blood pressure lowering, and invasive procedures such as thrombectomy.

Acute treatment of intracranial hemorrhage

At present, there are no specific treatment options with proven efficacy for intracerebral hemorrhage. Trials of recombinant factor VII⁹⁹ and neuroprotective agents in intracerebral hemorrhage have met without success. Surgical intervention for decompression may also be considered in patients with cerebellar hematoma at risk of brainstem herniation.

RECOVERY AND REHABILITATION

Stroke recovery

Most patients who survive a stroke make some functional recovery. Recovery is of two types: intrinsic, which involves a degree of return of neural control, and adaptive, in which alternative strategies are used to overcome disability. Although the exact neural mechanisms underlying stroke recovery are still poorly understood, there is emerging evidence that the plasticity of the adult brain may play a role. It is postulated that recovery from brain injury occurs because of restoration of function in damaged neural structures (restoration), and by the development of new pathways in the unaffected areas of brain, which take over the lost function (substitution).¹⁰⁰ The process of reorganization of neural activity has been demonstrated in stroke patients.¹⁰¹ It is now believed that there are multiple motor circuits in the brain that serve similar functions. Conventional pathways dominate in healthy subjects and inhibit the activity of alternative pathways in other areas of the brain. Disruption of traditional pathways in cerebral ischemia reduces or eliminates the inhibition normally exerted by these pathways and allows activation of alternate pathways in the premotor areas of the affected side and primary motor areas on the unaffected side. Hence, the paradigm for function has

shifted from strict cerebral localization to that of interactive functioning of brain networks. It is conceivable that interventions in rehabilitation may act by modifying the process of reorganization and recovery in stroke patients. With the advent of neuroimaging techniques such as functional magnetic resonance imaging (fMRI) and transcranial magnetic stimulation (TMS), there has been considerable recent interest in the study of neural activation that may be facilitated by sensory stimulation,¹⁰² repetitive movement of the affected limbs,¹⁰³ or the use of drugs which modify neurotransmitter release.¹⁰⁴

The highest rate of recovery usually occurs in the first few weeks after stroke, with lesser amounts occurring over the next 12 months.¹⁰⁵ Measurable recovery seldom occurs after 12 months, although there are the occasional exceptions to this rule. The degree of recovery depends largely on the severity of the initial deficit, with the likelihood of complete recovery lower in those with severe initial deficit. There is also considerable variation in rates or patterns of recovery between patients and it is often difficult to make predictions of recovery in individual patients except those with very mild stroke. Recovery may be affected adversely by the development of stroke-related complications and importantly by the presence of comorbidity and frailty.¹⁰⁶

Rates of recovery may vary for different types of impairments. Some problems such as homonymous hemianopia, dysphagia, lower extremity weakness, and sitting balance may resolve more rapidly in stroke survivors, whereas arm paralysis, perceptual disorders, and language impairment recover more slowly and less completely. Although minor cognitive deficits have the potential to recover, most patients with poststroke cognitive impairment early after stroke will have some persisting deficit at 2 years.¹⁰⁷ Urinary incontinence also tends to persist in many stroke survivors, with the Erlangen Stroke Project reporting a prevalence of 53% immediately after stroke decreasing to 32% at 1 year,¹⁰⁸ whereas the South London Stroke Register reported an initial prevalence of approximately 48%, which decreased to 10% at 2 years.¹⁰⁹

Overall functional recovery, which is probably more relevant than the recovery of individual impairments, depends on the level of initial disability and the level of prestroke disability. Mild to moderately disabled patients with little preexisting disability usually make good improvements in the first 3 months. The older, more frail patient with significant preexisting physical or cognitive disability, on the other hand, faces an uphill task in functional improvement. Anecdotally, some patients with severe stroke attain relative independence after a prolonged rehabilitation, some continuing to show functional improvement beyond 3 months.

Rehabilitation

There is mounting evidence showing that functional recovery can be influenced by coordinated rehabilitation.¹¹⁰ Rehabilitation techniques in stroke are now being examined in light of their potential ability to modify brain plasticity and thus influence recovery.¹¹¹ Rehabilitation is not simply a matter of being treated by a therapist or a group of therapists but involves a whole range of approaches to managing disability provided by a coordinated multidisciplinary team and tailored to restore patients to their fullest possible physical, mental, and social capability.¹¹² It is now recognized that

the best models of rehabilitation may be those that emphasize commencement of active therapy very early after stroke with acute care and rehabilitation being provided in a seamless fashion preferable at the same location.¹¹³ The goals of rehabilitation are not always easy to define because it deals with many aspects of human performance. In general, rehabilitation should aim to maximize patients' role fulfillment and independence in their environment within the limitations imposed by underlying impairment and availability of resources. It should help them to make the best adaptation possible to any difference between the roles desired and the roles achieved following stroke.

According to the revised World Health Organization International Classification of Impairments, Disabilities, and Handicaps, the major areas of concern in rehabilitation are limitation of activity (disability) and restriction of participation (handicap).¹¹⁴ *Disability* is defined as "restriction, or lack of ability, to perform an activity in the manner or within the range considered to be normal." Disability relates to function, and the ability to undertake basic activities of self-care is fundamental to any physical rehabilitation program. *Handicap*, the social consequence of disability, is defined as "limitations faced by stroke patients in fulfilling their normal role in the society." It is not always possible to differentiate handicap from disability, and most pragmatic approaches tend to combine these two dimensions, referring to them as social disability.

Rehabilitation in stroke is essentially a multidisciplinary activity that has been described as a problem-solving process focusing on disability and intended to reduce handicap.¹¹⁴ The basic principles that should be applied throughout rehabilitation of stroke patients are the following: Documentation of impairments, disabilities, and handicaps and, where possible, measuring them using simple, valid scales; maximization of independence and minimization of learned dependency; and a holistic approach to patients, taking into account their physical and psychosocial background, their environment, and their caregivers. It is accepted that goals of rehabilitation vary according to the expectations of the parties involved. The goal of hospitals may be to discharge patients as soon as possible, whereas the goal of patients may be to return to their previous functional status even if this is unattainable. There is good evidence to suggest that early supported discharge works well with regard to patient outcomes including quality of life provided that such a program is well resourced.¹¹⁵ The goal of caregivers may be to minimize the level of input they need to provide even at the cost of institutionalization. Many of the difficulties ultimately faced in managing patients and in evaluating the effectiveness of interventions can be traced back to conflicts between the goals and objectives of different parties.

Studies on specific therapeutic interventions in stroke rehabilitation are limited but growing in number. Techniques that are being investigated for efficacy include device-assisted gait or locomotion training, functional intramuscular stimulation, constraint-induced therapy, mirror therapy, and even transcranial magnetic stimulation.^{116–120} There is, however, no evidence supporting any specific treatment technique for stroke patients. A pragmatic functional approach individualized for each patient's needs is recommended.

The amount of formal therapy received by stroke patients may be small even in organized stroke units with only 13%

of patients shown to receive mobility-improving therapy within the first 14 days after stroke in a recent study.¹²¹ There have been many misconceptions about the risks of early mobilization of stroke patients, but consensus is emerging that immobilization is more likely to be harmful.^{122,123} Evidence may soon become available about the efficacy of early mobilization (within 24 hours) after stroke from randomized controlled trials.¹²³ The effects of intensive therapeutic input on recovery from stroke have been investigated in well-designed controlled studies.^{124–126} These investigations have shown a small but definite relationship between the amount of therapy given and the amount of improvement in functional ability, which is independent of the nonspecific effects of changes in attention or adaptive mechanisms.

The impact of premonitory cognitive status, age, and frailty are also important issues to consider in the selection of patients for rehabilitation. Unless there is clear evidence of severe preexisting cognitive impairment (such as a severe dementia) that may interfere with the process of rehabilitation, there is no good argument to exclude stroke patients from rehabilitation on the grounds of cognition or age alone. In fact, one may argue that such a patient may require more specialized attention in a rehabilitation setting to ensure a return to his or her usual living environment.¹²⁷ There are extremely limited data demonstrating the efficacy of rehabilitation following stroke in the oldest old (85+ years) and it may be that the effort invested in rehabilitating patients in this group is no less justified than in younger elderly patients.¹²⁸ Specific clinical issues requiring medical input in a rehabilitation setting include poststroke spasticity, neuropathic pain, shoulder pain, incontinence, and depression, all of which can significantly impede recovery and need specialized medical therapies such as botulinum toxin, neural pain modulators, continence management, and antidepressant therapy.

SECONDARY STROKE PREVENTION

Secondary prevention refers to the treatments that may be used to prevent a recurrent stroke, or a first stroke after a TIA. There have been significant advances in secondary prevention in the last decade with the conduct of several large scale randomized controlled trials.

Antiplatelet therapy

These form the cornerstone for secondary stroke prevention. There are a variety of antiplatelet drugs on the market. These range from prostaglandin inhibitors such as aspirin, to adenosine diphosphate inhibitors such as clopidogrel. Older adenosine diphosphate inhibitors such as ticlopidine are now superseded by clopidogrel. Aspirin appears to be the drug of choice for arterial noncardioembolic ischemic stroke and is as effective as warfarin in this setting.^{129,130} A collaborative meta-analysis showed that aspirin was effective even at the low dose of 75 mg/day with recommendation that the loading dose be at least 150 mg.¹³¹ The addition of dipyridamole (200 mg twice a day) to aspirin provided an additional stroke reduction of 1% per year over aspirin alone.^{132,133} Contrary to the theoretical concern regarding the potential for dipyridamole to exacerbate ischemic heart disease, this combination also reduced the risk of nonfatal myocardial infarction and vascular death.¹³⁴

The drawback to the aspirin-dipyridamole combination is that up to 18% of people may drop out of therapy because of vasodilatory headache caused by dipyridamole.^{132,133} Very recently, it was also shown that the combination of aspirin-dipyridamole appears to have equivalent efficacy to clopidogrel alone.¹³⁵ Although the combination of aspirin and clopidogrel provides additive benefit in acute coronary syndrome, this combination does not offer better stroke protection than clopidogrel alone.¹³⁶

Warfarin

Warfarin has clearly been shown to be effective for secondary prevention in patients with atrial fibrillation (AF)¹³⁷ but not in cases of intracranial artery stenosis.¹³⁸ The optimal INR for stroke prevention is 2–3.¹³⁹ The annual risk of intracranial hemorrhage associated with warfarin is relatively low at approximately 2%.¹⁴⁰ The risk of hemorrhage with warfarin is higher in patients with renal or liver impairment or history of bleeding. The risk of falling is often cited as the reason for not starting warfarin in very elderly people, although the benefits of stroke prevention in this high risk group may still outweigh the risk of bleeding in older patients.¹⁴¹ Recent application of a computerized clinical decision-making tool was successful in identifying nonvalvular AF patients who were potentially at a higher risk of hemorrhagic complications.¹⁴² Such tools if validated in different settings may become extremely useful in secondary prevention of stroke related to AF. Aspirin is mildly effective in preventing stroke in people with AF compared with warfarin,¹⁴⁰ and should be considered when warfarin is contraindicated. Following intracerebral hemorrhage, it is relatively safe to discontinue warfarin for approximately 1 week even in patients at high risk of embolism (prosthetic heart valve). Warfarin's effect needs to be reversed aggressively with fresh frozen plasma, vitamin K, and prothrombinex. Reversal of warfarin is always necessary in intracerebral hemorrhage but may not be necessary in patients with hemorrhagic infarct.

Blood pressure reduction

Blood pressure reduction has assumed great importance in secondary stroke prevention. The paradigm for the management of blood pressure has changed with a trial involving the combination of the Angiotensin Converting Enzyme Inhibitor (ACE-I) perindopril and the diuretic indapamide, showing a significant reduction in the risk of stroke among both hypertensive and nonhypertensive individuals with a history of stroke or transient ischemic attack.¹⁴³ In this study the combination therapy arm produced larger blood pressure reductions and larger risk reductions than did single drug therapy with perindopril alone. This finding regarding the benefit of perindopril with or without indapamide has been confirmed in patients over the age of 80 years,¹⁴⁴ suggesting that there needs to be a very good reason why older, more frail people should not be given blood pressure lowering therapy for stroke prevention. There is no evidence that the effect is limited to the angiotensin-converting enzyme inhibitor with a recent trial showing that angiotensin receptor blocker (telmisartan) is as effective.¹⁴⁵ In this study, telmisartan had a higher incidence of symptomatic hypotension but lower risk of angioedema and cough compared with the ACE-I ramipril.¹⁴⁵ Overall, successful secondary

prevention hinges heavily on blood pressure control, whether it is achieved with lifestyle modifications or medication, with the latter often being required.

Lipid lowering agents

A role for hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins) in lipid lowering and stroke prevention was initially suggested by the observed risk reduction for ischemic stroke in trials involving simvastatin (40 mg) and pravastatin (40 mg) for prevention of coronary heart disease. Recently, the first trial specifically examining their effects in stroke prevention showed that atorvastatin (80 mg) provided an absolute risk reduction of approximately 2% over 5 years.⁷³ Despite this trial focusing on patients 75 years or less, data from secondary prevention trials involving statins in heart disease suggest a benefit in patients above the age of 80.¹⁴⁶ There is a small increase in the risk of hemorrhagic stroke with statins that is outweighed by the overall benefit, and this increased risk is associated with having an initial hemorrhagic stroke, being older, having poorly controlled blood pressure, but not with low cholesterol levels.¹⁴⁷ The use of statins for stroke prevention in the very old must be cautious and preferably at lower doses. The mechanism by which statins provide benefit against stroke is likely multifactorial, involving both the low-density lipoprotein cholesterol-lowering effect with stabilization of vulnerable plaque, and other effects such as improvement of endothelial function, increased nitric oxide bioavailability, antioxidant properties, and inhibition of inflammatory responses.¹⁴⁸

Carotid endarterectomy

Carotid endarterectomy is one of the most effective secondary measures for the prevention of recurrent ischemic stroke in patients with 70% to 99% symptomatic internal carotid artery stenosis,^{149,150} with seven patients needing to be treated to prevent one ischemic stroke. In a pooled analysis of large trials, the benefit of carotid endarterectomy appeared to be magnified in elderly patients given their greater overall risk of stroke.¹⁵¹ There is no justification for withholding carotid endarterectomy for patients older than 75 years who are deemed medically fit to undergo surgery. The benefit is likely to be greatest in this group because of their high risk of stroke on medical treatment, although it should be noted that the trials included very few patients older than 80 years. Approximately 5 patients aged 75 years or older with symptomatic internal carotid stenosis need to be treated to prevent one ipsilateral stroke over 5 years.

Endovascular therapy

The role of endovascular therapy (angioplasty and stenting) of the carotid artery is evolving. Two European trials in patients with symptomatic carotid stenosis suggested that angioplasty and stenting were less effective than endarterectomy.^{152,153} By contrast, a U.S. trial consisting of symptomatic and asymptomatic patients has shown equivalence between the two modes of therapy.¹⁵⁴ There is evidence suggesting that perioperative risk of stroke and other complications such as restenosis are higher with angioplasty and stenting than endarterectomy.¹⁵⁵ Such endovascular procedures may have to be used with extreme caution and not preferred as first line treatment for symptomatic carotid stenosis.

Patent foramen ovale (PFO) has been linked with stroke in the young rather than elderly patient but is present in 15% to 20% of normal individuals. In a randomized trial, treatment with warfarin did not confer an advantage over aspirin for these patients.⁶⁹ At present, randomized clinical trial evidence demonstrating benefit for endovascular closure of a PFO is not yet available.

TIA clinics

TIA clinics are a relatively new advance in secondary stroke prevention. These are clinics that are aimed to attend quickly to patients having a TIA with the knowledge that the risk of stroke is highest in the first few days after a TIA.¹⁵⁶ Recent studies have shown that such urgent evaluation of patients with TIA or minor stroke leads to a dramatic reduction in the risk of recurrent ischemic event at 90 days by up to 80%.^{156,157} The principal focus of the clinic would be to assess and institute appropriate secondary prevention strategies, such as antiplatelet therapy, blood pressure control, and lipid lowering, keeping in mind that patients with atrial fibrillation and carotid stenosis may need special and rapid attention. Such clinics, if well organized, may have the potential to prevent unnecessary admission of TIA patients to the hospital.

PRIMARY STROKE PREVENTION

Primary prevention refers to efforts to prevent a first stroke or a TIA and may adopt the population or mass approach, or a high-risk individual approach. There have been several proposed population primary prevention strategies to reduce hypertension, which in turn will reduce the incidence of stroke. The relationship between excessive salt intake and the risk of hypertension has been firmly established.¹⁵⁸ Reducing salt intake by half would not only reduce blood pressure in hypertensive and normotensive individuals,¹⁵⁹ but is also estimated to reduce stroke incidence by 22%.¹⁵⁸ Eighty percent of the salt we consume is hidden within processed food, thus reducing the amount of salt added to food during manufacture would have an enormous public health impact. Reductions in salt content of processed food by 10% to 20%, an amount imperceptible to salt taste receptors, could result in reductions in daily salt intake of about 6 grams. This could lead to a significant drop in blood pressure levels in the population without requiring any lifestyle changes—the latter generally being associated with poor compliance. The major difficulty, however, lies in moving governments to legislate such drastic changes within the food industry. Other potentially cost-effective population-wide prevention strategies may be tobacco control via the regulation of tobacco accessibility and taxation, and promotion of healthy diets and exercise.

The high-risk individual approach involves identifying and treating those with hypertension, atrial fibrillation, and diabetes mellitus, these disorders potentially contributing to a large proportion of population-attributable risk of stroke, given their high prevalence and strong association with stroke risk. A meta-analysis conducted by the Blood Pressure Lowering Treatment Trialists' Collaboration demonstrated that treatment with antihypertensive medication reduces the incidence of stroke by 28% to 38%, depending on the medication used.¹⁶⁰ The efficacy of warfarin for stroke prevention

in atrial fibrillation is well established.¹⁶¹ The combination of aspirin and clopidogrel is inferior to warfarin in reducing stroke recurrence and carries the same risk of intracranial hemorrhage.¹⁶² A large trial of intensive blood sugar lowering in type 2 diabetes mellitus was not associated with a reduction of macrovascular outcomes, and hence its role in primary stroke prevention is uncertain at the present time.¹⁶³

ORGANIZATION OF STROKE SERVICES

Given the rapid advances in stroke care in the past decade, it is now recognized that there needs to be a well-organized network of stroke services to deliver such care effectively to stroke patients, and this often requires integration of hospital and community services. There is much debate about how such services must be organized within hospitals, and it is clear that different systems will operate in different countries and regions.¹⁶⁴ Most evidence for benefit from organized stroke units in hospitals is seen for comprehensive stroke units, which are those combining acute care and rehabilitation.¹⁶⁵ Pure rehabilitation units also confer some benefit for patients, whereas the evidence is weakest for mobile stroke teams roving within general wards and for purely acute units.¹⁶⁵ The core requirements of a comprehensive stroke unit are a well-staffed multidisciplinary team of physicians, nurses, and therapists whose work is coordinated through regular meetings, and the presence of protocol-guided care pathways.¹⁶⁵ The physician who is associated with a stroke unit must have a significant passion for stroke care. In addition to neurologists, geriatricians, internists, and rehabilitation specialists may each have the ability to

manage stroke units provided they have appropriate training in acute and subacute care. Nursing, in particular, is an integral part of any stroke service, particularly given the constancy of nursing provision in any phase of stroke care. A key person within a stroke service is the "stroke nurse manager," whose role involves acute triaging and delivery of acute treatment; coordination of care on the ward; liaison between the stroke team, patients, and their caregivers; and external organizations involved in stroke care. There needs to be greater emphasis on improving communication with caregivers and closely involving them in the care of patients, particularly in ensuring adequate support for them on discharge. The development of community-based support networks and rehabilitation services (home-based or outpatient) are important to develop in the context of an integrated stroke care service. Such community services will enable early supported discharge from hospitals and ongoing support for patients after leaving the hospital. Obviously, key factors in developing such services include cost-effectiveness analyses and regional resources and needs. Such systems have been established and tested in developed nations, but the challenge of providing stroke care in developing nations remain enormous. In populous developing nations such as China and India, urban hospital stroke care is emerging, but the vast majority of the populations in these countries may need to be serviced by region-specific modifications of community-based stroke care.

Disorders of the Autonomic Nervous System

Horacio Kaufmann
Italo Biaggioni

We will focus on the consequences of aging on autonomic cardiovascular control. The neurobiology of aging and the effects of aging on gastrointestinal and urinary tract function are detailed in other sections in this book.

We will first provide a brief summary of autonomic pathways involved in cardiovascular control, and the methods used to assess their function. We will then review the effect of aging on the different components involved in autonomic cardiovascular control, namely, alterations in afferent and efferent function, and in end-organ responsiveness. We will then discuss the integrated effect of these changes on the response of elderly people to daily stresses of life (i.e., response to upright posture and to food ingestion). We conclude by discussing pathologic disorders of the autonomic nervous system that are present clinically in elderly people, such as orthostatic hypotension, syncope, pure autonomic failure, and multiple system atrophy.

BASIC CONCEPTS OF AUTONOMIC PHYSIOLOGY

Autonomic pathways

Autonomic regulation depends on three main components. Afferent fibers continuously sense changes in blood pressure (baroreceptors), blood content of oxygen, and other chemical signals (chemoreceptors), pain (sensory afferents), and cortical stimulation. These signals are integrated in brainstem centers that ultimately modulate sympathetic and parasympathetic outflows, which are transmitted to target organs via efferent fibers. The baroreflex provides an example of these pathways (Figure 63-1). This is a redundant system, with input from multiple independent afferent pathways that ensure maintenance of cardiovascular regulation even after partial damage.¹ The afferent limb of this reflex includes pressure-sensitive receptors located in the walls of cardiopulmonary veins, the right atrium, and within almost every large artery of the neck and thorax, but particularly within the carotid and aortic arteries. Stimulated by stretch, these low- and high-pressure baroreceptors monitor venous and arterial pressures, respectively, and relay that information to brainstem centers. Information both from the venous and the aortic arch baroreceptors is carried centrally via fibers that course within the vagus nerve (X cranial nerve). Carotid sinus baroreceptor nerve activity is relayed centrally by passage first through the carotid sinus (Hering's) nerve, then through the glossopharyngeal nerve (IX cranial nerve) before arriving at the same brainstem centers.

Afferent fibers from these multiple baroreceptors have their first synapse in the nucleus tractus solitarius (NTS) of the medulla oblongata.² This nucleus inhibits sympathetic tone and is crucial to baroreflex function. Its destruction (e.g., by experimental lesion³ or neurologic damage)⁴ leads to loss of baroreflex function, resulting in episodes of hypertension and tachycardia.⁵ In addition to the afferent input arising from the baroreceptors, the NTS also receives modulating

input from many other cardiovascular brain centers, such as the area postrema. The NTS provides excitatory inputs to the caudal ventrolateral medulla (CVLM), which in turn inhibits the rostral ventrolateral medulla (RVLM),^{6,7} where the pacemaker neurons that originate sympathetic tone are believed to be located.⁸ RVLM neurons project to the preganglionic sympathetic neurons in the intermediolateral column of the spinal cord that send fibers outside the CNS. Parasympathetic activity is also modulated by the NTS, through projections to preganglionic parasympathetic neurons in the nucleus ambiguus and the motor nucleus of the vagus (Figure 63-1).

The importance of autonomic mechanisms in the regulation of blood pressure is most evident when they fail. Damage of baroreflex afferents (e.g., as consequence of radiation or surgery, leads to labile blood pressure that is very difficult to control).⁵ At the other extreme, degeneration of central or efferent structures, as seen in patients with primary autonomic failure, leads to disabling orthostatic hypotension.⁹ In the most severe cases, patients are unable to stand but for few seconds before profound orthostatic hypotension and loss of consciousness ensues. These disorders are described later in this chapter.

Methods used to test autonomic function

POSTURE (ORTHOSTATIC) TEST

Perhaps the most informative and simplest autonomic evaluation is the posture test. The patient's blood pressure and heart rate are measured after 5 to 10 minutes in the supine position, and repeated after the subject stands motionless for 3 to 5 minutes. There is some value in repeating measurements at each of these time points, but just one measurement is informative. Virtually all patients with severe autonomic failure will have an immediate fall in blood pressure on standing. Other autonomic conditions associated with delayed orthostatic hypotension require a 30-minute stand test for their diagnosis,¹⁰ but these are usually not associated with widespread autonomic neuropathy. Heart rate is crucial in interpreting blood pressure changes. Patients with severe autonomic failure characteristically have no or little (about 10–15 beats/min) increase in heart rate despite profound orthostatic hypotension. A greater increase in heart rate usually indicates that other conditions (e.g., volume depletion or medications) are contributing to orthostatic hypotension.

NONINVASIVE AUTONOMIC TESTS

Heart rate responses to deep breathing (i.e., respiratory sinus arrhythmia) and to the Valsalva maneuver are simple yet informative autonomic tests. They require real-time monitoring of heart rate. Respiratory sinus arrhythmia is assessed during controlled breathing at a rate of six deep breaths per minute (Figure 63-2). The sinus arrhythmia ratio is calculated by dividing the longest to the shortest R-R interval. This expiratory/inspiratory (E/I) ratio decreases progressively with age. Subjects younger than 40 usually have a ratio

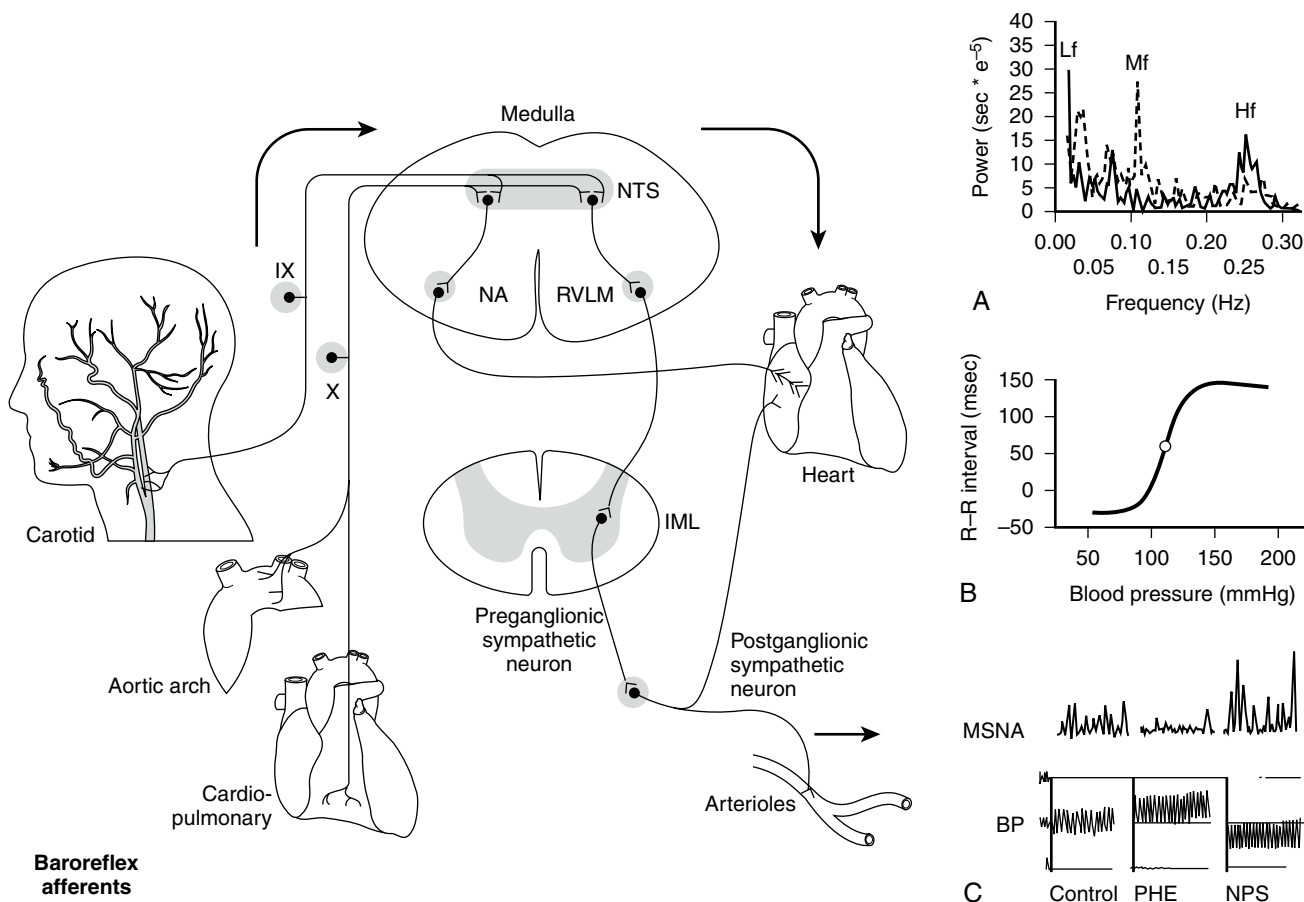

Figure 63-1. Simplified anatomic/functional scheme of baroreflex function. Afferent fibers located in the right atrium and in the cardiopulmonary veins (low-pressure baroreceptors), and in the aortic arch and carotid sinus (high-pressure baroreceptors) are activated by stretch, and relay this information through the vagus (X) or glossopharyngeal (IX) nerves to the nucleus tractus solitarius (NTS) of the brainstem. The NTS provides excitatory inputs to the caudal ventrolateral medulla, which in turn inhibits the rostral ventrolateral medulla (RVLM)^{6,7} (for simplicity the NTS is shown as projecting direct inhibitory pathways to the RVLM), where pacemaker neurons that originate sympathetic tone are believed to be located. These cell bodies send their efferent projections through the intermediolateral column of the spinal cord (IML). Baroreflex function can be simplified as follows: an increase in blood pressure is detected by arterial baroreceptors, which increase their firing into the NTS; activation of the NTS leads to a greater inhibitory output to the RVLM; inhibition of pacemaker cells in the RVLM results in a compensatory reduction in sympathetic tone. Conversely, a decrease in blood pressure results in decreased firing in the NTS, withdrawal of the inhibitory influence of this nuclei on the RVLM, and a compensatory increase in sympathetic tone. Parasympathetic activity is also modulated by the NTS, through projections to the nucleus ambiguus (NA). An increase in blood pressure will lead to activation of the NTS and of the NA, with increased parasympathetic activity. Methods to assess baroreflex function include (A) spectral analysis, by correlating spontaneous changes in blood pressure and heart rate, and (B) by the neck barocuff method. Results obtained by these methods are influenced by afferent baroreceptor input, brainstem pathways, and end-organ responsiveness. Baroreflex modulation of sympathetic activity can be assessed with (C) microelectrode recording of postganglionic efferent sympathetic nerve activity (MSNA). In this example, blood pressure increment with phenylephrine (PHE) produced a baroreflex-mediated decrease in MSNA and blood pressure reduction with nitroprusside (NPS) produces a baroreflex-mediated increase in MSNA.

Figure 63-2. Successive electrocardiographic R-R intervals during paced breathing in a normal subject (left) and in a patient with autonomic failure (right).

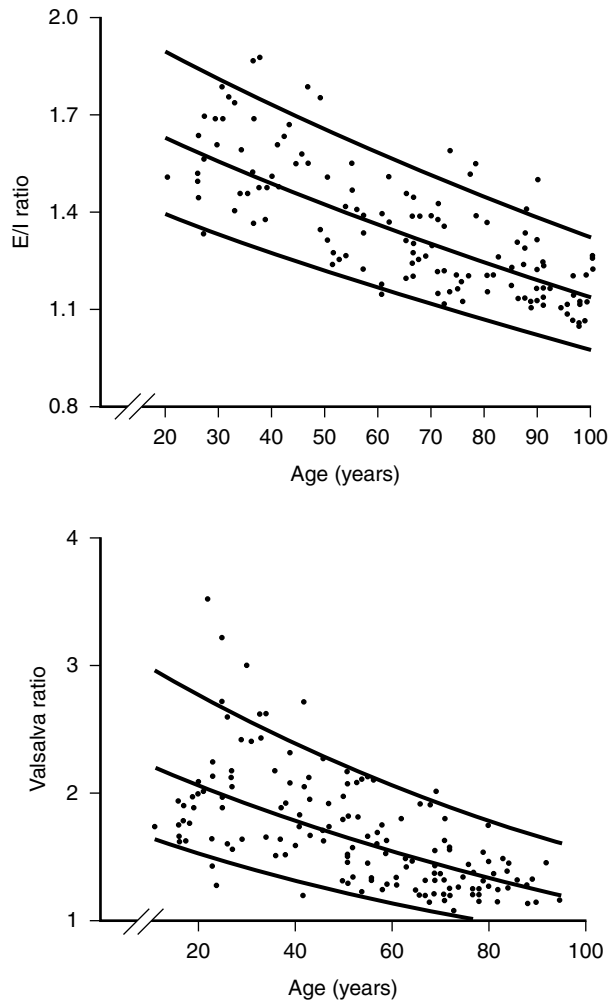

Figure 63-3. (Top) Expiratory/inspiratory (E/I) ratio during paced breathing in normal subjects according to age. Linear regression and confidence limits are shown. (Bottom) Valsalva ratio in normal subjects according to age. Linear regression and confidence limits are shown.

less than 1.2 (Figure 63-3). A Valsalva maneuver is induced by having the subject blow against a 40 mm Hg pressure for 12 seconds. A 5 to 10 cc syringe can be used as a mouthpiece and can be connected to a sphygmomanometer to monitor pressure. A small leak should be introduced into the system to ensure the subject uses thoracic effort. The increase in intrathoracic pressure produces a transient fall in blood pressure with narrowing of pulse pressure during phase II (strain), whereas blood pressure overshoots above baseline values during phase IV (after release) (Figure 63-4). In autonomic failure blood pressure continues to fall during phase II and the normal overshoot is absent during phase IV. Thus appropriate evaluation of the Valsalva response requires continuous recording of blood pressure, which can be accomplished noninvasively with finger plethysmography (Finapres, Portapres) or tonometry of the radial artery (Colin). Even if blood pressure cannot be monitored, however, heart rate responses are useful. The blood pressure changes described previously produce reciprocal baroreflex-mediated changes in heart rate; heart rate increases during the hypotensive phase II of the Valsalva maneuver, and decreases during the blood pressure overshoot of phase IV. The Valsalva ratio is calculated by dividing the fastest heart rate during phase II by the slowest heart rate during phase IV. As with the E/I ratio, the Valsalva ratio decreases with age and results should be interpreted accordingly (see Figure 63-3).

SPECTRAL ANALYSIS OF HEART RATE AND BLOOD PRESSURE

Blood pressure and heart rate are kept within a relatively narrow range because of autonomic baroreflex mechanisms. Within this narrow range, however, blood pressure shows substantial variability. Most of this variability is not random, but follows natural rhythmic patterns, which can be studied using spectral analysis techniques. These patterns are importantly modulated by the respiratory frequency. In particular, respiration frequency influences heart rate variability, and this interaction is under baroreflex control via the vagus

Figure 63-4. Muscle sympathetic nerve activity (MSNA), electrocardiogram (ECG), and blood pressure (FBP) during Valsalva maneuver in a normal subject.

nerves. The “respiratory peak” of heart rate variability, evident in the high-frequency spectrum, can be used to assess cardiac parasympathetic function. Respirations also modulate blood pressure, but this is mediated through mechanical events and does not reflect autonomic mechanisms and is not affected by autonomic blockade.¹¹ In contrast, blood pressure shows a lower frequency rhythm (Mayer waves). This is mediated in part by sympathetic modulation of vascular tone. There is substantial interindividual variability in the spectral analysis of heart rate and blood pressure, making these methods less suitable for the diagnosis of individual patients with less than severe autonomic impairment. Nonetheless, population studies have shown that impaired heart rate variability as shown by spectral analysis of heart rate is an independent predictor of mortality in patients after myocardial infarction, and in patients with diabetes mellitus.

Assessment of baroreflex function

Several methods can be used to quantify the changes in heart rate (or R-R interval) produced by unit change of blood pressure. These methods require the simultaneous monitoring of blood pressure and heart rate. Baroreflex function can be assessed by measuring the reciprocal changes in blood pressure and heart rate that occur spontaneously, or during the phase IV of the Valsalva maneuver. Blood pressure can be increased with phenylephrine or decreased with nitroprusside and the gain of the baroreflex expressed as the change in R-R interval per unit of blood pressure (expressed in msec/mm Hg) during the linear portion of this relationship. Each of these methods provides slightly different normative values of baroreflex gain. It is important to note that changes in blood pressure affect all baroreflex afferents, including carotid sinus and aortic high-pressure receptors and low-pressure receptors located in the venous circulation. The carotid sinus reflex can be selectively investigated by producing positive and negative pressure to the neck, to simulate decreases and increases in intracarotid pressure, respectively. All of the methods described above rely on instantaneous changes in heart rate, which depend exclusively on the parasympathetic limb of the baroreflex. The sympathetic limb of the baroreflex can be assessed by relating changes in blood pressure to reciprocal changes in muscle sympathetic nerve activity (see later discussion).

BIOCHEMICAL ASSESSMENT OF SYMPATHETIC FUNCTION

Plasma norepinephrine provides a useful measure of sympathetic activity. It is particularly useful when measuring acute changes to standard stimuli. For example, upright posture induces a doubling of plasma norepinephrine. Patients with autonomic impairment have a blunted response. Basal norepinephrine, however, is different depending on the underlying pathology. It is low in patients with PAF and normal or slightly decreased in patients with MSA (see later discussion). In contrast, patients with volume depletion will have enhanced norepinephrine response to upright posture.

ESTIMATION OF NOREPINEPHRINE SPILLOVER

Despite the usefulness of plasma norepinephrine measurements, it is noteworthy that only a small percentage of the norepinephrine released by noradrenergic nerves actually

reaches the circulation. Most of it is taken back into nerve terminals by the norepinephrine transporter (i.e., reuptake) or is metabolized. Norepinephrine clearance can be measured by infusing a known amount of titrated norepinephrine. During steady-state infusion, it is assumed that clearance of titrated norepinephrine reflects clearance of endogenous norepinephrine. Once clearance is calculated, the norepinephrine appearance rate into the circulation (spillover) can be estimated. A comprehensive review of the advantages and limitations of this technique is beyond the scope of this chapter and can be found elsewhere.¹²

MUSCLE SYMPATHETIC NERVE ACTIVITY

Nerve activity can be recorded directly by introducing a recording electrode into an accessible peripheral nerve. Afferent and efferent fibers can be recorded using this technique. Sympathetic efferent activity can be selectively recorded by careful placement of the electrode. The peroneal nerve at the level of the knee is commonly used to measure postganglionic sympathetic nerve activity. Although there is considerable interindividual variability in muscle sympathetic nerve activity, baseline recordings expressed as sympathetic bursts per minute are highly reproducible in a single individual between different recording sites, and when measured on different occasions. Muscle sympathetic nerve activity effectively monitors central sympathetic outflow and is tightly modulated by the baroreflex. Stimuli that increase blood pressure by activating central sympathetic outflow will be reflected as an increase in muscle sympathetic nerve activity. Conversely, stimuli that increase blood pressure directly (e.g., an injection of phenylephrine), will produce baroreflex-modulated suppression of muscle sympathetic nerve activity. This recording is also exquisitely sensitive to sympathetic withdrawal. For example, sympathetic activity disappears during neurogenic syncope.¹³

EFFECT OF AGING ON THE DIFFERENT COMPONENTS OF AUTONOMIC CARDIOVASCULAR CONTROL

Baroreflex function

There is a progressive decline in baroreflex sensitivity with aging¹⁴ due to both vascular and neural deficits. Cardiovascular baroreflex gain (i.e., the reciprocal heart rate changes produced by changes in arterial pressure) declines with age, but the ability of the cardiopulmonary baroreflex to inhibit sympathetic nerve traffic has been reported to be well preserved with age in healthy adults. Hence, vagal, but not sympathetic baroreflex gains vary inversely with subjects' ages and their baseline arterial pressures. There is no correlation between sympathetic and vagal baroreflex gains.¹⁵

Cardiac parasympathetic function

Cardiac vagal innervation decreases with age as clearly shown by a progressive reduction in respiratory sinus arrhythmia (see Figure 63-3). Experimental evidence suggests that long-term physical activity attenuates the decline in cardiovagal baroreflex gain by maintaining neural vagal control,¹⁶ but among older adults, the level of fitness does not prevent the decrease in cardiac vagal function, suggesting that the age decline in cardiac vagal function cannot be completely prevented by physical activity.¹⁷

Systemic sympathetic function

Muscle sympathetic nerve activity (MSNA) increases progressively with age likely because of increased central nervous system drive (Figure 63-5). Sympathetic nerve traffic increases in a region-specific manner; however, outflow to skeletal muscle and the gut increases, but not to the kidney.¹⁸ The increase in central sympathetic outflow results in higher levels of plasma norepinephrine with age, but reduced norepinephrine clearance appears to play a role as well.^{19,20} It is suggested that age-related elevations in whole-body and abdominal adiposity can explain the increase in basal MSNA with age in healthy humans.²¹ The relation between body fat and MSNA is observed in both young and older populations.²² Tanaka et al²¹ showed that although body mass index (BMI) was similar in groups of younger and older subjects, both total body fatness and abdominal adiposity were greater in the older subjects and were directly related to baseline levels of MSNA. Preliminary data²³ indicate that circulating concentrations of leptin are related to both adiposity and MSNA. Thus age-associated elevations in total and abdominal adiposity may be linked to increases in MSNA, at least in part, via elevations in leptin levels.¹⁸ In contrast to sympathetic neuronal activity, adrenaline secretion from the adrenal medulla is greatly reduced with age, and adrenaline release in response to acute stress is attenuated in older men. Plasma adrenaline concentration remains normal, however, because of reduced plasma clearance.

End-organ responsiveness

Despite the number of β -adrenergic receptors in lymphocytes being unaltered with age²⁴ and higher neurotransmitter levels, β -adrenergic responses to norepinephrine are blunted with progressive aging, probably because of β -adrenergic receptor downregulation in response to higher circulating levels of norepinephrine and a defect in G-protein receptor complexes and reduced adenyl cyclase activity.^{25,26} Depressed β_1 responses lead to impaired cardioacceleration and reduced cardiac contractility. Reduced β_2 responses are manifested by increased vascular tone because α_1 vasoconstriction ability remains unchanged. The combination of age-related vascular stiffening and depressed β -adrenergic function result in reduced arterial baroreflex sensitivity²⁷ in elderly subjects.^{28–30} This reduces cardioacceleration during hypotension.³¹ Reduced postural cardioacceleration, and decreased baroreceptor gain with age, increases the risk for orthostatic hypotension in elderly people.^{32,33} Blood pressure in older subjects is sustained by increased peripheral vascular tone, despite depressed cardioacceleration. Due to a higher reliance on vascular resistance, dehydration and vasodilator medications pose a high risk for hypotension and syncope in older subjects. On the other hand, vasovagal syncope is reportedly less frequent in elderly subjects.³⁴ Postjunctional α -mediated vasoconstriction is also impaired in older adults.³⁵

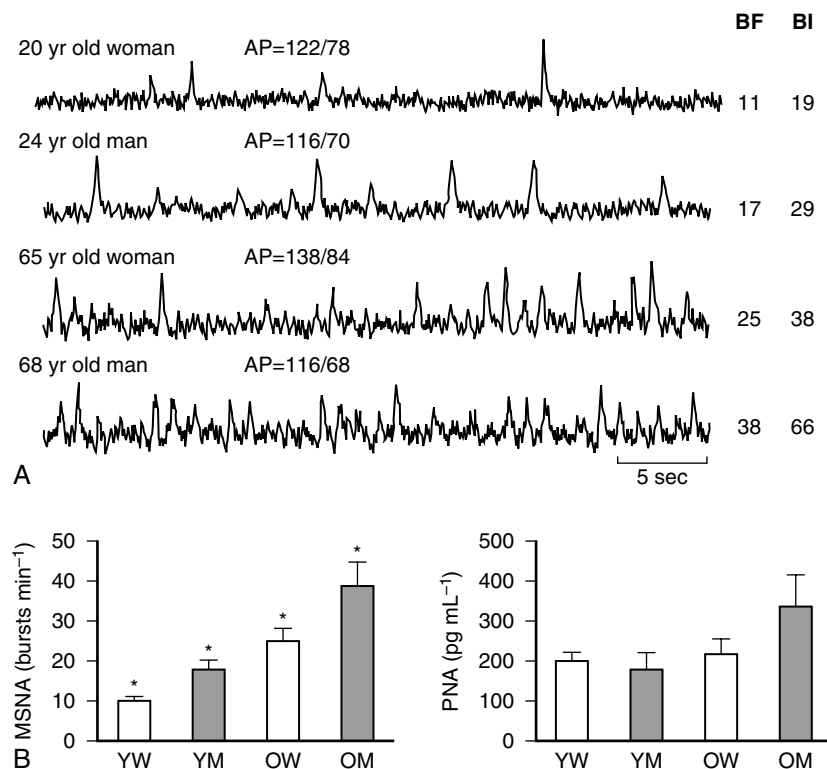

Figure 63-5. Age-associated increases in muscle sympathetic nerve activity. (A) Muscle sympathetic nerve activity (MSNA) from four healthy adult humans under supine resting conditions (top to bottom): young female, young male, older female, older male. MSNA burst frequency (BF; bursts min⁻¹) and burst incidence (BI; bursts (100 heart beats)⁻¹) are higher in the neurograms of the older adults in both sexes. However, the female subjects demonstrate lower MSNA than the males at each age. AP, arterial blood pressure. (B) Mean \pm SEM; values for MSNA in four groups of subjects: young women (YW), young men (YM), older women (OW), and older men (OM). MSNA was at least twice as great in the older compared with the young subjects of the same sex. At each age, however, MSNA was significantly lower in the women. These age and sex differences in MSNA were not reflected in the corresponding antecubital venous plasma noradrenaline concentrations. PNA, plasma noradrenaline concentration; *P < 0.05 versus all other groups. (Reproduced from Seals and Esler.¹⁸)

Vascular changes

Aging stiffens blood vessels³⁶ and alters vasomotor function. In elderly subjects, coronary vasodilation capacity is reduced because of reduced nitric oxide release by the senescent endothelium. Conversely, endothelin release by the endothelium is increased in elderly people, promoting vasoconstriction.³⁷ These alterations increase susceptibility to myocardial ischemia, particularly during increased demand stresses such as tachyarrhythmias³⁸ and may also impair cerebral autoregulation, increasing susceptibility to syncope. Other age-dependent cardiovascular alterations that may increase predisposition to syncope are increased left ventricular afterload, and myocyte hypertrophy. These alterations lead to impaired diastolic filling and chronic ischemia that may predispose subjects to cardiac arrhythmias and decrease ventricular volume that may manifest as syncope. Decreased preload volume precipitated by vasodilators, dehydration, or blood pooling can dramatically reduce cardiac output and precipitate syncope. Susceptibility to atrial fibrillation increases with age because of reductions in pacemaker cells, progressive fibrosis of the cardiac conduction system, and concomitant cardiovascular diseases that alter atrial morphology. In older patients, impaired diastolic filling and a reduction of up to 50% in cardiac output may develop during atrial fibrillation and lead to syncope.

Neuroendocrine changes

Plasma renin and aldosterone levels fall with age^{39,40} and atrial natriuretic peptide increases fivefold to ninefold.⁴¹ The vasopressin response to hypotension may also be reduced.⁴² These changes make sodium and water conservation less effective and intravascular volume depletion more frequent, thus increasing the tendency for syncope. In addition, many elderly people have an impaired thirst response to increases in osmolality and do not consume sufficient fluids to prevent hypovolemia.

EFFECT OF AGING ON AUTONOMIC RESPONSE TO STRESS

The most frequent autonomic stress is the cardiovascular adaptation to upright posture and other physiologically induced changes in intravascular volume. Vascular and neurogenic dysfunction, and a host of medications, can cause orthostatic hypotension in the elderly. In the Cardiovascular Health study,⁴³ the prevalence of orthostatic hypotension was 18% in subjects age 65 years or older, although only 2% of the subjects reported dizziness with standing. There was a modest association with systolic hypertension when supine, carotid stenosis greater than 50%, and with the use of oral hypoglycemic agents, but only a weak association with the use of β -blockers and no association with other antihypertensive drugs. In other reports, however, as expected, the use of antihypertensive medications was significantly related to postural hypotension in elderly people⁴⁴ and discontinuing antihypertensive medications led to an improvement of orthostatic hypotension.

Orthostatic hypotension

Elderly people have impaired defenses against the fluid shifts that normally accompany upright posture. Their threshold to develop symptomatic orthostatic hypotension is, therefore,

lower compared with younger subjects. A variety of symptoms develop with a reduction in blood flow to the brain. Typically, patients will complain of visual disturbances (e.g., blurring, tunneling, or darkening of vision), dizziness, light-headedness, giddiness, feeling faint, and a dull neck and shoulder ache (coat hanger pain). When orthostatic hypotension is pronounced and cerebral blood flow decreases below a critical level (approximately 25 mL/min per 100 grams), syncope (i.e., loss of consciousness) occurs. A decrease in baroreceptor sensitivity is probably involved in the mild, frequent postural hypotension seen in elderly people. One study, for example, showed a diminished response to tilt (a baroreceptor-mediated response) but not to non-baroreceptor-mediated stimuli, such as the cold pressor test or isometric exercise.⁴⁵ The reduced baroreceptor response in elderly people (when compared with younger controls) was seen in both hypertensive and normotensive subjects. Insults that would be compensated for in the young may induce symptomatic hypotension in elderly people. For example, drug-induced orthostatic hypotension is the cause of recurrent dizzy spells or syncope in 12% to 15% of elderly patients and should always be suspected.⁴⁶ Diuretics, calcium antagonists, angiotensin-converting enzyme (ACE) inhibitors, and nitrates are frequently prescribed in elderly patients for the management of hypertension, congestive heart failure, and ischemic heart disease. Other pharmacologic agents frequently associated with orthostatic hypotension include phenothiazines, antidepressants, sedatives, and narcotics. Similarly, prolonged bed rest is frequent in elderly people and an important cause of cardiovascular deconditioning. Several mechanisms contribute to decreased orthostatic tolerance and syncope after prolonged bed rest.⁴⁷ Bed rest reduces extracellular fluid volume, and the skeletal muscle deconditioning impairs the lower limb muscle pump that facilitates venous return in the upright posture. Under normal conditions, important mechanical adjustments to counteract orthostatic pooling of the blood are the muscle and respiratory pumps. Skeletal muscle tone has critical bearing on the volume of blood displaced into the legs when standing. Because intramuscular pressure is decreased after prolonged bed rest, venous pooling augments and venous return to the heart is easily compromised in the standing posture. Thus skeletal muscle atrophy due to prolonged bed rest should be considered as a primary or aggravating factor in any patient with symptoms of light-headedness on standing or documented orthostatic hypotension. If the problem persists after adequate measures are taken, a pathologic impairment of autonomic function should be considered. The occurrence of orthostatic hypotension in elderly people is predictive of mortality.⁴⁸ A study of 3522 Japanese-American men, age 71 to 93 years, found that orthostatic hypotension, defined as a decrease in systolic blood pressure by 20 mm Hg or in diastolic blood pressure by 10 mm Hg, was present in 7% and increased with age.

Postprandial and heat-induced hypotension

A frequent reason for falls and syncope in elderly people is postprandial and heat-induced hypotension.^{49,50} In normal subjects, eating, especially carbohydrates, is accompanied by splanchnic vasodilation, and hot weather produces cutaneous vasodilation but there is little change in arterial pressure because of a compensatory increase in sympathetic vasoconstrictor outflow. In elderly people, however, similarly to what occurs in patients with autonomic failure,

both eating and hot weather significantly lower blood pressure (even in the supine position) because these subjects cannot compensate for the vasodilation with an appropriate increase in sympathetic outflow.^{51,52} Among elderly residents of nursing homes, for example, 24% to 36% have a 20 mm Hg or greater fall in systolic blood pressure within 75 minutes after eating a meal.⁵³ In patients with autonomic failure, postprandial hypotension occurs within 30 minutes of meal ingestion, lasts about 1.5 to 2 hours, and can be profound; blood pressure falls of as much as 50 to 70 mmHg can be observed. This is not only a useful diagnostic test, but it is important to consider the timing of meals when measuring blood pressure in these patients. The initial syncopal episode in patients with chronic autonomic failure is frequently triggered by postprandial hypotension.

DISORDERS OF THE AUTONOMIC NERVOUS SYSTEM IN ELDERLY PEOPLE

Neurally mediated syncopal syndromes

The most frequent cause of hypotension and syncope in otherwise normal subjects is neurally mediated syncope, also referred to as vasovagal, vasodepressor, or reflex syncope. Vasovagal syncope is generally, although not exclusively, observed in patients with no evidence of structural heart disease. Prodromal symptoms include dizziness, blurred vision, nausea, and diaphoresis. This syncope results from acute vasodilation and bradycardia. According to the apparent trigger mechanism, neurally mediated syncope can be classified in several distinct syndromes: emotional faint, carotid sinus syncope, micturition or gastrointestinal syncope, glossopharyngeal or trigeminal syncope, ventricular or neurocardiogenic syncope, and exercise syncope (commonly seen in aortic stenosis).

Neurally mediated syncope is an acute hemodynamic reaction produced by a sudden change in autonomic nervous system activity.⁵⁴ The normal pattern of autonomic outflow that maintains blood pressure in the standing position (increase sympathetic and decreased parasympathetic activity) is acutely reversed. Parasympathetic outflow to the sinus node of the heart increases, producing bradycardia, while sympathetic outflow to blood vessels is reduced, resulting in profound vasodilation.

Classic neurally mediated syncopal syndromes are triggered after compression of carotid baroreceptors in the neck (carotid sinus syncope),¹³ following rapid emptying of a distended bladder (micturition syncope)⁵⁶ or distention of the gastrointestinal tract.⁵⁵ Glossopharyngeal or trigeminal neuralgia can induce syncope by a similar mechanism.^{57,58} In several clinical types of neurally mediated syncope the trigger locus is easily identified, but frequently neurally mediated syncope occurs with no obvious trigger. Although in these cases the source of abnormal afferent signals was believed to be sensory receptors in the heart (i.e., neurocardiogenic or "ventricular" syncope,^{59,60} neurally mediated syncope has recently been induced in patients with heart transplants in whom the ventricle is likely to be denervated.⁶¹ Perhaps sensory receptors in the heart transplant patients are in the arterial tree rather than the ventricle. Similarly, the threshold to trigger neurally mediated syncope can be lowered by a reduction in cardiac preload caused by reduced intravascular volume or excessive venous pooling. Intravascular volume

depletion is common in elderly people because sodium and water conservation are less effective, renin and aldosterone levels fall, atrial natriuretic peptide increases, and the vasopressin response to hypotension may be reduced. Moreover, many elderly subjects have an impaired thirst response to increases in osmolality and are prone to hypovolemia, particularly during febrile illnesses. Excessive venous pooling occurs postprandially in the splanchnic circulation, in the skin during exposure to heat, and in the lower limbs because of muscle atrophy when standing after prolonged periods of bed rest, significantly increasing susceptibility to syncope.

Despite the diverse trigger mechanisms of these different types of neurally mediated syncope, the efferent reflex response is remarkably similar. There is an increase in parasympathetic efferent activity to the sinus node producing bradycardia or even a few seconds of sinus arrest, and a decrease in sympathetic activity responsible, at least in part, for the fall in blood pressure. Bradycardia is not the only or even the main cause of hypotension because neither atropine nor a ventricular pacemaker, which prevent bradycardia, is able to prevent hypotension and syncope. Blood pressure falls mainly because of vasodilation. The mechanisms responsible for vasodilation are not completely understood. Sympathetic efferent activity decreases as shown by studies using microneurography and measurements of circulating norepinephrine.⁶²⁻⁶⁴ Sympathetic "withdrawal," however, seems an incomplete explanation for profound vasodilation. Norepinephrine fails to increase but vasopressin, endothelin-1, and angiotensin II vasoconstrictor peptides, important to maintain blood pressure—which should partially compensate for the fall in sympathetic activity—increase normally during neurally mediated syncope.⁶³ To explain the profound fall in blood pressure, β -mediated vasodilation induced by a rise in adrenaline has been postulated.⁶⁵ Nitric oxide-mediated vasodilation due to a rise in cholinergic activity may be involved.^{54,66} In summary, current understanding of neurally mediated syncope shows inappropriate reduction in sympathetic nerve activity and norepinephrine release. There is an appropriate increase in epinephrine, angiotensin II, vasopressin, and endothelin release, and preliminary evidence suggests that nitric oxide synthesis is activated.

Baroreflex failure

The most common cause of baroreflex failure is iatrogenic damage during neck surgery or radiation therapy of neural structures that carry afferent input from the baroreceptors. Neurologic disorders involving the nucleus tractus solitarius, where these afferents have their first synapse, can also produce baroreflex failure.⁴ In a few cases, the underlying cause is not found. Baroreflex function is impaired in essential hypertension, and may be transmitted as a genetic trait.⁶⁷ It is not clear if these cases of baroreflex failure of unknown etiology represent the extreme of the spectrum of baroreflex impairment in essential hypertension. Baroreflex failure patients have severe labile hypertension and hypotension, often accompanied by headache, diaphoresis, and emotional instability. Wide fluctuations of blood pressure are observed, with systolic blood pressure ranging from 50 to 280 mm Hg. The hypertensive crises are accompanied by tachycardia, and are due to sympathetic surges, as documented by notable increases in plasma norepinephrine. Treatment with sympatholytics may provide some benefit, attenuating

these surges of hypertension and tachycardia, but adequate blood pressure regulation is seldom achieved in the absence of functional baroreflexes. Of interest is that virtually all reported cases are due to bilateral lesions, whereas unilateral lesions are usually clinically silent. This clinical observation underscores the redundancy of the baroreflex system and its importance in cardiovascular regulation.

Chronic autonomic failure

Autonomic failure is divided into primary and secondary forms. Primary autonomic failure is caused by a degenerative process affecting central autonomic pathways (multiple system atrophy [MSA]), or peripheral autonomic neurons (pure autonomic failure). Secondary autonomic failure results from destruction of peripheral autonomic neurons in disorders, such as diabetes, amyloidosis, and other neuropathies, and very rarely by an enzymatic defect in catecholamine synthesis (dopamine β -hydroxylase deficiency). In chronic autonomic failure, orthostatic hypotension and syncope are caused by impaired vasoconstriction and reduced intravascular volume. Vasoconstriction is deficient because of reduced baroreflex-mediated norepinephrine release from postganglionic sympathetic nerve terminals and low circulating levels of angiotensin II caused by impaired secretion of renin.⁶⁸ In patients with autonomic failure and central nervous system dysfunction (i.e., MSA), impaired endothelin and vasopressin release also contribute to deficient vasoconstriction in the standing position.^{63,69}

Primary autonomic failure

Primary autonomic failure includes several neurodegenerative diseases of unknown cause: pure autonomic failure (PAF), in which autonomic impairment (i.e., orthostatic hypotension, bladder, and sexual dysfunction) occurs alone; MSA (also called Shy-Drager syndrome) in which autonomic failure is combined with an extrapyramidal and/or cerebellar movement disorder; Parkinson's disease (PD) in which autonomic failure is combined with an extrapyramidal movement disorder; and diffuse Lewy body disease (DLB), in which autonomic failure is combined with an extrapyramidal movement disorder and severe cognitive impairment.

Recent findings suggest that the same neurodegenerative process underlies MSA, PD, DLB, and PAF, as accumulation of α -synuclein in neuronal cytoplasmic inclusions occurs in all these disorders. A gene encoding for α -synuclein, a neuronal protein of unknown function, is mutated in autosomal dominant PD.⁷⁰ Nonfamilial PD does not have the mutation but α -synuclein accumulates in Lewy bodies in these patients, suggesting a toxic role for aggregates of this protein.⁷¹ Interestingly, cytoplasmic inclusions in MSA also stain positive for α -synuclein,⁷² and Lewy bodies in PAF⁷³ are strongly synuclein positive. Thus abnormalities in the expression or structure of α -synuclein or associated proteins may cause degeneration of catecholamine-containing neurons. α -Synuclein, therefore, is an important component of intraneuronal inclusions in PAF, PD, DLB, and MSA neurodegenerative disorders, all of which affect the autonomic nervous system to a variable degree. Thus these disorders are best classified as α -synucleinopathies. It is not surprising, therefore, that there is overlap in the clinical presentation of these disorders, and the clinical differences may reflect the type of deposits (forming Lewy bodies or not) and the

localization of these deposits within the nervous system. These similarities and differences are discussed later.

PURE AUTONOMIC FAILURE (PAF)

Pure autonomic failure, a disorder first described by Bradbury and Eggleston is a sporadic, adult onset, slowly progressive degeneration of the autonomic nervous system characterized by orthostatic hypotension, bladder and sexual dysfunction, and no other neurologic deficits. Neuropathologic reports of patients with pure autonomic failure showed α -synuclein-positive intraneuronal cytoplasmic inclusions (Lewy bodies) in brainstem nuclei and peripheral autonomic ganglia.^{73,74} These patients are otherwise normal and their prognosis is relatively good. Complications are usually those related to falls and associated disorders.

MULTIPLE SYSTEM ATROPHY

Multiple system atrophy (MSA) is a term introduced by Graham and Oppenheimer in 1969 to describe a group of patients with a disorder of unknown cause affecting extrapyramidal, pyramidal, cerebellar, and autonomic pathways. MSA includes the disorders previously called striatonigral degeneration (SND), sporadic olivopontocerebellar atrophy (OPCA), and the Shy-Drager syndrome (SDS). The discovery in 1989 of glial cytoplasmic inclusions in the brain of patients with MSA provided a pathologic marker for the disorder (akin to Lewy bodies in Parkinson's disease), and confirmed that SND, OPCA, and SDS are the same disease with different clinical expression.⁷⁵ MSA is a progressive neurodegenerative disease of undetermined cause that occurs sporadically and causes parkinsonism, cerebellar, pyramidal autonomic, and urologic dysfunction in any combination.⁷⁶

Because parkinsonism is the most frequent motor deficit in MSA, these patients are regularly misdiagnosed as suffering from PD. Data from PD brain banks showed how frequently the diagnosis of PD was incorrect; up to 10% of these brains turn out to have MSA.⁷⁷ Indeed, even case 1 of James Parkinson's original description (1817), upon which much of his description of paralysis agitans was based, was probably suffering from MSA.

Life expectancy in MSA is shorter than in PD. Ben-Shlomo et al⁷⁸ analyzed 433 published cases of pathologically proven MSA over a 100-year period. Mean age of onset was 54 years (range 31–78) and survival 6 years (range 0.5–24). Survival was unaffected by gender, parkinsonian, or pyramidal features, or whether the patient was classified as SND or OPCA. Survival analysis showed a secular trend from a median duration of 5 years for publications between 1887 and 1970, to 7 years between 1991 and 1994. These figures may be biased toward the worst cases, however.

PARKINSON'S DISEASE

Autonomic dysfunction in Parkinson's disease is rarely as severe as in patients with MSA. There is a subgroup of patients with PD, however, with severe autonomic failure even early in the course of the disease. In most cases, autonomic failure occurs late in the course of the illness and is associated with levodopa and dopamine agonist therapy. In patients with PD, Lewy bodies are found in central and in peripheral autonomic neurons, and autonomic dysfunction in this disorder may be caused by both preganglionic and postganglionic neuronal dysfunction.

DIFFUSE LEWY BODY DISEASE

The clinical presentation of these patients is that of PD, but dementia often dominates the clinical picture. Autonomic failure is frequently associated with this disorder.

DIFFERENTIAL DIAGNOSIS AMONG THE α -SYNUCLEINOPATHIES

During the early stages of MSA, autonomic deficits may be the sole clinical manifestation, thus resembling PAF, but after a variable period of time, sometimes several years, extrapyramidal or cerebellar deficits or both invariably develop. In PD, extrapyramidal motor problems are the presenting feature, but later in the disease process, patients may suffer severe autonomic failure, making the clinical distinction with MSA difficult. Complicating the distinction further, similar to what occurs in PD, some MSA cases display motor deficits before autonomic failure is apparent. In clinical practice all these possibilities lead to two main diagnostic problems. First, it cannot be determined whether a patient who has autonomic failure as the only clinical finding and is believed to have PAF, will develop more widespread nonautonomic neuronal damage and turn out to have MSA. Second, it may be difficult to establish if a patient with autonomic failure and a parkinsonian movement disorder has PD or MSA. Clinically, the classic parkinsonian resting tremor of unilateral predominance is rarely seen in patients with MSA, in whom bradykinesia and rigidity predominate. Also, with rare exceptions, patients with MSA do not respond as well to antiparkinsonian medications and the progression of disease is faster.

In addition to clinical criteria, several tests have been used to distinguish between PD, PAF, and MSA. For example, vasopressin release in response to hypotension and growth hormone secretion in response to clonidine are blunted in MSA but preserved in PAF and PD, because brainstem-hypothalamic-pituitary pathways are only affected in MSA.^{69,79} Plasma norepinephrine concentration while supine is frequently normal in MSA but low in PAF because postganglionic neurons are normal in MSA.⁸⁰ Sphincter EMG shows denervation in MSA because the Onuf's nucleus in segments S2-S4 of the spinal cord is affected in MSA but is normal in PD.⁸¹

There are also important differences in cardiovascular control between MSA, PAF, and PD with autonomic failure. Although patients with MSA have substantial CNS degeneration, the brainstem centers where sympathetic tone originates (most likely the rostroventrolateral medulla) and distal pathways are intact. In support of this postulate, supine plasma norepinephrine is normal or slightly decreased in MSA, but this residual sympathetic activity is not baroreflex-responsive, hence their inability to maintain upright blood pressure. Furthermore, interruption of this residual sympathetic activity with the ganglion blocker trimethaphan leads to a profound decrease in supine blood pressure in MSA. In contrast, supine plasma norepinephrine is very low in PAF and treatment with trimethaphan produces small or no changes in blood pressure, indicating that the lesion is distal to brainstem centers.⁸²

Similarly, sympathetic cardiac innervation is selectively affected in PD and PAF but is intact in MSA. Several studies using single photon emission computed tomography (SPECT) imaging with ¹²³I metaiodobenzylguanidine (MIBG),^{83–85} and positron emission tomography (PET) with 6-[¹⁸F] fluorodopamine⁸⁶ have shown abnormal cardiac sympathetic innervation in patients with PD, while it was normal in patients with

MSA.⁸⁷ This may turn out to be a useful diagnostic test to distinguish between PD and MSA because sympathetic innervation of the heart is impaired in PD, and not in MSA. Moreover, in a patient with presumed PAF, finding normal sympathetic cardiac innervation indicates a likely development of MSA.

AUTONOMIC AND NEUROENDOCRINE TESTING

Numerous studies have described abnormal cardiovascular reflexes in MSA patients. A characteristic of MSA is that afferent and central autonomic and neuroendocrine reflex pathways are selectively affected, whereas postganglionic autonomic fibers are spared.⁶⁹ Baroreceptor-mediated vasopressin release—a measurement of afferent baroreceptor function—is spared in PAF, and presumably in PD, but is blunted in MSA.⁶⁹ Intravenous clonidine, a centrally active α_2 -adrenoceptor agonist that stimulates growth hormone (GH) secretion, also tests the function of hypothalamic-pituitary pathways. Clonidine raised serum growth hormone in patients with PD and patients with pure autonomic failure but did not in those with MSA. This finding suggests that the growth hormone responses to IV clonidine can differentiate MSA from PD and pure autonomic failure, and suggests a specific α_2 -adrenoceptor-hypothalamic deficit in MSA.⁷⁹

Brain imaging

In patients with MSA, magnetic resonance imaging (MRI) of the brain can frequently detect abnormalities of striatum, cerebellum, and brainstem.^{88–92} Striatal abnormalities in MSA include putaminal atrophy and putaminal hypointensity (relative to pallidum) on T2-weighted images, and slitlike signal change at the posterolateral putaminal margin. The striking slitlike signal change in the lateral putamen corresponds to the area showing the most pronounced microgliosis and astrogliosis, and the highest amount of ferric iron, at necropsy. This abnormal intensity is frequently asymmetric (Figure 63-6).

Infratentorial abnormalities in patients with MSA seen on MRI include atrophy and signal change in the pons and middle cerebellar peduncle. The pontine base and the middle cerebellar peduncle may appear as high signal intensity on T2-weighted images and as low intensity on T1, suggesting degeneration and demyelination.

Figure 63-6. Moderate putaminal (P) hypointensity relative to the globus pallidum (GP) in a patient with parkinsonian multiple system atrophy (MSA-P), axial T2 weighting, 1.5 tesla MRI.

Most if not all these tests are frequently ambiguous and accurate methods to distinguish PD from other diseases with extrapyramidal involvement, particularly MSA, are needed. It is argued that because the diagnosis of MSA during life is based on clinical features, it can only be made with possible or probable certainty, and that definite diagnosis requires pathologic confirmation.

TREATMENT

There are no known treatments targeted at the underlying degenerative disorder or therapies that will modify the course of any of these disorders. Treatment outcomes of the motor abnormalities in MSA patients remain dismal. As mentioned before, these patients often do not respond to anti-parkinsonian medications. Of the autonomic abnormalities, orthostatic hypotension is often treated successfully. An outline of treatment strategies is included later in this chapter.

Secondary autonomic failure

CHOLINERGIC FAILURE

Botulism and the Lambert-Eaton myasthenic syndrome (LEMS) impair the release of acetylcholine in both somatic and autonomic nerves, producing muscle weakness and cholinergic dysautonomia. Botulism presents as an ascending, predominantly motor polyneuropathy with cranial nerve involvement, beginning 12 to 36 hours after ingesting food contaminated with the neurotoxins of the anaerobic bacteria *Clostridium botulinum*. The toxin impairs the presynaptic calcium-associated release of acetylcholine leading to symptoms of cholinergic failure: dry eyes, dry mouth, blurred vision, dizziness, paralytic ileus, urinary retention, and anhidrosis. Treatment is supportive; respiratory failure and cardiac arrhythmia can occur. Recovery is often protracted with autonomic dysfunction lasting as long as 6 months after onset.

LEMS is an autoimmune disorder, most commonly paraneoplastic, associated with small-cell lung carcinoma. Autoantibodies to voltage-gated calcium channels, most commonly the P/Q type, have been found in these patients. Electrophysiologic and pharmacologic studies have reproduced the functional effects of LEMS in passively immunized mice, and confirmed that anti-P/Q-type calcium channel antibodies inhibit transmitter release from autonomic neurons and are likely to be responsible for the autonomic dysfunction in this syndrome.

Dry mouth, erectile dysfunction, proximal muscle weakness, and depressed tendon reflexes are characteristic.^{93–95} The risk of developing cancer is estimated to be 62% over the next 2 years following diagnosis; this risk decreases over time.^{93,96} Autonomic dysfunction is worse in older patients with a carcinoma⁹⁴ but improves with treatment of the underlying carcinoma.⁹⁵

PANDYSAUTONOMIAS

Pandysautonomias involve both sympathetic and parasympathetic neurons. Pandysautonomic neuropathies can be divided into preganglionic (most frequently demyelinating) and postganglionic (most frequently axonopathic).⁹⁷ These neuropathies are acute or subacute with gradual but often incomplete recovery of autonomic function.^{97,98} Patients have blurred vision, dry eyes and mouth, nausea, vomiting, abdominal pain, diarrhea, constipation, and loss of sweating.

The acute pandysautonomias are uncommon in elderly people and affect almost exclusively healthy young individuals. Those with a protracted course and incomplete recovery are, more frequently, postganglionic axonal.^{97,99} The preganglionic demyelinating pandysautonomia with variable involvement of the somatic nervous system is part of a spectrum ranging from pure pandysautonomia—with minimal somatic deficits—to classic Guillain-Barré syndrome (GBS)¹⁰⁰ and profound muscle weakness and may have a better outcome than the postganglionic axonopathic pandysautonomia.⁹⁷ The cause of these pandysautonomias is unknown but a postinfectious or other immune-mediated process is postulated. In some cases they are paraneoplastic,^{101,102} and many patients have autoantibodies to ganglionic acetylcholine receptors (see later discussion). Patients with anti-Hu antibody-related paraneoplastic syndrome having progressive dysautonomia have also been described, both with acute onset and a subacute course of neurologic symptoms. Autonomic symptoms may improve with treatment of the underlying cancer.

Signs of autonomic hyperactivity or hypoactivity are present in one third to two thirds of patients with the acute inflammatory demyelinating polyradiculoneuropathy (AIDP) or GBS.^{103,104} In the majority of cases, there is mild autonomic hypoactivity with resting tachycardia because of decreased parasympathetic activity and ileus. Urinary retention is less common. With autonomic hyperactivity, sweating is excessive and there can be alternating hypertension or hypotension and alternating bradycardia or tachycardia. Mortality is increased with significant dysautonomia.¹⁰⁵

Chronic small fiber (postganglionic) neuropathies can be metabolic (e.g., diabetes or amyloidosis), inherited (e.g., Fabry's disease), or infectious (e.g., HIV). Autonomic dysfunction in both amyloid and diabetes tends to involve all organs. Autonomic failure (orthostatic hypotension and a fixed heart rate) may be the presenting feature. More frequently, patients show a mixed pattern of distal small fiber autonomic and sensory neuropathy or predominantly small fiber sensory neuropathy with only mild autonomic involvement.^{101,106} The autonomic symptoms may accompany, precede, or follow the somatic neuropathy.^{107,108} Alternating diarrhea and constipation, explosive diarrhea, urinary retention, anhidrosis or gustatory hyperhidrosis may be present. Erectile dysfunction is the most common autonomic symptom in diabetes^{109,110} and sudomotor changes may be the earliest sign in diabetic neuropathy.^{111–114}

Pandysautonomias are commonly associated with the acquired immunodeficiency syndrome (AIDS),^{115–117} often combined with a distal sensory polyneuropathy.^{118,119} Autonomic symptoms such as bladder and sexual dysfunction are present in up to 60% of patients.

Mild, chronic (or subacute) autonomic neuropathies or ganglionopathies, affecting both sympathetic and parasympathetic fibers, are sometimes associated with Sjögren's syndrome.^{101,102} Tonic pupils, sudomotor dysfunction, and cases of severe pandysautonomia have been reported.¹²⁰

AUTOIMMUNE AUTONOMIC GANGLIONOPATHY

Acetylcholine is the neurotransmitter in sympathetic and parasympathetic autonomic ganglia, activating nicotinic receptors. Antibodies against ganglionic nicotinic receptors have recently been identified and proposed to play a causal

role in cases of dysautonomia.¹²¹ Clinical presentation can be that of classic acute pandysautonomic following a viral type of illness, or can be indistinguishable of pure autonomic failure. Recent reports show complete (but in some cases transient) recovery in a few patients with acute pandysautonomic that were treated early with intravenous immunoglobulin therapy¹²² or plasma exchange.¹²³ Although encouraging, it is difficult to establish a definitive treatment of this condition based on case reports, and it is likely that some form of immunosuppression will be needed to manage these patients. Nonetheless, they do provide preliminary evidence of the causal role of these antibodies in causing autonomic impairment.

MANAGEMENT OF ORTHOSTATIC HYPOTENSION

Pathophysiology-guided therapy

Maintenance of blood pressure in the standing position requires a sustained increase in peripheral vascular resistance (i.e., vasoconstriction) and adequate intravascular volume. In patients with chronic autonomic failure, orthostatic hypotension is due to deficient baroreflex-mediated vasoconstriction and also because of reduced intravascular volume and reduced venous return.

DEFICIENT VASOCONSTRICTION

In autonomic failure, vasoconstriction is mainly deficient because of reduced baroreflex-mediated norepinephrine release from postganglionic sympathetic nerve terminals and lack of activation of postsynaptic α -adrenergic receptors in the vascular wall.⁶⁸ Also contributing to blunted orthostatic vasoconstriction in these patients are low circulating levels of angiotensin II resulting from deficient renal sympathetic innervation and reduced secretion of renin.^{9,124} In patients with autonomic failure and central nervous system dysfunction (i.e., MSA), impaired endothelin and vasopressin release are also likely to contribute to the deficient vasoconstriction.^{63,69}

Summary of Management Algorithm

Stepwise approach to the management of orthostatic hypotension in elderly people

- Remove aggravating factors:
 - Volume depletion
 - Drugs (e.g., diuretics, tricyclic antidepressants, venodilators, antihypertensives, insulin in diabetics with autonomic impairment)
 - Inactivity/prolonged bed rest/deconditioning
 - Alcohol
- Nonpharmacologic treatment:
 - Liberalized salt intake
 - Head-up tilt during the night
 - Waist-high support stockings
 - Exercise/physical activity as tolerated
- Pharmacologic treatment:
 - Sodium chloride 1 g with meals
 - Fludrocortisone (Florinef) 0.1–0.2 mg/day
 - Midodrine (Proamatine) 5–10 mg PRN
 - Yohimbine 5.4 mg PRN
 - Pyridostigmine 30–60 mg PRN
 - Atomoxetine 18 mg PRN

REDUCED INTRAVASCULAR VOLUME

There are several reasons for reduced extracellular fluid volume in patients with autonomic failure. First, impaired sympathetic activation directly decreases sodium reabsorption in the kidney.¹²⁵ Second, impaired sympathetic activation inhibits renin secretion so that aldosterone is low and renal sodium reabsorption is decreased.¹²¹ Finally, other hormones involved in fluid homeostasis are also impaired in autonomic failure. For example, hypophyseal vasopressin release in response to hypotension is markedly reduced in patients with autonomic failure caused by CNS lesions (e.g., MSA).⁶⁹ Low vasopressin levels prevent water conservation contributing to intravascular volume depletion.

Anemia is a common complication of autonomic failure, likely the result of inadequate erythropoietin levels.^{126,127} Although basal erythropoietin synthesis is not reduced in autonomic failure, the increase in erythropoietin synthesis in response to anemic hypoxia appears to be blunted in these patients. The reason for this abnormality is unknown, but in patients with autonomic failure, the lower the plasma norepinephrine levels in the upright posture, the lower the hemoglobin levels, suggesting some relationship between decreased sympathetic activity and reduced erythropoiesis.¹²⁶ Similar to what occurs with the secretion of renin, another renal hormone, decreased renal sympathetic nerve activity may be the cause of impaired erythropoietin response to anemia in patients with autonomic failure. The modest decrease in red blood cell mass is another contributing factor to reduced intravascular volume.

Nonpharmacologic treatment

A complete medication history should be obtained to identify and possibly eliminate agents that can cause orthostatic hypotension, such as antihypertensives or diuretics. Levodopa and dopamine agonists exacerbate orthostatic hypotension, especially during the first weeks of treatment. Gradual dosage increases when initiating therapy or dose reductions in established patients can minimize this adverse effect. Dietary sodium and water intake should be maximally increased in these patients. Patients also should be instructed not to lie prone. Lying flat when sleeping at night results in accelerated sodium loss from pressure-natriuresis and reduced renin release leading to loss of intravascular volume. This leads to overnight volume depletion and worsening of orthostatic hypotension in the morning. Elevating the head of the bed by 6 to 9 inches is helpful. The beneficial effect of nocturnal head and torso elevation results from lessening supine hypertension, thus reducing "pressure-natriuresis" by the kidney and, in some patients, by increasing renin secretion. Patients should be educated about the hypotensive effects of food, hot weather, and physical exertion. Isotonic exercise produces less hypotension than isometric exercise, and exercise in a pool prevents blood pressure reductions. In patients with autonomic failure, eating can significantly lower blood pressure because the splanchnic vasodilation induced by food is not appropriately compensated by vasoconstriction in other vascular beds. In some patients, hypotension only occurs postprandially. Thus patients should eat frequent, small meals with a low carbohydrate content and alcohol intake should be minimized. Caffeine taken with breakfast may be helpful. Hot baths should be avoided, and patients should be especially careful during warm weather. This is because heat-induced vasodilation still

occurs but sympathetic vasoconstriction is impaired. Straining at stool with a closed glottis (i.e., producing a Valsalva maneuver), playing wind instruments, and singing can be particularly dangerous for patients with hypotension. A high-fiber diet is encouraged to prevent constipation. The use of knee-high compressive stockings is not effective, but waist-high stockings (i.e., Jobst stockings) or abdominal binders may be an effective, albeit poorly tolerated, countermeasure for orthostatic hypotension.

Pharmacologic treatment

Only patients with symptomatic orthostatic hypotension should be treated pharmacologically. Perhaps because of adaptive cerebral autoregulatory changes, some patients with autonomic failure tolerate very low arterial pressures when standing without experiencing symptoms of cerebral hypoperfusion. Blood pressure levels change throughout the day and from one day to another. Thus the patient's normal cycle of blood pressure and orthostatic symptoms should be identified before treatment is initiated. The treatment strategy is based on counteracting the underlying pathophysiology, by increasing intravascular volume (fludrocortisone, desmopressin, erythropoietin), potentiating the pressor effects of endogenous norepinephrine and angiotensin (fludrocortisone), or using short-acting pressor agents to improve upright blood pressure.

Fludrocortisone

Fludrocortisone, a synthetic mineralocorticoid, is practically devoid of glucocorticoid effect.¹²⁸ This pharmacologic action leads to sodium and water retention, but this effect is not targeted to the intravascular space and is only transient. It is postulated that its improvement in orthostatic hypotension is due to potentiation of the pressor effects of endogenous vasoconstrictors such as norepinephrine and angiotensin II. Therapy with fludrocortisone (Florinef) is initiated with a dose of 0.1 mg per day. At least 4 to 5 days of treatment are necessary for a therapeutic effect to be evident. Special attention should be given to the development of hypokalemia. Fludrocortisone increases extracellular and intravascular volume by increasing sodium reabsorption by the kidney, thus increasing cardiac output and standing blood pressure. The dose of fludrocortisone should be increased slowly. Body weight, blood pressure, and the possible development of heart failure because of volume overload should be monitored. Weight gain of 2 to 5 pounds is expected. A certain degree of pedal edema should not be of concern. Indeed, it may be necessary to support the venous capacitance bed (water jacket).

Desmopressin

Desmopressin (DDAVP) is a synthetic vasopressin analog, which acts specifically on the V2 receptor (renal tubular cell) responsible for the antidiuretic effect of the hormone. At the dose given, DDAVP has no vasoconstrictor effect because it does not activate the V1 receptor, which is in vascular smooth muscle.¹²⁹ Nocturnal intranasal administration of DDAVP reduces nocturnal polyuria and raises standing blood pressure in the morning without worsening supine hypertension.¹³⁰ A problem with the use of DDAVP is the potential development of hyponatremia. Treatment with this drug, therefore, should always be started with caution, and serum sodium should be monitored.

Recombinant erythropoietin

Anemia is a common complication of autonomic failure.¹²⁶ Because blood pressure in autonomic failure is extremely sensitive to even small changes in intravascular volume, modest decreases in red blood cell mass and blood viscosity may exacerbate orthostatic hypotension. Recent studies in patients with autonomic failure have shown that reversing the anemia using recombinant erythropoietin increases upright blood pressure and ameliorates symptoms of orthostatic hypotension.^{126,127,131} Erythropoietin, a polypeptide hormone produced mostly by the kidney, plays a central role in the regulation of red blood cell production. The synthesis of erythropoietin is controlled by a feedback mechanism based on an oxygen sensor.¹³² When oxygen delivery to the kidney decreases, as with blood loss or chronic anemia, the synthesis of erythropoietin by renal interstitial cells increases.¹³³ The hormone is released into the bloodstream and stimulates red cell progenitors in the bone marrow, thereby increasing red cell production. In some patients with autonomic failure, chronic anemia does not produce an adequate increase in serum erythropoietin levels.^{126,127,134} This is similar to what occurs in renal disease, malignancy, and other chronic disorders.

A likely mechanism for the increase in blood pressure following erythropoietin treatment is an increase in intravascular volume and blood viscosity because of increased red blood cell mass. In patients with renal failure receiving erythropoietin treatment, however, no correlation was found between increased blood pressure and increased hematocrit¹³⁵; this suggests additional mechanisms for the hypertensive effect of the hormone.

Midodrine

When volume expansion is not sufficient to control symptoms, a pressor agent should be added. The pressor agent of choice is now midodrine, a selective α_1 -adrenergic agonist, which is well absorbed after oral administration and does not cross the blood-brain barrier.^{9,136} A 10 mg dose of midodrine is effective in increasing orthostatic blood pressure and ameliorating symptoms in patients with orthostatic hypotension.¹³⁷ Because this dose increases pressure for only 4 hours, it can be prescribed two or three times daily, depending upon the physical activity of the patient and can be avoided later in the day because it increases supine blood pressure. An advantage of a pressor agent over fludrocortisone is that its blood pressure raising effect lasts only a few hours. Thus it can be administered specifically when the patient needs it; typically before breakfast and before lunch and preceding physical activity.¹³⁷ Recumbent hypertension is a common sideeffect but standing up readily lowers blood pressure. The dose of midodrine should be titrated slowly starting with 2.5 mg. The dose can be quickly increased to 10 mg two or three times a day based on the blood pressure response. Most patients with orthostatic hypotension require chronic treatment with fludrocortisone; it is likely that by adding midodrine to fludrocortisone, the dose of the latter can be reduced. This combination treatment may reduce the long-term complications associated with chronic mineralocorticoid administration. Piloerection and scalp itching are frequent side-effects, and may be used as evidence of a pharmacologic effect.

DOPS

DL threo-dihydroxyphenylserine (DL-threo-dops [DOPS]) is an unnatural amino acid that is converted to norepinephrine through a single decarboxylation step by the enzyme dopa decarboxylase. In patients with autonomic failure due to congenital dopamine β -hydroxylase deficiency (the enzyme that converts dopamine to norepinephrine), DOPS is extremely efficacious in relieving orthostatic hypotension.^{138,139} In patients with other forms of autonomic failure, DOPS¹⁴⁰⁻¹⁴² showed a significant pressor effect and significantly ameliorated postprandial hypotension.

Pyridostigmine

By inhibiting cholinesterase enzymes that degrade acetylcholine, pyridostigmine facilitates neurotransmission at the level of the autonomic ganglia. This results in an increase in blood pressure that is proportional to residual sympathetic tone. Thus pyridostigmine has the advantage of preferentially increasing blood pressure on standing, without worsening supine hypertension.¹⁴³ On average, it is not as potent as other short-acting pressor agents, but it can be effective in a given patient.

Atomoxetine

Residual sympathetic tone can also be harnessed in these patients by prolonging the actions of synaptic norepinephrine by inhibiting its reuptake with atomoxetine.¹⁴⁴ In patients with multiple system atrophy and residual sympathetic tone, atomoxetine can be a potent pressor agent even at pediatric doses (18 mg). In contrast, it has little if any effect in patients with pure autonomic failure.

Other agents

Several other agents have been used in the treatment of orthostatic hypotension in autonomic failure. Prostaglandin synthesis inhibitors (indomethacin, ibuprofen),^{145,146} and the somatostatin analog octreotide^{147,148} are sometimes effective in improving orthostatic hypotension. The dopaminergic blocker metoclopramide increases blood pressure in some patients with autonomic failure,^{149,150} but may aggravate or induce extrapyramidal symptoms. Moreover, it was recently reported that metoclopramide infusion acutely lowered blood pressure and worsened orthostatic tolerance in patients with autonomic failure, which should discourage the use of this drug in the treatment of orthostatic hypotension. β -blockers with and without intrinsic sympathomimetic activity (propranolol and pindolol) have been used,¹⁵¹ but we have not found them consistently effective. Clonidine, an α_2 -adrenergic agonist, has been used with occasional success in patients with severe pure autonomic failure by inducing peripheral vasoconstriction.¹⁵² Conversely, the α_2 -adrenergic antagonist yohimbine is often useful in less severe patients, by increasing residual sympathetic tone.¹⁵³ Ergotamine by nasal inhalation has also been reported effective.¹⁵⁴

Treatment of related conditions

SUPINE HYPERTENSION AND DIURNAL BLOOD PRESSURE VARIATION

In addition to orthostatic hypotension, two distinct features of autonomic failure are hypertension when the patient is supine and notable diurnal variation in blood pressure. The mechanism responsible for supine hypertension is unclear.

It is surprising that despite low norepinephrine and low angiotensin levels, systemic vascular resistance is increased in patients with autonomic failure when they are supine. The nocturnal supine hypertension causes pressure-natriuresis. The subsequent reduction in extracellular fluid volume aggravates orthostatic hypotension in the morning. Patients with chronic autonomic failure frequently have elevated supine blood pressure and may be incorrectly diagnosed with arterial hypertension.

Postprandial hypotension

Although the precise mediators of postprandial hypotension have not been fully characterized, adenosine and insulin are prime suspects. Not surprising, treatment of postprandial hypotension is targeted at these mediators. Caffeine, an adenosine receptor antagonist, and octreotide, which blocks the release of insulin, are effective in preventing postprandial hypotension.^{155,156} Octreotide may not be tolerated in patients with diabetic autonomic neuropathy because of gastrointestinal side effects. Acarbose, an α -glucosidase inhibitor, also prevents postprandial hypotension at doses of 50 to 100 mg, likely through its ability to prevent the quick rise in insulin levels that occurs after meals.¹⁵⁷

SUMMARY

Evaluations of antihypertensive therapy and nonpharmacologic interventions are the first steps in treating orthostatic hypotension. Hypotensive therapy should be discontinued if possible. Salt and fluid intake should be increased, and patients should be instructed to elevate the head of the bed and never to lie flat. Education about the effects of eating, hot weather, bathing, exercise, and rising quickly from a prone position will assist in effective behavior modification. If pharmacotherapy is needed, fludrocortisone, midodrine, and erythropoietin (for anemia) may be helpful in normalizing blood pressure regulation.

KEY POINTS

Disorders of the Autonomic Nervous System

- Dysautonomia is common with age and with a variety of illnesses, which can be grouped as instances of primary autonomic failure (chiefly neurodegenerative) and secondary autonomic failure (paraneoplastic or autoimmune).
- Age-related changes in the autonomic nervous system are not uniform.
- Age-related baroreflex changes can be seen even in older adults who exercise regularly.
- Routine clinical tests of the integrity of the autonomic nervous system rely on orthostatic changes in blood pressure, heart rate responses to deep breathing, and assessment of baroreflex function.
- Orthostatic hypotension and neutrally mediated syncope are the most common manifestations of autonomic impairment in older adults.

Parkinsonism and Other Movement Disorders

Jolyon Meara

Movement disorders can be broadly classified into the akinetic–rigid hypokinetic conditions in which voluntary movement is reduced and hyperkinetic conditions in which excess involuntary movements called dyskinesias are present (Table 64-1). Dyskinesias can be further classified into tremor, dystonia, tics, myoclonus, and chorea. This distinction is not absolute as, for example, in Parkinson's disease (PD), the most common akinetic–rigid syndrome, involuntary movements are often present. Akinetic–rigid syndromes are usually associated with poor mobility and difficulty with walking because of the presence of a gait apraxia.

Movement disorders are common in older age and are a significant cause of impairment, disability, and handicap.¹ Once diagnosed, these disorders can often be effectively treated. These conditions often present medically in older people at an advanced stage. On an average posttake ward round, it is not uncommon in older patients to make the diagnoses of hitherto unrecognized essential tremor, parkinsonism, orofacial dyskinesia, or drug-induced movement disorder.

THE AKINETIC–RIGID SYNDROMES

The akinetic–rigid syndromes are a group of disorders characterized by parkinsonism which results from the combination of akinesia, rigidity, and often, but not always, tremor (Table 64-2). Parkinsonism is often associated with impaired balance, and a gait apraxia leading to falls and impaired mobility. Levodopa-responsive parkinsonism of unknown cause that has particular clinical features, a characteristic clinical progression and Lewy body neuropathology in the substantia nigra (SN) is called *idiopathic parkinsonism* or *PD* and accounts for around 70% of cases of parkinsonism.^{2,3} The remaining causes of parkinsonism are due to drug-induced parkinsonism, vascular parkinsonism, and, much less frequently, multisystem degenerative conditions. These include progressive supranuclear palsy, multiple system atrophy, and corticobasal degeneration. With increasing age, not only does the risk of parkinsonism increase, but also the likelihood of parkinsonism being due to a cause other than PD increases.

PARKINSON'S DISEASE

Although PD can present at any age and juvenile-onset forms are well described, it is a rare disorder outside of old age.⁴ Cross-sectional prevalence studies of PD and parkinsonism

show that at least two thirds of subjects to be over the age of 70 years. PD is usually insidious in onset and may have a long symptomatic phase before eventual diagnosis with symptoms being mistakenly attributed by patients and their physicians to the inevitability of "old age." The rate of progression in PD is strongly related to age at onset rather than to disease duration, which explains the often rapidly disabling disease seen in subjects with late-onset disease arbitrarily described as beginning after 70 years of age. Minimal signs of parkinsonism may result from normal aging changes in the basal ganglia, making the diagnosis of PD in the very elderly even more difficult.⁵

Clinical features

Classically PD has been considered a localized disorder of motor control, which in young subjects is a reasonable assumption. However, the increasing realization of the widespread nature of neuropathology in PD, coupled with our increasing recognition of nonmotor symptoms, has now led to the concept of PD being a multisystem disorder.⁶ Nonmotor symptoms are increasingly common with disease progression and older age at disease onset and therefore are a major feature of PD in older subjects.^{7–9} Cognitive impairment, often progressing to dementia, is the most powerful factor that determines quality of life in older people with PD. Late-onset PD is probably best thought of as being primarily a dementing illness.^{10,11}

Table 64-2. Causes of Parkinsonism

Primary Parkinsonism
Parkinson's disease (idiopathic/sporadic parkinsonism)
Secondary Parkinsonism
Drug-induced parkinsonism
Neuroleptic drugs
Calcium blocker cinnarizine
Vascular parkinsonism (pseudoparkinsonism)
Multi-infarct states
Single basal ganglia/thalamic infarct
Binswanger's disease
Multisystem degenerative diseases
Progressive supranuclear palsy
Multiple system atrophy (striatonigral type)
Corticobasal degeneration
Alzheimer's disease
Wilson's disease (young-onset parkinsonism)
Dementia with Lewy bodies
Neurofibrillary tangle parkinsonism
Toxins
MPTP
Manganese
Familial parkinsonism
Postinfectious parkinsonism:
Creutzfeldt–Jakob disease
AIDS
Postencephalitis (encephalitis lethargica)
Miscellaneous causes
Hydrocephalus
Posttraumatic
Tumors
Metabolic causes (postanoxic)

Akinetic–Rigid States
Parkinsonism
Hyperkinetic States
Tremor
Chorea
Dystonia
Myoclonus
Complex movement disorders
Drug-induced movement disorders (tardive dyskinesia)

Neuropathology

PD is characterized by cell loss and gliosis in the SN and other pigmented brainstem nuclei that is often visible to the naked eye on sectioning the midbrain.^{12,13} Aging also results in cell loss in the substantia nigra, although the distribution of cell loss is very different from that seen as a result of PD.¹⁴ Surviving cells in the SN contain typical inclusions in the cytoplasm called Lewy bodies, which are now known to be largely an aggregation of a protein called alpha-synuclein.¹⁵ Most cases of PD diagnosed in life are found to have Lewy bodies in the substantia nigra.¹⁶ However, Lewy body pathology in the substantia nigra does not necessarily lead to the clinical picture of PD and conversely, largely from the studies of familial parkinsonism, other pathologies not involving Lewy bodies can give rise to a clinical picture typical of PD.^{17,18} Lewy bodies are also found in other specific brain sites outside the brain stem including the cerebral cortex, olfactory bulb, and enteric plexi.^{19,20} Lewy bodies can be found in up to 10% of postmortem examinations in elderly subjects with no apparent history of parkinsonism in life (incidental Lewy body disease). It is unclear whether such individuals, if they had survived, would have developed PD or, because of protective mechanisms, were able to contain the disease process in a subclinical state.²¹ The role of the Lewy body in the pathology of PD is still unknown, and it is unclear whether the Lewy body represents a defense mechanism or the result of the primary disease process.

PD also involves the ascending serotonergic, noradrenergic, and cholinergic projections to the cortex and basal ganglia.²² Clinicopathologic studies have demonstrated that coexisting neuropathology within the striatum and in other areas of the brain is extremely common in elderly subjects with histologically confirmed PD.²³ Braak has proposed that the primary degenerative process in PD, based on the assumption that the presence of Lewy bodies indicates neuronal loss, begins not in the substantia nigra but in the olfactory tracts, lower brain stem, and enteric nervous tissue.²⁴ This model fits well with the increasing recognition that REM sleep disorders, hyposmia, and constipation may precede the motor symptoms of PD by several years. The proposed pattern of disease progression also indicates the potential for interaction with environmental agents via the olfactory system and gut.

MOTOR FEATURES

Akinesia is the central motor abnormality in PD that refers to a lack of spontaneous voluntary movement, slowness of movement (bradykinesia), and faulty execution of movement.²⁵ Marsden brilliantly described akinesia as the "failure to execute automatic learned motor plans."²⁶ Voluntary movements tend to be of low amplitude and to show increased fatigability. There is a particular difficulty with sequential and concurrent self-paced movements. Patients when asked to oppose the index finger to the thumb in a tapping motion often start with reasonably fast, large-amplitude movements but the speed and amplitude then rapidly decrease with the movement fading away. Akinesia in the lower limb is best tested by asking the patient to tap the heel of the foot on the floor as rapidly as possible—in this situation, akinesia can be heard as well as seen. Older patients often find bedside tests for akinesia difficult to execute and

may perform poorly because of cognitive impairment, painful arthritis, restricted joint range, and muscle weakness. Action tremor from any cause may interfere with the quality of normal hand and finger movements, and this can make the assessment of akinesia difficult in the presence of essential or dystonic tremor.

Rigidity is an increased resistance of muscle to passive stretch felt by the examiner. Clinically, rigidity is best detected at the wrist joint. The subject is asked to relax as fully as possible while the examiner makes flexion and extension movements of the wrist joint with the subject's forearm supported. Passive movements of the head can be used to detect axial rigidity. Parkinsonian rigidity is not velocity-dependent and is present to the same degree at all joint positions in flexion and extension ("lead-pipe" rigidity). Activation procedures, akin to the Jendrassik maneuver to enhance tendon jerks, can bring out "activated rigidity" that was not present before. Transient activated rigidity may be a normal finding in anxious individuals. Activated rigidity in the neck muscles may be the first sign of rigidity in PD. The presence of tremor in the upper limb due to any cause will result in a ratchet-like quality of intermittent resistance at the wrist joint called *cogwheel rigidity* that is not specific for PD.

Tremor, usually of the hand, is the presenting feature of PD in around 70% of cases. Hand tremor characteristically occurs at rest when the postural muscles are relaxed and has a frequency of around 4 to 6 Hz. In an anxious patient, postural tremor can easily be misidentified as a resting tremor. Most patients with PD manifest a range of resting, postural, and action tremors. A resting tremor of the hand involving the thumb and index finger described as "pill-rolling" and often brought out when the subject is observed walking is very suggestive of PD or drug-induced parkinsonism. Tremor usually begins insidiously in one hand before spreading to the leg on the same side. After a further delay of sometimes a year or more, the opposite hand and leg become affected. Head and voice tremor, as opposed to jaw tremor, is unusual in PD and suggests a diagnosis of essential tremor. Rest tremor can occur in essential tremor but only when postural and action tremor is prominent. Rarely, PD can present with tremor alone (tremor dominant PD) with variable degrees of mild rigidity and akinesia found on examination. Tremor dominant PD is difficult to distinguish from essential and dystonic tremor. Subjects with a diagnosis of PD recruited into trials of neuroprotection in PD, who are subsequently found to have no evidence of nigrostriatal dysfunction on positron emission tomography (PET) and single-photon emission computed tomography (SPECT) scans, may well have dystonic tremor.

Postural balance can be assessed clinically by asking the patient to stand and then gently pushing the patient forward from behind, with the other hand in front to prevent a fall. Falls or feelings of imbalance strongly suggest the presence of impaired righting reflexes, even if this is not evident at the time of examination. Axial motor disturbances leading to gait disturbance, dysphagia, and dysarthria are a feature of late-onset PD and often respond poorly to drug treatment.

NONMOTOR FEATURES

Nonmotor symptoms, particularly hyposmia, sleep disorder, and constipation, may predate the onset of motor symptoms by many years. Nonmotor features of PD are very varied

and with disease progression come to dominate the clinical picture.^{9,27} In late-onset PD, nonmotor features are usually advanced by the time of diagnosis and progress more rapidly than in earlier-onset disease. Autonomic system involvement leads to postural hypotension, urinary incontinence, sexual dysfunction, constipation, and abnormalities of sweating.²⁸ The progression of PD pathology in the cerebral cortex leads to a range of neuropsychiatric and cognitive problems including dementia, psychosis, hallucinations, apathy, and depression.^{29,30} Sensory symptoms, usually painful in nature and involving the lower limbs, also occur and are difficult to treat successfully. A rating scale for nonmotor symptoms has recently been developed.³¹

Dementia and cognitive impairment are common problems in the management of PD in older subjects.³² The cause most frequently appears to be Lewy body pathology in the cerebral cortex.²⁹ Dementia that develops a year or more after parkinsonian motor symptoms is described as PD dementia (PDD), whereas dementia present at the start of the illness is called dementia with Lewy bodies (DLB). These two conditions are generally thought to represent two ends of a spectrum of Lewy body disease.^{33,34} The risk of dementia in older subjects with PD is five times that of age-matched subjects without PD,¹¹ and after 8 years of follow-up the prevalence of dementia may reach nearly 80%.¹⁰

Dysthymia, or mild depression, is fairly common in PD,^{7,35–37} but major depression is unusual in the absence of previous significant depressive illness. The natural history of depression/depressive symptoms in PD and the response to antidepressant drug treatment has to date been poorly studied.³⁸ Apathy is also frequently described in subjects with PD and may be mistaken for depression.³⁹ A range of nocturnal and daytime sleep disorders is now well described in PD and include rapid eye movement (REM) sleep behavior disorder and excessive daytime sleepiness.⁴⁰

Visual hallucinations are common in PD and occur early in late-onset disease.⁴¹ Rather than simply being due to side effects from antiparkinsonian medication, visual hallucinations are now thought to directly be the result of Lewy body pathology in the ventral-temporal brain areas, indicating that the second half of the course of the disease has been reached.^{42,43} Visual hallucinations have been suggested as a useful marker to distinguish PD from non-Lewy body parkinsonism.⁴³

Psychosis in PD usually occurs in older subjects with established cognitive impairment/dementia and again indicates the presence of significant cortical disease.⁴⁴

Delirium in PD is also common in older subjects with cognitive impairment and is precipitated by the usual suspects commonly invoked in geriatric practice. All antiparkinsonian medications increase the risk of delirium, though this risk is greatest with anticholinergics, dopamine agonists, selegiline, and amantadine. Visual hallucinations commonly occur in conjunction with psychosis/delirium. Delirium has a remarkable but unexplained and little researched effect on motor symptoms in PD. Patients with acute delirium are often hyperactive and wander around the ward despite refusing all antiparkinsonian medication for days at a time. As the delirium lifts and medication is reintroduced, motor function again deteriorates to the previous parkinsonian state of frozen immobility.

Clinical diagnosis

The diagnosis of PD is a two-stage process that is still dependent on clinical skills.⁴⁵ First, the symptoms of parkinsonism need to be sought in the history and the signs of parkinsonism established by clinical examination. Progressively small handwriting (micrographia) with the written word disappearing into a shaky line is strongly suggestive of parkinsonism, though it is surprising how few people write letters by hand today. Difficulty turning over in bed is also a good clue to the early development of axial akinesia. A good witness account, usually from a spouse, is very useful in confirming the often rather general and nonspecific slowing down seen in older patients with PD. The gradual inability to keep up with a spouse on daily routine walks is again a useful early indication of gait disturbance and akinesia. Second, if parkinsonism is detected, consideration has to be given to what type of parkinsonism is present by applying validated clinical diagnostic criteria^{23,46} (Table 64-3).

In older patients, the diagnosis of parkinsonism can be extremely difficult, even in expert hands, particularly when the clinical picture is complicated by other diseases, cognitive impairment, depression, and atypical features.⁴⁷ A confident diagnosis of parkinsonism cannot always be made in older people, and sometimes a trial of levodopa therapy may be required. However, even the results of a 6-week trial of levodopa at adequate dosage (at least 600 mg daily) may be inconclusive. The use of DaTSCAN-SPECT imaging of the nigrostriatal tract using a radiolabeled tracer for the dopamine transporter may help distinguish atypical postural and action tremors in older patients leading to the correct diagnosis of PD, essential tremor, and dystonic tremor.^{48,49}

How good are experts at distinguishing PD from other types of parkinsonism? Two important clinicopathologic brain bank studies have addressed this problem and have demonstrated that diagnostic accuracy for PD at death, when diagnostic accuracy is going to be highest, was only around 76%.^{23,50} Diagnostic accuracy in more recent cases

Table 64-3. Guideline Diagnostic Criteria for Parkinson's Disease

A progressive usually nonfamilial disorder with bradykinesia (slowness of initiation of voluntary movement, progressive reduction in speed and amplitude of repetitive movement, and difficulty switching smoothly from one motor program to the next) and at least one of the following:

- Muscular rigidity
- Coarse 4 to 6 μ Hz resting tremor
- Impaired righting reflexes (not caused by primary visual, vestibular, cerebellar, or proprioceptive dysfunction)

Absolute exclusion criteria are the following:

- Exposure to neuroleptic drugs within the year before the onset of symptoms or to MPTP
- Presence of cerebellar or corticospinal tract signs
- Past history of encephalitis lethargica or viral encephalitis with oculogyric crises
- Stepwise progression or a history of multiple strokes
- Presence of communicating hydrocephalus or a supratentorial tumor
- Presence of severe early autonomic failure
- Supranuclear gaze palsy

Modified with permission from Gibb WRG, Lees AJ. A comparison of clinical and pathological features of young and old-onset Parkinson's disease. *Neurology* 1988;38:1402–6.

Table 64-4. Subtypes of Parkinson's Disease

Early onset < 50 years old versus late onset > 70 years old
Tremor dominant versus postural imbalance and gait disorder
Benign slow progression versus malignant rapid progression
Unilateral with or versus bilateral disease with or without axial disease and without impaired balance
Lewy bodies mainly in brain stem (PD) versus Lewy bodies mainly in cortex (DLB)

Modified from Meara J, Bhowmick BK. Parkinson's disease and parkinsonism in the elderly. In: Meara J, Koller WC, editors. Parkinson's Disease Parkinsonism in the Elderly. Cambridge: Cambridge University Press; 2000, pp. 22–63, with permission of Cambridge University Press.

referred to a brain bank was shown to have improved to around 84%.⁵¹ The use of stringent clinical diagnostic criteria can improve the specificity for correct diagnosis to over 90% but at the expense of a reduced sensitivity of around 70% as true but clinically atypical cases are excluded.

Clinical subtypes

Clinical observation suggests that subtypes of PD exist, though surprisingly little scientific study of this phenomenon has been undertaken (Table 64-4).^{46,52,53} Late-onset disease tends to progress more quickly than early-onset disease (symptoms before the age of 40 years) and is more often associated with cognitive impairment.⁵⁴ Patients in the longitudinal DATATOP study who were classified as having rapidly progressive disease were older, had more severe postural imbalance and gait disorder (PIGD group), and exhibited less tremor at study entry than the group with slowly progressive disease. Tremor-dominant disease was associated with less disability, less cognitive impairment, and less depression compared to a group with akinetic rigidity and postural imbalance. The DATATOP analysis suggested that cognitive function and motor deterioration were relatively independent once adjustment for age had taken place.⁵⁴ However, patients with late-onset disease appear to become demented sooner than patients with early-onset disease of similar duration.⁵⁵ The risk of disabling levodopa-induced dyskinesias appears to be much lower in patients with late- compared with early-onset disease. Motor fluctuations are also less evident in late-onset disease with the possible exception of the end-of-dose "wearing off" of drug benefit. A further probable subtype of PD is DLB, though some authorities would still argue that this is a separate disease entity.

The clinical expression and progression of PD with age is likely to reflect the impact of additional neuropathology from vascular or Alzheimer type pathology as well as effects of cell loss because of aging.⁵⁶ Indeed, vascular and Alzheimer type changes in the striatum and cortex may protect elderly subjects from levodopa dyskinesia and motor fluctuations but reduce the therapeutic response to levodopa and increase the risk of cognitive impairment/dementia.

Epidemiology

PD has a strong age-associated risk, and both prevalence and incidence increase exponentially with age.^{57,58} Whether incidence truly falls in extreme old age is still unclear. The apparent drop in incidence in extreme old age may reflect diagnostic difficulties or limitations of case ascertainment in small populations. PD affects all racial groups and, after adjusting crude rates to a standard population and allowing

for differences in study methodologies, has a fairly uniform worldwide distribution of around 110 per 100,000.⁵⁷ Differences in adjusted prevalence rates may still be explained by differential survival, diagnostic bias, and variable mortality rates. Population-adjusted prevalence rates for PD in European subjects over the age of 65 years have been reported as 2.3% for parkinsonism and 1.6% for PD.⁵⁹ Studies in which all eligible subjects are examined using the total census approach have shown that up to a third or more of subjects ascertained as having PD were medically undiagnosed before the study.^{60,61} A longitudinal study of 4341 elderly subjects initially free of parkinsonism reported an average annual incidence rate for parkinsonism of 530 per 100,000 and 326 per 100,000 for PD.⁶²

The strong age-associated risk of PD means that over the next few decades the burden of PD worldwide will increase, particularly in the most populous regions of the Far East and China where the greatest increase in older people and incident cases of PD will occur.⁶³ The number of people over 50 with PD is likely to double in the 10 countries with the biggest populations over the next quarter of a century.⁶³

Parkinsonism in institutional care has received little research attention despite the fact that 15 years from diagnosis around 40% of survivors will need long-term care.⁹ The prevalence of parkinsonism appears to be high in hospitals, nursing homes, and residential/retirement homes.⁶⁴ A survey in the United States of 5000 nursing home residents over the age of 55 years reported a prevalence for medically diagnosed PD of nearly 7%.⁶⁵ A European study found that 42% of cases of PD in elderly subjects living in institutions were medically undiagnosed.⁶⁶ Nursing home residents with PD tended to be more disorientated, depressed, and functionally disabled than residents without PD.^{67,68} Psychosis and dementia are the two main factors increasing the risk of admission to nursing homes of elderly people with PD.^{67,68}

Etiology

The cause of sporadic PD is unknown but is likely to represent interaction between environmental agents and genetic susceptibility. Potential mechanisms to explain this interaction are suggested by the Braak hypothesis of disease progression,²⁴ the existence of environmental neurotoxins such as 1-methyl-4-phenyl-1,2,2,6-tetrahydropyridine (MPTP),⁶⁹ and the occurrence of incidental Lewy body disease.

Twin studies suggested that, apart from early-onset disease, genetic mechanisms were relatively unimportant in the etiology of PD.⁷⁰ However, since then rare monogenic forms of familial parkinsonism have been described, the most common relating to mutations in the *LRRK2*, *Parkin*, and *PINK1* genes.⁷¹ A total of 13 genetic loci have been reported that result in dominant and recessively inherited parkinsonism usually of early onset and often with clinical features atypical of PD. These genes are most likely to be involved in protein degradation, oxidative stress responses, and mitochondrial function. Neuropathologic findings resulting from these gene mutations are variable but consistently reveal nigral degeneration with or without Lewy bodies. Even when the clinical picture is indistinguishable from PD, as occurs in *LRRK2* mutations, the pathologic findings can be remarkably varied. Mutations at the *LRRK2* locus result in dominantly inherited PD with reduced penetrance causing an age of onset typical of PD that may account for 1% of "sporadic" cases of PD.⁷²

Table 64-5. Drugs Used to Treat the Motor Impairment in Parkinson's Disease

Group	Drug	Trade name
Levodopa	Co-careldopa	Sinemet 110
		Sinemet 275
		Sinemet-plus
		Sinemet-S
		Sinemet CR, Half CR
	Co-beneldopa	Madopar 62.5
		Madopar 125
		Madopar 250
		Madopar CR
		Madopar dispersible 62.5/125
COMT inhibitors	Entacapone	Comtess
	Tolcapone	Tasmar
MAO-B inhibitors	Selegiline	Eldypryl
		Zelapar (sublingual)
Dopamine agonists	Rasagiline	Azilect
	Bromocriptine	Parlodel
	Pergolide	Celance
	Ropinirole	Requip
	Cabergoline	Cabasar
	Pramipexole	Miramaxin
	Apomorphine	Britaject
Miscellaneous	Amantadine	Symmetrel
	Anticholinergics	
	Levodopa plus entacapone	Stalevo

Several environmental agents, such as MPTP and manganese, can cause parkinsonism, but no environmental exposure that is widespread enough and persistent enough over thousands of years to cause sporadic PD has yet been found.

TREATMENT OF PD

In the United Kingdom, a wide range of drugs is available to treat the motor symptoms of PD (Table 64-5). Detailed discussion of their use can be found in recent reviews of drug therapy.⁷²⁻⁷⁴ Clinical guidance from the National Institute for Clinical Excellence (NICE) in the United Kingdom has also been issued.⁷⁵ Worldwide, many drugs for PD are either unavailable or unaffordable. Levodopa without dopa decarboxylase inhibitors would be a cheap and effective treatment for PD, though it would result in distressing nausea and discomfort for some patients for a time until tolerance developed. No drug treatment appears to delay disease progression. Drug treatment improves, though rarely abolishes, motor impairment.

Considerable interest has been generated by the recent concept of "continuous dopaminergic stimulation" as a strategy to try to replicate physiologic dopaminergic function in the basal ganglia.⁷⁶ This has been fostered by the pharmaceutical industry with the development of a range of long-acting dopaminergic drugs. The thrust of this approach is to prevent or delay the future emergence of levodopa-induced dyskinesias and motor fluctuations in at-risk subjects. For elderly people at low risk of these complications, this matter is of far less concern than obtaining the best response to drug therapy possible for the *present* time. A reasoned critique of the thinking behind much of the treatment of younger patients by neurologists has recently been proposed by Nutt.⁷⁷

Naturally, especially in older subjects, drug treatment should be combined with rehabilitative approaches involving physical therapists, occupational therapists, speech and language therapists, and a range of other allied health and welfare professionals.⁷⁹⁻⁸¹

The model of holistic care in PD has been supported by the development of the PD nurse specialist role.⁸² Specialist nursing rehabilitative expertise has undoubtedly led to significant improvements in the care of older patients with PD, however, possibly because of study design and methodology, the results of a randomized trial of this service were disappointing.⁸³

Drug treatment of motor features

LEVODOPA

The most effective and widely available drug treatment for PD remains levodopa combined with dopa decarboxylase inhibitors (co-careldopa/co-beneldopa), and virtually all people are prescribed these drugs at some stage in their disease. Side effects of levodopa commonly include nausea and vomiting, dizziness on standing, and daytime drowsiness. Confusion and hallucinations are usually only seen in older subjects who already have evidence of cognitive impairment/dementia. Postural hypotension should be assessed before starting levodopa. To avoid falls and injury, care needs to be taken getting out of bed and rising from the table after meals. Many older people will still be driving, so advice should be given about the risk of daytime drowsiness and the need to inform the driving authorities and motor insurers.

To minimize side effects, a "low slow" introduction of levodopa should be adopted. A suggested regime for initiating levodopa treatment in older frail subjects in whom nausea is likely to be an early problem is shown in Table 64-6. Domperidone given half an hour before each levodopa dose is useful in reducing levodopa-induced nausea. In fitter older subjects, domperidone could be omitted and levodopa started at 50 mg daily with food and increased by 50 mg each week until a dose of 200 mg three times daily is reached. Levodopa-induced side effects of disabling dyskinesias and motor fluctuations are of little relevance to older people, and there is no point in delaying levodopa treatment in this group who are often already significantly disabled by PD. Although there is no convincing evidence that levodopa accelerates disease progression, it seems sensible to use the minimum dose of levodopa that leads to an acceptable health-related quality of life for the patient. Unfortunately, many elderly subjects are unable to tolerate a maximally therapeutic dose of levodopa. Conversely, some older people are undertreated with levodopa, and the first stage in management is often to gently increase levodopa dosage and closely monitor the response. In drug-naïve subjects, it is important to clearly document the response to a 6-week period of adequate levodopa treatment (ideally if achievable a minimum of 600 mg daily) as this can help to clarify the clinical diagnosis and can also give some indication of the likely degree of the future control of the disease.

Delayed controlled-release (Sinemet-CR/Madopar-CR) and dispersible formulations of levodopa are available and may be useful in selected individuals. Controlled-release preparations may help early sleep disturbance resulting from PD symptoms in the first few hours of the night.⁸⁴

Table 64-6. Starting Levodopa in Frail Older People

Baseline measures of disease state and lying/standing blood pressure
Pretreat for 3 days with domperidone 20 µmg three times daily
Start levodopa 50 µmg as co-careldopa/co-beneldopa with food three times daily, 30 minutes after taking the domperidone
Continue for 4 days before increasing the levodopa by 50 µmg increments in divided doses every 4 days until a total daily dose of 300 µmg levodopa is reached continuing throughout with the domperidone
Review patient to assess motor response, side effects, and postural blood pressure changes
Continue to slowly build the daily dose of levodopa by 50 µmg increments every 4 days in divided doses as before until a total daily dose of 600 µmg is reached
Review to assess motor response and side effects after 4 weeks of 600 µmg levodopa daily
Adjust levodopa dose to obtain optimal benefit with the smallest dose possible
In nonresponders increase levodopa slowly as before until limited by side effects
Failure to respond to a dose of greater than 1.2 µg levodopa daily in the absence of malabsorption makes a diagnosis of Parkinson's disease very unlikely

Unpredictable absorption is a problem with these drugs and may account for the failure of these drugs to reduce levodopa-induced dyskinesias and fluctuations.⁸⁵ Dispersible formulations of levodopa (Madopar Dispersible) have a rapid onset of action and may be used to rescue subjects from sudden "off" periods and to provide a "kick start" on getting up in the morning. Subjects with dysphagia may also benefit from dispersible formulations. Sinemet tablets can be crushed and dissolved effectively in fizzy drinks and will readily pass down a fine bore nasogastric tube.

INHIBITION OF LEVODOPA METABOLISM

The effects of levodopa can be boosted by treatment with drugs that inhibit the breakdown of levodopa by the enzymes MAO-B and COMT. Entacapone given at a dose of 200 mg with each daily dose of levodopa prevents the peripheral metabolism of levodopa by COMT and increases the uptake of levodopa in the brain. A combination tablet of levodopa and entacapone (Stalevo) is also now available. Entacapone has been shown to increase the duration of the clinical response to levodopa in patients with and without motor fluctuations.^{86–88} Entacapone can cause nausea and vomiting, dyskinesias, discoloration of the urine, and diarrhea. Tolcapone, previously withdrawn because of liver toxicity, is now available again in the United Kingdom for specialist-restricted use under close supervision with careful monitoring of liver function.

Endogenous and exogenous levodopa can also be enhanced by central MAO-B inhibition using selegiline or the newer rasagiline,⁸⁹ which, unlike selegiline, is not metabolized to troublesome amphetamine-like metabolites. Both drugs have modest antiparkinsonian effects. The issue of potential neuroprotective effects of both these drugs is unresolved. The combination of selegiline and levodopa in older frail subjects appeared to be associated in one study with increased mortality and falls. Whether this also applies to rasagiline is unknown, but this class of drug may be best avoided in older patients with cognitive impairment or a history of falls and syncope.

LEVODOPA-INDUCED FLUCTUATIONS AND DYSKINESIAS

Chronic levodopa treatment can induce disabling motor fluctuations and dyskinesias.^{90,91} Sensory, psychic, cognitive, and autonomic fluctuations can also occur. The mechanisms behind these effects are poorly understood but presumably arise from the abnormal pulsatile stimulation of dopamine receptors resulting from standard drug treatment.^{76,92,93} Pulsatile receptor stimulation could lead to dysregulation of basal ganglia genes and proteins, such as preproenkephalin and dynorphin, and the induction of abnormal neuronal discharge in the basal ganglia output nuclei. The half-life of levodopa is only 1 to 1.5 hours, and this may explain why levodopa is so commonly associated with these problems. Longer-acting dopaminergic drugs appear to be less likely to cause these problems. Recent clinical studies have shown that motor fluctuations and dyskinesias can be significantly reduced in patients treated with dopamine agonist monotherapy compared with levodopa alone as the initial treatment.⁹⁴ Motor complications were also lower in a group of patients in whom levodopa was added to dopamine agonist treatment to improve efficacy compared to levodopa alone.

Clinical impressions suggest that motor fluctuations and dyskinesia are common after 5 years or so of levodopa exposure. The DATATOP study in 352 de novo patients reported a prevalence of 50% for motor fluctuations and 33% for dyskinesia after only a mean of 20 months levodopa exposure.⁹⁵ However, a study in 618 patients on levodopa treatment reported motor complications in only 22% of the study group after nearly 5 years of follow-up.⁸⁵ This difference may reflect methodologic differences between the two studies in the definitions of motor complications. Factors governing the risk of levodopa-induced complications appear to be the age of the patient at presentation, disease severity, and the dose and duration of levodopa treatment. Young patients presenting before 60 years old appear to be at particular risk of these problems. The risk of these problems, and much more relevantly the risk of *disabling* dyskinesias and motor fluctuations, seems to fall rapidly with increasing age of disease onset.⁹⁶ Above a disease onset age of 60 years, disabling dyskinesias as a result of levodopa are rare. Several strategies can be used to treat these problems when they do arise in elderly patients.⁹³ Amantadine has antidyskinetic effects, and more effective drugs to combat this problem are in development.

DOPAMINE AGONISTS

Dopamine agonist drugs have a limited role in older subjects in whom the risk of disabling levodopa-induced dyskinesias is very low.^{97,98} Dopamine agonists, with the exception of apomorphine, are less effective than levodopa, and side effects are more common, especially postural hypotension, confusion, and psychosis. Monotherapy with dopamine agonist drugs in order to delay the use of levodopa is rarely justified in older subjects, though agonists may be useful as adjunctive therapy to levodopa in carefully selected older people.⁹⁸ The ergot agonist group (bromocriptine, pergolide, and cabergoline) can rarely cause pleuroperitoneal fibrosis. Pergolide and cabergoline have also recently been linked with an increased risk of regurgitant heart valves.⁹⁹ Dopamine agonist treatment probably should now be restricted to nonergot agonists such as pramipexole, ropinirole, or the new transdermal

delivery formulation rotigotine. The rotigotine transdermal patch may be particularly useful in patients undergoing planned or emergency surgery to maintain treatment throughout the operation and in patients unable to absorb drugs orally after bowel surgery.¹⁰⁰

APOMORPHINE

Apomorphine is a particularly valuable but underused dopamine agonist that is administered subcutaneously by intermittent injection or continuous infusion.^{101,102} Apomorphine has a rapid onset of action and has a magnitude of effect similar to levodopa but of much shorter duration. Apomorphine by intermittent injection can be used to rescue patients from distressing motor (immobility, rigidity, tremor) and nonmotor (including sleep disturbance, pain, dyspnea, anxiety, depression, panic, dystonia) symptoms refractory to oral medication. Severe nausea and vomiting are commonly induced by apomorphine and can be controlled by pretreatment for a few days with oral or rectal domperidone 20 to 30 mg three times daily. Rotation of injection sites, massage of the skin before and after injection, reduction of apomorphine dose, and good injection technique can reduce the incidence of painful nodules at injection sites. Unfortunately, many older patients are unable to administer apomorphine by injection when they develop an "off" state and then rely on their spouse or partner to help out. Continuous administration by pump over the waking hours can decrease "off" time by around 50% to 70% and can also reduce levodopa-induced dyskinesias¹⁰³ and improve neuropsychiatric symptoms. An effective program of apomorphine treatment really requires the expertise and commitment of a PD nurse specialist who can work in both the hospital and the community. The successful use of apomorphine often requires the support of a spouse or partner, which is not often available for single, divorced, or widowed elderly people.

Elderly frail patients with advanced disease who still appear to get reasonable benefit from their oral drugs for at least some period of the day should be considered for a trial of apomorphine therapy.¹⁰² Apomorphine can lead to hypotension and drowsiness, which can limit its use, and nonresponsive features such as dysarthria, freezing, and postural imbalance will continue to progress. After a time, the benefits of apomorphine will become outweighed by side effects, disease progression, and difficulties of administration and will lead to drug withdrawal. In our practice we have successfully managed older patients for up to 5 years on apomorphine therapy with good results over this time.

DRUG TREATMENT OF NONMOTOR FEATURES

The treatment of nonmotor features remains a major challenge, particularly since dopaminergic drugs often make these worse. Cognitive impairment, depression, anxiety, autonomic failure, and sleep disturbance can be improved in some patients by using a wide range of drug and non-drug interventions. Depression can respond well to selective serotonin reuptake inhibitors such as sertraline¹⁰⁴ and citalopram,³⁸ and low-dose buspirone can help anxiety. Excessive sweating may be controlled by β -blockers in some subjects.¹⁰⁵ Postural hypotension that does not improve after simple measures can be managed by the careful use of fludrocortisone.¹⁰⁶ Domperidone can also be useful in this situation. Levodopa-induced neuropsychiatric

complications including hallucinations, delusions, and delirium may respond to atypical neuroleptic drugs such as clozapine and quetiapine started at a very low dose and slowly increased.^{107–109} Further research evidence is needed to determine whether acetylcholinesterase inhibitors such as rivastigmine and donepezil are useful to treat cognitive impairment in PD. Daytime drowsiness may respond to modafinil^{110,111} and REM sleep behavior disorder to low-dose clonazepam.¹¹²

DRUG STRATEGIES IN ADVANCED DISEASE AND PALLIATIVE CARE

With time, disabling features of PD dominate the clinical picture and do not respond to dopaminergic drug treatment. These include dementia, postural imbalance, dysarthria, and dysphagia. Falls become increasingly common, drooling is often a major source of embarrassment, and social isolation and difficulties in communication are common. At this stage in the disease, weight loss can be quite marked, appears out of proportion to the difficulties in nutrition caused by dysphagia, and occurs despite apparent adequate nutritional intake. Patients at this stage are less tolerant of dopaminergic drugs, and the insidious onset and development of cognitive impairment results in hallucinations, confusion, and psychosis. A common early sign of intolerance of levodopa is marked drug-induced drowsiness. Drug treatment at this stage is largely limited by the presence and extent of cognitive impairment. All medication needs to be reviewed, and any drugs with anticholinergic activity or known to cause confusion should be slowly withdrawn. Amantadine, selegiline, and dopamine agonist drugs tend to be poorly tolerated at this stage. Finally, if problems persist the dose of levodopa may also have to be reduced and a balance found between mental clarity and mobility.

In advanced stages of the disease, drug regimes often need to be simplified using low doses of standard formulation levodopa to try to maintain mobility as far as possible. Dispensable levodopa can be given by nasogastric tube. Severe rigidity may on occasion respond to intermittent apomorphine used at critical times of the day. Patients approaching the stage of palliative care will often be resident in nursing homes, particularly if cognitive impairment is advanced. The primary care team supported by the PD nurse specialist will need to work closely together to optimize treatment at this time. Pain can be a significant problem in some patients and again may respond to apomorphine. A clear management plan needs to be developed to deal with issues such as the use of antibiotics, the provision of artificial hydration and feeding, cardiopulmonary resuscitation, and the appropriateness of transfer to acute medical facilities.

SURGICAL TREATMENT

Neurosurgery, particularly deep brain stimulation of the subthalamic nucleus, is becoming increasingly used as a treatment option in PD.^{113–114} Unfortunately, it is unlikely that older patients will be suitable for neurosurgical interventions as most of these procedures primarily improve drug-induced dyskinesia or improve "off" time in patients with motor fluctuations, neither of which is a common situation in patients with late-onset disease. Additionally, cognitive impairment, which is the major contraindication to neurosurgery, is frequently already present in older patients. Deep

brain stimulation also requires a considerable ongoing commitment from both the patient and neurosurgical team. Furthermore, even in older patients with a good initial response, disease progression may result in any benefit from neurosurgery being short-lived.

PROGNOSIS OF PD IN OLDER PATIENTS

Patients and their families faced with the diagnosis of PD are understandably concerned about what the future holds for them in terms of keeping independent and minimizing disability. As with every chronic progressive disease, it is difficult to predict accurately an individual's prognosis. In older people the prognosis may also be determined by concurrent morbidity. Prognosis needs to be based on a detailed clinical assessment, the physician's clinical experience and judgment, and the application of research-based evidence. One large prospective clinical study of drug treatment in PD indicated that disability scores based on clinical assessment scales tended to return to pretreatment levels by 4 years of follow-up.¹¹⁵ This study recruited 782 patients who mostly had mild disease, though it is unclear how long symptoms had been present before study entry. The mean age of patients in this study was around 62 years old. The unified parkinson's disease rating scale (UPDRS) score of subjects requiring the addition of levodopa in the DATATOP study increased by around 7 points per year over the 3-year follow-up, most of the increase being due to deterioration in the motor subscale.⁹⁵ A total of 273 (34%) out of the original 800 patients recruited in this study needed to start levodopa treatment after 1-year follow-up. Clinical features associated with more rapid disease progression and a poor prognosis include older age at onset, impaired cognitive function, dominant akinesia-rigidity, and postural imbalance.^{54,55} In the absence of poor prognostic features, most older patients at diagnosis could reasonably be told to expect a period of 5 to 6 years of good disease control. Deteriorating cognitive function is likely to determine health-related quality of life more than advancing motor impairment.

Mortality is significantly increased in older patients with PD despite optimum drug treatment, and age-specific mortality rates appear to be increasing as frailer subjects reach older age. Cognitive impairment/dementia has a powerful influence on the survival of older people with PD.¹¹⁶

Other causes of Parkinsonism

Parkinsonism can arise from several causes (see Table 64-2), though these, with the exception of drug-induced parkinsonism, are much rarer than PD. Even though PD is the most common cause of parkinsonism, accounting overall for around 70% of cases, this proportion falls with increasing age.

DRUG-INDUCED PARKINSONISM

The most common form of secondary parkinsonism, largely the result of the use of neuroleptic (dopamine blocking) drugs in the treatment of serious mental illness, is drug-induced parkinsonism (DIP), which may still be frequently overlooked in older patients.¹¹⁷⁻¹¹⁹ A total of 32% of a series of patients with parkinsonism referred to a neurology clinic were found to have DIP. Older patients, especially women, have increased risk of DIP and may inadvertently be prescribed neuroleptic drugs to treat dizziness (prochlorperazine) and gastric upset (metoclopramide). Other non-neuroleptic drugs such as the calcium channel blocker

cinnarazine, tetrabenazine, and very rarely lithium, fluoxetine, paroxetine, and amiodarone can cause DIP. Clinically, DIP is indistinguishable from PD. Over 90% of cases tend to develop within 3 months of starting the offending drug. After withdrawal of the drug, signs of parkinsonism may take several months to resolve. In some older patients the signs never resolve, and careful monitoring reveals the subsequent development of PD. Presumably, subclinical PD was "brought on" by the neuroleptic drug. The treatment of DIP involves whenever possible stopping the causative drug. When this is not possible, anticholinergic medication can help control symptoms, as can amantadine. The value of levodopa is uncertain as it can worsen the mental condition for which the neuroleptic drug may have been originally prescribed and may be ineffective because of the dopamine receptor blockade.

PARKINSONISM-PLUS

Several rare multisystem degenerative conditions, such as progressive supranuclear palsy,^{120,121} multiple system atrophy,^{122,123} and corticobasal degeneration,^{124,125} can present with parkinsonism. Of these, multiple system atrophy can on occasion be impossible to distinguish clinically from sporadic PD for the whole length of the natural history of the disease. The response to treatment can also be misleading as multiple system atrophy can respond well to levodopa. Warning signs suggesting the possibility of parkinsonian-plus disease are a poor response to levodopa, poor tolerance of levodopa, striking asymmetry of motor signs, early onset of dementia, the presence of pyramidal or cerebellar signs, early onset of falls, rapidly deteriorating mobility, severe autonomic disturbance, and evidence of progressive supranuclear gaze abnormalities.

VASCULAR PARKINSONISM

Parkinsonism can result from vascular disease of the brain presenting with gait apraxia, truncal ataxia, relative sparing of the upper limb, and absence of tremor.^{126,127} A history of hypertension and of other vascular risk factors is often present, and brain imaging usually shows widespread deep white matter ischemic changes. Rarely, strategic infarcts within the basal ganglia can give rise to a condition indistinguishable from PD. The use of DaTSCAN-SPECT may be useful in this situation.

HYPERKINETIC MOVEMENT DISORDERS

Essential tremor

Essential tremor (ET) is the most common involuntary movement disorder and usually presents as a long-standing bilateral persistent postural tremor involving the hands and forearms.^{1,128} An action tremor is often also present. The head, voice, and legs may also be involved with decreasing frequency. In around a half of cases, a family history of similar tremor also exists, as does a temporary improvement of tremor after alcohol. Although usually annoying and embarrassing, ET can also result in severe disability and handicap. The prevalence of ET increases with age, reaching a crude figure of 39.2/1000 individuals over the age of 65 years old.¹²⁸

ET is commonly misdiagnosed as PD and is also sometimes confused with dystonic and drug-induced tremor. Dystonic

tremor can be easily confused with ET and tremor-dominant PD, though it tends to be more jerky in nature and is often associated with subtle dystonic posturing of the head.¹²⁹ Sometimes a trial of treatment is needed to help distinguish between these two conditions. Head tremor is rare in PD, though jaw tremor is not infrequently found. The distinction between ET and PD in older subjects is made more difficult as a resting tremor can occur in ET and tremor-dominant PD can be associated with a postural rather than resting tremor. A trial of drug therapy may again be needed. In this situation, diagnostic difficulty may be resolved by the use of DaTSCAN-SPECT.⁴⁸ The prevalence of PD in patients with ET appears to be slightly higher than that expected by chance alone, though this could reflect the diagnostic difficulties in relation to postural tremors.

The treatment of ET is disappointing, though some patients obtain benefit from β -adrenergic drugs such as propranolol or the anticonvulsant primidone. Side effects, especially in older subjects, limit the usefulness of these drugs. Severe cases of ET may respond to repeated botulinum toxin injections or bilateral thalamic stimulation. Primary orthostatic tremor, a fast palpable but not visible tremor of the thigh and calf, should also be recognized as a rare cause of unsteadiness on standing.¹³⁰

Dystonia

In older patients, dystonia most commonly presents as task-specific dystonia such as writer's cramp, blepharospasm, torticollis, dystonic head tremor, laryngeal dystonia, and cranial dystonia. Blepharospasm commonly presents in later life and when severe may respond to botulinum toxin injections. Blepharospasm can also complicate progressive supranuclear palsy and PD. Dystonia can respond to high-dose anticholinergic medication, though older patients tolerate this poorly.

Chorea

The rapid, often jerky, nonrepetitive and dancelike movements that typify chorea are not uncommonly seen in older subjects and require a diagnosis rather than the label of "senile chorea." Drugs are a common cause of this condition, particularly neuroleptics giving rise to tardive chorea. Levodopa also commonly causes choreiform dyskinesias. In older people, chorea can also result from subcortical vascular lesions. Hemiballismus, a high-amplitude form of usually unilateral chorea involving the arm and leg and occasionally the trunk, is seen in older patients as a result of infarction or hemorrhage in the region of the subthalamic nucleus. This movement disorder when severe can be life-threatening but is usually self-limiting and responds to neuroleptic drugs and tetrabenazine. Late-onset Huntington's disease must always be excluded.¹³¹ In this situation, chorea is usually associated with cognitive impairment. The diagnosis can be confirmed by genetic testing for evidence of an expanded cytosine-adenosine-guanine (CAG) repeat sequence on the short arm of chromosome 4.¹³² Other rare causes of chorea include systemic lupus erythematosus, neuroacanthocytosis, polycythemia rubra vera, hyperthyroidism, and electrolyte disturbances. Oro-buccal-lingual choreiform dyskinesia is not uncommon in studies of nursing home residents who have never been exposed to neuroleptic drugs, and appears to be related to loss of teeth and failure to wear dentures.¹³³

Restless legs syndrome

The condition of unpleasant deep sensory disturbances in the legs associated with irresistible leg movements on trying to get to sleep increases in prevalence with age.^{134,135} Subjects with these symptoms usually also have abnormal leg movements in the early stages of pre-REM sleep. Restless legs syndrome occurs in many other neurologic diseases as well as in medical conditions such as anemia and renal failure and in response to certain drugs such as lithium and tricyclic antidepressants. This condition can respond to levodopa, dopamine agonist drugs, clonazepam, and codeine.

Drug-induced movement disorders

Drugs commonly cause involuntary movements, usually as a result of the indiscriminate and inappropriate use of neuroleptic drugs in older people.¹³⁶ A wide range of other drugs have been linked usually by isolated case reports in the literature to involuntary movements, though it is often difficult to evaluate the clinical significance of such reports. In addition to parkinsonism and acute dystonic reactions, neuroleptics can also cause a wide range of tardive movement disorders including an intense and distressing motor restlessness called akathisia.¹³⁷ Neuroleptic malignant syndrome can result from the introduction or increase in dose of a neuroleptic drug or from sudden reduction in dopaminergic drug treatment for PD.¹³⁸ This syndrome consists of fever, intense rigidity, confusion, autonomic disturbance, and involuntary movements. Rigidity elevates the muscle enzyme creatinine phosphokinase, and rhabdomyolysis can develop with associated renal failure. Mortality from this condition can be high. A similar condition, the toxic serotonin syndrome, can result from the combination of a selective serotonin reuptake inhibitor with a monoamine oxidase inhibitor. Many drugs, including lithium, sodium valproate, amiodarone, tetrabenazine, amphetamine, tricyclic antidepressants, and beta agonists, can cause tremor. Chorea can result from the use of estrogens, lithium, and amphetamines, and myoclonus can result from the use of tricyclic antidepressants and chlorambucil.

KEY POINTS

Parkinsonism and Other Movement Disorders

- The prevalence of essential tremor, parkinsonism, and drug-induced movement disorders increases significantly with age.
- Movement disorders in older people often remain undetected and are difficult to diagnose, and individuals in whom such a diagnosis is considered should be referred for specialist assessment.
- Accurate diagnosis, comprehensive assessment, and careful documentation of the response to drug therapy and rehabilitation are key factors in the successful long-term management of these disorders.
- Delaying levodopa treatment in older patients with PD is rarely justified given the disabling nature of the condition and the low incidence of disabling levodopa-induced dyskinesias and motor fluctuations in this age group.
- PD is a multisystem degenerative disease and nonmotor features, particularly dementia and cognitive impairment, dominate the clinical picture in older subjects and largely determine quality of life.

Aging is associated with substantial decline in neuromuscular performance.¹ This is perhaps best exemplified by age-associated loss of muscle mass and strength, a phenomenon often referred to as sarcopenia (see Chapter 73 for full review of sarcopenia). Neuromuscular disorders are an important cause of disability at all ages but often result in greater impairment and disability in older adults as they are superimposed on age-related impairment of both motor and sensory function in the peripheral nervous system. For example, it is well established from both anatomic and in vivo electrophysiologic studies that aging alone is associated with significant reductions in the numbers of functioning motor neurons and motor axons.¹⁻⁴ This appears true for both distal and proximal muscles in the upper and lower limbs, but it may be more severe in distal lower limb muscles. Moreover, these losses of motor neurons (motor units) approach 70% in distal lower limb muscles by 80 years of age and are a major contributing factor to age-related loss of muscle mass, strength, and power (i.e., assessment of dynamic strength or force at a given velocity).^{5,6} In healthy older adults, lower limb strength and power are strongly related to functional indices such as gait speed and balance; these factors become of even greater importance in the frail elderly.^{7,8} What is less well appreciated is the substantial impact on function that occurs when a disorder affecting the motor or sensory system is superimposed on the normal aging process. Often this combination results in significant disability and contributes substantially to the frailty syndrome. For example, an 80-year-old woman with preexisting lower limb weakness following a fall and hip fracture who develops a peroneal nerve palsy superimposed on a diabetic neuropathy will experience much greater disability as a result of these combined problems than a younger counterpart with a simple foot-drop from peroneal nerve injury.

The impact of aging on the sensory system is less well established. Postmortem and biopsy studies show that aging results in losses of dorsal root ganglion cells and a decline in the numbers of sensory axons.^{9,10} This is apparent in reduced sensory nerve action potential amplitudes from standard nerve conduction studies in older men and women.¹¹ This likely translates to impaired sensory function that can impact balance and motor control. As with the motor system, any superimposed disorder will have a greater functional impact.

In addition, given these observations, in some cases slowly progressive disorders, such as inclusion body myositis (IBM) or polyradiculopathy, are mistaken for the expected or typical losses of muscle mass, strength, and power associated with aging. Therefore, it is imperative that clinicians appreciate common presenting features of neuromuscular disorders and recognize how they differ from so-called normal aging.

To this end, this chapter focuses on disorders that commonly present in older adults including polyneuropathies, spinal stenosis and neurogenic claudication, myopathies, motor neuron disease, and neuromuscular junction disorders. The general clinical approach is outlined, followed by a discussion of individual disorders and their treatment.

APPROACH TO THE PATIENT WITH NEUROMUSCULAR DISEASE

History

Weakness, fatigue, atrophy, and altered sensation are the most common presenting symptoms of neuromuscular disease (Table 65-1). An accurate history documenting the onset, pattern, and progression of weakness and sensory loss is crucial in differentiating diagnostic possibilities and may require several meetings with the patient and in some cases additional information from a spouse or relatives. In general, most myopathies and disorders of neuromuscular transmission present with proximal weakness and no sensory symptoms. Notable exceptions are myotonic dystrophy type I (DM1) and IBM that may present with predominantly distal weakness. Muscle wasting and loss of reflexes are late manifestations of most myopathies. Alternatively, most neuropathies present primarily with sensory symptoms, earlier loss of reflexes, and distal weakness. Early in the course of polyneuropathies, distal muscle wasting of intrinsic hand and foot muscles is often more impressive than strength loss. Notable exceptions are acute or chronic inflammatory demyelinating polyradiculopathy and diabetic amyotrophy, which may present with mainly proximal weakness.

Table 65-1. Typical Features of Neuromuscular Disorders Based on Their Localization

Motor neuron	Weakness and atrophy in segmental distribution Bulbar/respiratory involvement Fasciculations Upper motor neuron signs in ALS No sensory involvement
Nerve root	Pain and altered sensation in nerve root distribution Reduced or absent reflexes in same distribution Weakness and atrophy in myotomal distribution
Polyneuropathy	Sensory symptoms with distal to proximal progression Depressed or absent reflexes Distally predominant atrophy and weakness Distal sensory deficits
Neuromuscular junction	Proximal fatigue and weakness No atrophy Absence of sensory symptoms Diplopia, ptosis, bulbar involvement Fatigable weakness of proximal muscles
Muscle	Proximal weakness Weakness > atrophy No sensory involvement Retained reflexes

*Material in this chapter contains contributions from the previous edition, and we are grateful to the previous author for the work done.

Inquiries into sporting abilities, hobbies, occupational history, and military service often help establish the onset of symptoms. Many patients initially ascribe their neuromuscular symptoms to normal aging or painful conditions such as arthritis, and directed questioning is often required. Questions include "How far could you walk five years ago?" or "When did you first use a cane?" or "When could you last climb stairs?" More active patients are asked, "When could you last run?" This question is useful because increasing weakness may be present for months, and only the loss or impairment of some well-established task brings it to the patient's attention.

The distribution of weakness is often suggested by the history: difficulties reaching up to a shelf or combing hair suggest upper limb proximal weakness. Proximal lower limb weakness is suggested by difficulty in rising from a low chair or toilet, climbing stairs, and getting in or out of the bathtub. Primary neuromuscular disease rarely presents with falls early in the course, with the exception of inclusion body myositis (IBM), an inflammatory myopathy often associated with asymmetric quadriceps wasting and weakness that may present with "buckling" around the knees and falls. Catching the foot on stairs or difficulty in depressing car pedals, turning a key, or opening a jar suggest distal weakness. In myasthenia gravis (MG), power may be reported as normal at rest, with fatigable weakness developing after exercise or later in the day. Speech and swallowing problems, including coughing and choking after ingestion of solids or liquids, and unexplained recurrent pneumonia may suggest bulbar weakness. Weakness of the cervical muscles may lead to head drop, and some patients will report the need to use the hand to support the head. Some patients with cervical muscle weakness present with neck pain, reflecting prolonged and ineffectual voluntary attempts to keep the head up. The causes of dyspnea are numerous and most often in the elderly not primarily related to neuromuscular disorders. However, many neuromuscular disorders involve respiratory musculature. This may be manifest as shortness of breath on exertion and especially on lying flat, because of diaphragmatic involvement. Inflammatory myopathies, motor neuron disease, and neuromuscular transmission disorders should be considered in this setting. Other symptoms suggestive of neuromuscular hypoventilation include disrupted nocturnal sleep, daytime hypersomnolence, early morning mental clouding, and headache as a result of CO₂ retention with associated cerebral vasodilatation.

Myalgia is a relatively nonspecific feature seen in many patients with progressive muscular disease. Patients often find myalgia hard to describe and differentiate from joint pain. Prominent myalgia is a feature of many inflammatory myopathies, polymyalgia rheumatica, and the metabolic myopathies. However, pain at rest and lack of pain or cramp with exertion is less suggestive of an underlying defect in muscle metabolism and more suggestive of inflammatory muscle disease, referred pain from joint disease or a myofascial pain syndrome. Uncommonly, myalgia is a presenting feature of the muscular dystrophies such as fascioscapulohumeral dystrophy. Proximal myotonic myopathy (PROMM) or DM2, a myotonic disorder with some similarities to myotonic dystrophy (DM1 or Steinert's disease), often presents with muscle pain, stiffness, and proximal weakness. Painful nocturnal muscle cramps can reflect

neurogenic diseases including motor neuron disease (MND), polyneuropathies, or chronic lumbosacral nerve root injury. Alcohol and drugs, especially those that induce hypokalemia (e.g., diuretics) or those with a structural effect on muscle (e.g., the statins), may induce myalgia. Finally, myalgia may be a prominent symptom in patients with endocrine dysfunction (especially hypothyroidism and hypocalcemia) and those with connective tissue disorders such as systemic sclerosis.

A wide-ranging systemic inquiry is essential in patients with suspected myopathies, as myositis may be a component of many collagen vascular diseases. Both DM1 and PROMM are multisystem disorders whose manifestations are varied and include diabetes, cataracts, cardiac conduction defects, and muscular weakness and wasting. Cardiac involvement is common in many neuromuscular diseases manifesting with cardiac conduction defects or cardiomyopathy or both. Prominent weight loss is a common feature in MND, reflecting both poor nutritional state and loss of muscle bulk.

Many neuromuscular diseases are inherited, and therefore it is important to inquire specifically about family members and, where appropriate, about consanguinity. Premature cardiac and respiratory deaths in family members may reflect complications of an inherited neuromuscular disease or possible associated malignant hyperthermia, if associated with anesthetic exposure. It is often useful to examine first-degree relatives in a family suspected of having an inherited neuromuscular disorder even when the history does not suggest that the elderly relative is affected, as this can be confirmed by direct examination and has clear genetic implications for the wider family. Myotonic dystrophy, because of its marked variability in expression and the presence of anticipation, may present in older patients with minor manifestations only (e.g., cataracts), compared with major symptoms in siblings. The genetic defect, a trinucleotide repeat expansion, is unstable and may worsen in successive generations particularly via the female line, leading to "anticipation," with earlier onset and more severe disease in successive generations.

Sensory symptoms suggest involvement of the dorsal root ganglion, nerve roots, or sensory fibers (including the central projections such as the dorsal columns). Numbness and paresthesias distally in the toes and feet are the most common presenting symptoms of symmetrical polyneuropathies. Symptoms of burning pain, coldness, tightness, and prickling may suggest predominantly small fiber involvement, whereas numbness and loss of balance may indicate predominantly large fiber involvement. The presence of orthostatic hypotension, gastrointestinal disturbance, dryness of the eyes and mouth, and erectile dysfunction in men indicate autonomic involvement. Sensory loss when patchy or asymmetrical may indicate an underlying vasculitic process or sensory neuronitis. Loss of balance, particularly when in the dark (reducing visual input), may indicate large fiber sensory loss and poor proprioception. Other early clues are difficulty with balance when showering or when walking on uneven surfaces. Again, as with some early motor symptoms, these complaints are often attributed to normal aging and it is not until they are particularly disabling that medical attention is sought or investigation pursued.

Examination

The aim of the examination of the neuromuscular system is to determine the distribution of muscle weakness, sensory loss, and reflex abnormality in order to localize the lesion within the peripheral nervous system (see Table 65-1). Furthermore, it is important to assess the respiratory, cardiovascular, and dermatologic systems for associated abnormalities. The examination may provide clues to the etiology and allows for grading of severity. Most acquired and inherited myopathic disorders present with proximal weakness and wasting (a limb girdle distribution). Selective patterns of muscle involvement may suggest facioscapulohumeral dystrophy (FSHD) or one of the many subtypes of limb girdle muscular dystrophy, but confirmation often relies on DNA analysis or muscle biopsy. A scapulo-peroneal distribution of weakness may reflect a myopathic disorder, such as FSHD, or a neurogenic problem, such as spinal muscular atrophy. Myasthenia gravis (MG) presents with fatigable proximal weakness but without wasting. Lambert–Eaton myasthenic syndrome (LEMS) presents with fatigable proximal weakness and wasting that can be hard to distinguish clinically from a myopathy, although the reduction in deep tendon reflexes (DTRs) provides a valuable diagnostic clue. Distal weakness, with involvement of the forearm and hand muscles in the upper limb and the anterior and posterior tibial compartment in the lower limb, is commonly due to a peripheral neuropathy or MND but can also be seen in myotonic dystrophy, IBM, very rare distal forms of spinal muscular atrophy, and in distal myopathies. Weakness of neck flexion and extension (head drop) occurs in myopathic (e.g., DM1, inflammatory myopathy, FSHD), neuromuscular junction (myasthenia gravis), and neurogenic (e.g., MND) disorders. Paradoxical abdominal movements and indrawing of intercostal muscles on inspiration may indicate respiratory muscle and diaphragm weakness.

Having established the pattern of weakness, the symmetry of involvement is often a guide to the underlying etiology. Most myopathic diseases result in symmetric weakness. In addition, around a joint, all of the muscles will be involved to about the same degree. IBM is a noteworthy exception to this as asymmetric quadriceps involvement is common. In some neurogenic diseases, such as MND, asymmetry and unequal involvement around a joint are seen, as the weakness tends to follow a segmental pattern of spinal cord involvement, often starting locally and then progressing.

In primary muscle disorders, tone and reflexes are either normal or mildly reduced. Increased tone and reflexes suggest an upper motor neuron disorder, amyotrophic lateral sclerosis (which ultimately has combined upper and lower motor neuron involvement), or cervical spondylitic myelopathy. Fasciculations are spontaneous, involuntary, visible discrete muscle twitches and reflect motor neuron or motor axon hyperexcitability. Fasciculations are not seen in muscle disease and rather reflect neurogenic disorders such as MND but also peripheral neuropathies and chronic nerve root disease where denervation is a feature. As it is sometimes difficult to differentiate myopathic and neurogenic weakness on symptoms alone, a careful search should be made for fasciculations in all patients presenting with neuromuscular weakness. Fasciculations may be missed if patients are not undressed fully. The back, abdomen, and tongue should be

inspected as well as the limbs. Difficulty is often encountered in observing fasciculations in the tongue; these are best seen with the tongue lying at rest in the floor of the mouth. Apparent fasciculation may be seen in the normal individual when the tongue is protruded due to anxiety and tremor.

Myotonia (delayed relaxation) is an uncommon presenting complaint in the older patient, and usually signifies myotonic dystrophy, which usually presents in the second or third decade. Joint contractures are occasionally due to inherited muscle disease, whereas foot deformities such as pes cavus reflect longstanding, often genetic, peripheral neuropathies or a slowly progressive upper motor neuron disorder such as hereditary spastic paraparesis.

Depressed or absent reflexes generally indicate a neuro-pathic disorder, with reflex loss a late sign in muscle diseases. The combination of muscle wasting, weakness, and hyper-reflexia is typical of amyotrophic lateral sclerosis (ALS), but can also be seen with cervical polyradiculopathy and concomitant cervical myelopathy. In these cases, the presence of upper motor neuron signs (e.g., jaw jerk) rostral to the most caudal lower motor neuron signs is a useful observation suggestive of ALS.

Distal, symmetric loss of sensation to pain (pinprick) and temperature are common features of typical, length dependent neuropathies with small fiber involvement. In the elderly, mild loss of vibration sense in the toes is nonspecific, but loss at the ankle or more proximally indicates large fiber involvement, either as a result of a peripheral neuropathy or myelopathy with involvement of the dorsal columns. Loss of proprioception is often a late finding of large fiber sensory loss, as is a positive Romberg's test. Obviously it is important to recognize sensory deficits that follow the distribution of individual peripheral nerves (e.g., median, ulnar or peroneal nerve) or dermatomes as they indicate a focal mononeuropathy or radiculopathy. The combination of intermittent sensory symptoms in the hands and distal sensory loss in the feet may indicate polyneuropathy, but in the elderly carpal tunnel syndrome in combination with multilevel lumbosacral nerve root compression and spinal stenosis should also be considered. As outlined later, electrophysiologic testing is invaluable in sorting these cases out.

Investigations

It is sometimes impossible on the basis of history and examination alone to make an accurate diagnosis in many cases of neuromuscular disease, not least because of the overlap in clinical signs between some neurogenic and myopathic disorders. Confirmation of a neuromuscular diagnosis requires the application of electrophysiologic, pathologic, biochemical, and, increasingly, genetic testing.

With several caveats, measurement of "muscle enzymes" is useful in patients with neuromuscular disease. Serum creatine kinase (CK) appears to be the most sensitive index of muscle necrosis from primary muscle disease and from secondary muscle fiber necrosis because of chronic denervation from neuropathic conditions. The magnitude of CK rise gives some indication of the nature of the pathology: in denervating conditions such as MND, CK levels are commonly mildly elevated in the 200 to 500 IU/L range and rarely above 1000 IU/L, whereas a more significant increase of 10- to 1000-fold suggests a primary muscle (especially inflammatory myopathy). However, CK levels must be interpreted with

caution, as “muscle enzymes” are also found in other tissues. CK consists of three separate isoenzymes: MM, derived from skeletal muscle, MB, derived largely from cardiac muscle, and BB, derived mainly from brain. High CK levels may therefore be seen in patients with acute myocardial injury, large strokes, and occasionally with hepatic disease, as well as in patients with muscle disease. Even so, given that the major isoenzyme of CK is MM, a high CK level is most likely to reflect neuromuscular disease. Finally, it is also important to appreciate that mild increases in what are typically thought to be liver enzymes such as AST and ALT can occur in primary muscle disease (ALT proportionally higher is more indicative of hepatic disease).

ELECTROPHYSIOLOGY

Electrophysiologic studies are invaluable in the diagnosis of neuromuscular disorders. A detailed discussion of electrophysiologic (electromyographic, EMG) techniques in the diagnosis of neuromuscular disease is outside the scope of this chapter but can be found in appropriate textbooks.¹² Nerve conduction studies (NCS), in which the conduction velocities and amplitudes of motor and sensory (compound) action potentials in response to electrical stimulation of nerves are measured, are used to detect primary pathology of peripheral nerves. NCS are extremely useful in detecting focal nerve injuries such as median neuropathy at the wrist in the carpal tunnel syndrome, or common peroneal nerve injury around the fibular head. Reduced amplitudes of motor and sensory studies with mild conduction velocity slowing in the legs are typical of many of the common axonal, length-dependent polyneuropathies (e.g., drug-related, diabetes, idiopathic). Severe conduction slowing and conduction block in multiple nerve segments are important observations as they indicate an acquired demyelinating, often treatable chronic inflammatory demyelinating polyneuropathy (CIDP).

The most common method for the electrophysiologic assessment of muscle is with concentric or monopolar needle electromyography (NEMG), which detects characteristic patterns that can be used to distinguish neurogenic and myopathic disorders. Normal muscle is electrically silent at rest. In neurogenic disorders resulting in denervation (e.g., ALS), positive sharp waves or fibrillation potentials are seen in NEMG studies, and on voluntary activation a reduced interference pattern of the motor unit potentials is seen, reflecting the loss of motor units. By contrast, in many myopathies NEMG reveals small, short-duration motor unit potentials. Electromyography (EMG) studies may also reveal complex repetitive and myotonic (audible as a “dive bomber” or “revving motorcycle” sound) discharges, useful in confirming myotonic disorders, and may suggest a previously unsuspected diagnosis such as PROMM (DM2) where weakness predominates and myotonia is often subclinical.

Repetitive nerve stimulation studies are useful in neuromuscular transmission disorders. In both MG and LEMS, a decrement in compound muscle action potential response occurs at low frequency (2 to 3 Hz) stimulation, which mirrors the clinical phenomenon of fatigable weakness. In LEMS, a characteristic incremental response occurs with high-frequency stimulation or after brief maximal voluntary contraction, which mirrors the clinical phenomenon of post-tetanic, or post-contraction facilitation. Single-fiber EMG (SFEMG) is useful in confirming a neuromuscular junction disorder, particularly in regional

forms of MG. It is important to note that whereas SFEMG is highly sensitive for neuromuscular junction disorders (> 95%), it is, in turn, very nonspecific with abnormal results possible in any chronic neurogenic condition or myopathies.

MUSCLE BIOPSY

Despite advances in biochemistry, neurophysiology, and genetics, the final diagnosis in patients with muscle disease often requires a muscle biopsy. The development of the technique of needle muscle biopsy, which can be undertaken as a simple outpatient procedure, has made possible one-stop diagnostic neuromuscular clinics with combined clinical, neurophysiologic, and muscle sampling. The vastus lateralis and deltoid are commonly biopsied, ideally sampling a muscle that is weak but only moderately affected clinically but not too atrophied, for fear of sampling muscle with only end-stage pathology. Routine histologic stains can be employed on both paraffin-embedded and fresh frozen material and permit assessment of muscle fiber size, fiber morphology, and the presence or absence of inflammation. Other stains allow differentiation of muscle fiber types and can be used to study the distribution of cellular enzymes and metabolic reserves.¹³ Immunohistochemistry on frozen muscle using antibodies directed against sarcolemmal muscle proteins, such as dystrophin and the sarcoglycans, is crucial in the diagnostic workup of suspected dystrophinopathies and limb girdle muscular dystrophies and permits a more focused search for genetic abnormalities. Western blotting techniques on muscle are often essential in confirming the suspicion of muscular dystrophies. Direct measurement of enzymic activity in fresh muscle is sometimes useful in diagnosing rare metabolic disease such as acid maltase disease and in mitochondrial myopathies where respiratory chain enzymes can be assayed. Electron microscopy of muscle is useful to confirm suspected mitochondrial abnormalities seen on light microscopy and especially to look for intracellular inclusions, which occur in some inherited and acquired muscle disease. Muscle samples are hard to process, hard to orient, and degrade rapidly—all of which combine to make the technique unsuitable for routine laboratories. Furthermore, interpretation of muscle biopsies and exclusion of artifactual change is difficult, and it is important therefore that muscle samples are sent to special neuromuscular laboratories or to an experienced pathology center. As percutaneous needle and punch biopsies are far less invasive than open procedures, it is possible to follow a patient with a muscle disease and monitor response to treatment in individual patients using sequential biopsies.

PERIPHERAL NEUROPATHIES

Peripheral neuropathies are overall the most common neuromuscular disorders that present in older adults. It is beyond the scope of this text to provide an in-depth review of all peripheral neuropathies, and the reader is directed to a number of excellent texts in this regard.¹² This section provides an overview of peripheral neuropathies and specifically addresses diabetic neuropathy because of its high prevalence in the elderly.

Typical symptoms of peripheral neuropathy include distally predominant weakness, sensory loss, poor balance, and autonomic dysfunction. Weakness in the majority of

polyneuropathies follows a length dependent pattern and is therefore often more severe in the lower than upper limbs. Weakness tends to become symptomatic in the extensors of the toes and ankles and evertors of the ankle earlier than in the plantar flexors. In the upper limb, difficulties with fine motor tasks such as fastening buttons or picking up coins can be early indications of weakness.

Sensory symptoms of polyneuropathies can be divided into those that indicate involvement of small, thinly myelinated fibers that subserve pain and temperature and those that suggest involvement of large myelinated fibers that are involved in position sense. Common symptoms of small fiber neuropathies include hypersensitivity to footwear or bedclothes, shooting or stabbing pain, difficulty detecting temperature of bath water, and burning sensation. These symptoms usually predominate in the feet, as most neuropathies are length-dependent. However, when sensory symptoms reach the level of the knees, they often begin in the hands. Small fiber sensory symptoms of burning, prickling, and allodynia are a common cause of sleep disturbance in the elderly. These symptoms should prompt a careful assessment for decreased sensation to pinprick and temperature for consideration of a small fiber–predominant neuropathy.

Large fiber involvement will typically present with loss of balance and gait difficulty because of the loss of proprioception or position sense. These symptoms often result in mobility limitations in the elderly and fear of falling. In particular, patients with balance impairment secondary to peripheral neuropathy tend to avoid crowded areas such as grocery stores and shopping malls. These symptoms should prompt an examination for decreased sensation to light touch, vibration, and position sense as well as loss of deep tendon reflexes.

Autonomic symptoms include urinary retention or incontinence, abnormal sweating, constipation and diarrhea, and symptoms of orthostatic hypotension. These symptoms are often initially overlooked as indicative of a neuropathic disorder and prompt assessment for a primary cardiac or central neurologic disorder cause.

Most neuropathies affect both motor and sensory fibers; however, pure or predominantly sensory involvement can be seen in concert with diabetes, malignancies (paraneoplastic neuropathies), and idiopathic sensory neuropathy in the elderly. Pure motor involvement may indicate multifocal motor neuropathy (MMN), a rare demyelinating disorder that typically presents initially with focal weakness of upper limb muscles, or may suggest motor neuron disease. Along the same lines, most neuropathies present with symmetric, distally predominant features. Asymmetry may indicate mononeuritis multiplex associated with vasculitis, hereditary neuropathy with liability to pressure palsies, or common focal or entrapment neuropathies. [Table 65-2](#) outlines some common presentations based on the predominant fiber population involved.

Once a pattern of small or large sensory fiber predominance has been established, the absence or presence of motor involvement has been defined, and the symptoms and signs have been determined as symmetrical or asymmetric, it is often of considerable value to obtain electrophysiologic studies before other investigations. Most expert clinicians agree that is also useful to obtain a fasting blood sugar, serum creatinine, electrolytes, a complete blood count, vitamin B₁₂

level, and serum protein electrophoresis (and immunofixation if indicated) as part of the initial workup. Further, often expensive testing for specific antibodies or genetic testing should await the results of electrophysiologic testing and is often best directed by clinicians and centers with specialized expertise.

Electrophysiologic testing is extremely helpful in tailoring future investigation as it can determine whether the process is predominantly axonal (most common) or demyelinating. The presence of a demyelinating process is extremely important to establish, as these often indicate a treatable acquired neuropathy (CIDP, MMN) or a hereditary neuropathy if there is uniform slowing of conduction velocities. If an axonal neuropathy is present, it is important to determine if it is symmetric (most common) or asymmetrical and multifocal, which may indicate an underlying vasculitic process requiring further investigation and treatment.

It is important to note that standard nerve conduction studies only examine large, myelinated fibers. Therefore, the studies may be normal or only mildly affected in small fiber neuropathies (e.g., diabetes).

Diabetic neuropathy

Diabetic neuropathy is the most common form of peripheral neuropathy in the Western hemisphere with increasing prevalence resulting from the growing prevalence of Type II diabetes. A number of different classification schemes exist for diabetic neuropathy and a common one is outlined in [Table 65-3](#). The commonest form is a mixed but predominantly sensory, motor and autonomic diabetic peripheral neuropathy (DPN) which may comprise up to 70% of cases.¹³

Table 65-2. Peripheral Neuropathies Based on Predominant Symptoms

Motor predominant
Guillain-Barré syndrome, chronic immune demyelinating polyneuropathy, Charcot-Marie-Tooth disease, multifocal motor neuropathy, motor neuron disease
Sensory predominant
Idiopathic, diabetic symmetric polyneuropathy, paraneoplastic (often ganglionopathy), Sjögren's syndrome, paraprotein-associated, vitamin E deficiency (very rare)
Small fiber sensory only
Diabetic neuropathy, idiopathic (acute or chronic), hereditary sensory and autonomic neuropathy (very rare)

Table 65-3. Clinical Classification of Diabetic Neuropathies

Symmetric
<ul style="list-style-type: none"> • Diabetic polyneuropathy • Diabetic autonomic neuropathy • Painful diabetic neuropathy
Asymmetric
<ul style="list-style-type: none"> • Diabetic radiculoplexopathy • Diabetic thoracic radiculoneuropathy • Mononeuropathies <ul style="list-style-type: none"> • Carpal tunnel syndrome • Ulnar neuropathy at the elbow • Peroneal neuropathy at fibular head • Cranial neuropathies

A predominantly sensory, often painful, neuropathy comprises the other largest group. Diabetic neuropathy is common and may be present in up to 50% of type I diabetics and 45% of type II diabetics if comprehensive batteries of testing are used.¹⁴ In patients with only impaired glucose tolerance, the prevalence figures remain controversial.¹⁵ Risk factors for DPN include the duration and severity of hyperglycemia, smoking, and the presence of other complications including retinopathy and nephropathy, and cardiovascular disease. The pathophysiology of DPN remains somewhat controversial but includes axonal injury from polyol flux, particularly sorbitol through the aldose reductase pathway, microangiopathy and hypoxia, oxidative and nitrate stress from free radicals, and deficiency of growth factors.¹³

Symptomatically, patients with DPN typically present with positive neuropathic features such as prickling, tingling, and pins and needles, burning, or occasionally shooting sensations. Negative symptoms such as numbness of the toes or feet can paradoxically occur along with the positive features. Many patients experience symptoms mainly at night and experience painful allodynia (pain in response to nonpainful stimuli) from bed sheets or through the day with walking or footwear. True sensory ataxia is less common but can occur with severe involvement. Symptoms may stay confined to the lower extremity but may advance to the hands as they progress to the level of the knees in the lower limb. Early sensory symptoms in the hands should raise the question of a superimposed carpal tunnel syndrome (CTS), which has a very high prevalence in those with DPN.¹⁶

Clinical examination in DPN reveals distal, sensory greater than motor deficits to all sensory modalities and often loss of ankle deep tendon reflexes. Motor deficits are less common but patients may have weakness of toe extensors and flexors and in more severe cases weakness of ankle dorsiflexors.

Diabetic foot ulcers are of considerable importance when assessing elderly patients with DPN. Diabetic ulcers occur because of a combination of sensory loss and repetitive pressure on bony prominences such as the metatarsal heads or heel. This in combination with drying and cracking of the skin leads to chronic tissue injury. Further progression may occur as a result of loss of proprioception leading to abnormal foot position and biomechanics. Careful inspection of the feet on a daily basis, screening for early evidence of sensory deficits, proper footwear with adequate height of the toe box or forefoot, and foot orthoses are all useful in terms of preventing the occurrence of ulceration and reducing the risk of amputation.¹⁷

Diabetic lumbosacral radiculoplexopathy neuropathy (DLRPN), often referred to as diabetic amyotrophy or proximal diabetic neuropathy, requires special mention due to its higher prevalence in the elderly and the severe disability often associated with it. DLRPN is a devastating condition that may affect only about 1% of typically type II diabetics.¹⁸ It typically presents with severe, acute onset of proximal leg pain and weakness. Frequently it occurs in concert with a large concomitant weight loss. In many cases, affected patients have not been diabetic for a long period of time and have no other end organ complications from DM. The symptoms are usually unilateral and involve proximal lower limb segments such as the hip flexors and knee extensors. The condition may spread more distally and to the contralateral side over a few days. Although pain is the

most severe initial manifestation, often requiring narcotic analgesia, severe weakness typically develops in the first few days, often severely affecting the hip flexors and knee extensors but also in the more distal muscles including the ankle plantar and dorsiflexors. Gait aids or wheelchairs are often required for mobility.

The cerebrospinal fluid will reveal elevated protein providing evidence that the disease process is proximal at the level of the spinal roots. Electrophysiologic (EMG) testing reveals axonal injury or denervation in affected muscles, including the para-spinals, often with severe loss of recruitment implying substantive loss of axons. Given that axonal loss is the mechanism, the time course of recovery is typically many months. In the authors' experience, most of these patients do well, if provided supportive therapy and then treated later with appropriate physical therapy in the form of resistance exercise and gait retraining.

The pathophysiologic basis of diabetic lumbosacral radiculoplexopathy (DLRP) is ischemic injury possibly secondary to microvasculitis. Given this, immunomodulation may be useful if started early in the course of disease, as has been demonstrated in nondiabetics with idiopathic lumbosacral plexopathy. To date, however, clinical trials in diabetics have not supported this theory.¹⁸

NEUROGENIC CLAUDICATION AND SPINAL STENOSIS

Lumbosacral radiculopathy and specifically multilevel root disease often associated with lumbosacral spondylosis, and associated spinal stenosis is a common, often debilitating problem that typically affects older adults.¹⁹ Symptoms of neurogenic claudication are often mistaken for polyneuropathy; however, there are specific features on history, physical examination, and electrodiagnostic testing that help distinguish these conditions. The most common symptom of neurogenic claudication secondary to lumbosacral spinal stenosis is back pain and aching pain that refers into the buttocks, hamstrings, thighs, and lower legs worsened with exercise. Often there is associated numbness and weakness that occurs in association with the pain and discomfort. Typically, contrary to most neuropathies, the symptoms of pain, numbness, and weakness improve with rest or when seated. Lumbar extension tends to worsen symptoms, and most patients improve with flexion of the spine (e.g., walking while pushing a shopping cart or riding a bicycle, which may be much easier than walking similar durations). This is in contrast to vascular claudication, which tends to produce more localized pain in the calves, no sensory symptoms, and tends to be unaffected by spinal position.^{20,21} The physical examination is often uninformative in patients with features of neurogenic claudication. It may reveal reduced or absent ankle jerks if the S1 roots are affected and distal sensory loss in the L5 and S1 distribution. Fixed weakness is uncommon and usually mild.

Imaging with computed tomography (CT) scanning or magnetic resonance imaging (MRI) typically reveals multilevel degenerative spondylitic disease, foraminal narrowing and encroachment, and central canal narrowing. The latter two are secondary to disk protrusion, thickening of the ligamentum flavum, and facet hypertrophy secondary to degenerative disease. Spondylolisthesis, usually degenerative, also may lead to significant canal narrowing.

Electrodiagnostic testing in patients with neurogenic claudication may reveal reduced distal compound muscle action potentials in the intrinsic foot muscles secondary to chronic axonal injury in the L5 and S1 roots. The sural and superficial peroneal sensory nerve action potentials may be mildly reduced but are typically well preserved given that the injury is proximal to the dorsal root ganglion. This pattern of severe motor involvement and mild sensory involvement is sometimes erroneously interpreted as indicative of a polyneuropathy. However, this is the opposite pattern of that seen in the vast majority of polyneuropathies that present with earlier and more severe sensory involvement on nerve conduction studies with less severe motor involvement. Needle EMG of lower limb muscles (tibialis anterior, gastrocnemius, quadriceps) often reveals mild, chronic denervation, reinnervation changes in the form of large amplitude, long duration motor unit potentials with little or no evidence of active denervation.

Conservative treatment is often undertaken initially and includes physiotherapy mainly focusing on spinal flexion and aerobic exercise such as cycling, which tends to be better tolerated than walking. Pain usually responds to nonsteroidal anti-inflammatory drugs (NSAIDs) or mild narcotic analgesics (e.g., codeine). Patients with severe back and radicular pain may benefit symptomatically from epidural corticosteroid injections.

Surgical intervention should be considered for those who do not respond adequately to nonoperative treatment or if their disability is severe (principally mobility limitations). The typical approach involves laminectomy and partial facetectomy. The role of fusion is less clear but is often recommended when there is stenosis accompanied by spondylolisthesis. There is some evidence from randomized controlled trials supporting surgery over conservative management, at least in the 2 years following surgery,²¹ and the surgical outcomes tend to favor those with greater canal narrowing.²²

INFLAMMATORY MYOPATHY

Inflammatory myopathy, or myositis, is among the most common muscle disorder presenting acutely or subacutely in elderly patients and can be subdivided into infectious and idiopathic categories. Infectious causes, including viral and bacterial pathogens, are the most common causes of myositis worldwide but tend to be transient. Idiopathic inflammatory myopathies are a significant cause of chronic neuromuscular disease and constitute a spectrum that includes polymyositis (PM), dermatomyositis (DM), and inclusion body myositis (IBM). PM and DM are related but distinct conditions and are discussed together first.

Etiology of polymyositis and dermatomyositis

Both PM and DM are autoimmune disorders, though the antigenic targets are ill defined. There is strong circumstantial evidence that PM is an autoimmune (AI) disorder: like most AI disorders, PM is more common in women; PM may arise or fluctuate in pregnancy; PM is often associated with other organ- and nonorgan-specific AI disorders; a PM phenotype can be triggered by viral illnesses (HIV and HTLV-1) or by certain drugs, especially D-penicillamine; PM responds

to immunosuppression and modulation; finally, as further discussed later, muscle biopsies provide evidence of T-cell-mediated cytotoxic process directed against unknown muscle antigens. Similarly, DM is more common in women, may arise or fluctuate in pregnancy, is often associated with other AI disorders, can be triggered by D-penicillamine, responds to immune therapies, and muscle biopsies show damage reflecting a humoral-mediated capillary angiopathy.

Clinical features of polymyositis and dermatomyositis

DM presents in childhood or in the elderly with a female predominance, as with many other AI disorders. PM is rare in children and the majority of patients present in the third to fifth decade.²³ PM and DM present with symptomatic proximal weakness causing functional impairment (neck extensors and flexors, shoulder girdle, trunk and abdominal muscles, and hip and knee extensors and flexors), diffuse myalgia in up to a third of patients (especially in DM), or a rash. Examination reveals symmetric proximal weakness and wasting with preserved deep tendon reflexes, and neck and bulbar weakness are common. The pathognomonic rash of DM is a purplish-red butterfly discoloration over the face, often associated with periorbital edema and a heliotrope rash over the eyelids. An additional V-shaped rash may be seen in the sun-exposed areas of the chest. Patients may present with a typical rash of DM without clinically apparent weakness (amyopathic DM), though interestingly these same patients do have subclinical changes evident on muscle biopsy.²⁴ Polymyalgia rheumatica, sometimes confused for an inflammatory myopathy, causes myalgia that is often worse in the shoulder girdle but without significant weakness.

Symptomatic myoglobinuria may occur in rare, acute presentations of both PM and DM, and can precipitate acute renal failure.

PM and DM are frequently associated with connective tissue disorders: PM with lupus, Sjögren's syndrome, and rheumatoid arthritis; and DM with scleroderma and mixed connective tissue disease.⁵ Systemic features including vasculitis of the heart or gut, subcutaneous calcinosis, Gottron's nodules around the knuckles, and nail fold capillary changes are seen in DM.²⁵

Respiratory muscle weakness occurs rarely in both PM and DM, but fibrosing alveolitis is relatively common in DM, and it is then often associated with antibodies against Jo-1 (t-histidyl transferase synthase).²⁶ Aspiration pneumonia can occur in patients with severe bulbar weakness and in DM patients with esophageal involvement.

DM, and perhaps PM, can be associated with an underlying malignancy, though estimates of the frequency of this association vary widely from around 5% to 40% in published series.²⁷ This disparity in part reflects differences in case ascertainment: many case reports are anecdotal and there are few prospective or retrospective studies. Moreover, diagnostic criteria have also differed between reports, and muscle biopsy has not always been employed to confirm the presence of necrosis. Whatever the true incidence of this association, simple investigations, along with a systemic examination including mammography, a chest radiograph, and an abdominal ultrasound, are appropriate. The underlying malignancies mirror those found in the population of similar age and gender.

Differential diagnosis of polymyositis and dermatomyositis

The clinical diagnosis of DM is usually straightforward, though lupus associated with a facial rash and motor neuropathy might cause confusion. Differential diagnosis of PM is wider, as it may be confused with inclusion body myositis (discussed later), motor neuron disease, or myasthenia. The weakness in MG often affects deltoids and triceps, whereas the inflammatory myopathies more commonly affect deltoid and biceps. Additionally, in myasthenia muscle weakness occurs without significant muscle wasting, and in motor neuron disease both upper and lower motor neuron features are apparent. Finally, as inflammatory myopathies presenting in elderly patients can be confused with muscular dystrophies, it is always prudent to take a family history, particularly in those who have not shown the expected response to immunosuppression.

Investigations of polymyositis and dermatomyositis

Serum creatine kinase (CK) is usually, but not always, elevated, often 10 to 50 times the normal value, and this is almost exclusively due to increases in the CK-MM fraction. However, CK values do not correlate well with either myalgia or weakness in PM and DM patients, and in up to 15% of clinically affected individuals CK values are normal. Although the erythrocyte sedimentation rate (ESR) is also usually elevated, this is nonspecific, and it is not a reliable disease marker. An autoantibody screen is worthwhile given the frequent association with collagen vascular disease. Other appropriate baseline investigations include lung function tests, a chest x-ray, and an electrocardiogram. Particularly in the presence of DM, appropriate screening for malignancy is recommended and includes CT or ultrasound of the abdomen and pelvis, mammogram in women, and colonoscopy if indicated.

Neurophysiologic investigations are crucial in the evaluation of patients with suspected myositis. Concentric or monopolar needle EMG studies in PM and DM patients usually show myopathic features with short-duration myopathic discharges but with additional indications of muscle irritability: increased insertional activity and spontaneous activity (including positive sharp waves and fibrillation potentials), reflecting myogenic denervation secondary to muscle fiber necrosis. To increase the sensitivity of EMG, very proximal muscles should be studied, including the hip flexors, thoracic paraspinals, and proximal shoulder girdle muscles. Nerve conduction and repetitive nerve stimulation studies are useful to exclude motor neuropathy and neuromuscular junction disorders, respectively (however, false positive repetitive stimulation can rarely occur in patients with myositis, with low levels of decrement of less than 20%).

Muscle biopsy is crucial to confirm the diagnosis. As already noted, the biopsy should be performed from a weak but not wasted muscle. Almost invariably the muscle biopsies are abnormal in both PM and DM, but if normal and a strong clinical suspicion remains, a second biopsy should be performed as the pathology can be patchy and sampling errors therefore occur. In PM the pathology consists of a T-cell-mediated cytotoxic necrosis: initially, CD8+ cells

and macrophages surround healthy muscle fibers and subsequently invade them. Muscle fibers show increased HLA class I expression (normally minimal or absent).^{28,29} Endomysial fibrosis is common in PM, and massive fibrosis may underlie some apparently treatment-resistant cases.²⁹ In DM, it is thought that circulating antiendothelial antibodies activate complement and C3, triggering further changes in the complement cascade and generating membrane attack complex (MAC), which traverses and destroys endomysial capillaries. With destruction and reduced number of muscle capillaries, ischemia or microinfarcts occurs in the periphery of the muscle fascicle (watershed area). Finally, as a late event, complement-fixing antibodies, B cells, CD4+ T cells, and macrophages traffic to the muscle.²⁹ There is often a surprising divergence between clinical and pathologic features in DM, and perifascicular atrophy is a useful feature in otherwise bland biopsies.

Treatment of polymyositis and dermatomyositis

Treatment of PM and DM is largely based on clinical practice and experience. Although there have been many studies of immunotherapy in inflammatory myopathies, they often group together adult and childhood DM, PM, and IBM patients. Most studies are retrospective and uncontrolled; and in several studies subjective measures and reduced CK are defined as a response. To date, there have only been a few small randomized trials of intravenous immunoglobulin in PM and DM (see the discussion in Mastalgia).³⁰

Oral prednisone remains the drug of first choice for patients with both PM and DM. Patients should be started on oral prednisone 1 mg/kg body weight per day.³⁰ A clinical response should be evident within 3 months in the majority of patients, with a biochemical response (a reduction in the serum CK level) often preceding clinical improvement. Many now advocate the early use of a second-line immunosuppressive agent such as azathioprine or methotrexate as these have a useful steroid sparing action in the longer term. Intravenous immunoglobulin is useful as a rescue therapy for patients with acute or severe DM, but it has not been proven to work in PM, has been shown not to work in IBM, and is occasionally used at intervals for patients with problems related to steroids. A few patients remain resistant to steroids, and if the diagnosis is secure, cyclophosphamide is a useful alternative agent. It is important to remember that the dose of steroids should be tapered according to the clinical response rather than the CK. It can be difficult for doctor and patient alike to detect subtle improvements, and objective physiotherapy assessments including myometry are useful. Although it is usually possible to taper off the dose of steroids after about 3 months, many patients do require a maintenance dose of steroids. In all cases where prednisone is started and is likely to continue beyond 3 months, but especially in the elderly, osteoporosis prophylaxis with bisphosphonates, calcium, and vitamin D is essential, as is regular screening for diabetes and hypertension.

The prognosis of both DM and PM is generally good, unless associated with an underlying malignancy. Respiratory involvement, and especially fibrosing alveolitis, carries a poor prognosis. If patients fail to respond to steroids, IBM

may be the diagnosis. Patients should be reevaluated and sometimes rebiopsied.

INCLUSION BODY MYOSITIS

IBM, initially considered to be a rare inflammatory myopathy in older adults, is emerging as the most common cause of new onset myositis in this age group. The clinical, muscle biopsy, neurophysiologic, and prognostic features of IBM are different from both PM and DM.

The pathogenesis of IBM is unclear, but it is most likely a degenerative condition with a secondary immune attack on muscle. IBM may be an immune disorder as there is a modest association with other autoimmune disorders such as diabetes, and muscle pathology shows inflammatory features similar to PM, with CD8+ cells, macrophages, and increased HLA class I expression. However, IBM may be a degenerative condition involving intracellular muscle protein trafficking as (1) muscle contains increased levels of amyloid, prion protein, and other molecules as seen in Alzheimer's disease and (2) to date there is no evidence of maintained response to immunotherapy in the vast majority of cases.

IBM usually presents as a painless, profound, progressive wasting of quadriceps muscles associated with a characteristic genu recurvatum stance and frequent falls. In a minority of patients, weakness and wasting begins in the arms. It is of note that muscle weakness and wasting is often asymmetric and may develop over many years. Myalgia and myoglobinuria are rare. Between a quarter and a third of patients have profound distal weakness especially in the forearms associated with a wasting of the medial flexor compartment, and weakness of finger flexors, particularly the deep ulnar component. This may be mistaken for ulnar neuropathy or motor neuron disease early in the course of the disease. Deep tendon reflexes are often depressed, out of keeping with the extent of weakness giving rise to confusion with neuropathies. Dysphagia and neck flexion weakness are common in IBM. IBM is not associated with malignancy, and there is a male preponderance.

The differential diagnosis of IBM is wide: upper limb presentations of IBM may be confused with cervical radiculopathies or MND.³¹ The depressed reflexes seen in most IBM patients may cause confusion with neuropathies, but the clinical sensory examination is normal. The combination of a weak quadriceps muscle group and a depressed knee reflex may suggest LEMS, but, of course, in IBM no post-tetanic potentiation of reflexes is seen. The indolent history in most patients with IBM may suggest an inherited disorder, but the asymmetric weakness and wasting, as well as the pattern of involvement with IBM, reflect its acquired nature.

Several investigations are helpful in patients with suspected IBM. Nerve conduction studies are usually normal but may show features consistent with a mild axonal neuropathy. On EMG studies, myopathic, neurogenic, or a mixed picture is seen, and a high index of clinical suspicion is therefore necessary if the diagnosis is to be considered. CK may be significantly elevated, but more often it is normal or only mildly elevated reflecting the low turnover of muscle cells in this disorder. Muscle biopsies show inflammatory changes, far more marked than one would expect given the often modest elevation of CK, with an infiltration of CD8+ cells, and macrophages. In addition, muscle fibers

may contain eosinophilic inclusions and rimmed vacuoles with basophilic stippling, hinting at a degenerative process. On electron microscopy, characteristic intracellular filamentous inclusions are seen, as in other degenerative conditions. Immunohistochemistry demonstrates an increased expression of "degenerative" proteins including amyloid precursor protein, prion protein, ubiquitin, and alpha-synuclein, prompting comparisons between IBM and Alzheimer's disease.³² The lack of response to immunotherapy (discussed later) suggests that the inflammatory changes may be secondary to a degenerative process within the muscle, rather than a primary event.

The outcome of treatment of IBM is disappointing and to date all attempts at immunosuppression and immunomodulation have failed to induce a consistent and long-lasting benefit. High-dose steroids, methotrexate, azathioprine, cyclophosphamide, and intravenous immunoglobulin (IVIG) have all been tried separately and in various combinations, with inconsistent and largely negative results.³⁰ Early studies suggested that some patients might benefit from IVIG, but larger randomized studies failed to substantiate this idea.^{33–35} There is some evidence that exercise is of benefit early in the course of the disease, and many patients benefit from the use of canes and walkers. Patients with severe weakness often require wheelchairs or motorized scooters for mobility. Severe dysphagia may require enteral nutrition in the form of a gastrojejunal feeding tube.

DRUG-INDUCED MYALGIA AND MYOPATHY

A large number of drugs induce muscle symptoms, but a simple classification is not possible,³⁶ and an overview with important examples of each is given. Clinical and neurophysiologic combinations of a myopathy, neuropathy, and neuromuscular junction abnormalities often suggest a drug-related toxic or endocrine cause.

Several drugs, including statins, fibrates, and aminocaproic acid, can induce a painful cramping acute or subacute necrotizing myopathy. Most commonly, statins produce myalgia or a mild asymptomatic elevation of the CK level, with no weakness or electrophysiologic abnormalities. However, statins may cause a painful myopathy a few weeks after starting the drug, and this is more common in patients with diabetes, preexistent renal disease, and hepatic disease, especially if on other P450-inhibiting drugs, multiple lipid-lowering agents, or higher than recommended statin doses. Unfortunately, clofibrate and other fibrates may also induce a myopathy; a useful etiologic clue may be subclinical neurophysiologic evidence of associated neuropathy and myotonia. The underlying mechanisms remain unclear, though secondary mitochondrial dysfunction may be important.³⁶ Statin- and fibrate-induced myopathies might be confused with inflammatory myopathies; drug-induced myopathies evolve quicker and improve, though often slowly, with cessation of the drug. In the presence of a statin-induced myopathy, the CK level is almost always elevated.

Antimalarial agents (including chloroquine), amiodarone, and perhexiline may all induce a chronic painless proximal myopathy with vacuolar change and lysosomal inclusions on muscle biopsy. Amiodarone-induced neuropathy is more common than a myopathy, though the two may coexist.

Similarly, vincristine commonly induces a neuropathy, though some patients also have a myopathy. Diuretics and laxatives may induce muscle pains and or cramps secondary to hypokalemia and occasionally with very low serum potassium levels can be associated with a painful or painless vacuolar myopathy.

D-Penicillamine may induce an inflammatory myopathy resembling polymyositis, or a drug-induced myasthenia gravis; both conditions tend to improve on withdrawal of the drug.

Critical-illness neuropathy is well recognized and may be associated with a myopathic counterpart. Its pathogenesis is unclear and is likely to reflect a combination of immobility, high-dose steroid treatment, electrolyte imbalance, sepsis, multiorgan failure, and the toxic effects of antibiotics and paralyzing agents, together with vitamin deficiency.

Excessive alcohol consumption is often associated with neuromuscular disease. Alcohol can induce an acute myopathy, often associated with hypokalemia, and possibly a chronic myopathy, though chronic wasting and weakness is more common because of a toxic neuropathy, as is a small fiber neuropathy with painful burning feet.

ENDOCRINE AND METABOLIC MYOPATHIES

Steroid-induced myopathy

The majority of patients with Cushing disease have clinical and neurophysiologic features of a myopathy.³⁷ The prolonged use of steroids is also often associated with a chronic, painless myopathy and less commonly an acute painful necrotizing (critical-illness) myopathy. Steroid-induced myopathy is typically associated with obesity, moon facies, and other classic stigmata of glucocorticoid excess. Steroid myopathy may be difficult to recognize in patients receiving steroids for inflammatory muscle disease, though steroids are unlikely to be the culprit unless used for more than 4 weeks, when patients will have other stigmata of glucocorticoid excess. Proximal leg weakness is the most common clinical manifestation of a steroid myopathy. Needle EMG is usually normal or mildly abnormal, although the presence of fibrillation potentials or positive sharp waves should suggest another etiology. As CK levels may be normal in both steroid-induced and inflammatory myopathies, and EMG findings can occasionally be similar, muscle biopsy is sometimes required to distinguish disease activity from iatrogenic myopathy. The pathogenesis of steroid-induced myopathy is complex and involves hypokalemia and alterations in carbohydrate and protein metabolism. Structural changes on muscle biopsy include type 2 fiber atrophy, although this is nonspecific, lipid deposition, and vacuole formation. Using second-line immunosuppressives such as azathioprine to treat the inflammatory disease in question may facilitate treatment, which consists of slowly withdrawing steroids. Unfortunately, patients recover from steroid-induced myopathy only slowly, and an exercise program may be useful.

Thyroid dysfunction

Muscle weakness is seen in the vast majority of thyrotoxic patients. Hyperthyroid myopathy may be associated with myalgia and fatigue, and thyrotoxic patients may readily overlook it. Weakness may be proximal or generalized

and occasionally involves bulbar and respiratory muscles.³⁸ Ocular involvement (Grave's disease) may occur in patients with hyperthyroidism and reflects both excessive adrenergic activity and inflammatory changes in extraocular muscle and surrounding orbital tissue.³⁹ Hyperthyroid myopathy is commonly associated with proximal weakness without wasting, resembling that seen in myasthenia gravis. Patients with autoimmune dysthyroid states may have myasthenia and vice versa. Dysthyroid ophthalmopathy, where the extraocular muscles are often enlarged, producing restricted extraocular muscle movement, can be confused with ocular myasthenia and can coexist within the same patient. Recognition of such associations is important in targeting treatment. Patients with thyrotoxicosis may also have alterations in deep tendon reflexes and fasciculations, which may mimic MND and cause diagnostic confusion. Given these potential diagnostic pitfalls, it seems reasonable to recommend initial thyroid function tests, and in some cases screening for autoantibodies against thyroid tissue, in all patients presenting with neuromuscular disease.⁴⁰ Investigation of serum CK, EMG, and muscle biopsy is usually unhelpful, because there are no specific diagnostic features of the condition, but it may be useful in rare cases where dual pathology is suspected (e.g., polymyositis and thyroid myopathy). Occasionally, thyrotoxicosis is associated with a neuropathy, though mixed neuropathic and myopathic features are seen in EMG. The pathogenesis of thyroid myopathy is complex and likely to involve alterations in both muscle metabolism and electrical properties, principally through increased Na⁺, K⁺-ATPase pump activity. Finally, thyrotoxic periodic paralysis⁴¹ is a rare but well-recognized disorder, more common in individuals of Asian descent. (The periodic paralyses are a group of predominantly inherited neuromuscular disorders in which paralysis is related to electrolyte imbalances.)⁴²

Hypothyroidism is also frequently associated with neuromuscular manifestations, which may dominate the clinical picture and rarely may predate the development of overt biochemical abnormalities.³⁸ A recent prospective study underlies the strength of these associations: in patients with recently diagnosed thyroid dysfunction, 79% of hypothyroid patients had neuromuscular complaints including pain and stiffness and 38% had clinical weakness.⁴³ Symptoms did not correlate with serum CK levels and improved slowly with thyroxine therapy. Muscle biopsy shows glycogen accumulation at the periphery of the muscle fiber. The exact relationship between the muscle biopsy and clinical features remains unexplained. Hypothyroid myopathy may cause diagnostic confusion. First, patients may have delayed relaxation of deep tendon reflexes and occasionally myotonia (Hoffman's syndrome), simulating features of the genetic myotonic disorders. Second, occasionally patients have very high CK levels and marked muscle wasting, simulating an inflammatory or inherited muscle disease.³⁷

MOTOR NEURON DISEASE (MND)

MND is a common, fatal, progressive disorder with degeneration of both upper and lower motor neurons of uncertain cause. Death usually occurs as a consequence of respiratory failure. MND has an incidence of 1 to 3 per 100,000 and a prevalence of around 4 to 6 per 100,000.

The etiology of MND is unclear, and a number of potential mechanisms have been suggested: excessive glutamate, an influx of calcium, and a subsequent excitotoxic cascade triggering cell damage and apoptosis are likely to be important. Mutations in the gene for superoxide dismutase (SOD 1) have been found in a minority of patients (fewer than 5%) with the uncommon familial form of MND, suggesting that free-radical damage and excessive oxidative stress are important.⁴⁴

Clinical features of MND reflect upper and lower motor neuron involvement. Nocturnal cramps are an early feature but rarely prompt patients to consult physicians. MND often begins in an asymmetric fashion in a single body region (intrinsic hand muscles, arms, legs, trunk, bulbar musculature) but ultimately involves all four regions; bulbar, cervical, thoracic, and lumbosacral. Lower motor neuron features include asymmetric muscle wasting and weakness, fasciculations, and depressed reflexes. Upper motor neuron features include spastic hypertonia, pyramidal weakness, and brisk deep tendon reflexes with extensor plantar responses. A combination of a wasted, weak quadriceps muscle with a pathologically brisk knee jerk is very suggestive of MND, as is the combination of a wasted and fasciculating tongue but with a pathologically brisk jaw jerk. Neck weakness is common in motor neuron disease and may lead to a head drop. Eye movement disorders, sensory signs (in the absence of entrapment neuropathies), and sphincter involvement are all distinctly rare in motor neuron disease and should suggest another diagnosis.

Investigations in MND (1) provide support for the clinical diagnosis and (2) exclude structural or other potentially treatable pathologies. Serum CK levels may be modestly increased (<1000 IU/mL) but are nonspecific. Neurophysiologic tests are useful in excluding another neurogenic disorder (e.g., multilevel root disease, multifocal motor neuropathy), myopathic process, or neuromuscular transmission disorder; they are also more sensitive than the clinical exam in demonstrating lower motor neuron involvement, with the neurogenic abnormalities reflecting both denervation and chronic reinnervation. A careful search for nerve conduction block is warranted in patients without upper motor neuron signs, who might have multifocal motor neuropathy, a rare but treatable autoimmune neuropathy frequently associated with antibodies against GM1 ganglioside.⁴⁵ Structural imaging, ideally MRI scanning, is sometimes useful to exclude pathologies such as degenerative disk disease, which may cause both cord and nerve root compression with consequent mixed upper and lower motor neuron signs. Structural imaging is especially important when signs are confined to the limbs and there are no upper or lower motor neuron signs above the cervical involvement.

Unfortunately, no effective therapies are available, and to date, trials with a variety of nerve growth factors have been disappointing. Riluzole, an antiglutamate agent, produces a moderate prolongation of life and should be considered at an early stage in all patients with possible MND.⁴⁶ The lack of curative drug therapy should not be taken to imply that nothing can be done to mitigate the impact of the disease. Rehabilitation utilizing the many different skills of the multidisciplinary team should be available at every stage.⁴⁶ Gastrostomy feeding is useful at an early stage both to maintain the patient's nutritional state and to reduce the chance

of aspiration in those with significant bulbar weakness. The role of noninvasive and formal ventilation in patients with motor neuron disease remains controversial but overall appears to improve survival and quality of life.⁴⁷

Myasthenia gravis (MG)

Myasthenia gravis is an autoimmune disorder in which neuromuscular transmission is disrupted by antibodies against postsynaptic skeletal muscle proteins, usually the nicotinic acetylcholine receptors (AChR).^{48,49} This produces fatigable weakness, characteristically involving extraocular, bulbar, axial, and proximal extremity muscles.⁴⁹ Therapies for MG are highly effective, although potentially toxic, and include acetylcholinesterase inhibitors, immunosuppression, and temporary immunomodulation. The clinical features and management of MG in the aged person are similar to that in younger individuals. MG may be more common in the elderly than was thought, and an increased risk of adverse effects of medications as well as increased likelihood of comorbidities in the elderly mandates even more careful monitoring of therapy.^{50,51} Thymectomy, though helpful in patients with "early-onset" MG, may not be beneficial for late-onset MG apart from its role in the removal of a thymoma.⁵²

Clinical and epidemiologic features of myasthenia gravis

The clinical hallmark of MG is fatigable and fluctuating weakness of skeletal muscles.⁴⁹ The initial presentation is often with ocular symptoms: diplopia and ptosis. Most develop generalized weakness subsequently. In 20% to 25% of patients with "ocular MG," the weakness remains restricted to the extraocular muscles.^{53,54} In the remainder, generalized weakness can affect bulbar muscles, producing weakness of chewing or facial expression, dysphagia, dysarthria, neck flexion, or extension. Extremity weakness, usually proximal and symmetric, affects arms more than legs. Characteristic in MG is weakness that is worse at day's end and fluctuates in severity over weeks or months.

MG is uncommon, with an estimated prevalence of 80 to 100/10⁶ and an incidence of about 6/10⁶.^{55,56} Although myasthenia can present at any age, two peaks of onset define two clinical subgroups.^{57–59} In "early-onset" MG, more common in females, onset is between 18 and 50 years. "Late-onset" MG, with onset after 50, is more common in males.^{59,60} Epidemiologic evidence suggests that MG is more common in the elderly than was thought, and it may be misdiagnosed more commonly.^{9,50,51,60–62} "Seronegative" MG, without detectable anti-AChR antibodies, is clinically similar to seropositive MG, responds to the same treatments, and likely has a similar humoral mediation.⁶³ In a third of seronegative generalized MG patients, antibodies against muscle-specific kinase (MuSK) are found.⁶⁴ Rare nonimmune "congenital myasthenic syndromes" occur when mutations produce a structural abnormality in one of the proteins at the neuromuscular junction.

The Lambert-Eaton myasthenic syndrome (LEMS) is an even more rare disorder, with antibodies against presynaptic nerve terminal voltage-gated calcium channels (VGCC).⁶⁵ It is often paraneoplastic, usually secondary to an underlying small-cell lung cancer. The clinical manifestations of LEMS consist of fatigable muscle weakness, mainly affecting the

legs and presenting as a gait abnormality, autonomic dysfunction, and depression of the deep tendon reflexes. The diagnosis and treatment of LEMS is similar in many respects to that of MG and will not be discussed further here.

Neuromuscular transmission and the pathophysiology of myasthenia gravis

Depolarization of the nerve terminal at the neuromuscular junction opens presynaptic VGCC, allowing calcium influx and the release of acetylcholine (ACh) from the nerve terminal. ACh binds reversibly to AChRs on the postsynaptic skeletal muscle surface, resulting in muscle fiber depolarization and eventually muscle contraction. Finally, ACh dissociates and is metabolized by acetylcholinesterase (AChE) in the synaptic cleft, or it diffuses away from the neuromuscular junction.⁶⁶

In MG, anti-AChR antibodies impair neuromuscular transmission.⁶⁷ If action potential generation fails at enough muscle fibers, the clinical result is weakness. Serum anti-AChR antibodies are found in about 85% of generalized MG patients, although titers may be lower in the elderly.^{48,60} The thymus seems to be implicated in the genesis or perpetuation of MG, as most early-onset MG patients have thymic hyperplasia.⁶⁸ The other main pathologic alteration, a thymoma, is present in 10% to 20% of all MG patients, in 24% to 38% of late-onset patients, much less commonly in ocular MG, and rarely in seronegative MG.^{69,70} When there is a thymoma, MG tends to be more severe, with a higher mortality.⁷¹ In 10% to 20% of MG patients, especially those over 50 years of age, the thymus is atrophic.⁶²

Diagnosis

Suspicion for a diagnosis of MG is often delayed as a result of fluctuating weakness.²² The weakness in MG may be temporarily improved with a "Tensilon test," which involves administering a short-acting acetylcholinesterase inhibitor and assessing for signs of clinical improvement. Routine electrophysiologic studies in myasthenia gravis are usually normal. Repetitive nerve stimulation may reveal a "decrement" in the motor amplitude.⁶⁶ Single-fiber EMG (SFEMG) is highly sensitive (>90%) at detecting impaired neuromuscular transmission, but it is less specific.^{72,73} Serum anti-AChR antibodies, highly specific for MG, are detected in approximately 85% of patients with generalized MG and in 50% with ocular MG.⁴⁸ They are almost always present if there is a thymoma. Approximately 5% of seronegative generalized MG patients have antibodies against a different muscle protein, muscle-specific kinase (MuSK).⁶⁴ MuSK antibodies are found more commonly in female MG patients with prominent bulbar weakness and are not found in purely ocular MG.

Treatment

Before effective treatment was available, the mortality from MG was high, even worse in late-onset MG or if a thymoma was present. With treatment, the mortality from MG is less than 5%, although bulbar or respiratory muscle weakness continues to be a major source of morbidity.^{74,75}

Treatment options include drugs that mask symptoms and more specific therapies to suppress or modulate the aberrant autoimmune response. The choice of specific therapies is dictated by the need for rapid improvement, convenience, expense, and the frequency of adverse effects.

Mestinon (pyridostigmine) inhibits acetylcholinesterase, increasing ACh at the neuromuscular junction. It does not affect the underlying immune process. Its duration of action is usually 3 to 6 hours but variable, ranging from 2 to 12 hours.⁷⁶ A long-acting preparation (Mestinon Supraspan 180 mg) is used at bedtime for patients with significant nocturnal or early morning weakness. Side effects, usually gastrointestinal, are mild. Although usually effective, Mestinon alone is often insufficient, even less so in ocular MG. Most patients eventually require treatment with corticosteroids (CST) or other immunosuppressives.⁷⁷

The efficacy of immunosuppressive agents is similar, and there may be synergism when used in combination. Prednisone is the most commonly used drug after Mestinon. Although highly effective, it has a significant risk of adverse effects. Low doses have fewer side effects but are less effective and take longer. Immediate high dose treatment (50–100 mg/day) may cause transient worsening in weakness, so a gradual increase in dose is preferable.⁷⁸ Maximal benefit can take 4 to 9 months. There are numerous adverse effects, especially with prolonged high-dose CST therapy and in the elderly.^{69,79} Osteoporosis, more likely in the elderly, can be anticipated and prevented with bisphosphonates, calcium, and vitamin D. Once MG is improved, the dose of prednisone is tapered slowly to lessen the chance of relapse, less likely when other immunosuppressives like azathioprine are also used.⁸⁰

Azathioprine is used as a sole therapy in MG when the situation is less pressing or when there are contraindications to CST. A more common role is as a steroid-sparing agent. Azathioprine is effective with fewer adverse effects than CST. However, its use requires monitoring for hepatic and hematologic toxicity, and it has a long delay (12 to 18 months) before optimal benefit. Cyclosporine is one of the few agents shown in a randomized-controlled trial (RCT) to be of benefit in MG. It is expensive, and has many adverse effects. Therefore, it is used mainly in severe MG not responding to prednisone and azathioprine. Mycophenolate, in widespread use in MG, seems to be effective, although no more so than other available agents, but with less toxicity. Two trials showed no additional benefit to prednisone, probably because prednisone alone is effective in the short term in mild MG. Several other immunosuppressive agents, including cyclophosphamide, tacrolimus, and rituximab, have also been used in MG. None is proven to be superior to the previously mentioned drugs, and they are used mainly when MG is unresponsive to these agents.

Although there is widespread acceptance for thymectomy in MG, the precise indications and surgical approach remain controversial, and a randomized controlled trial is needed to clarify its role in MG.⁸¹ It is generally accepted as effective in early-onset AChR antibody positive patients with generalized MG. Its role is unproven and even more controversial in seronegative patients and in the elderly (in the absence of a thymoma) when the thymus is often atrophic.^{82,83} A thymoma is removed to avoid local growth and infiltration of adjacent mediastinal structures, yet it has less effect on the clinical course of MG than removal of a hyperplastic thymus. In MuSK-positive MG patients, the thymus is less pathologically involved, if at all, and the role of thymectomy even more uncertain.⁸⁴

Incomplete benefits or delayed benefits from medical treatment are problematic for patients with moderate or severe MG. Plasma exchange (PE) and intravenous immunoglobulin (IVIg) are both equally useful with significant respiratory and bulbar involvement (a "myasthenic crisis"), as well as before surgery to reduce postoperative complications. Both temporarily improve neuromuscular transmission. Clinical benefit is usually maximal 1 to 2 weeks after treatment begins and lasts for 2 to 8 weeks. Sustained benefit requires immunosuppression. Both are expensive, produce temporary improvement, and are not advisable for the long-term management of most MG patients.^{85,86}

Several other drugs may worsen neuromuscular transmission and should be avoided in a patient with MG. However, many myasthenics can take one or more of these medications without any obvious ill effect. It is important to educate the patient and her or his general physician about this possibility and to consider these medications as a cause of otherwise unexplained worsening.

More is known about the pathogenesis of MG than any other autoimmune disorder. As a result, the treatment of MG is highly successful, although the frequency of adverse effects is often a limiting factor. MG may be more common in the elderly, and the aged patient is more susceptible to the adverse effects of medications. Managing a patient with MG is usually a rewarding experience, with most patients

responding to treatment and achieving significant improvement in their symptoms, although the adverse effects of long-term treatment can be significant.

KEY POINTS

Neuromuscular Disorders

- Neuromuscular disorders are common in the elderly and may be mistaken for normal biologic aging.
- A careful history and examination is crucial in determining the presence or absence of a neuromuscular disorder superimposed on aging.
- Most acquired and inherited myopathies present with symmetric proximal weakness.
- Most neuropathies present with distal sensory symptoms and weakness as a late manifestation.
- When weakness and fatigue predominate and sensory symptoms are absent, consider a neuromuscular transmission disorder, motor neuron disease, or a myopathy.

Intracranial tumor (“brain tumor”) is perhaps the diagnosis most feared by patients presenting for neurologic evaluation. While neoplasms are less common than many of the other conditions that produce neurologic symptomatology, their importance in the elderly population becomes proportionately greater because the incidence of brain tumor increases throughout adult life. Furthermore, the incidence and mortality of primary brain tumor have been increasing since at least the 1970s, and this change has also been most evident in the elderly population.

Although the clinical presentation often suggests the diagnosis, the manifestations of brain tumor are protean. The clinical picture may be even more obscure in an elderly person. The introduction of noninvasive brain imaging modalities—computed x-ray tomography (CT) and magnetic resonance imaging (MRI)—has greatly aided the diagnosis of tumors and intracranial disease in general. Although treatment options and prognosis are less favorable in older adults, recent advances in neurosurgery, radiation treatment, and chemotherapy have to some degree improved this outlook.

CLASSIFICATION

Intracranial brain tumors are neoplasms that arise within the central nervous system (CNS) or spread there from elsewhere (metastatic). Primary brain tumors are a heterogeneous group of neoplasms that arise from a diverse group of cells residing in the CNS. They can be benign or malignant. In 2009, it was estimated that 22,920 people would be diagnosed with a primary malignant brain tumor in the United States, resulting in 12,920 deaths.¹ In keeping with other malignancies, the incidence of brain tumors increases with advancing age.

Metastatic tumors

Metastatic brain tumors have an incidence in the United States of 150,000 each year. Metastatic lesions are more common in the elderly group.^{2,3} Of tumors metastatic to the brain, the lung is the most frequent source (50%), and the breast is the second. Renal, gastrointestinal tract, and melanomas account for the majority of remaining metastatic brain tumors.

Primary tumors

Primary brain tumors arise from the brain parenchyma, supporting structures, cranial and spinal nerves, and other specialized structures. Lymphomas can also occur in the brain as the primary site. The latest WHO classification of tumors of the central nervous system includes seven major categories based on tissue of origin and includes tumors of neuroepithelial tissue, tumors of cranial and paraspinal nerves, tumors of the meninges, lymphomas and hematopoietic neoplasms, germ cell tumors, tumors of the sellar region, and metastatic tumors.^{4,5} These tumors are further described based on histologic appearance and graded in an attempt to assign biologic behavior, with low grade (I/II) behaving in a more benign fashion and high grade (III/IV) being the most aggressive.

The neuroepithelial derived gliomas and tumors of meningeal origin make up approximately 78% of all incident brain tumors in the geriatric group.⁶ Gliomas are made up of astrocytomas, oligodendrogliomas, mixed tumors, and ependymal tumors.⁴ The astrocytomas are the most common malignant brain tumor in older adults. They have an infiltrative growth pattern, making a true complete surgical resection impossible. Astrocytomas may be low-grade (I and II), with a favorable behavior, or high-grade anaplastic astrocytomas (grade III) and glioblastoma multiforme (GBM, grade IV) the most aggressive. High-grade tumors predominate in the elderly. Oligodendrogliomas or mixed oligoastrocytomas, and ependymomas, which tend to behave more favorably, occur more often in younger adults. Meningeal derived meningiomas are another common tumor in older adults. These tend to cause less morbidity than gliomas, as most are benign and slow growing with only a small number being malignant. Pituitary-derived adenomas and acoustic neuromas make up most of the remainder, with all other subtypes occurring rarely. Germ cell tumors (neuroepithelial derived) almost never occur in this age group.⁶

Primary CNS lymphomas account for about 1% of parenchymal tumors. They are most often seen in immunocompromised patients (those with AIDS and the transplant population), are uncommon in the immunologically normal, and occur principally in the sixth and seventh decades of life.^{7,8} The incidence is increasing in the elderly population.⁹

EPIDEMIOLOGY

As with most cancers, the incidence of tumors of the CNS increases with advancing age. The median age at diagnosis for cancer of the brain and other sites in the nervous system for 2001–2005 was 56 years of age. According to the latest figures from the Surveillance, Epidemiology, and End Results Program (SEER) of the United States covering the period of 2001–2005, children up to 4 years of age have an age-specific incidence rate of 4 cases per 100,000.¹ The rate declines thereafter, reaching its lowest in adolescence, and then climbs again, peaking in the 70-to-74 age group (22 cases/100,000), then slowly declining to 17 cases per 100,000 in those older than 85. Proportionally, this represents approximately 1% of all incident cancers in adults and 23% in children.^{1,6,10,11}

Tumor location within the CNS, predominant histologies, behavior, and mortality also vary between young and old.⁶ In adults, most brain tumors (malignant and nonmalignant) arise in the cortex or the meninges and only rarely occur in other sites, whereas in children brain tumors primarily arise in the brain stem and cerebellum.⁶ Ninety percent of malignant brain tumors in older adults are glial derived, with GBM making up three quarters of these tumors in those 65 to 74, versus 50% in those 45 to 54 years of age. The remaining glial tumors in the elderly are mainly anaplastic astrocytomas. Children most often develop low-grade astrocytomas (e.g., pilocytic) and more primitive types such as primitive neuroectodermal tumors and medulloblastomas.^{6,11}

Unfortunately, mortality from brain tumors also increases with age.^{6,11} The median age at death for cancer of the brain and other nervous system locations in 2001–2005 was 64 years. The 5-year relative survival rate following the diagnosis of a primary malignant brain tumor for ages <45, 45 to 54, 55 to 64, 65 to 74, and >74 were 63.2%, 28.4%, 13%, 7.4%, and 4%, respectively.¹ This same trend holds true even within histologic subtypes, such as glioblastoma, which has a relative 5-year survival rate of 11% in those 45 to 54 and only 2.7% in those older than 65.⁶ Malignant brain tumors make up 2% of all cancer-related deaths in adults, making it among the top 10 malignant causes of death. The strongest prognostic factors for survival therefore remain age and histology. Why tumors such as the malignant gliomas behave more aggressively as one ages is not known. Intensive research into the possible molecular mechanisms is ongoing, with no definitive answers yet.¹²

In the early 1990s, reports surfaced raising concern about the dramatic increase in the incidence of brain tumors in older adults, with rates almost five times higher in 1985 compared to 1973.¹³ The rise was seen in both sexes and involved mainly glioblastoma and anaplastic astrocytoma. Similar trends were reported in Canada, Europe, Britain, and Japan, with mortality noted to be increasing as well.^{14–16} This raised concern that an as yet unknown etiologic factor might be responsible for the increased incidence.¹⁶ Legler et al, using SEER data to compare age-specific incidence rates from 1977–1995, were able to demonstrate that the increase in age-specific incidence trend was starting to stabilize by 1987 for those 65 years of age and older, and finally by 1995 for those over 85 years of age. They elegantly showed that trends in the use of CT, MRI, and stereotactic biopsy procedures in the elderly over this time period had a similar pattern as the incidence of brain tumors. This offers compelling evidence indicating increases in incidence rates are likely artifactual and may be due in part to physicians adopting more aggressive diagnostic approaches in the elderly. Other factors that may have contributed to this probable artifactual increased incidence rate involve changes in diagnostic classification that have occurred over time, increased availability of neurologists and neurosurgeons, changes in patterns of access to medical care, inaccuracies of data collection, and a changing attitude toward care of the elderly.^{11,17–20} Recent reports from the United States and Canada have continued to show that the incidence rates of CNS tumors have leveled off.^{21,22}

The main associated causes of brain tumors in all age groups remain hereditary syndromes, prior therapeutic radiation, and immune suppression (predisposing to CNS lymphomas).¹⁷

CLINICAL PRESENTATION

A brain tumor is a progressively expanding intracranial mass lesion and its clinical hallmark is insidious progression of neurologic deficits. In up to 10% of cases, however, the onset may be abrupt, suggesting a stroke²³; alternatively, stuttering or paroxysmal symptoms may appear during the course of the illness. These phenomena are occasionally related to intratumoral or peritumoral hemorrhage, secondary vascular compromise, or partial epileptic seizures, but they often remain unexplained. On the other hand, fewer than 1% of

those presenting with the clinical picture of stroke will be found to have a tumor.²⁴

Typically, brain tumors produce progressive dysfunction related to destruction or compression of areas of cortex and subcortical nuclei. With malignant tumors, symptoms develop over weeks to months, whereas meningiomas may present with insidious progression over months or years.

Primary tumors generally involve the cerebral hemispheres in this age group.²⁵ Manifestations may include changes in memory, mood, or personality with anterior frontal, deep-seated limbic lesions and temporal tumors; hemiparesis with posterior frontal location; hemisensory loss and hemianopia with parietal lesions; and aphasia with left-sided tumors in the region of the sylvian fissure.

In addition to local effects, because the skull forms a rigid case, the volume increase caused by the tumor and associated edema often raises intracranial pressure. Thalamic tumors may cause obstructive hydrocephalus, leading to the early development of elevated pressure. Intracranial hypertension typically produces both diffuse and remote effects, including headache associated with nausea and vomiting, dizziness, diplopia, gait abnormality, and mental changes—most important and ominously is depressed level of consciousness, suggesting impending brain herniation, which is usually fatal.

Although primary tumors of the brainstem and cerebellum are a rarity in the elderly population, about 20% of metastatic tumors are located in the posterior fossa, more than 75% in the cerebellum.²⁶ They often present with ataxia or cranial nerve abnormalities.

Acoustic neuromas are very slow-growing Schwann cell tumors of the 8th nerve that produce unilateral hearing loss as the earliest symptom; the adjacent 5th and 7th cranial nerves may be subsequently involved. Only late in their course, with advancing size, do they produce the combination of brainstem and cerebellar signs implicit in their location at the cerebellopontine angle. Audiometric testing (including brainstem auditory potentials) reveals unilateral retrocochlear hearing loss and indicates the need for an imaging study, ideally contrast-enhanced MRI.²⁷

Pituitary adenomas may secrete ACTH, growth hormone, or prolactin, but are more commonly nonfunctioning and produce no symptoms.²⁸ With progressive enlargement, they may cause headache, change in mental status, or change in personality, and they can produce varying degrees of hypopituitarism. If the tumor grows into the suprasellar cistern, it may compress the optic chiasm and result in bitemporal hemianopia, an almost pathognomonic visual-field defect.

Several factors modify the clinical picture of brain tumor in the elderly person, tending to make the diagnosis less readily evident. The loss of brain parenchymal volume that occurs with age allows tumors to grow for a longer time and become larger without producing an increase in cerebrospinal fluid pressure. Consequently, morning headache, with projectile vomiting and papilledema, considered classic signs of brain tumor, is less likely to be prominent in the geriatric patient.²³ Furthermore, elderly individuals are prone to develop mental changes and delirium early in their course, and these changes may be phenomenologically indistinguishable from similar states induced by toxic or metabolic disturbances. The clinical picture may at times be difficult to distinguish from degenerative dementia or depression. Such changes in

the absence of detectable motor or sensory abnormalities on examination are more likely to occur with meningiomas, which because of their slow growth and extraaxial location allow neural structures to accommodate to their presence. Focal abnormalities on neurologic examination in a patient presenting with delirium should, of course, raise the suspicion of tumor, as should progression of a deficit that presents as a "stroke." The most frequent clinical manifestations of brain tumor in the elderly population include motor signs in more than one half, mental changes in a third, and sensory changes, hemianopia, or speech abnormalities in one fifth.²³ The incidence and prevalence of seizures (both partial and secondarily generalized) increase progressively with advancing age, and although vascular lesions account for more than half of the cases of epilepsy beginning after the age of 60, a third are caused by brain tumors.²⁹

INVESTIGATIONS AND DIAGNOSIS

As in the field of neurology in general, a comprehensive history supplemented by a competent neurologic examination is likely to bring the clinician close to the correct diagnosis and to suggest the most efficient diagnostic plan. In the elderly person, because of the complexities described earlier, it is essential that a high index of suspicion be maintained regarding the possibility of brain tumor, particularly since it is generally a treatable and often curable cause of disability.

Brain imaging

Before CT scanning became widely available in the mid-1970s, a definitive evaluation to exclude or diagnose a brain tumor required hospitalization for invasive, uncomfortable, and relatively high-risk procedures—specifically cerebral arteriography or pneumoencephalography. Clinicians were reluctant to submit patients, particularly the fragile elderly, to such risks in the absence of clear indications, and patients were often followed clinically without definitive testing as "brain tumor suspects." Today, most experienced neurologists would agree that an individual presenting with a new or progressive neurologic deficit or with dementia should, after appropriate clinical evaluation, undergo a definitive brain imaging study. Although CT revolutionized the diagnostic evaluation of these patients, contrast-enhanced MRI has proven to be significantly more sensitive in the detection of focal brain lesions and is currently recognized as the optimal screening technique for the detection of most intracranial neoplasms.²⁷

Details of the neuroimaging appearances of different types of tumors are beyond the scope of this chapter, but comprehensive reviews are readily available.²⁷ A few points are worth making here.

By their nature as growing lesions, tumors generally exert a mass effect and displace surrounding structures. Astrocytomas, in addition, infiltrate and replace normal brain parenchyma. A zone of edema typically surrounds a tumor, with characteristic appearance on CT and MRI, though in the case of gliomas some of this "edema" also consists of "fingers" of infiltrating tumor tissue.³⁰ Because the blood-brain barrier is defective in most tumors, contrast enhancement is an important diagnostic characteristic, though frequently absent in the low-grade gliomas.²⁷ None of these features, of course, is pathognomonic, and each finding must be interpreted in

its clinical context. Contrast enhancement of a parenchymal tumor suggests a relatively more malignant process, but high-grade pathology can be seen in patients with nonenhancing MRI scans. Multiple lesions, best appreciated with contrast MRI, are typical of metastatic disease but can be seen in 3% of astrocytomas. Primary cerebellar tumors are rare in the elderly population and suggest metastasis.

A primary CNS lymphoma is often seen as a densely enhancing lesion in the deep periventricular white matter.³¹ In a third of patients, the lesions are multiple. In 20% of cases, there is either evidence of leptomeningeal spread or concomitant vitreal/retinal disease.³²

Meningiomas are extra-axial in location and usually have a broad base of attachment to the dura; they show extensive, uniform contrast enhancement and as they enlarge can exert a mass effect.

Functional MRI (perfusion/spectroscopy) is proving helpful in the initial workup of a patient with a nonenhancing mass. In a heterogeneous inoperable glioma it can help the surgeon plan the biopsy target. Functional MRI also is used in treated patients to help determine whether findings on conventional MRI are due to tumor progression or radiation necrosis. In some centers it is used to help assess therapeutic response to chemotherapy and other treatments.

CSF examination

Lumbar puncture is *not* indicated for the diagnosis of brain tumor. While elevation of CSF protein is commonly seen, this is a nonspecific finding whose utility has been eclipsed by the advent of noninvasive imaging. Cytologic examination may reveal malignant cells and aid in pathologic diagnosis, particularly with primary CNS lymphomas, leukemia, or metastases involving the meninges (meningeal lymphomatosis or carcinomatosis).³³ Rarely a glioma will present with a meningeal picture (meningeal gliomatosis) diagnosable by CSF cytology. Since there is a small but real risk that lumbar puncture will cause brain herniation, particularly in the presence of a large tumor and increased intracranial pressure, CT or MR imaging should be performed first to rule out such a situation.

Biopsy

The role of surgery and surgical tumor resection is discussed more fully in the section on treatment. As a rule, a definitive tissue diagnosis should be achieved when practicable. This is both because the particular treatment will depend on the tumor type and because not all space-occupying lesions seen on brain imaging prove to be neoplastic.^{34,35} On the other hand, a recent study of 200 patients undergoing stereotactic biopsy concluded that biopsy may not be needed when a clear presumptive diagnosis can be made on the basis of clinical and neuroimaging evidence.³⁶ Furthermore, the decision to perform a biopsy must be conditioned by the overall clinical context and the patient's medical and psychosocial status. For example, a patient with known malignancy and uncontrolled systemic metastases who presents with brain lesions typical of metastatic disease does not usually require biopsy; nor does a frail patient with end-stage Alzheimer's disease and a large, radiologically malignant brain tumor. In a patient with a single tumor or multiple brain lesions consistent with metastatic disease, workup to identify a primary source beyond complete physical examination (with testing

for occult blood in stool) and CT scan of chest is often unrevealing and probably not cost-effective.³⁷ In this situation, biopsy (or resection, if appropriate—discussed later) would be the logical next step. When biopsy is indicated, the procedure of choice is a CT- or MRI-guided stereotactic needle biopsy, which has an overall morbidity of just 2%.³⁸

Summary of Management Algorithm

Intracranial Tumors

- Enhanced MRI is the diagnostic test of choice.
- Pathologic diagnosis is mandatory unless the patient is dying from widespread metastatic disease or has a severe, unrelated neurologic or medical condition.
- Older adults should not be denied surgery, radiation therapy, or chemotherapy based on age alone. Even so, precise criteria for which levels of fitness allow surgery and which levels of frailty preclude it are lacking.
- All patients who are eligible for clinical trials should be encouraged to participate.

TREATMENTS

Surgery

The ideal treatment for brain tumor is total surgical resection resulting in cure. As indicated, this is generally possible only for the “benign” lesions: meningioma, acoustic neuroma, and pituitary adenoma. Even here the anatomic location of the tumor or the general health of the patient may preclude aggressive surgery. Age itself is not a contraindication to neurosurgery, and perioperative mortality and morbidity are not necessarily increased after the age of 65.²³ It has also been found that patients over 65 undergoing craniotomy for brain tumor, although sicker and having a higher rate of complications than those under 65, had similar outcomes, including quality-of-life scores.³⁹ However, because elderly people are more prone to coexisting medical conditions that worsen their prognosis, the approach to treatment is usually balanced toward the less aggressive side, particularly in those who are frail. Even so, precise criteria of who is fit enough for surgery and who is too frail are lacking. A common dilemma in this regard, especially in relation to slower growing tremors, is to know how much of impaired function to attribute to the tumor and how much impaired function reflects underlying frailty. Because the natural history of “benign” tumors is often measured in decades, an incidentally discovered asymptomatic lesion may not require treatment, and partial removal of a tumor that cannot be completely resected may render the patient asymptomatic for the duration of the life span. Stereotactic radiosurgery for unresectable tumors is proving to be an important option (discussed later). Pituitary adenomas can be treated with a high rate of success and low morbidity by transsphenoidal removal,⁴⁰ prolactin-secreting tumors are often effectively treated with bromocriptine⁴¹ or other dopaminergic agents, and tumors that are inoperable or incompletely removed should be treated with radiation (discussed later). Radiation therapy may also be useful in preventing recurrence of partially resected meningiomas or in treating recurrences.⁴²

For malignant tumors and those that cannot be fully removed, and where the clinical situation does not contraindicate an aggressive approach (see the previous discussion in the section on biopsy), as much of the tumor as is readily accessible should be removed, with care taken not to disturb adjacent brain tissues. Such “debulking” reduces the mass effect, tends to decrease local and diffuse symptoms, often permits a reduction in steroid dose, and may allow the patient to better tolerate the edema that can accompany radiotherapy.⁴³ Postoperative morbidity is no greater in those undergoing large resections than in those having small resections or biopsies,⁴⁴ and large removals, in patients with malignant gliomas, have been shown in some studies to improve survival.^{45–47} On the other hand, in the treatment of malignant gliomas many neuro-oncologists feel that resection offers no survival advantage over biopsy, particularly stereotactic serial biopsy.⁴⁸ An attempt to study this important question from an evidence-based review of the literature found no qualifying studies.⁴⁹

Primary CNS lymphoma patients should be biopsied for accurate diagnosis. If possible the patient should not be on steroids.

In patients with brain metastasis proven by MRI to be solitary and whose primary cancer is controlled, surgical removal followed by radiation has been shown to increase duration of life (40 vs. 15 weeks) and to greatly prolong the period of functionally independent survival (38 vs. 8 weeks) compared to biopsy plus radiation.⁵⁰ Unfortunately, the applicability of this study to older adults is unclear, because the median age of the patients was 60 years and none was over 74. As with gliomas, age is a negative prognostic factor for patients with brain metastases. Of note is that, in this study of 54 patients with known systemic cancer and brain lesions diagnosed by CT or MRI to be consistent with brain metastasis, six patients proved to have lesions that were *not* metastatic. Two were abscesses and one was a nonspecific inflammatory reaction⁵⁰—a compelling argument for tissue confirmation of diagnosis before treatment.

Low-grade gliomas are uncommon in this population and require treatment only when they become symptomatic. This involves maximal feasible resection followed by local radiotherapy.

Adrenal corticosteroids and supportive medications

Malignant glial tumors, metastatic tumors, and some meningiomas are surrounded by edema, which increases the mass effect, accentuates focal deficits, and produces diffuse signs (headache, and mental and gait abnormalities). This “vasogenic” edema is caused by breakdown of blood–brain barrier secondary to abnormal fenestration of vascular endothelium in the tumor, allowing leakage of water and solutes into and around the tumor.⁵¹ Glucocorticosteroids are effective in reversing this leakiness⁵² and have been used as palliative and adjunctive therapy since the 1970s. Significant symptomatic improvement occurs within 24 to 48 hours in the majority of patients and may be dramatic. Elderly patients respond as well as the young.⁵³

Primary CNS lymphoma may disappear when treated with steroids alone, but it almost invariably recurs. Best results are obtained with chemotherapy followed by whole-brain radiation.^{7,31,34}

Dexamethasone is the standard preparation because of its potency, its relatively minimal mineralocorticoid effect, and because it may cause less psychiatric disturbance than other preparations. It has a prolonged biologic half-life that makes it suitable for twice-a-day dosing, and when given with meals, proton pump inhibitors are needed only for patients with a history of peptic ulcer disease. The usual dose is 16 mg a day, with greater doses given if there is not a satisfactory response. One study, however, found that 4 mg a day was as effective as 16 mg (in patients without impending herniation), with significant reduction in toxicity.⁵⁵

The toxicity of glucocorticoids can be quite important, particularly when they are taken for prolonged periods.⁵⁶ The most serious relate to immunosuppressive and antipyretic effects, which predispose to infection while masking some of its signs. Weight gain and the development of Cushingoid habitus and facies adversely affect quality of life. Sleep disturbance and emotional lability may occur, the latter to the point of frank psychosis. Hyperglycemia, hypertension, increased gastric acid secretion, and osteoporosis can all lead to major complications. Steroid myopathy, manifesting with proximal muscle weakness, may be quite disabling.⁵⁷ The incidence of these toxicities increases with dose and duration of therapy, so that corticosteroids should be used at the lowest effective dose—and tapered, if possible, once definitive therapy has been implemented.

Radiation therapy

Radiotherapy is an important treatment modality in the management of CNS tumors, helping to control tumor growth and improve survival. For elderly patients with malignant gliomas, if no treatment is given after biopsy or resection, median survivals of 1 to 2 months have been reported, whereas radiotherapy administered postoperatively improved median survival to 5 to 10 months.^{58–61} These results have been confirmed in a recent randomized trial, where 84 patients with malignant gliomas over the age of 70 years, with a Karnofsky Performance Status (KPS) of >70, were randomized to best supportive care (BSC) after biopsy or surgical resection, versus 50 Gy of radiation for 5 weeks.⁶² No chemotherapy was given. Median survival improved from 4 months in the BSC group to 7 months in those receiving radiation. Quality of life and cognitive function declined similarly in both arms over time, indicating radiotherapy did not have an adverse effect on patients. Unfortunately, none of the scales showed improvement in the treatment group relative to BSC.

Appropriate patient selection for treatment is necessary, as there are many factors to consider when treating the elderly.⁵⁸ After age, functional status is one of the most important prognostic factors for survival in malignant gliomas. Those patients with a low functional status have poor tolerance for radiation and limited survival of to 1 to 2 months, making supportive care most appropriate.^{59,60,63} Few patients experience improvement in neurologic function, as shown in one series where only 20% of elderly patients experienced improved neurologic function after treatment, 13% worsened, and 67% had no change.⁵⁹ This has important implications for home support and social functioning. Radiotherapy-induced cognitive decline and fatigue are major problems for the elderly, and some will experience continued global functional decline without signs of tumor progression. Traveling

daily for treatment is not manageable for some due to lack of supports and financial issues, not to mention the associated psychological drain and physical fatigue.⁶⁴

Recognizing the limited gains in median survival of 3 months,⁶² and the toxicity and inconvenience of daily clinic visits, altered fractionation schemes using higher dose per fraction over shorter time intervals (3 weeks) have shown survival benefits similar to that achieved with longer courses of radiation.^{65,66} There is currently no consensus regarding the optimal radiation dose in those older than 70 years, but ongoing studies should help.

“Involved-field” radiation has replaced whole-brain radiation for malignant gliomas. Primary CNS lymphoma is highly sensitive to radiation and is generally treated, as noted earlier, with whole-brain radiation,¹³ often preceded by chemotherapy.^{31,54}

The remaining CNS tumors that occur in the elderly tend to be infrequent. Radiotherapy is often considered in cases where there has been incomplete surgical excision of the tumor to improve local control, or it can be the primary modality when surgery is not feasible. Discussion of specialized radiotherapy techniques, such as brachytherapy or stereotactic radiotherapy, is beyond the scope of this chapter. These techniques allow a focused beam of radiation to be given, limiting toxicity to surrounding structures, and are used for such things as acoustic neuroma or meningiomas.⁴

Chemotherapy

The role of chemotherapy in the treatment of brain tumors in the elderly is confined mainly to malignant gliomas and primary CNS lymphomas. The usefulness of chemotherapy for benign tumors is limited, as it is in younger adults, where surgery and radiation are the main treatment modalities.

A meta-analysis from 2002, using individual patient data from 12 randomized trials, showed that chemotherapy administered after surgery and radiation (adjuvant therapy) in adults with high-grade gliomas improved median survival by 2 months, with a 1-year survival experienced by 6%.⁶⁷ All age groups benefited, including those older than 60 years of age. What is not apparent is how many patients were older than 65. The drugs used in these trials included alkylators such as carmustine or lomustine, which are not easy to administer to older patients as they cause significant neutropenia and thrombocytopenia, even when dose is reduced.⁶⁸ There is some evidence that older patients may not respond as well to these alkylators, and the survival benefit in the elderly using these drugs in the adjuvant setting has been questioned.⁶⁹

Fortunately, a newer alkylator, temozolomide, has been developed, showing an improved toxicity profile, with better tolerance, ushering in improvements in the care of patients with glioblastoma multiforme (GBM). A landmark trial from 2005 changed the standard of care for GBM worldwide.⁷⁰ This study, which included patients up to the age of 70, compared 6 weeks of radiotherapy (RT) given with daily oral temozolomide (TMZ) chemotherapy, followed by 6 months of adjuvant TMZ versus the same radiotherapy given alone. Treatment was well tolerated in both arms, with combination therapy proving superior, achieving median and 2-year survivals of 14.6 months and 26% versus 12.1 months and 10% in the RT-alone arm. Quality of life was similar between arms.⁷¹ The degree of survival benefit

from combined treatment was less in those older than 50 years of age. Patients older than 70 were not included in this trial, so the benefit of adding chemotherapy to radiation in this group is not known. There is evidence, however, from single institutions, showing that RT and TMZ can be given together in patients 65 to 76 years of age with reasonable tolerability, achieving median survivals of 11 to 12 months.^{72,73} Degree of surgical resection and performance status (not age) were the most important factors influencing outcome in these series.

Temozolome alone postoperatively has been tried in patients 70 to 80 years of age, achieving median survivals of 5 to 6 months.^{74,75} It is unlikely there will be one treatment approach that fits all patients. High functioning older adults with a complete surgical resection might do well and achieve improved survival with more aggressive treatment regimens.¹² The frailer and less fit may be served best with shorter radiation treatments or chemotherapy only. Molecular factors may prove useful in deciding on appropriate therapy, helping determine tumor sensitivity to specific treatments.⁷⁶ Future studies should help clarify some of these issues. There are a host of newer drugs specifically designed to attack particular molecular targets that are currently being tested in trials; the hope is that these trials will lead to further improvements in outcome.⁷⁷ With recurrent tumors there is currently no accepted standard treatment.

In contrast, chemotherapy does seem to prolong survival in those with primary CNS lymphoma (PCNSL),^{54,78,79} although again the prognosis is significantly worse in the elderly population.⁸⁰ Attempts to treat PCNSL with chemotherapy alone (methotrexate) have shown some initial success.⁷⁹ Avoidance of whole-brain irradiation in elderly people is an important goal.⁸⁰

CONCLUSION

Although the manifestations of a brain tumor in an elderly person can be subtle and nonspecific, careful attention to the neurologic evaluation and appropriate use of brain imaging studies should minimize any delay in diagnosis. It is important to recognize that, ominous as the diagnosis

may seem, the majority of primary brain tumors in this population are benign, eminently treatable, and usually curable. Even in the case of malignant tumors, advances in neurosurgical technique, radiation oncology, and chemotherapy have greatly improved the outlook for many elderly patients, in terms of both prolongation of life and enhanced quality of survival. Numerous experimental approaches are currently under investigation, and although a therapeutic breakthrough does not appear imminent, it is to be hoped that in the not-too-distant future more effective treatments for malignant neoplasms of the brain will be found.

KEY POINTS

Intracranial Tumors

- The incidence of all types of brain tumor increases significantly with age.
- Clinical diagnosis in older adults may be more difficult, and a high index of suspicion is appropriate. Although insidious progression of neurologic deficits remains the most common presentation, acute onset-mimicking stroke can occur, together with such "geriatric giant" presentations as delirium, impaired mobility, and falls. Morning headache, projectile vomiting, and papilloedema often are less common.
- Neurologic evaluation and MRI scan will nearly always lead to the correct diagnosis.
- Tissue diagnosis is desirable for treatment planning but, depending on clinical context, is not always necessary.
- Benign tumors—meningiomas, pituitary adenomas, and acoustic neuromas—are common in the elderly population, usually have a very good prognosis, and are often surgically curable.
- For malignant growths, surgery may have an important palliative role, but glucocorticoid and radiation therapies are the mainstays. Chemotherapy shows promise as new drugs are developed.

Disorders of the Spinal Cord and Nerve Roots

Sean D. Christie
Richard A. Cowie

The majority of the pathologic processes affecting the spinal cord in elderly people are related to degenerative diseases of the spinal column or to insufficiency of the cord's blood supply. However, old age does not exclude many of the disorders that are more commonly seen in other age groups. In most patients, a definite diagnosis can be made clinically by taking a directed history and performing a careful examination.

Neurologic assessment of an elderly person is sometimes made difficult by failure to obtain a clear history or by the presence of osteoarthritis of the limb joints and consecutive atrophy of the musculature, which masks weakness and reflex changes. Nonetheless, analysis of the way that a neurologic disorder develops and of the pattern of neurologic signs should provide a guide to the location of the lesion along the neural axis. A lesion can usually be localized in the cervical, thoracic, lumbar, or sacral segments before specialized neuroradiologic investigations.

CERVICAL RADICULOPATHY AND MYELOPATHY

General issues

The neuroradiologic sequelae of degenerative disease of the cervical spine were established in the 1950s.¹ The degenerative changes of cervical spondylosis begin with desiccation and fragmentation of the intervertebral disks. As the elasticity of the annulus is reduced, the disk height diminishes. Extremes of movement are less well tolerated, and the vertebral end plates are subjected to greater stress. Secondary osteophytic spurs develop circumferentially around the disk, projecting posteriorly into the spinal canal as bony ridges. Parallel degeneration of the hypophyseal joints combines with spurs from the vertebral bodies to reduce the size of the neural foraminae. In most patients there is progressive loss of movement between vertebrae, although in some cases excessive motion between vertebrae and a degree of subluxation may develop. Pathologic changes in the ligamentum flavum cause lack of elasticity and a tendency to buckle, particularly during extension. The compressive effects of the osteophytic spurs and buckled ligamentum flavum on the spinal cord are greatest when the neck is extended.²

These changes bring about restriction of the natural motion of the spinal cord and nerve roots within the spinal canal. Repetitive compression and obstruction of the radicular arteries supplying the cord in the neural foramina may further compromise cord function. This effect is aggravated if there is occlusive vascular disease of the proximal arteries in the neck. Occasionally, acute rupture of a cervical disk can follow sudden twisting or flexion/extension movements of the neck and cause cord or nerve root compression.³ The same mechanism can also cause hemorrhage into the spinal cord (hematomyelia).

The older the population, the more these degenerative changes increase in severity and extent. It is clear from epidemiologic studies^{4,5} that the prevalence of degenerative

changes is increased when heavy laboring work has been undertaken.

Atomic and radiologic studies have shown that the neurologic sequelae of cervical spondylosis are more prevalent when the natural size of the spinal canal and neural foramina are restricted.⁶ However, the presence of large osteophytic ridges and subluxation of the vertebrae aggravate the situation. The C5–C6 and C6–C7 levels are most commonly affected at the point of transition from the more mobile cervical spine to the relatively fixed section in the upper part of the thoracic spine.^{5,7}

Clinically, there is generally loss of lordosis so that the head is held flexed and downward. However, if the natural kyphosis of the thoracic spine is exaggerated, there may be a compensatory extension of the upper cervical spine to maintain forward gaze. Most patients complain of recurrent neck pain and stiffness, together with crepitus on movement. Pain radiates to the occiput, shoulders, and scapula regions.

Radiculopathy

Progressive narrowing of the neural foramina results from osteophytic ridges alongside the intervertebral disks and hypertrophy of the facet joints and causes compression and restriction of movement of the nerve root. Pain radiates down the arm in the distribution of the nerve root(s) with a deep, boring quality, aggravated by activities such as lifting and reaching. The pain is generally accompanied by paresthesiae and some sensory loss in the affected dermatomes. In some patients, sensory symptoms predominate. Muscular weakness is generally mild, but occasionally wasting can occur. The appropriate reflexes are lost.⁷

Cervical myelopathy

Cervical spondylosis is the most frequent cause of chronic cord compression in older adults. The clinical spectrum is wide, depending on many interrelating factors and the pathogenesis of cord damage. Compression leads to atrophy of the anterior horn cells and the lateral and posterior funiculi of the cord.⁸ Most commonly the onset of symptoms and signs is insidious, and a clinical history can extend for many months or years before help is sought. Most frequently there is a mixed picture of lower motor neuron features in the arms, together with long tract signs below.⁹

In the upper limbs, complaints of numb, clumsy hands with weakness and loss of dexterity are common. Muscle wasting follows segmental anterior horn cell damage, affecting proximal muscles when compression is high in the neck or the intrinsic muscles of the hand when compression is lower. The tendon reflexes in the arms are usually lost at the segmental level of the cord lesion and are exaggerated below. An inverted radial reflex occurs when the site of compression is above the fifth cervical segment, which has been shown to be the most common in an elderly population.¹⁰

In contrast, there is commonly a marked lower limb spasticity when the patient complains of a heavy, leaden

weakness and a tendency to drag the limb. Some degree of ataxia may be present with reduction of vibration and joint position sense. Many patients complain of paresthesiae and intermittent numbness in the upper and lower limbs.

Occasionally, symptoms may arise abruptly because of severe trauma or sudden extension of the neck such as after a fall. In this situation, a central cord syndrome is common, with marked weakness of the upper limbs because of anterior

horn cell damage and a mild spastic weakness of the lower limbs as the peripheral regions of the cord are relatively spared. Frequently this syndrome is accompanied by allodynia in the upper extremities, particularly the hands. Very rarely a Brown-Séquard syndrome can be identified. These neurologic disorders can be associated with vertebrobasilar insufficiency, where symptoms are typically related to rotation and extension of the neck. As the clinical presentation of spondylosis varies, it must be distinguished from other conditions with similar symptoms and signs, including multiple sclerosis, cerebrovascular disease, cord tumor or syrinx, normal pressure hydrocephalus, amyotrophic lateral sclerosis, and peripheral neuropathies.

Investigations

Plain radiographs of the cervical spine reveal narrowing of the intervertebral disk space with sclerosis of adjacent cortical bone. Secondary anterior and posterior osteophytes are demonstrated in Figure 67-1, together with an indication of the size of the spinal canal. Oblique radiographs allow visualization of the neural foramina. However, several authors¹¹⁻¹³ have shown that degenerative changes increase in frequency with age, and that 70% to 90% of those over 65 years of age have radiologic abnormalities. In consequence, there is poor correlation between symptomatic and asymptomatic groups and the structural changes revealed on plain radiographs, with problems of both sensitivity and, especially, of specificity. Rarely, then, do plain radiographs alone dictate therapy.

When the clinical state suggests segmental cord or root compression and surgery is contemplated, then specialized neuroradiologic investigation is required. Magnetic resonance imaging (MRI)—which has largely replaced myelography—reveals degeneration of intervertebral disks, the size of osteophytes, and the presence and degree of cord compression (Figure 67-2). Computed tomography (CT)^{14,15} reveals the size and shape of the vertebral canals and the presence of extensive ligamentous calcification, but it cannot give details of vertebral displacements, disk protrusions, and corrugation of the bulging longitudinal ligament unless intrathecal

Figure 67-1. Lateral cervical spine radiograph showing widespread spondylosis. Note the loss of disk height and large anterior osteophytes. This patient has a small spinal canal into which project osteophytes at the posterior margin of the C3-C4 of the 4-5 disks.

Figure 67-2. A, Lateral magnetic resonance image of the cervical spine showing compression of the spinal cord by posterior osteophytes and buckling of the ligamentum flavum. B, Transverse image of normal cervical spine reveals spinal cord surrounded by cerebrospinal fluid. C, Transverse image of the patient seen in (A) showing severe narrowing of the spinal canal and compression of the cord.

contrast medium has been injected. Myelography is now performed only when MRI is contraindicated, such as in a patient with an implanted pacemaker or neuromodulatory device or in the presence of cerebral aneurysm clips made from materials other than titanium or titanium alloy.¹⁶ Magnetic resonance imaging also allows visualization of intrinsic disorders of the spinal cord (see [Figure 67-2](#)).

Management

Patients with neck pain and radiculopathy generally respond to a treatment regimen that may include a supportive collar, restriction of upper limb and shoulder movement, and nonsteroidal antiinflammatory drugs, supplemented by opioid analgesics if necessary.¹⁷ Physical methods of treatment and the application of local heat pads may be soothing. If the symptoms are severe, a brief period of bed rest and cervical traction may provide some relief.¹⁸ Lees and Turner¹⁹ showed that 22 of 51 patients were symptom-free within a few months and generally remained symptom-free during follow-up. These authors showed that patients with radiculopathy rarely progress to a myelopathic state.

Surgery is not generally required unless there is clinical evidence of myelopathy, such as progressive sensorimotor deficits or abnormalities in bladder and bowel control attributable to spinal cord dysfunction. In selected patients, persistent radicular pain that inhibits daily activities and decreases level of function may also be a relative indication. Both anterior and posterior approaches can be used to decompress the nerve roots; each carries a good prognosis for neurologic recovery,²⁰⁻²² although recovery of muscle wasting is rarely satisfactory. The decision to operate is made after taking into account the severity of the disability, its effect on the patient's quality of life, and the patient's ability to withstand surgery.

The natural history of myelopathy complicating cervical spondylosis is variable and unpredictable; many patients run a chronic course characterized by episodes of deterioration separated by periods of stability.^{9,19} The majority of elderly patients with cervical myelopathy will not need surgical intervention. Surgical treatment is indicated when the myelopathy interferes with daily activities, where there is a short progressive history, or when there is radiologic evidence of severe cord compression or instability. Anterior decompression of disk and osteophytic spurs is usually carried out when one or two intervertebral levels are affected, whereas laminectomy/laminoplasty is indicated for more widespread stenosis and compression of the spinal cord. In general, the prime objective of surgery has been to halt the decline in neurologic function before further damage to the cord has occurred. However, more recently studies suggest that there may be a more reliable improvement in neurologic function than previously appreciated.²³

There is poor correlation between the presenting severity, the duration of the symptoms, and the outcome.⁶ Hukaka et al²⁴ found that posterior decompression gave better results for more advanced myelopathy and that a short duration of symptoms was associated with better results, although these were not influenced by the age of the patient. Phillips²⁵ suggested that patients with focal disease who underwent anterior surgery had a better outcome. However, some patients continued to deteriorate, in spite of adequate decompression, possibly because of vascular insufficiency.⁹ This may

be related to persistent motion across the decompressed segments, and concomitant fusion procedures may reduce the incidence of postoperative neurologic decline.

CORD COMPRESSION IN RHEUMATOID ARTHRITIS

Neck pain and stiffness are common complaints in patients with progressive rheumatoid arthritis (RA). Radiation of pain to the occipital region and cutaneous numbness at the back of the head may occur when the upper cervical nerve roots are compressed. These symptoms may herald the development of atlantoaxial subluxation as a result of destruction of the transverse atlantal ligament by synovitis. There may be rotatory subluxation, and vertical migration of the odontoid into the foramen magnum of the skull (cranial settling). Atlantoaxial subluxation, which occurs in approximately 33% of patients with RA, can be asymptomatic until the slip reaches 8 to 9 mm when cord compression begins. Once myelopathy develops, most patients deteriorate and 50% die within 6 months. Approximately 20% of patients show subaxial subluxation on cervical radiography, often affecting several segments to produce "staircase" deformity of the vertebrae. Compression of the cord is common.

Most patients present with progressive deterioration of upper limb function, accompanied by tingling, numbness, LHermitte's phenomenon, gait disturbance, and possibly bladder and bowel dysfunction. It is common for these symptoms to be attributed to severe peripheral joint disease and muscle atrophy. Abnormality of spinothalamic function, hyperreflexia and hypertonia, and extensor plantar responses help differentiate the cause from peripheral nerve lesions. Compression of the trigeminal nucleus and tract at the craniocervical junction may produce facial numbness or paresthesiae. Lower cranial nerve findings may be present with cranial settling.

Radiologic assessment requires flexion and extension radiographs of the cervical spine followed by MRI, which will reveal compression or distortion of the spinal cord ([Figure 67-3](#)).

Surgical management has to be considered when there is progressive or significant atlantoaxial subluxation, or clinical evidence of increasing neurologic morbidity. As most patients have significant medical problems such as pulmonary fibrosis, anemia, atrophic skin, and the effects of prolonged steroid or other immunosuppressive therapies, there is significant risk from surgical intervention that needs to be reviewed with patients and their families. For some patients, particularly the frail, the use of a cervical collar in lieu of surgery may be the best option to manage craniocervical instability, though tolerance of use can be limited.

The surgical approach and procedure may consist of an anterior, transoral, or posterior decompression combined with internal fixation; however, the timing of these interventions remains controversial.²⁶

SPINAL CORD COMPRESSION AND THORACIC DISK PROTRUSION

The central protrusion of a thoracic intervertebral disk is an unusual cause of cord compression, but one that occurs in older age groups as it is associated with degeneration of the

Figure 67-3. Magnetic resonance image of cervical spine, illustrating pathology attributable to rheumatoid arthritis; cranial settling, cervical stenosis, and subaxial instability.

disk annulus. Russell²⁷ noted that 67% occurred between the eighth and eleventh interspaces. The majority of patients present with a long history of gradually progressive myelopathy where sensory and motor symptoms are equally common. However, 49% of patients complained of radicular symptoms of pain and dysesthesiae. Sometimes the onset is more rapid, leading to a flaccid paraplegia.²⁸

The presence of a thoracic disk protrusion is generally recognized when MRI is carried out to investigate the progressive neurologic deficit. Cord compression from this source carries a poor prognosis unless surgery is performed. The results of simple decompressive laminectomy are unsatisfactory; either costotransversectomy, transpedicular, or transthoracic approach is recommended.^{27,29} Recent minimal access approaches³⁰ are better tolerated and may lead to quicker postoperative recovery, particularly in an elderly population.

CORD COMPRESSION FROM INTRADURAL TUMORS

Intradural extramedullary tumors cause local compression of the spinal cord and nerve roots. Meningiomas represent approximately 25% of primary spinal cord tumors, and 80% of them occur in females. They are most commonly seen in the sixth decade, rather later than for neurofibromas; 80% occur in the thoracic spine. The majority of patients complain of local or radicular pain, the significance of which often goes unrecognized for a long period until progressive spastic paraparesis, followed by sensory and bladder dysfunction, develops.³¹

Plain radiographs are rarely helpful, and the condition is diagnosed only by myelography or more commonly MRI.³² Results of decompressive surgery are generally good. Levy et al³³ reported that one third of paraplegic patients were able to walk after tumor excision. Similar successes have been observed in septagenarians.³⁴ Neurofibromas are slightly more common than meningiomas, but their peak incidence is in younger age groups, so they are less frequently encountered in an elderly patient.³⁵ Radicular pain is more common, and enlargement of a neural foramen may be seen on plain radiographs if the tumor extends into the paravertebral tissues. Multiple tumors can be encountered in neurofibromatosis. As with meningiomas, surgical excision should be undertaken and carries a good prognosis for neurologic recovery. However, for the medically unfit radiosurgery is an emerging option that appears to afford long-term clinical stability.³⁶

METASTATIC SPINAL TUMORS

The most common extradural and spinal tumors to cause cord compression are those metastasizing from distant carcinomas or primary hematologic tumors. Spread may be hematogenous or via the vertebral venous plexus. Although myeloma and carcinomas of prostate and kidney seem to metastasize preferentially to the spine, in practice the most commonly encountered tumors are those that occur with the greatest frequency in the community. Therefore, primary lung, breast, kidney, and prostate tumors are seen, although in some patients the primary tumor cannot be identified. The thoracic region of the spine is most frequently involved, followed by the lumbosacral and cervical regions.

The majority of patients present with progressive walking difficulty, because of weakness and clumsiness, the significance of which may go unrecognized until the patient is no longer able to bear weight. Many patients have a history of preceding spinal pain, which should always lead to a suspicion of vertebral metastasis in a patient known to have malignant disease. The neurologic deficit may develop very rapidly, with collapse of the vertebra or occlusion of the vascular supply to the cord. An analysis of the level of the sensory deficit helps in assessing the site of the spinal disease and planning the appropriate radiologic investigations. However, plain radiographs of all of the spine and chest should be carried out and may reveal loss of outline of a pedicle, reduction in height of a vertebral body, or a soft tissue mass. MRI of the spine is the investigation of choice. However, CT may reveal evidence of bone destruction and allow percutaneous needle biopsy of the lesion.

There has been considerable debate about the value of decompressive surgery, as laminectomy alone has produced suboptimal results.³⁷ As a result there has been considerable experience with alternate conservative therapies. Commonly steroids, dexamethasone, are pre-scribed for both their effect on vasogenic edema and to improve tumor-related pain.^{38,39} In the 1970s and 1980s, radiotherapy became the mainstay of treatment, and surgical intervention was primarily used as a salvage therapy if patients deteriorated during radiation. In some centers, radiation remains the initial treatment.³⁹ However, recently there has been a resurgence in surgical interest for these patients. This has been motivated by a randomized controlled trial by Patchell et al.⁴⁰ This

trial compared radiation alone to surgery (circumferential decompression and stabilization) and radiation. The authors showed that the surgical group had improved bladder control and ambulation status compared to the radiation-alone group, and there was no change in survival. Improvements in ambulation and continence are now felt to be appropriate benefits to offset the risks of surgery in these palliative patients and have been reported by other groups.⁴¹ However, surgery is not indicated for all patients with metastatic epidural compression. Patients with desmatted disease and an expected survival less than 4 months, those with multiple lesions at multiple levels, those medically unfit for surgery, or those with very radiosensitive tumors (lymphoma, myeloma) may not derive the benefits from surgery.

VASCULAR DISORDERS OF THE SPINAL CORD

The peculiar anatomic arrangement of the arterial blood supply of the spinal cord may protect it from the effects of occlusion of one feeding vessel. The anterior and posterior spinal arteries are fed by radicular arteries, which are branches of vessels arising from either the aorta or the subclavian arteries. There is generally a large feeding artery in the lower thoracic region, most commonly on the left at T10. A watershed lies at the second thoracic segment of the spinal cord, between areas supplied by thoracic vessels and those from the neck. Interruption of supply can occur in atheroma of the aorta,⁴² in dissecting aneurysm,⁴³ or as a complication of aortic open and endovascular surgery.⁴⁴ The extent and severity of the spinal cord neurologic deficit varies considerably, probably depending on the anatomic variation of the spinal cord vessels in the individual patient.

The syndrome of the anterior spinal artery arises when this vessel is obstructed by thrombus. The onset is sudden with pain in the back or neck and paresthesias down the arms. The posterior columns receiving a blood supply from the posterior spinal network are preserved, so that proprioception remains intact, whereas thermal and pain appreciation are impaired. In addition, a lower motor paralysis of the arms is associated with spastic paraparesis, or paraplegia. In some cases, the presence of cervical spondylosis and an osteophytic ridge has been implicated in local occlusion of the anterior spinal artery.⁴⁵ This phenomenon is also recognized in the setting of thrombophlebitis secondary to epidural abscess.⁴⁶

SPINAL CORD INJURY

Acute spinal cord injury (SCI) is a severe and devastating event for both patients and their families, regardless of age. However, there has been a perception that older adults fare considerably worse than their younger counterparts. A number of authors have observed an increasing proportion of older patients presenting with acute SCI, with falls (often from standing heights) as the leading mechanism of injury in contrast to motor vehicle collisions, which are more common in younger age groups.⁴⁷⁻⁵¹ The reasons for these observations are likely multifactorial and include an aging population, alteration in bony structural support secondary to osteopenia/osteoporosis, cervical spondylosis (leading to undiagnosed myelopathic symptoms and predisposing

to central cord syndrome), a more fragile ambulation status (because of altered sensory mechanisms), osteoarthritis/decreased mobility, neurologic disorders such as Parkinson's disease or diabetic peripheral neuropathy and the effects of polypharmacy.⁵⁰

Several authors have endeavored to reassess the outcomes of SCI in the geriatric setting to evaluate whether current treatment modalities have altered clinical outcomes. Furlan and coworkers⁵¹ found, in a retrospective review of a prospective cohort, that patients with SCI 65 years of age and older had a significantly higher mortality rate than younger patients (46.88% vs. 4.86%; $p < 0.001$). However, they also reported that, among survivors, age had no impact on motor or sensory outcomes. This suggests that a significant number of patients (the survivors) could benefit from aggressive treatment and with a better understanding of predictors of outcome, preferably those modifiable, the expected survivors could be identified and treated. Fassett et al⁴⁹ conducted a retrospective review of 412 patients over the age of 70 years treated between 1978 and 2005. They observed an increase in the incidence from 4.2% to 15.4%, and the elderly cohort as a whole tended to have less severe injuries based on the American Spinal Injury Association (ASIA) grading scale. However, the mortality rate in the elderly patients with severe neurologic impairment was uniformly higher, high enough to yield a statistical difference in mortality between the age groups. Unfortunately their data did not contain information of preinjury medical conditions. Krassioukov and colleagues⁴⁷ in a previous study examined the effect that preexisting conditions had on outcomes. In their cohort the ASIA grade was similar between the young and elderly; however, the number of preexisting medical conditions was statistically greater in the geriatric group which correlated to the difference in secondary complications observed between the two groups. When this observation was taken into account there was no statistical difference in complications or mortality reported attributable solely to age. It needs to be borne in mind that this study had relatively small cohorts (28 geriatric, 30 younger) and the conclusions may differ with more statistical power. Despite this the authors advocate for an aggressive multidisciplinary approach to SCI in the elderly and caution against allowing "agism" to bias treatment.

PAGET'S DISEASE

Paget's disease is a generally progressive disorder of bone that causes neurologic sequelae of the brain, spinal cord, or peripheral nerves, depending on which bones are involved. It is important to recognize these complications, as many respond to treatment of the underlying disorder. In the spine, pagetic changes may affect one or several vertebrae. The disease is characterized by bony destruction followed by repair, which leads to flattening and expansion of the diameter of the vertebral bodies, and thickening of the pedicles and laminae. Bony projections in the vertebral canal cause spinal cord and nerve root compression. Neurologic symptoms may develop suddenly if collapse of a vertebral body occurs.

Spinal cord compression is most common in the thoracic region and is generally slowly progressive, causing a spastic weakness of the lower limbs combined with sensory symptoms and signs. Pain may be due to local bony changes,

malignant degeneration, or nerve root compression. In some patients progressive myelopathy occurs, yet imaging fails to reveal direct compression of the spinal cord. In these patients, progressive ischemia may be the cause of neurologic deterioration.

When the disease affects the lumbar region, symptoms of single or multiple nerve root compression can develop, producing back pain and sciatica. When the spinal canal is constricted, neurogenic claudication may be the presenting symptom.

Surgical treatment is indicated only when medical treatment fails to control the progression of the neurologic sequelae of the condition. However, control of blood loss from the diseased bone during surgery can be troublesome.^{52,53}

NEUROLOGIC COMPLICATIONS OF DEGENERATIVE DISEASE OF THE LUMBAR SPINE

Spondylosis of the lumbar spine increases in severity and extent with advancing age, often occurring simultaneously with disease in the cervical region.^{4,54} Biochemical and pathologic changes are similar at both sites. Loss of disk height and the development of traction spurs and osteophytes are associated with sclerosis and enlargement of the vertebral bodies. Simultaneous changes in the facet joints occur, with destruction of articular cartilage, laxity of the joint capsule, and osteophytic enlargement of the joint surfaces.⁵⁵ This process may be asymmetric, so that rotational subluxation of one vertebra on the other can develop. The lowest intervertebral disks of the lumbar spine are most commonly affected, at the point of transition from the mobile lumbar spine to the fixed sacrum.

A number of discrete neurologic conditions may complicate lumbar spondylosis.

Acute nerve root entrapment

True herniation of an intervertebral disk can occur in an elderly person and produce a pattern of symptoms and signs similar to that seen in younger patients.⁵⁶ However, compared with the average adult population, elderly people have a higher incidence of motor deficits and are more likely to have a sequestered disk nucleus. Acute root entrapment may also result from compression secondary to rapid expansion of a degenerative spinal cyst.⁵⁷

Chronic nerve root entrapment

Lumbar mono- and polyradiculopathy occur in elderly people, more commonly as a result of nerve root compression in the lateral recess of the spinal canal and in the neural foramen than from disk rupture. As degeneration of the intervertebral disk advances, there is loss of disk height and formation of osteophytes that bulge into the neural foramen; hypertrophy of the facet joint further compromises its capacity. At the same time, partial subluxation of the posterior joint with upward and forward movement of the superior articular surface narrows the lateral recess of the spinal canal.⁵⁸ At first extension and rotation of the spine aggravate the process, so that dynamic stenosis (Figure 67-4) may produce intermittent compression and symptoms, although, as the condition advances, permanent compression occurs.

Figure 67-4. Magnetic resonance images of (A) normal lumbar spine and (B) severe spinal canal stenosis.

Typically, patients complain of pain and stiffness of the back, accompanied by the insidious onset of sciatic pain. These symptoms are generally aggravated by standing or walking and relieved by rest or lying, particularly when the spine is flexed. Patients complain of paresthesias in the legs, which are also precipitated by the same types of activity. In chronic nerve root entrapment caused by stenosis, coughing and straining aggravate the pain, and nerve root stretch tests are generally negative. Some patients show mild weakness of the legs, although objective sensory deficits are rare. The progression of symptoms and signs is generally much slower than for a herniated nucleus pulposus.⁵⁹⁻⁶¹

Nerve root entrapment may complicate degenerative spondylolisthesis. This develops when degeneration of the facet joints and laxity of the disk annulus allow the upper vertebral body to slide forward on the lower. The L4-L5 intervertebral joint is most commonly affected, but other intervertebral levels can be involved and produce sciatic pain and symptoms of nerve root compression.

Neurogenic claudication

Narrowing of the central spinal canal can develop as a result of a combination of degenerative hypertrophy of the facet joints, hypertrophy and corrugation of the ligamentum flavum, and bulging of the disk and osteophytes. As the available space in the spinal canal narrows, there is compression of multiple nerve roots of the cauda equina and its circulation. The symptoms of claudication develop. Bilateral leg pain is precipitated by walking or standing and improved with rest, especially when the spine is flexed or when the patient sits or squats.⁶¹

Patients frequently develop a stooped posture. As the distance walked increases, a heavy leaden weakness builds up in intensity, accompanied by burning paresthesias and a fear of the limb giving way.⁶² Sometimes neurologic signs are present only after an exercise provocation test on a treadmill.

In older adults, the clinical picture is often confused with the effects of peripheral vascular disease. Sharr et al⁶³ reported that urinary symptoms due to a neuropathic bladder often complicate central stenosis of the spinal canal.

Investigations

Plain radiographs reveal the extent and severity of degenerative changes of the disks and facet joints. Radiography has been superseded by CT and MRI of the lumbar spine, which reveal the cross-sectional anatomy of the spinal and neural canals and can reveal the degree of degeneration of the disk. However, only MRI can adequately display detail of the neural structures.

Radionuclide scanning is generally not helpful, as increased uptake is common in areas of osteoarthritis, but it can exclude spinal infection or neoplasm.

Management

The majority of elderly patients do not require surgical decompression, and their symptoms can be controlled by analgesic and anti-inflammatory medication and modification of their activities of daily living. Rest and physical treatment, combined with restriction of spinal movement, often produce satisfactory results. However, older adults can withstand surgery well, and age alone is rarely a contraindication to operation. Surgery is indicated when sciatic pain and other symptoms significantly reduce a patient's physical capacity or cannot be controlled by medical treatment. Signs of severe nerve root compression, such as weakness or sensory loss, neurogenic claudication, and cauda equina compression, are firm indications for surgical intervention. The aim of surgery is to decompress the spinal canal and neural foramina, thus freeing the nerve roots. Getty et al^{64,65} obtained satisfactory results in 85% of patients after a partial undercutting facetectomy. However, low backache persists after surgery in many patients, owing to the background degenerative changes, and patients must be advised accordingly.^{66,67} However, this effect may be in part related to the surgical approach, as persistent back pain is not reported as

commonly following minimal access surgery in the elderly.⁶⁸ Approaches to the spine using minimal access surgical techniques (MAST) are becoming more commonplace and may have a particular role in the treatment of the older adult. MAST involves utilizing smaller skin incisions and working through small portals or "tubes" via a muscle splitting/sparing approach; in contrast to the traditional "open" surgical approaches, which involve stripping the paraspinal muscles off the spine to gain adequate access. MAST techniques have been shown to minimize surgical trauma and blood loss, reduce postoperative pain, and hasten mobilization/recovery. These advantages may be particularly important when treated a potentially frail population. Rosen et al⁶⁸ recently described their experience utilizing a MAST approach for lumbar decompression in a cohort of 50 patients with a mean age of 81 years. They observed no mortality or significant morbidity in their cohort and showed statistical improvement in multiple validated clinical outcome scales with a mean follow-up of 10 months. In addition to MAST, other novel approaches, such as dynamic stabilization, are promising adjuncts to decompressive procedures and are intended to address the issue of concomitant back pain without the need for a surgical arthrodesis.^{69,70} However, all of these approaches still require the rigors of future randomized clinical trials to prove their potential merits.

KEY POINTS

Disorders of the Spinal Cord and Nerve Roots

- The majority of pathologies observed in the spines of older adults relate to degenerative processes.
- Spinal cord compression in the elderly population is most frequently caused by cervical spondylosis or metastatic vertebral body tumors.
- Less common causes of cord compression in the elderly population include intraspinal tumor and thoracic disk protrusion.
- The clinical presentation of cervical myelopathy is usually either insidious gait disturbance or numb, clumsy hands.
- In patients with advanced rheumatoid arthritis, subluxation at the craniocervical junction may require surgical treatment by internal decompression and fixation.
- The incidence of spinal cord injury in the elderly is rising, and the causes and sequelae are unique in this population.
- Claudicant leg pain needs to be differentiated between neurogenic and vascular etiologies.
- Given current operating room techniques, age alone should not deter surgical intervention when indicated.

Infections of the Central Nervous System

Steven L. Berk
James W. Myers

Bacterial meningitis is a disease that presents particular challenges in the elderly patient. The mortality rate from bacterial meningitis is higher in elderly people than in younger adults. Bacterial meningitis has become a more common problem in elderly patients over the past 2 decades. In 1973, Fraser et al¹ reported that the mean age of death from meningitis in Olmsted County, Minn., had gone from 11.5 years in the period 1935 to 1946 to 64 years during the period 1959 to 1970. In the latter period more than one half of all deaths from meningitis occurred in those over 60 years of age. The incidence of bacterial meningitis rose from 5 cases per 100,000 to 15 cases per 100,000.¹ A Centers for Disease Control and Prevention survey performed between 1978 and 1981 showed an increasing incidence of meningitis in older patients² as did a survey on the incidence of meningitis conducted in Rhode Island.³ In one review of 445 adults treated for bacterial meningitis at the Massachusetts General Hospital, 56% of community-acquired meningitis occurred in patients over 50 years of age.⁴ In this study and all previous studies, the mortality rate was much higher in older patients. The mortality rate in the Massachusetts General Hospital study was 37 in those over 60 years of age compared with 17 in younger adults. In the Rhode Island study, 55% of elderly patients died compared with an overall mortality rate of 10%.³

The increased incidence of meningitis in this age group probably is explained, in part, by the more aggressive care given to elderly patients, including more rigorous evaluation of fever, change in mental status, and coma. Nosocomial meningitis particularly related to neurosurgical procedures is also a cause of the increasing incidence of meningitis in this age group. Durand et al⁴ have shown that nosocomial meningitis has increased from 28% of all meningitis between 1962 and 1970 to 45% of all cases of meningitis from 1980 to 1988. Many of these cases occur in the chronically ill, frequently hospitalized elderly.

Bacteria may reach the subarachnoid space of the elderly patient by several different mechanisms.⁵ Elderly patients with focal infections may develop bacteremia and seed the meninges. This occurs, for example, in the elderly patient with pneumococcal pneumonia, or less frequently in the patient with pyelonephritis and gram-negative meningitis. Meningitis develops by way of direct inoculation of bacteria into the meninges such as occurs in head trauma or after a neurosurgical procedure. Elderly patients are prone to frequent falls and head injuries. *Staphylococcus aureus*, coagulase-negative staphylococci, and gram-negative bacilli are responsible for most cases of meningitis secondary to head trauma or neurosurgery. Meningitis may occur from contiguous spread of infection to the meninges as in patients with otitis media, sinusitis, or mastoiditis. This mechanism of infection is probably somewhat less common in elderly people, compared with younger adults.

In the bacteremic, elderly patient, symptoms of fever, chills, and rigors will usually be present but afebrile

bacteremia in elderly people is well described. Patients with contiguous spread of infection usually complain of localized findings, such as ear or facial pain. Bacteria in the subarachnoid space will cause an inflammatory reaction in the pia and arachnoid matter that will manifest itself as neck pain and stiffness with protective reflexes that cause the Kernig and Brudzinski signs. Structures that lie within the subarachnoid space are involved in the inflammatory reaction. Pial arteries and veins may become inflamed and cranial nerve roots damaged.

A diffuse encephalopathy may occur. Abnormal mental status results from cerebral ischemia, edema, or toxic encephalopathy. Confusion, headache, or lethargy is a manifestation of this diffuse, inflammatory process. Papilledema, hydrocephalus, and other focal findings may occur as a result of pus occluding the foramina of Luschka and Magendie, resulting in increased intracranial pressure.

The clinical features of meningitis in elderly patients are more subtle than in younger adults. This is a recurring theme in almost all studies that involve older patients with meningitis.^{6,7} Most, but not all, studies have found that elderly patients with bacterial meningitis are less likely to have neck stiffness and meningeal signs. At the same time, older patients often have cervical spine disease and poor neck mobility, making interpretation of clinical signs more difficult. Berman et al⁸ found meningismus present in only 58% of elderly patients with meningitis. Gorse et al⁹ compared signs and symptoms of patients with meningitis over 50 years of age to those in patients under 50. Older patients had more mental status abnormalities and were more likely to have seizures, neurological deficits, and hydrocephalus. Berk,⁶ Roos,¹⁰ Massanari,¹¹ and others have noted that a delay in diagnosis is frequently associated with meningitis in the elderly and this delay may explain the high mortality rate noted in this group of patients.

Elderly patients with bacterial meningitis may not have as pronounced fever or may at times be afebrile. The change in mental status that occurs in elderly people may be attributed to senility, delirium, psychosis, transient ischemia, or stroke. In the elderly patient who has undergone neurosurgery, postoperative lethargy may be mistakenly attributed to an expected postoperative course. A stiff neck in an elderly patient may not arouse the same concern that it would in a young adult.

Physical examination is a critical part of the evaluation of an elderly patient with suspected meningitis. Nuchal rigidity is reported in between 56% and 92% of elderly patients depending on the series.⁷ When neck stiffness is the result of meningeal irritation, the neck will resist flexion but can be rotated from side to side. A fundoscopic and cranial nerve examination are mandatory to alert the clinician to associated increased intracranial pressure or brain abscess. Mental status should be carefully described and followed. Lethargy and coma are poor prognostic signs. Examination of the

head should include a search for skull fracture, avulsion, or hematoma. Careful otoscopic examination is also a necessity as otitis media may be missed in the elderly patient, particularly when mental status is abnormal and a history cannot be obtained. The elderly patient may have pneumonia and concomitant meningitis. Gorse et al⁹ found pneumonia to be much more common in older adults with meningitis. The elderly patient may not complain of respiratory symptoms so examination of the lung may be the first clue to pneumonia. Examination of the heart is necessary to detect underlying valvular heart disease that might predispose the elderly patient to endocarditis with seeding of the meninges. Examination for costovertebral tenderness, decubitus ulcers, and petechial lesions will also provide important information in determining the source and causal agent in meningitis.

Performance of a lumbar puncture without delay is the critical element in the diagnosis of bacterial meningitis in both young and old. About 35% of elderly patients with meningitis have focal neurologic findings.⁹ Because lumbar puncture is contraindicated in patients with brain abscess, computed tomography (CT) or magnetic resonance imaging (MRI) will be necessary in some older patients. However, the high mortality rate from meningitis in the elderly makes time of the essence in the diagnosis and treatment of meningitis in this group. Many infectious disease experts now support the strategy of beginning empirical antibiotic therapy, pending lumbar puncture, particularly when a delay of hours is anticipated due to an imaging study.

There is very little in the literature to suggest that the cerebrospinal fluid (CSF) findings in elderly patients with meningitis differ from young adults with meningitis. Lumbar puncture will show purulent fluid with white blood cell counts between about 500 and 10,000 cu/mm. Polymorphonuclear leukocytes predominate, usually making up more than 90% of total cell count. Meningitis caused by *Listeria monocytogenes* sometimes has a mononuclear cell predominance. At least one study has shown that elderly patients with meningitis are more likely to have a lack of cellular response in CSF than younger adults.¹² Those elderly patients with meningitis who have few cells in CSF but many bacteria have a poor prognosis.¹³ CSF glucose levels are usually low in bacterial meningitis. CSF to serum glucose ratios are usually less than 50%. Seventy percent of patients with meningitis will have a ratio less than 31%.¹⁴ Spinal fluid protein is elevated above 50 mg/dL. Very high protein levels are associated with poor prognosis. Gram stain of CSF will be positive in 60% to 90% of all patients with meningitis.¹⁴ In the study by Berman et al,⁸ only 50% of elderly patients with meningitis had a positive Gram stain. The Gram stain is most likely to be negative in patients who have received prior antibiotic therapy. In those patients whose Gram stain is negative, a variety of methods to detect bacterial antigen are now in common use. These include latex fixation, coagglutination, and counter-immunoelectrophoresis. The limulus lysate assay has been used to detect gram-negative meningitis, an important cause of meningitis in elderly people. Other tests such as lactic acid levels and measurement of C-reactive protein have been recommended to help distinguish bacterial from viral meningitis, but clinical decisions are rarely based on them.

Blood cultures are recommended in all patients in whom bacterial meningitis is suspected. In the study by Berman et al,⁸ almost one-half of all elderly patients with meningitis

had concomitant bacteremia. In addition, other cultures—such as sputum, urine, and wound—may be extremely helpful in determining the causal agent and source of infection.

Streptococcus pneumoniae is the most common organism to cause meningitis in elderly patients.⁵ *S. pneumoniae* was responsible for more than one half of all cases of meningitis in the elderly in several studies.^{15–17} The organism caused 43% of all cases in the study of Berman et al⁸ and 24% of cases in the study of Gorse et al.⁹ Gram-negative bacilli cause meningitis in elderly patients both by bacteremic spread of infection, such as in urinary tract infection or pneumonia, and as a nosocomial infection after neurosurgery.^{18,19} *Escherichia coli* is the most common organism to cause meningitis secondary to bacteremic spread. *E. coli* and *Klebsiella pneumoniae* are the more common gram-negative bacilli to cause meningitis after neurosurgery but more unusual organisms, particularly *Acinetobacter*^{20–22} have been more commonly reported. In a review of 581 cases of bacterial meningitis in elderly patients between 1967 and 1980, about 8% of cases were caused by gram-negative bacilli⁶ (Figure 68-1). However, more recent studies have shown gram-negative bacilli to be responsible for 20% to 25% of cases.^{8,9} This increase is not unexpected in light of the reported increase in nosocomial meningitis in all age groups. Gram-negative meningitis occurs at the extremes of life: in the neonate and debilitated elderly people. In a study of 158 patients with gram-negative meningitis in New York City, more than one half of the patients were over 60 years of age. Almost all of these elderly patients died.²³ However, third-generation cephalosporins have replaced chloramphenicol for treatment of gram-negative meningitis with improvement in overall survival.

Listeria monocytogenes is also an organism more likely to cause meningitis in elderly people than the younger adult. Because this infection is T-cell mediated, it is possible that immunologic senescence of this system may explain the predisposition of elderly people to this infection. Although *Listeria* accounts for 4% to 8% of all cases of meningitis in elderly people, it is an extremely rare cause of meningitis in young healthy adults. Of 53 cases of *L. monocytogenes* meningitis in New York City, 77% of patients were older than 50 and 87% of these elderly patients died.²³

Meningococcal meningitis is the most common cause of meningitis in young adults, but a less common cause of meningitis in elderly people. The incidence of meningococcal meningitis in the elderly patient population varies from one study to another, reflecting the epidemic nature of the disease. Outbreaks have occurred in nursing homes and institutional settings.²⁴ The infection should be considered in elderly patients who have meningeal signs and have a petechial or macular rash. No focus of infection will be noted.

S. aureus was the most common cause of meningitis in elderly people in a Mayo Clinic study between the years 1948 and 1958.²⁵ All cases were secondary to neurosurgery. Overall the organism is probably responsible for about 10% of cases of meningitis in older patients, either as a neurosurgical infection or part of a complicated staphylococcal sepsis secondary to pneumonia or endocarditis. Coagulase-negative staphylococci have become a more common cause of meningitis in elderly people, being associated with CSF shunts and other neurosurgical procedures.

β -Hemolytic streptococci are a relatively rare cause of meningitis in elderly people. However, this appears to be

Figure 68-1. Bacterial meningitis in elderly patients. (Modified from Berk SL, Smith JK. *Infectious diseases in the elderly*. *Med Clin North Am* 1983;67:273-93.)

another organism that causes life-threatening infection and meningitis at the extremes of life.²⁶ *Hemophilus influenzae*, a cause of meningitis in children, is unusual in adults and elderly people. When *H. influenzae* does occur in older patients, it is usually a nonencapsulated organism.²⁷ This is in contrast to children, where the type B encapsulated organism is most likely to cause infection.

The treatment of bacterial meningitis requires prompt initiation of antibiotic therapy. The antibiotic chosen must have excellent activity against the causal agent. Information from the history and physical examination in combination with a careful review of the CSF Gram stain will be the foundation on which the causal agent will be determined and the optimal antibiotic chosen. An infectious disease specialist, when possible, should be involved in the case as the mortality rate from the disease is high and the margin of error is small. The antibiotic chosen should be bactericidal for the causal agent and must diffuse across the blood-brain barrier. Table 68-1 lists the causal agent and the antibiotic generally recommended.

However, the particular epidemiology of the hospital or community of the patient will take on increasing importance in determining the antibiotic of choice. The rapid emergence of penicillin-resistant pneumococci in the United States has created some uncertainty in regard to the initial treatment of pneumococcal meningitis. Given the rising incidence of high-level penicillin-resistant organisms, empirical therapy of pneumococcal meningitis should include vancomycin and a third-generation cephalosporin.²⁸ Pneumococci with an MIC of > 2 µg/mL are especially worrisome in that failures have been noted when these patients were treated with cephalosporin alone.²⁹ The role of dexamethasone, rifampin, and the new fluoroquinolones for pneumococcal meningitis is unclear at this time, and infectious disease consultation is advised. In the treatment of gram-negative meningitis, the antibiotic sensitivity pattern of gram-negative bacilli at a particular hospital is also critically important. If the infection has occurred after a neurosurgical procedure, the organisms responsible for prior neurosurgical infections should

Table 68-1. Antibiotic of Choice for Bacterial Meningitis

<i>Streptococcus pneumoniae</i>	Penicillin
<i>Streptococcus pneumoniae</i> (penicillin resistant)	Vancomycin + ceftriaxone
<i>Staphylococcus aureus</i> (methicillin sensitive)	Nafcillin
<i>Staphylococcus aureus</i> (methicillin resistant)	Vancomycin
Gram-negative bacilli	Third-generation cephalosporin (see text)
β-Hemolytic streptococci	Penicillin
<i>Listeria monocytogenes</i>	Ampicillin
<i>Neisseria meningitidis</i>	Penicillin
<i>Hemophilus influenzae</i>	Ceftriaxone or cefotaxime

be noted. If *Pseudomonas aeruginosa* is suspected as the causal agent, ceftazidime is the antibiotic of choice. Cefotaxime or ceftriaxone is generally used for other gram-negative bacilli including *H. influenzae*. Ampicillin is the drug of choice for *L. monocytogenes*. Oxacillin or nafcillin are drugs of choice for methicillin-sensitive staphylococci; vancomycin is the antibiotic of choice for methicillin-resistant staphylococci and most coagulase-negative staphylococci. As previously noted, ampicillin plus a third-generation cephalosporin is recommended for treatment of meningitis in elderly people when the causal agent is unknown. Although corticosteroids are now recommended in the treatment of acute bacterial meningitis in children, there is no evidence at present to establish their use in the adult or elderly patient. Elderly patients with meningitis are generally admitted to an intensive care unit, where vital signs and neurologic status can be carefully monitored. Some patients will be severely dehydrated or volume depleted, and others will be in septic shock. Colloid or crystalloid may be necessary to improve blood pressure and urine output. Inappropriate antidiuretic hormone secretion may accompany central nervous system (CNS) infections but should be self-limited if hypotonic solutions are avoided.

The comatose, elderly patient requires specialized care. The patient may need frequent suctioning, particularly if

pneumonia is present. The patient should be turned frequently to prevent decubiti. A condom catheter is preferable to a Foley, unless urinary retention develops. In patients who develop relapsing or prolonged fever, a repeat lumbar puncture is necessary. Drug fever, phlebitis, urinary tract infection, and pulmonary emboli are all possible explanations for prolonged fever.

The currently available pneumococcal vaccine is routinely recommended in all patients over 65 years of age. Although there are no specific data to support the prevention of pneumococcal meningitis in the elderly, it is clear that the vaccine does decrease the incidence of serious pneumococcal respiratory infection. Because most cases of pneumococcal meningitis in older patients are caused by pneumonia as the initial infection, it is likely that a vaccination program in elderly patients would be of benefit in preventing meningitis.

FOCAL LESIONS, ENCEPHALITIS, AND CHRONIC MENINGITIS

Brain abscess

A brain abscess often presents as a mass lesion with focal neurologic deficits. Since the advent of the CT scan, mortality has decreased from 30% to 50% to as low as 4% to 20%. The duration of symptoms before hospitalization usually has a mean of 15 days.³⁰ Risk factors for adverse outcomes include a severe change of mental status on admission, neurologic abnormalities on admission, and a short duration between the first symptoms and presentation suggesting a rapid progression. Fever may be absent in 40% to 50% of patients; common symptoms such as headache, change of mental status, and focal neurologic deficits may be misdiagnosed as cerebral tumors or cerebral vascular accidents, which are very common in elderly people.

The white blood cell count is ordinarily normal to slightly elevated. A lumbar puncture, which may be dangerous, particularly in patients with focal neurologic signs, reveals nonspecific findings. Seventeen percent of patients may have a white count greater than 500, suggesting a bacterial meningitis. Cultures of the spinal fluid, however, are usually negative.³⁰ Because 15% to 40% of patients with brain abscesses may die within 24 to 48 hours of a diagnostic lumbar puncture, this should be avoided in most cases.

The radiologic appearance of a "doughnut ring" lesion may be detectable in the majority of patients with brain abscesses. However, ring-enhanced lesions can also be seen with necrotic tumors and cerebral infarction. Surrounding edema may also be seen on CT scan and might be an indication for corticosteroids.^{31,32} In cases of a single abscess, the most common location is generally that of the frontal lobe or parietal lobe rather than the occipital or temporal. Sites of brain abscesses are often independent from presumed origin of infection except for the possibility of ear and sinus infections more often leading to abscesses within the frontal brain.

Generalized seizures can prompt hospitalization of many patients including older adults. Often 50% of patients with a brain abscess may have a focal neurologic sign such as a hemiparesis or focal seizure. Patients may also present with a diffuse neurologic dysfunction such as a coma, generalized seizure, or neuropsychiatric manifestations. Funduscopic examination may also reveal papilledema. In Seydoux and

Francioli's study³⁰ of 39 cases of brain abscesses, predisposing factors were not equally distributed in the different age groups in contrast to previous studies. They were more common in patients less than 50 years of age. Direct spread from a sinus or otologic focus appears to be more common with brain abscesses in younger adults, and was infrequently noted in patients older than 60 years of age. A short duration of symptoms before hospitalization also characterized patients between 20 and 60 years of age and was often associated with a poor outcome. The microbiology of brain abscesses does not appear to be significantly different between younger and older patients. Often viridans streptococcus and *Streptococcus milleri* are the most frequently isolated aerobes. *Fusobacterium* and other anaerobes were also common isolates.

Surgery is the only procedure that allows optimal microbiologic documentation. Several authors recommend medical therapy, particularly in cases in which the abscess is less than 2 cm in diameter and when the lesion is of high density, suggesting a cerebritis. Repeated aspiration and serial CT scans may be required to achieve a satisfactory response.³³⁻³⁵

A combination of a β -lactam agent with chloramphenicol or metronidazole generally has been recommended as standard therapy for brain abscesses. Microbiologic data obtained from a stereotaxic biopsy will be a further guide to therapy. The optimal duration of brain abscesses has been variable.³⁶ Usually most authors recommend approximately 4 to 6 weeks of antibiotics, including the combination of parenteral and oral agents. Neurologic sequelae can be quite high, occurring in as much as 46% of cases.³⁰

Subdural empyema

Subdural empyema may arise as a complication of a sinusitis or otitis media. Presenting symptoms can often mimic a brain abscess. A contrasted study of the CNS is indicated and neurologic drainage is mandatory. Antibiotic therapy is targeted at many of the same organisms that cause brain abscess. Length of therapy is generally several weeks with intravenous antibiotics.

Tuberculous meningitis

Tuberculosis of elderly people is a serious disorder. Previously this was thought to be a diagnosis of the pediatric age group but recent reports indicate a rising incidence in elderly people.³⁷ Tuberculous meningitis is often an insidious disease and may be especially difficult to diagnose in elderly people. Nonspecific symptoms of fatigue, anorexia, nausea, and an altered mental status may suggest dementia in an elderly patient. A miliary picture on chest x-ray may be the only feature that is useful to distinguish tuberculous meningitis from cryptococcal meningitis. Duration of symptoms may range from 2 days to 6 months. Hospitalization is often precipitated by change in mental status, headache, or fever. Meningeal signs are present in less than one half of the cases. Ocular palsies, particularly due to involvement of nerve VI, are found in 30% to 70% of cases.

CSF findings often reveal a protein level above 50 and a low glucose below 40. Acid-fast positivity varies among the studies but can range anywhere from 10% to 80% depending on how many spinal taps were performed. A chest x-ray and purified protein derivative should be routinely obtained. Several attempts have been made to develop a rapid, common, and specific method for diagnosing tuberculous meningitis.

Adenosine deaminase activity has been detected in the spinal fluid. At levels greater than 9 units/L, the test was found to be sensitive and specific. Levels can also be increased in patients with sarcoid or lymphoma. Levels appear to perhaps correlate with disease activity. Radioimmunoassay has been used for detecting a *Mycobacterium tuberculosis* antigen. The assay becomes negative after therapy.

Tuberculostearic acid, a structural component of *M. tuberculosis*, can be identified by gas-liquid chromatography and may also be useful to diagnose tuberculosis.³⁸ Recent methodologies, such as polymerase chain reaction (PCR) testing and immunomagnetic enrichment, may also prove to be useful for cases of tuberculosis including tuberculous meningitis.^{39–41}

Prognosis is influenced by age, duration of symptoms, and neurologic deficits. Mortality is greatest in patients younger than age 5 and older than 50 (60%). Clinical staging is often based on neurologic status: stage I—rational, no focal neurologic signs or hydrocephalus; stage II—confusion, depression, or focal neurologic deficits; stage III—stuporous or dense paraplegia or hemiplegia. Isoniazid (INH), pyrazinamide (PZA), and rifampin penetrate the blood-brain barrier to achieve adequate CSF concentrations. Multidrug-resistant tuberculosis may require several drugs.⁴² Many authorities recommend the adjunctive use of corticosteroids for stage II and III patients, beginning with the dose of prednisone at 80 mg/day, which may be gradually tapered over 4 to 6 weeks as guided by the patient's symptoms. If hydrocephalus is present, ventricular shunting procedures may be beneficial.

Cryptococcal meningitis

Cryptococcal meningitis may present in a manner very similar to tuberculosis. Between 20% and 50% of patients with *Cryptococcus* may have no underlying disease such as human immunodeficiency virus (HIV). Spinal fluid findings are very similar to tuberculosis in that there is a lymphocyte predominance. The India ink test may be positive in 50% or more of cases. A cryptococcal antigen is often positive in 90% of cases using a rapid simple latex fixation test. A CT scan may be helpful to rule out hydrocephalus, which is not uncommon in cryptococcal meningitis.

Poor prognostic signs for cryptococcal meningitis may be related to a high CSF opening pressure, low CSF glucose, fewer than 20 white blood cells in the CSF, and high titers of cryptococcal antigen in a positive India ink, and the presence of HIV disease.

Amphotericin B is the traditional drug of choice for cryptococcal meningitis.^{43,44} Flucytosine can serve as a useful adjunct, particularly when trying to lower the dose of amphotericin B to prevent renal insufficiency. However, flucytosine has bone marrow suppressive toxicities. Fluconazole is particularly useful for maintenance therapy but may also be useful as an acute therapy for patients with cryptococcal meningitis as well, particularly for those patients with less poor prognostic parameters.⁴⁵ Liposomal amphotericin B is also a new modality that may prove to be useful for treatment for cryptococcal meningitis. Combination therapy with fluconazole and flucytosine has also been investigated in patients with acquired immunodeficiency syndrome.

Coccidiomycosis is another common cause of chronic meningitis syndrome and a careful travel history may be an important clue to disease. Residents of the southwestern

United States and Mexico appear to be at increased risk for this disease. Two thirds of the patients, however, may have no risk factors. Blacks, Filipinos, pregnant women, and patients with HIV disease appear more likely to have disseminated disease. CSF parameters are very similar to cryptococcal and tuberculous meningitis. Detection of complement fixation antibody in the CSF is specific and sensitive for the diagnosis. Amphotericin B has been the traditional drug of choice. Many experts often recommend the use of an Ommaya reservoir for intraventricular therapy. Newer data suggest that fluconazole may be helpful as an alternative to amphotericin B for long-term treatment of *Coccidioides meningitis*.⁴⁶

Summary of Management Algorithm

Pneumococcal Meningitis

- Begin empirical therapy with vancomycin and a third-generation cephalosporin
- Dexamethasone administration is generally not recommended in adults
- Modify therapy based on the organism's MIC to penicillin

Herpes Simplex Encephalitis

- Begin therapy with high-dose acyclovir pending diagnostic tests
- An abnormal EEG can be suggestive of the diagnosis
- Temporal lobe enhancement on a cranial CT or MRI is highly suggestive of the diagnosis
- A positive CSF herpes simplex PCR test can eliminate the need for a brain biopsy

Herpes simplex encephalitis

Herpes simplex encephalitis is a serious infection of the CNS most commonly caused by herpes simplex virus type I. Mortality of untreated biopsy-proven cases is 60% to 80%, with fewer than 10% of the patients being left without any neurologic sequelae. This illness occurs in all age groups with an equal number of cases between the sexes. It has no seasonal association. Mortality may be higher in patients over 50 years of age.⁴⁷

Patients may have an abrupt onset of personality change, altered mental status, fever, and headache. Localizing signs such as speech deficits, olfactory hallucinations, temporal lobe seizures, hemiparesis, and nasal field defects are common and may suggest the diagnosis. The spinal fluid findings are nonspecific with an elevated number of lymphocytes. An elevated number of polymorphonuclear leukocytes may be found early in the disease process. This will later change to a mononuclear site cell predominance as the disease progresses. An elevated red blood cell count can be suggestive of the diagnosis but is not required. The electroencephalogram pattern may consist of slow wave complexes at regular 2- to 3-second intervals, usually localized to the temporal lobe. CT scanning eventually becomes positive in more than 70% of the patients but MRI is more sensitive and results are abnormal earlier in the course of the disease.

The virus cannot usually be isolated from the spinal fluid but newer PCR-based methodology may be helpful in making the diagnosis.^{48–51} The definitive diagnosis of herpes simplex encephalitis can be made by brain biopsy and appropriate culture and histology. Effective therapy usually consists of acyclovir at a dose of 10 mg/kg every 8 hours for

10 days, which must be adjusted for renal function in the elderly patient as acyclovir can cause nephrotoxicity, particularly in patients that are dehydrated. Survivals correlate with the patient's level of consciousness at the initiation of treatment. Neurologic sequelae are higher if treatment is delayed or the patient is comatose. A high index of suspicion is often required to make the diagnosis and to begin effective therapy for herpes simplex encephalitis. Rarely herpes encephalitis patients may relapse.^{52,53}

Spirochetal infections

NEUROSYPHILIS

Several studies have suggested that neurosyphilis remains an important and frequently encountered entity. An estimated two symptomatic cases of neurosyphilis occur per 100,000 patients yearly. Syphilis is often the cause of reversible dementia in an elderly patient. Although neurosyphilis is often felt to be a late manifestation of syphilis, spirochetes invade the nervous system throughout the entire course of syphilis. Syphilitic meningitis may occur at the same time as the rash of the secondary syphilis. Most patients with cerebrovascular syphilis have had a duration of approximately 5 to 10 years. This can manifest as a stroke in a young person. Elderly patients typically have a presentation of parietic neurosyphilis or tabes dorsalis. The interval between infection and symptoms often ranges from 20 to 30 years for these syndromes. Both races appear easily susceptible. Men, however, have an increased risk as compared to women. The neurologic examination may be entirely normal with neurosyphilis, and the diagnosis may only be made by an abnormal CSF examination. As the disease progresses, intellectual function can decline and psychotic changes can occur. Symptoms include irritability, fatigability, personality changes, impaired judgment, depression, confusion, and delusions. Patients may have coarse, movement-induced facial, lingular, and labial tremors. Patients also may have difficulty with distorted handwriting, and abnormal reflexes and focal findings may also occur.⁵⁴ Untreated, the disorder is fatal within a few months to 3 or 4 years. Penicillin treatment can effectively reverse the CSF abnormalities and arrest the disease, but the neurologic outcome depends on the degree of structural CNS damage that had occurred at the time of therapy.⁵⁵ CSF findings in general paresis include an opening pressure between 50 and 300. The cell count is usually less than 100 in 90% of the cases. The glucose may be normal or moderately reduced. The protein is greater than 100 in 25% of cases. CSF and blood serology are generally positive in greater than 95% of cases.⁵⁴

Tabes dorsalis continues to be a common form of CNS syphilis, although the percentage seems to be decreasing. This disease, again, is much more common in men than in women. It has the longest incubation period, being as high as 50 years in some patients. A triad of symptoms including lightning pains, dysuria, and ataxia may be seen in patients. A triad of signs including Argyll Robertson pupils, areflexia, and a loss of proprioception are characteristic of this disorder. Lightning pains last for a few seconds to minutes at a time and usually occur in the lower extremities. These can be separated by interval-free periods of a few months. Pain sensation is often strikingly impaired compared with that of hot and cold sensation.⁵⁵ Reduction or loss of ankle or knee jerks can occur in approximately 80% to 90% of patients.

Pupillary abnormalities are noted in 79% of patients and consist of pupils that accommodate but do not react. In the elderly patient, diabetes can mimic tabes. Other rare causes mimicking tabes include Wernicke's encephalopathy and Charcot-Marie-Tooth disease. As the disease progresses, sensory ataxia becomes a problem. Many patients may have a positive Romberg sign. Less common abnormalities include syphilitic optic atrophy and gastric crises. Characteristic CSF findings of tabes usually include a normal opening pressure in 90% of the patients. Only 9% to 10% of patients have a cell count greater than 160. The protein is usually normal to moderately elevated. The majority of patients have an abnormal serum and CSF venereal disease research laboratory (VDRL) test. In the series by Merritt,⁵⁴ completely normal findings including an unreactive CSF and blood serology occurred in 2 of the 100 cases reported. In "burned-out" tabes, the fluid may be entirely normal. Penicillin treatment should clear the CSF and arrest progression of the disease; however, findings such as urinary incontinence, lightning pains, and gastric crises may not completely respond to penicillin therapy.

An unreactive peripheral blood FTA-ABS usually excludes the diagnosis of neurosyphilis, and in most cases a CSF examination would not be warranted. Any patient with a positive blood serology for syphilis and neurologic symptoms would warrant a lumbar puncture. An abnormal CSF VDRL test would constitute proof of neurosyphilis. Patients with only an abnormal protein or cell count might also be strongly considered for penicillin therapy. In patients with signs of neurosyphilis but with an unreactive CSF (normal cells and protein), such as in "burned out" neurosyphilis, the neurologic deficit is probably due to fixed structural damage and will probably not respond to additional penicillin.⁵⁵ A treponemicidal level has been assumed to be 0.3 IU/mL. Comparisons of serum and CSF penicillin levels after benzathine penicillin use suggest that benzathine penicillin may not reach adequate treponemicidal levels in the CSF. Adequate levels are achieved by adequate intravenous penicillin doses given for neurosyphilis. The present authors generally tend to treat patients with neurosyphilis with 18 to 24 million units/day for approximately 10 to 14 days. Adequate therapy is suggested by a normal spinal fluid cell count and a falling protein count at 6 months following treatment.⁵⁶⁻⁵⁹ Repeat CSF examination should be performed every 6 months for the next 2 years during which time the protein count should fall and the cell count should remain normal. The VDRL will probably also disappear during this time period or reach a low-level "serofast" state. Any increase in the cell count or major deviation from this response would require retreatment with high-dose penicillin. Neurosyphilis is often an indication to consider desensitization if the patient has a penicillin allergy. Ceftriaxone may be a reasonable alternative in some patients. Penicillin allergy would be an indication for infectious diseases and allergy consultation. Many patients who have a positive serum test and no symptoms could potentially be treated with three injections of benzathine penicillin over a 3-week period. However, this would only be warranted if the physician is sure there is no symptoms of neurosyphilis. A negative CSF would be reassuring to the patient and physician before embarking on this treatment course. Hypothyroidism, cryptococcal, and tuberculous meningitis, or other causes of reversible dementia need to be considered in the differential diagnosis of neurosyphilis.

Lyme disease

The CNS effects of Lyme disease are receiving increasing attention in the literature. Lyme disease can cause a meningitis in the second stage weeks to months after the tick exposure. Bell's palsy and peripheral neuropathy syndromes are quite common. A CSF pleocytosis is often found with an elevated protein and a normal to low CSF sugar. Local CSF antibody production occurs. A positive enzyme-linked immunosorbent assay test for Lyme disease is usually recommended to be followed by a Western blot test. Ceftriaxone is generally considered the treatment of choice for the CNS manifestations of syphilis.⁶⁰ An exception might possibly be the use of doxycycline for facial nerve palsy.

KEY POINTS

Infections of the Central Nervous System

Fifty-six percent of community-acquired meningitis occurs in patients over 50 years of age.

Bacteria reach the subarachnoid space by three mechanisms:

1. Bacteremia
2. Head trauma and neurosurgery
3. Contiguous spread from sinusitis or otitis

Clinical features may be more subtle in elderly patients.

CSF findings in elderly patients resemble those of younger adults.

Streptococcus pneumoniae is the most common organism causing meningitis in elderly patients. *Listeria* is more likely to cause meningitis in older patients than in young adults.

Pneumococci may be resistant to β -lactam therapy. The addition of vancomycin to third-generation cephalosporins is recommended initially until culture results are available.

Focal Lesions

Brain abscess often presents as a mass lesion.

CSF findings are nonspecific.

Ring-enhancing lesions are detected by CT in the majority of patients.

Often viride streptococci and *Streptococcus milleri* are isolated.

A combination of metronidazole and a third-generation cephalosporin is usually recommended.

Subdural empyema arises as a complication of sinusitis and otitis media.

Tuberculous Meningitis

Tuberculosis

1. Meningeal signs are often absent.
2. CSF glucose levels are typically low.
3. Ocular palsies are common.
4. Acid-fast positivity varies.
5. Prognosis is related to clinical stage.

Cryptococcal Meningitis

India ink is positive about 50% of the time.

Poor prognostic signs include a high titer of antigen and fewer than 20 WBCs/hpf in the CSF.

Herpes Simplex Encephalitis

May present as an abrupt personality change, olfactory hallucinations, or temporal lobe epilepsy.

MRI is more sensitive than CT.

A CSF PCR test is usually positive.

Spirochetal Infections

Neurosyphilis

1. Often a cause of reversible dementia.
2. Elderly patients have tabes dorsalis or parietic syphilis more often than younger patients.
3. CSF serology is usually positive.
4. Patients who have a positive serum FTA-ABS and an abnormal cell or protein count should be considered for therapy.

Lyme Disease

Bell's palsy is common.

Ceftriaxone is the therapy of choice for all forms of CNS Lyme disease with the possible exception of facial nerve palsy.

INTRODUCTION

Bone is a living, dynamic tissue that undergoes constant remodeling throughout life. This is necessary to allow the skeleton to increase in size during growth, respond to the physical stresses placed on it, and repair structural damage due to structural fatigue or fracture. In addition to its mechanical properties, bone also plays an important role in calcium homeostasis, acting as a mineral reservoir that can be drawn on to maintain normocalcemia. The skeleton comprises two types of bone: cortical (or compact) and trabecular (or cancellous) bone. Cortical bone is predominantly found in the shafts of the long bones, whereas trabecular bone is mainly located in the vertebrae, pelvis, and the ends of long bones, where it forms a lattice-like structure within an outer shell of cortical bone. Trabecular bone has a larger surface area, undergoes greater remodeling, and is therefore more responsive to changes in calcium homeostasis than cortical bone. The respective proportion of cortical and trabecular bone varies with the anatomic site, but overall the skeleton is composed of 80% cortical and 20% trabecular bone.

The three major cell types involved in bone remodeling are osteoclasts, osteoblasts, and osteocytes. Osteoclasts are multinucleate cells derived from macrophage-monocyte precursors, which resorb bone, releasing mineral and removing degraded organic material. Osteoblasts are derived from fibroblast precursors and synthesize bone matrix or osteoid, which is subsequently mineralized around foci of crystal formation known as matrix vesicles. The matrix vesicles are extruded from osteoblasts by exocytosis and contain promoters of crystal formation such as alkaline phosphatase and pyrophosphatase. Osteocytes are mature osteoblasts that become trapped within calcified bone. These are interconnected by long dendritic processes, which may serve as mechanosensory receptors, leading to the production of paracrine factors that regulate bone resorption and formation.

Bone remodeling is initiated by a period of bone resorption lasting about 2 weeks, when osteoclasts erode an area of bone. Osteoblasts are then attracted to the resorption cavity, where over the subsequent 3 months new bone matrix is deposited and mineralized. The processes of bone resorption and bone formation are usually closely coupled, but bone formation exceeds resorption during skeletal growth, allowing the skeleton to increase in size and density. Later in life, resorption outstrips bone formation, leading to involutional bone loss. Bone remodeling may be influenced by mechanical forces applied to the skeleton, by paracrine factors, and by circulating hormones such as estrogen, testosterone, calcitonin, parathyroid hormone (PTH), and 1,25-dihydroxyvitamin D (1,25[OH]₂D).

One of the major regulators of bone remodeling is the receptor activator of nuclear factor kappa B (RANK) and RANK ligand (RANKL) system. RANKL, which is produced by osteoblasts, attaches to RANK on the cell surface of osteoclasts and osteoclast precursors, leading to stimulation of osteoclast differentiation and proliferation.¹ The interaction of RANKL and RANK is blocked by osteoprotegerin

(OPG), a soluble decoy receptor produced by osteoblasts and marrow stromal cells.¹ Studies show relationships between circulating concentrations of OPG and bone mineral density (BMD), and it is now apparent that the beneficial effects of osteoporosis treatments may be mediated in part by changes in the RANK, RANKL, and OPG system.²⁻⁴

Bone mass changes throughout life in three major phases: growth, consolidation, and involution. Up to 90% of the ultimate bone mass is deposited during skeletal growth, which lasts until the closure of the epiphyses. There is then a phase of skeletal consolidation lasting for up to 15 years, when bone mass increases further until the peak bone mass is achieved in the mid-30s. Involutional bone loss then starts between the ages of 35 and 40 in both sexes, but in women there is an acceleration of bone loss in the decade after the menopause. Overall, women lose 35% to 50% of trabecular and 25% to 30% of cortical bone mass with advancing age, whereas men lose 15% to 45% of trabecular and 5% to 15% of cortical bone.

OSTEOPOROSIS

Osteoporosis is a skeletal disorder characterized by compromised bone strength, predisposing a person to an increased risk of low trauma or fragility fractures. The three major fragility fractures are those of the forearm, vertebral body, and femoral neck, but fractures of the humerus, tibia, pelvis, and ribs are also common. These fractures are a major cause of mortality, morbidity, and health and social service expenditure in older people, but this is particularly the case with hip fractures. The annual health and social service cost of fragility fractures in the United Kingdom has been estimated at £1.7 billion, of which almost 90% is attributable to hip fractures.⁵

There is a strong inverse relationship between bone density and fracture risk, with a two- to three-fold increase in fracture incidence for each standard deviation reduction in BMD. The risk of fracture is also determined by other skeletal risk factors, such as bone turnover, trabecular architecture, skeletal geometry, and previous fragility fracture. Nonskeletal risk factors for fracture include postural instability, physical and mental frailty, and conditions associated with falling.^{5,6}

Prevalence of osteoporosis

The World Health Organization (WHO) has quantitatively defined osteoporosis as a BMD 2.5 standard deviations or more below the mean value for young adults (T score < -2.5).⁷ The prevalence of osteoporosis, as defined by a T score < -2.5 at the hip, increases in white women in the United States from 8% in the seventh decade to 47.5% in the ninth decade, whereas the prevalence at the forearm, spine, or hip rises from 21.6% to 70%.⁷ As regards the resulting probability of fragility fractures, the lifetime risk for a 50-year-old woman in the United Kingdom is 53.2%, compared with 20.7% for a 50-year-old man.⁸ The risk of individual symptomatic fractures in a 50-year-old woman is

16.6% for the forearm, 3.1% for the vertebra, and 11.4% for the hip, whereas the corresponding figures for a 50-year-old man are 2.9%, 1.2%, and 3.1%.⁸

Pathogenesis of osteoporosis

Bone mass at any age and therefore the risk of fracture is determined by the peak bone mass, the age at which bone loss starts, and the rate at which it progresses.

PEAK BONE MASS

Genetic factors account for as much as 80% of the variance in peak bone mass. Other potential determinants of peak bone mass include exercise, dietary calcium, smoking, alcohol consumption, and hormonal factors.⁶

INVOLUTIONAL BONE LOSS

Bone loss starts between the ages of 35 and 40 in both sexes, possibly related to impaired new bone formation as a result of declining osteoblast function. The onset of bone loss is likely to be genetically determined, and the subsequent rate of bone loss may also be influenced by genetic factors. Recent studies suggest that a number of gene polymorphisms influence BMD and fracture risk.⁶ The genes involved include those regulating RANKL, OPG, and the estrogen receptor gene.⁹ Although the individual effect of variation in these genes is relatively small, the combined impact of these is similar to other major risk factors for fracture.^{9,10}

Bone loss increases in the decade following the menopause in women, because of the marked reduction in the circulating estradiol concentrations. Other causes of age-related bone loss include low body weight, smoking, excess alcohol consumption, physical inactivity, declining vitamin D concentrations, and secondary hyperparathyroidism.⁶

Body weight is an important determinant of bone density and fracture risk, as bone loss is more rapid in postmenopausal women with low body weight and individuals with osteoporotic fractures are lighter than expected. The protective effects of high body weight on bone density and fracture risk may be due to the stimulation of bone formation by greater mechanical loading, increased conversion of adrenal androgens to estrogens in fat, and the shock-absorbing properties of subcutaneous fat.

Smoking may increase bone loss by reducing the age at menopause by several years, decreasing plasma estrogen levels by increasing their metabolism and possibly depressing osteoblast function. The deleterious effect of smoking on the skeleton may also be due in part to the association with low body weight. Although alcoholism is a recognized cause of osteoporosis, the effect of modest alcohol consumption on bone density remains unclear.

The decline in physical activity with advancing age is also likely to cause further bone loss. Physical activity is important to the skeleton because the associated weight-bearing and muscular activity stimulates bone formation and increases bone mass, whereas immobilization leads to rapid bone loss. The importance of physical activity is underlined by a number of studies, which show that physical inactivity is associated with an increased risk of hip fracture.

The role of dietary calcium intake in the pathogenesis of bone loss remains controversial. Although there is a relationship between dietary calcium and bone mass in adolescence, studies show little correlation between calcium intake and

bone density or bone loss in postmenopausal women. Other nutrients that have been suggested as potential determinants of the rate of bone loss include fluoride, protein, and sodium, but their importance is still uncertain.

There is a reduction in circulating 25 hydroxyvitamin D (25OHD) and 1,25[OH]₂D concentrations with advancing age, because of decreased cutaneous production and impaired metabolism of vitamin D. This is likely to contribute to the observed increase in circulating PTH with age. There is a weak relationship between serum 25OHD and bone density in middle-aged women, with an inverse correlation between bone density and serum PTH, suggesting that vitamin D status may influence bone loss. Other studies show that vitamin D insufficiency and secondary hyperparathyroidism are common in older patients with osteoporosis and fractures.¹¹

SECONDARY OSTEOPOROSIS

In addition to the factors influencing the attainment of peak bone mass and subsequent involutional bone loss, there are a number of conditions that may accelerate the development of osteoporosis. Secondary causes of osteoporosis may be found in up to 30% of women and 55% of men with symptomatic vertebral crush fractures.⁶ The most frequently encountered are oral steroid therapy, male hypogonadism, hyperthyroidism, myeloma, skeletal metastases and the use of antiepileptic drugs.

Clinical features of osteoporosis

Osteoporosis is generally considered to be asymptomatic until fractures occur. Fractures of the forearm and hip are usually easy to diagnose, but vertebral crush fractures may be more difficult to detect clinically. Only 30% of patients come to medical attention after a vertebral fracture, and there are many other causes of acute back pain.¹² Classically, however, a vertebral fracture is associated with an acute episode of back pain lasting for 6 to 8 weeks before settling to a more chronic backache. The pain may radiate anteriorly but rarely radiates to the hips or legs. Individuals with vertebral fractures may also be aware of loss of height of several inches and notice the development of a kyphosis. Physical signs include a kyphosis, local tenderness over the spine, and horizontal skin creases and abdominal protrusion resulting from the loss of trunk height.

Diagnosis of osteoporosis

Before the development of techniques that accurately measure bone density, osteoporosis was usually only detected after a fracture had occurred. The term *osteoporosis* was therefore reserved for the fracture syndrome resulting from reduced bone density. With the advent of bone densitometry and the development of effective treatments that decrease fracture risk, the term *osteoporosis* is increasingly used to describe reduced BMD before fractures have occurred.

Although accurate measurements of lumbar spine and femoral BMD can be made using dual energy x-ray absorptiometry (DXA), a population-based bone density screening program cannot be justified, as there is little evidence that such a strategy is effective in the prevention of fragility fractures.⁷ Nevertheless, an opportunistic case-finding strategy has been advocated in countries such as the United Kingdom, where a number of indications for BMD measurements

are recognized.¹³ These include previous fragility fracture, untreated hypogonadism, oral glucocorticoid therapy, other secondary causes of osteoporosis, and radiologic osteopenia.¹³ Although spine BMD may be spuriously elevated in older people, because of degenerative changes and aortic calcification, femoral neck and total hip measurements are less affected by osteoarthritis.

BMD measurements may be of limited value in the investigation of frail elderly patients with hip and other fragility fractures, many of whom will have osteoporosis and should therefore benefit from treatment. Furthermore, U.K. guidelines recommend that all people over the age of 65 years who are likely to be on treatment with oral glucocorticoids for at least 3 months should be offered treatment for osteoporosis.¹⁴

BMD measurements may be expressed as standard deviation units above or below the mean value for normal young adults or relative to the mean value for control subjects of the same age, to give T and Z scores, respectively. Although the WHO definition of osteoporosis (T score < -2.5) may be useful in epidemiologic studies, it does not necessarily represent a threshold for treatment. This is important as 70% of women above the age of 80 years have a T score < -2.5, but only a proportion of these will sustain an osteoporotic fracture.⁷ Furthermore, although more than half of patients with hip fractures have osteoporosis, fewer than 50% of those with other fragility fractures have a T score < -2.5 on DXA measurement.¹⁵

As the value of BMD in predicting fracture risk is relatively poor, there has been growing interest in using the combination of BMD and clinical risk factors for fracture to estimate the absolute risk of fracture. The WHO has developed a fracture risk assessment tool (FRAX), which estimates the 10-year risk of fractures of the major fragility fractures and of hip fracture in particular.^{16,17} Country-specific algorithms use age, gender, and the presence or absence of appropriately weighted risk factors, with or without femoral neck BMD measurements, to estimate fracture risk.¹⁸ The clinical risk factors for fracture used in FRAX, which are at least in part independent of bone density, are made up of low body mass index (BMI), prior fracture after age of 50 years, parental hip fracture, current smoking, oral steroid therapy, alcohol intake > 2 units/day, and chronic conditions associated with bone loss such as rheumatoid arthritis.¹⁶⁻¹⁸ Guidelines are being developed that will guide clinicians on the absolute risk of fracture above which osteoporosis treatment should be considered.¹⁹

Investigation of osteoporosis

As vertebral fractures may not always be easy to diagnose, spine x-rays should be considered in patients with acute back pain, loss of height, or kyphosis, to look for evidence of vertebral deformation, degenerative arthritis, or other pathology. Although spine x-rays are useful in the diagnosis of vertebral fracture, they are unreliable in the assessment of bone density. Spine x-rays may also show lytic or sclerotic lesions, which raise the possibility of neoplastic disease. Further investigations are then required, which may include isotope bone scan and magnetic resonance imaging (MRI) scan.¹²

In patients with vertebral fractures, causes of secondary osteoporosis should be identified by careful history, physical

Table 69-1. Investigations for Secondary Osteoporosis in Older People with Low Trauma Fractures or Low BMD

Serum 25OHD and PTH

examination, and appropriate investigation (Table 69-1), because specific treatment of underlying conditions such as hyperthyroidism, hypogonadism, and primary hyperparathyroidism increases bone density by up to 15%. Underlying causes of secondary osteoporosis should also be sought in older men and women presenting with hip and other non-vertebral fractures after minimal trauma. Serum 25OHD and PTH measurements may be used to confirm the diagnosis of vitamin D insufficiency and secondary hyperparathyroidism, but these are probably unnecessary if calcium and vitamin D supplementation is planned. Routine biochemical profile is worthwhile, as hypocalcemia and hypophosphatemia may indicate possible vitamin D deficiency osteomalacia, but these measurements lack diagnostic specificity or sensitivity. Serum 25OHD and PTH measurements are also useful in the further investigation of possible vitamin D deficiency osteomalacia, which is particularly likely in housebound patients or those with previous gastric resection, malabsorption, or the long-term use of antiepileptic drugs. Investigations for secondary osteoporosis should also be performed in patients found to have a BMD below the normal range for their age (Z score < -2.0), to identify underlying causes of bone loss, which may be modified.

Management of osteoporosis

All patients with fragility fractures should be given general advice on lifestyle measures to decrease further bone loss, including eating a balanced diet rich in calcium, moderating tobacco and alcohol consumption, and, if possible, maintaining regular physical activity and exposure to sunlight. As bone loss continues into old age in both men and women, the need for specific treatment should be considered in all patients with osteoporosis or fragility fractures. Although most studies of the treatment of osteoporosis have recruited few women above the age of 80 years, there is no evidence of an attenuated response to treatment with advancing age.

A number of treatments have been shown to increase BMD and decrease the risk of vertebral and hip fractures. The Royal College of Physicians has published guidelines on the management of osteoporosis,¹³ grading its recommendations on the levels of evidence for each therapeutic intervention (Table 69-2). Grade A recommendations are based on randomized controlled trials, whereas grade B recommendations result from controlled studies without randomization, studies with a quasi-experimental design, and epidemiologic studies. Although the grading of the strength of the recommendations based on study design is useful, this takes no account of study size, the magnitude of the treatment effect, the patient groups studied, or the other potential risks and benefits of treatment.

Table 69-2. Effect of the Major Treatment Options on the Risk of Vertebral, Non-vertebral, and Hip Fractures

	Vertebral Fractures	Non-vertebral Fractures	Hip Fractures

Grading of recommendations updated and adapted from the Royal College of Physicians Clinical Guidelines for Prevention and Treatment of Osteoporosis. Royal College of Physicians and Bone and Tooth Society of Great Britain. Osteoporosis clinical guidelines for prevention and treatment. Update on pharmacological interventions and an algorithm for management. London: Royal College of Physicians, 2000. (ND indicates that fracture reduction has not been demonstrated, whereas (A) reflects that a beneficial effect on fractures risk was only found in posthoc subgroup analysis.)

HORMONE REPLACEMENT THERAPY (HRT)

Although HRT was previously used in the prevention and treatment of osteoporosis in younger postmenopausal women, the situation changed with the publication of the results of the Women's Health Initiative Study.²⁰ This randomized controlled trial compared the effects of HRT with placebo in 16,608 postmenopausal women aged 50 to 79 years. Although this showed a reduction in colon cancer as well as vertebral, hip, and other fractures, the benefits were outweighed by the increased risk of breast cancer, coronary heart disease, stroke, and thromboembolism.²⁰ As a result of this study, HRT is no longer recommended for the prevention of osteoporosis, but it may be useful in younger postmenopausal women with osteoporosis and severe climacteric symptoms and in those unable to tolerate other osteoporosis treatments.

RALOXIFENE

Raloxifene is a selective estrogen receptor modulator (SERM), which has estrogen agonist actions on the skeleton but acts as an estrogen antagonist on the breast and endometrium. The Multiple Outcomes of Raloxifene Evaluation (MORE) study in postmenopausal women with osteoporosis showed that raloxifene increased lumbar spine and femoral neck bone density by 2% to 3%, reduced the risk of vertebral fractures by 30% to 50%, and decreased the incidence of breast cancer by 76%.^{21,22} There is no evidence that raloxifene decreases the risk of hip or other non-vertebral fractures. The main side effect of raloxifene is hot flashes, particularly when used shortly after menopause, but there is also an increased risk of venous thromboembolism. It is generally used in younger postmenopausal women with osteoporosis who are at high risk of vertebral fractures, but whose risk of non-vertebral fractures is low.

BISPHOSPHONATES

Bisphosphonates have become the treatment of choice for patients with osteoporosis, because of their proven antifracture efficacy and good safety profile. Intermittent cyclical etidronate therapy is now rarely used, because although it reduces the incidence of vertebral fractures, there are no interventional studies investigating the effect of treatment

on hip fracture incidence.¹³ Alendronate and risedronate have been shown in large studies to increase BMD and decrease the incidence of vertebral, hip, and other non-vertebral fractures.^{13,23–25} These oral agents are available as daily or weekly preparations but need to be taken on an empty stomach, 30 minutes before food, to ensure that they are absorbed from the bowel. Ibandronate has also been shown to improve BMD and decrease the incidence of vertebral fractures, but although a posthoc subgroup analysis suggests that it prevents non-vertebral fractures, no reduction in hip fractures has been demonstrated.²⁶ Ibandronate is available as a monthly oral preparation and a three-monthly intravenous injection. Annual intravenous infusions of zoledronate in women with osteoporosis have been shown to decrease the risk of vertebral fractures by 70% and hip fractures by 41%.²⁷ A further study in patients with recent hip fracture demonstrates that annual intravenous zoledronate decreases the risk of vertebral and non-vertebral fractures but also reduces mortality by 28%.²⁸

Although the antifracture studies with alendronate only recruited patients up to the age of 81 years, there was no evidence of any attenuation of the benefits with advancing age.²⁹ Risedronate has been shown to decrease vertebral fractures in women above the age of 80 years,³⁰ but although there is no definite evidence that it reduces the risk of hip fractures in women in this age group recruited on the basis of clinical risk factors for fracture,²⁵ there is no reason to suspect it will be ineffective in elderly women with osteoporosis. Over a third of the patients in the major study of zoledronate in osteoporosis were above the age of 75 years, suggesting that it is effective even in this older age group.²⁷

Oral bisphosphonates are generally well tolerated, but upper gastrointestinal side effects are not uncommon. Esophagitis has been reported with oral bisphosphonates, but the risk of this complication may be reduced by following the manufacturers' advice that these agents should be taken with water and recumbency avoided for 30 minutes. Intravenous bisphosphonates may cause an acute phase response, with transient flulike symptoms lasting for a few days. The severity of these symptoms may be reduced by the administration of paracetamol for 3 days starting on the day of bisphosphonate administration. Intravenous zoledronate may also cause symptomatic hypocalcemia, so it is important ensure that the patient is vitamin D replete before administering this treatment. Increased bone pain has been reported with bisphosphonate treatment but appears to be an uncommon side effect. The major antifracture study of intravenous zoledronate showed an increase in serious atrial fibrillation,²⁷ but this was unrelated to the timing of infusion and was not found in other studies with zoledronate.²⁸ Osteonecrosis of the jaw has been reported in patients receiving high dose intravenous bisphosphonates in malignancy, but this appears to be uncommon in patients taking lower-dose bisphosphonates for osteoporosis.³¹

STRONTIUM RANELATE

Strontium ranelate is a dual action bone agent which reduces bone resorption and increases bone formation. A large randomized controlled trial of strontium ranelate in postmenopausal women with osteoporosis and at least one vertebral fracture showed increases in BMD of 12.7% in the lumbar spine and 8.6% in the hip after 3 years' treatment.³²

About 50% of this apparent increase is spurious, because of the skeletal incorporation of strontium, which has a higher atomic number than calcium. This study also demonstrated a 41% reduction in the incidence of new vertebral fractures.³² Another large study in women with osteoporosis showed a 16% reduction in the incidence of non-vertebral fractures with strontium ranelate, but in a posthoc subgroup analysis in women aged over 74 years with low BMD (T score < -3.0), there was a 36% reduction in hip fractures.³³ Recent data suggest that strontium ranelate decreases the incidence of vertebral and non-vertebral fractures in women above the age of 80 years.³⁴ Strontium ranelate is available in powder form in sachets, the contents of which are dissolved in water. Preferably it should be taken at bedtime, at least 2 hours after eating, to ensure adequate absorption from the bowel. Strontium has been generally well tolerated in clinical trials, but reported side effects include diarrhea and an increased risk of venous thromboembolism. A severe hypersensitivity reaction associated with drug rash, eosinophilia, and systemic symptoms (DRESS) has been reported, which occurs within 3 to 6 weeks of starting treatment with strontium ranelate, but this is fortunately very rare.

PARATHYROID HORMONE

The continuously high circulating concentrations of PTH found in primary and secondary hyperparathyroidism is associated with an increase in bone turnover, but bone resorption is stimulated more than bone formation, resulting in loss of bone from the skeleton. In contrast, intermittent administration of PTH stimulates bone formation more than resorption, resulting in an increase in bone mass and density. Recombinant human parathyroid hormone 1–34 (teriparatide) and parathyroid hormone 1–84 have anabolic actions on the skeleton when administered by daily subcutaneous injection. Studies show a larger increase in BMD than that observed with bisphosphonates.^{35–37} Teriparatide decreases the incidence of vertebral and non-vertebral fractures, but no reduction in hip fractures has been demonstrated.³⁵ There also appears to be no attenuation of the effects of teriparatide on BMD or fracture reduction with advancing age.³⁶ Parathyroid hormone 1–84 has also been shown to reduce the incidence of vertebral fractures.³⁷ These agents are generally well tolerated but may cause transient mild hypercalcemia, nausea, dizziness, and headaches. As these preparations are 10-fold more expensive than bisphosphonates, their use is often restricted to patients with severe osteoporosis or those who fail to respond to bisphosphonates. There is evidence that concomitant administration of a bisphosphonate may attenuate the anabolic effect of PTH treatment,³⁸ but there is only transient attenuation after previous treatment.³⁹

CALCIUM AND VITAMIN D

Calcium and vitamin D supplementation has been shown to reduce the incidence of hip and other non-vertebral fractures in older people living in care homes, where vitamin D deficiency and secondary hyperparathyroidism are common.⁴⁰ In contrast, recent large studies cast doubt on the role of calcium and vitamin D supplementation in the primary or secondary prevention of low-trauma fractures in community-dwelling older people.^{11,41} Nevertheless, a recent meta-analysis shows a small reduction in hip fractures with calcium and vitamin D (relative risk 0.82, 95% confidence

intervals 0.71 to 0.94), with no beneficial effect of vitamin D alone on fracture incidence.⁴²

Calcium and vitamin D supplementation may cause abdominal bloating, other gastrointestinal symptoms, and change in bowel habit. These may account for the relatively poor compliance and persistence with supplementation, particularly with combined calcium and vitamin D preparations. Calcium and vitamin D supplementation is probably most appropriate in older people who are housebound or living in residential or nursing homes, where vitamin D insufficiency and secondary hyperparathyroidism are common.¹¹ The National Institute of Health and Clinical Excellence (NICE) in the United Kingdom recommends that patients receiving treatment for osteoporosis should also receive calcium and vitamin D supplementation, unless the clinician is confident that the patient has an adequate dietary calcium intake and is vitamin D replete.⁴³

OTHER TREATMENTS

Calcitonin is a potent antiresorptive agent with a rapid but short-lived effect on osteoclast function. The Prevent Recurrence of Osteoporotic Fractures (PROOF) study of 1255 women with established osteoporosis showed only marginal improvements in BMD with intranasal calcitonin.⁴⁴ Although there was a 36% reduction in new vertebral fractures with doses of 200 IU calcitonin daily, no significant decrease in fractures was seen with 100 or 400 IU daily.⁴⁴ In view of the unconvincing data on the antifracture efficacy of calcitonin, it is generally only used when other treatments are contraindicated or not tolerated. Nevertheless, there is some evidence that the short-term use of calcitonin may be useful in the management of pain associated with acute vertebral fracture.⁴⁵

Patients with established osteoporosis have lower calcium absorption than age-matched control subjects, which may be due to reduced serum 1,25[OH]₂D concentrations or to relative resistance to the action of vitamin D metabolites on the bowel.⁴⁶ Malabsorption of calcium in osteoporosis can be overcome by pharmacologic doses of parent vitamin D or by low doses of the active vitamin D metabolites, such as calcitriol and alfacalcidol. Studies of the effect of treatment with vitamin D metabolites on BMD and fracture incidence in established osteoporosis have produced conflicting results.⁴⁶ A study comparing calcitriol with calcium supplementation in women with vertebral fractures showed a significantly lower incidence of new vertebral fractures with calcitriol, but this was because of an increase in fracture rate with calcium rather than a reduction with calcitriol.⁴⁷ The inconsistent results of antifracture studies, potential risk of hypercalcemia, and the need for regular monitoring of serum calcium and renal function limit the use of vitamin D metabolites in the management of osteoporosis.

FUTURE TREATMENTS

Denosumab is a monoclonal antibody directed against RANKL, which it binds with high affinity and specificity. This inhibits the stimulatory action of RANKL on bone resorption. A randomized controlled trial in postmenopausal women with low BMD showed rapid suppression of bone resorption with twice yearly subcutaneous injections of denosumab, with significant increases in BMD.⁴⁸ Although the results of studies examining the effect of denosumab

on fractures are still awaited, this appears to be a promising treatment for osteoporosis. Other potential antiresorptive treatments for osteoporosis include cathepsin K inhibitors⁴⁹ and new SERMs such as bazedoxifene.⁵⁰

Novel anabolic treatments for osteoporosis include agents that inhibit the formation or action of sclerostin, a protein produced by osteocytes that is a potent inhibitor of bone formation.⁵¹ Selective androgen receptor modulators (SARMs) are also being evaluated as potential treatments for osteoporosis.⁵² Calcium-sensing receptor antagonists (calcilytics) stimulate the release of PTH, so they may also prove to be anabolic treatments for osteoporosis.⁵³

FALLS ASSESSMENT

The risk of fragility fracture is determined not only by skeletal factors, but also by nonskeletal risk factors associated with a propensity for falling.^{5,6} A study in older men and women presenting to hospital with a fragility fracture showed a higher prevalence of skeletal risk factors (53%) and falls-related risk factors (75%) than documented osteoporosis (35%) as defined by a BMD T score < -2.5 .⁵⁴ All patients with fragility fractures should therefore undergo falls assessment. Risk factors for falling are divided into intrinsic factors, including poor vision, neurologic disease and medication, and extrinsic or environmental factors, such as trailing wires, loose carpets, and ill-fitting footwear. Intrinsic causes of falls should be sought by history, examination, and review of medication, whereas extrinsic or environmental causes may be identified from the history and home visit. In older patients with unexplained falls or syncope, tilt testing may also be useful.

A number of randomized controlled trials have assessed the effect of modifying risk factors for falling, but the results have not all been consistent. A recent meta-analysis concluded that there is only limited evidence that multifactorial falls prevention programs in primary care, community, or emergency care settings are effective in reducing the number of fallers or fall-related injuries.⁵⁵ Although it is logical that preventing falls will reduce the incidence of fractures, no randomized controlled trial of falls prevention has been adequately powered to examine the effect on fracture risk. Nevertheless, a recent controlled study suggests that a single visit by an occupational therapist reduces the risk of falling in older women after hip fracture.⁵⁶

EXTERNAL HIP PROTECTORS

An alternative approach to fracture prevention is to decrease the impact of falls using external hip protectors, which are incorporated into specially designed underwear. A Danish study block randomized 665 elderly residents of nursing homes to receive external hip protectors or to serve as controls.⁵⁷ Over the 12-month study, there was a reduction in hip fracture risk of over 50% in those using the hip protectors. In the group randomized to receive hip protectors, the only patients who fractured were not using hip protectors at the time. A systematic review has examined the effect of external hip protectors in community-dwelling older people and in those living in residential or nursing home.⁵⁸ Pooled data from 11 studies in institutionalized older people, including six randomized controlled trials, showed some reduction in hip fractures (relative risk 0.77, 95% confidence intervals 0.62 to 0.97). In contrast, data from three individually randomized

controlled trials in community-dwelling older people showed no reduction in hip fractures with hip protectors.⁵⁸

CHOICE OF TREATMENT

In considering the choice of treatment in the individual patient, a number of factors are important. These include the underlying pathogenesis of bone loss, the evidence of efficacy in any particular situation, the cost effectiveness of treatment, tolerability, and patient preference. Although hormonal treatments are likely to be more effective in younger postmenopausal women with osteoporosis, where bone loss is largely due to estrogen deficiency, the risks of HRT outweigh the potential benefits in most cases.²⁰ Raloxifene may therefore be appropriate in younger postmenopausal women, who are at high risk for vertebral fractures. In contrast, calcium and vitamin D supplementation may be more appropriate in frail elderly people, who are likely to have vitamin D insufficiency and secondary hyperparathyroidism. Bisphosphonates are effective across a wide age range, but oral bisphosphonates may be inappropriate in individuals with cognitive impairment because of difficulties in coping with the complex instructions on administration. The use of alendronate may be precluded in older patients with hiatus hernia, esophageal disease, and peptic ulcers, because of concern about the risk of esophagitis. In patients with upper gastrointestinal disease and those with difficulty following the instructions for taking oral bisphosphonates, strontium ranelate or intravenous bisphosphonates provide alternative treatment options.

A number of factors may influence compliance and tolerability. Raloxifene is likely to aggravate hot flashes, particularly in women close to the menopause, so may be more appropriate in postmenopausal women between the ages of 55 and 70 years. Oral bisphosphonates have complex instructions for administration, which can preclude their use in unsupervised patients with cognitive impairment. Calcium and vitamin D supplements may be poorly tolerated in some individuals, because of gastrointestinal side effects and bowel symptoms.

A schematic representation of the management of osteoporosis is provided in [Figure 69-1](#). All individuals should be given lifestyle advice on diet, exercise, tobacco and alcohol consumption, and exposure to sunlight. In younger postmenopausal women with osteoporosis at high risk of vertebral fractures, raloxifene may be useful, particularly if there is also a significant risk of breast cancer. In older women at high risk of vertebral and non-vertebral fractures, bisphosphonates are currently the treatment of choice, but strontium ranelate provides a useful alternative, particularly above the age of 80 years. In frail, housebound, or institutionalized older people, calcium and vitamin D supplementation should be considered, because of the high prevalence of vitamin D insufficiency and secondary hyperparathyroidism. In patients with a past history of recurrent falls, measures should be taken to reduce the incidence of falls. Consideration should also be given to the use of external hip protectors, especially where caregivers are available to encourage compliance with their use.

OSTEOMALACIA

Osteomalacia is a generalized bone disorder characterized by an impairment of mineralization leading to accumulation of unmineralized matrix or osteoid in the skeleton.^{59,60} There

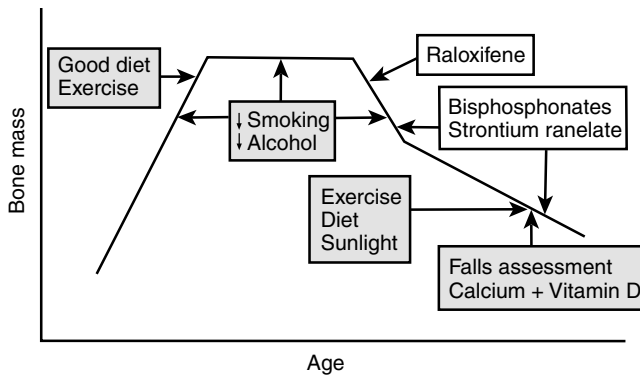

Figure 69-1. Schematic representation of the major therapeutic options in patients with osteoporosis of different ages, together with lifestyle measures in the shaded boxes.

are a number of causes of osteomalacia, but the majority of cases are due to vitamin D deficiency, abnormal vitamin D metabolism, or hypophosphatemia (Table 69-3).

Adequate amounts of calcium and phosphate are essential for mineralization of osteoid to proceed normally, and although vitamin D is important in the homeostasis of calcium and phosphate, the precise role of the vitamin D metabolites in mineralization remains uncertain. The major source of vitamin D is from cutaneous production, following the exposure of the precursor 7-dehydrocholesterol to ultraviolet irradiation.⁶¹ The diet provides much smaller amounts of vitamin D, but this becomes essential when cutaneous production is limited. Vitamin D itself has little biologic activity and is metabolized in the liver to 25OHD, the major circulating form of vitamin D. This undergoes further hydroxylation in the kidneys to form 1,25[OH]₂D, the hormonally active metabolite of vitamin D, which regulates calcium absorption from the bowel, influences bone remodeling, and affects muscle function.⁶¹

Vitamin D deficiency osteomalacia predominantly occurs because of reduced cutaneous production of vitamin D resulting from lack of exposure to sunlight, increased skin pigmentation, or adherence to strict religious dress codes where the skin is covered.^{59,60} It is therefore particularly seen in the housebound elderly or Asian immigrants, particularly when the dietary intake of vitamin D is poor.^{62,63} Vitamin D deficiency osteomalacia is also seen with malabsorption or after gastric surgery and is related to reduced sunlight exposure, decreased absorption of vitamin D, and malabsorption of calcium or phosphate.

Antiepileptic drugs and severe liver disease are also associated with low plasma 25OHD levels and the development of vitamin D deficiency osteomalacia.^{59,60} Antiepileptic drugs induce liver enzymes, which metabolize vitamin D to biologically inactive polar metabolites, whereas liver disease may be associated with impaired 25 hydroxylation of vitamin D. In addition, patients with epilepsy or liver disease may be less exposed to sunlight and therefore have reduced cutaneous production of vitamin D.^{59,60}

Renal impairment leads to the development of osteomalacia because of reduced production of 1,25[OH]₂D, malabsorption of calcium, and low plasma calcium, though plasma 25OHD concentration may also be low because of reduced sunlight exposure. Hypophosphatemic osteomalacia may result from decreased renal tubular reabsorption

Table 69-3. Classification of the Major Causes of Osteomalacia

Deficiency	Cause	Clinical Form
Vitamin D	↓ Sunlight exposure ↓ Dietary vitamin D	Housebound elderly Asian immigrants
25OHD	Malabsorption Abnormal vitamin D metabolism	Small bowel disease Antiepileptic drugs
1,25[OH] ₂ D	↓ 1 α -hydroxylase activity	Liver disease Renal failure
Phosphate	↓ Tubular reabsorption	Familial Tumoral Sporadic
	Phosphate depletion	Use of phosphate binders

of phosphate as in familial, tumor-associated, and sporadic cases, or from phosphate depletion associated with the use of phosphate binders.^{59,60}

Osteomalacia in the elderly

Vitamin D deficiency is the commonest cause of osteomalacia in the elderly. Renal failure is a smaller but significant cause in this age group. There is a reduction in plasma 25OHD with advancing age, which is mainly due to reduced sunlight exposure, though decreased capacity for cutaneous production, low dietary intake, poor absorption, and impaired hepatic hydroxylation of vitamin D may also contribute to this condition.⁶¹ Plasma 25OHD concentrations are lower in individuals living in residential care than in people living in the community, and they are lowest in residents of long-term geriatric wards.⁶² The reduction in renal function with age is associated with decreased plasma 1,25[OH]₂D concentrations which may contribute to the development of osteomalacia in the elderly.⁶¹

Osteomalacia is essentially a histologic diagnosis, so there is little information on its overall prevalence in the elderly. Nevertheless, as mentioned previously, low 25OHD concentrations are common in older people, particularly in subjects who are housebound or institutionalized. As about 10% of elderly people are housebound, a significant proportion are at risk of developing osteomalacia because of absent cutaneous production of vitamin D, and several investigators have shown that osteomalacia occurs in about 4% of elderly people admitted to hospital.^{64,65} An early histologic study from Leeds suggested that up to 40% of patients with hip fracture have evidence of osteomalacia, but the criteria used for this diagnosis were either excess osteoid or decreased calcification fronts.⁶⁶ Using the stricter diagnostic criteria of the combination of increased osteoid seam width and reduction in calcification fronts, a subsequent study from Cardiff showed osteomalacia in only 2% of patients with hip fracture.⁶⁷

Clinical features of osteomalacia

The presentation of osteomalacia may be variable, and the diagnosis may be easily missed in the early stages of the disease because of the vague nature of the symptoms. The patient may complain of aches and pains, aggravated by muscular contraction, but tending to persist after rest. Although there is a propensity for fracture in osteomalacia, the soft

Figure 69-2. Chest x-ray of a woman with osteomalacia, showing deformity of rib cage as a result of bone softening.

elastic bone also deforms easily, leading to kyphosis, scoliosis, and deformity of the rib cage, pelvis, and long bones. The patient may also develop a proximal myopathy, causing a waddling gait and difficulties rising from a chair or climbing stairs. Occasionally, the hypocalcemia associated with osteomalacia leads to latent tetany, with paraesthesias of the hands and around the mouth, cramps, a main d'accoucheur appearance of the hands, and positive Chvostek's and Trousseau's signs.

Radiology in osteomalacia

The classic radiologic appearances of osteomalacia are relatively rare and may not be found in the early stages of the disease. Osteomalacic bone is softer than normal and so becomes easily deformed. The intervertebral discs balloon out and deform the adjacent vertebrae to give them a uniformly biconcave codfish appearance. Similar deformity may occur in osteoporosis, but the biconcavity is more regular in osteomalacia than with osteoporosis, where the extent of vertebral deformity is variable. There may be radiologic evidence of deformity of the rib cage, pelvis, and long bones (Figures 69-2 through 69-4). A characteristic finding in osteomalacia is Looser's zones or pseudofracture, which consist of a large area of osteoid. These appear as bands of decalcification surrounded by more dense bone, which occur perpendicular to the bone surface, often where nutrient arteries enter bone (see Figure 69-4). Looser's zones are seen particularly in the proximal femur, humeral neck, pubic rami, ribs, metatarsals, and the outer border of the scapula. There may also be radiologic evidence of secondary hyperparathyroidism, with subperiosteal erosions in the metacarpals or phalanges.

Biochemical findings in osteomalacia

The biochemical findings in the major types of osteomalacia are shown in Table 69-4. In vitamin D deficiency osteomalacia, the plasma calcium tends to be low because of reduced calcium absorption resulting from low plasma 25OHD and

Figure 69-3. X-ray of the pelvis of a woman with osteomalacia, showing deformity of the pelvic bones as a result of bone softening.

Figure 69-4. X-ray of the pelvis of a woman with osteomalacia, showing Looser's zones in the pubic rami.

1,25[OH]₂D concentrations. The hypocalcemia leads to secondary hyperparathyroidism, which in turn stimulates the renal tubular reabsorption of calcium and reduces tubular reabsorption of phosphate. Plasma phosphate is therefore often low in osteomalacia because of reduced absorption from the bowel and decreased renal tubular reabsorption. The secondary hyperparathyroidism also increases bone remodeling, which is reflected in elevation of the plasma alkaline phosphatase and other biochemical markers of bone turnover. Not all patients with vitamin D deficiency osteomalacia will have hypocalcemia, hypophosphatemia, and raised alkaline phosphatase, and these abnormalities may occur individually in the elderly with intercurrent illness, so they lack specificity in the diagnosis of osteomalacia in the elderly.⁶⁸

Table 69-4. Biochemical Abnormalities in Major Types of Osteomalacia

	Vitamin D Deficiency	Renal Failure	Hypophosphatemic
Hypocalcemia	59%	63%	9%
Hypophosphatemia	68%	0%	73%
↑ Alkaline phosphatase	88%	88%	27%
↓ 25OHD	80%	58%	0%
↓ 1,25[OH] ₂ D	75%	81%	36%
↑ PTH	90%	100%	11%

Data derived from Peacock M. Osteomalacia. In: Nordin BEC, editor. *Metabolic Bone and Stone Disease*, 2nd ed. Edinburgh: Churchill Livingstone, 1984, pp. 72–111.

In osteomalacia associated with renal failure, hypocalcemia is seen in the majority of cases, although the plasma phosphate is normal or high because of reduced urinary excretion of phosphate. The plasma 1,25[OH]₂D is low because of impaired production by the kidneys, and the plasma 25OHD may also be reduced because of inadequate exposure to sunlight. Plasma alkaline phosphatase is raised in the vast majority of cases, whereas the serum PTH is invariably elevated.⁵⁹

In hypophosphatemic osteomalacia, the major biochemical abnormality is a low plasma phosphate, though this may vary in severity. A few cases may also show hypocalcemia, low plasma 1,25[OH]₂D, and elevation of serum PTH (see Table 69-4).

Diagnosis of osteomalacia in the elderly

The only definite way of diagnosing osteomalacia is by histologic examination of undecalcified bone and demonstrating excess osteoid and reduced calcification fronts or mineralization rate. Histologic confirmation of the diagnosis is required in the minority of cases, however. In patients with a typical history of bone pain and muscle weakness, with radiologic evidence of Looser's zones or typical biochemical changes there is little indication for bone biopsy. When the diagnosis is less clear-cut, measurement of plasma 25OHD and serum PTH may be useful, as the combination of low plasma 25OHD and elevated PTH is a strong indicator of the presence of osteomalacia. An alternative approach is to use a therapeutic trial of vitamin D in subjects likely to have osteomalacia and to monitor any subsequent clinical and biochemical improvement.

Treatment of osteomalacia

In cases of vitamin D deficiency osteomalacia, the condition will heal with ultraviolet irradiation or vitamin D treatment.⁶¹ It has been suggested that vitamin D deficiency is treated with oral 50,000 IU vitamin D weekly for 8 weeks, followed by long-term vitamin D 800 to 1000 IU daily, to prevent recurrence of vitamin D deficiency.⁶¹ Unfortunately, high-dose oral vitamin D is not always easy to obtain. Furthermore, although IM injections of 300,000 units vitamin D every 6 to 12 months provides an alternative approach to treatment, the absorption from the administered oily solution is relatively poor.⁶⁹ For these reasons, many clinicians treat patients with vitamin D deficiency osteomalacia with combined calcium and vitamin D supplements, providing

1000 to 1200 mg calcium and 800 IU vitamin D daily. The addition of supplemental calcium ensures that sufficient mineral is available for mineralization of the osteoid to occur.

In patients with osteomalacia associated with malabsorption, the active metabolites of vitamin D may be required, which are usually given in a dose of 1 to 4 µg daily of either alfalcidol or calcitriol. Calcium supplements may also be required, but the serum calcium should be monitored to avoid the development of hypercalcemia. Magnesium supplements may also be necessary if hypomagnesemia is present. If malabsorption is due to bacterial overgrowth, pancreatic insufficiency, or celiac disease, appropriate treatment of the underlying disorder with antibiotic therapy, pancreatic enzyme supplements, or gluten-free diet should be instituted.

In patients with osteomalacia and renal impairment, either alfalcidol or calcitriol should be used in a dose of 1 µg daily, together with calcium supplements as required. Serum calcium and renal function should be monitored regularly on this treatment.

Treatment of osteomalacia leads to a resolution of the proximal myopathy and any symptoms of hypocalcemia within a few weeks, although the bone pain may take longer to improve. The biochemical abnormalities also persist for up to 6 months after treatment is started, and the bone remains histologically and structurally abnormal during this time. Care should therefore be taken to avoid falls during rehabilitation, as these may easily lead to fractures of the abnormal bone. The plasma calcium and phosphate returns to normal within a few weeks, whereas the plasma alkaline phosphatase rises further on treatment and may take many months to return to normal. Serum PTH also remains elevated for up to 6 months. Ultimately, radiologic abnormalities such as Looser's zones and changes of secondary hyperparathyroidism will resolve on treatment, though deformity will persist despite the remodeling of bone.

Paget's disease

Paget's disease of bone is a common condition characterized by increased bone turnover, which can involve one or more of the bones in the skeleton. Although the condition may be asymptomatic, it can cause significant morbidity in older people, including bone pain, skeletal deformity, pathologic fractures, deafness, and osteoarthritis.⁷⁰

Prevalence of Paget's disease

The United Kingdom has the highest prevalence of Paget's disease in the world, but there is considerable regional variation in prevalence across the country.^{71,72} By the eighth decade of life, up to 8% of men and 5% of women in the United Kingdom have evidence of the condition.⁷³ Studies suggest that Paget's disease is also common in the rest of Europe and in British migrants to Australia, New Zealand, and South Africa.^{70,71} In contrast, the condition is rare in Scandinavia, Asia, and Africa.⁷¹ There has been a decrease in the prevalence of Paget's disease in the United Kingdom and New Zealand over the past 25 years,^{74,75} but this trend has not been observed in the United States or Italy.⁷¹ The reason for the decrease in prevalence of Paget's disease is unclear, but may reflect environmental changes or the immigration of people from countries with a low prevalence.⁷¹

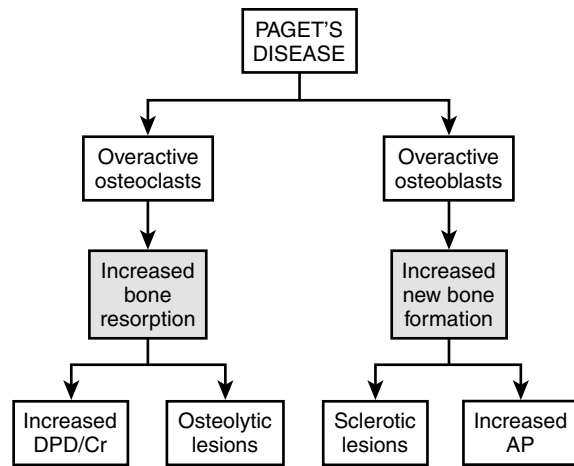

Figure 69-5. Pathophysiology of Paget's disease of bone, with the biochemical changes in the shaded boxes.

Pathophysiology of Paget's disease

Paget's disease is characterized by increased bone resorption mediated by enlarged, hyperactive osteoclasts.⁷¹ There is also an increase in osteoblastic activity and new bone formation (Figure 69-5). This is associated with biochemical changes, including increased bone resorption markers, such as urine deoxypyridinoline/creatinine (DPD/Cr) and by an elevation of alkaline phosphatase (AP). The rapid bone turnover leads to the deposition of woven bone, which is more vascular, structurally weak and prone to deformity and fracture. Inclusion bodies resembling paramyxoviruses have also been seen in affected osteoclasts,⁷⁶ but their role in the pathogenesis of Paget's disease remains uncertain.⁷¹ Osteoclast precursors from patients with Paget's disease appear to be particularly sensitive to factors that stimulate bone resorption, including 1,25[OH]₂D and RANKL.⁷⁷ Increased circulating concentrations of RANKL have also been reported in Paget's disease, but this requires confirmation in future studies.⁷⁸

The etiology of Paget's disease remains uncertain. There is a significant genetic component to the condition, as about 15% of patients have a family history of the condition. The risk of developing the condition may be up to 10-fold higher in first-degree relatives of patients with Paget's disease.⁷¹ Recent work has identified gene mutations that may contribute to the development of Paget's disease and related conditions. The most important of these is in the sequestosome 1 (*SQSTM1*) gene, which encodes for a protein involved in RANK/RANKL signaling.⁷⁹ Mutations in the *SQSTM1* gene are found in 20% to 50% of cases of familial disease and 5% to 20% of cases of sporadic disease.⁷¹ A much more rare cause of Paget's disease is a mutation in the *VCP* gene, which is associated with hereditary inclusion-body myopathy and frontotemporal dementia.⁸⁰

Although genetic factors may predispose to the development of Paget's disease, it is likely that other factors may influence its expression. The clustering of cases of Paget's disease within families includes spouses, so may reflect not only genetic factors but also shared environment. It has been suggested that Paget's disease may result from a slow virus infection, which either causes the disease or triggers it in a susceptible individual. As mentioned earlier, inclusion bodies resembling paramyxoviruses have been seen in affected

Figure 69-6. Skeletal involvement in 889 patients with Paget's disease. (Data derived from Davie M, Davies M, Francis R, et al. Paget's disease of bone: A review of 889 patients. *Bone* 1999;24 (Supplement):11S-12S.)

osteoclasts, but their role in the pathogenesis of Paget's disease remains uncertain. Other factors that may influence the development of Paget's disease in susceptible individuals include mechanical forces, low dietary calcium intake or vitamin D deficiency during childhood, and occupational exposure to toxins.⁷¹

Clinical features of Paget's disease

Paget's disease may present at any age over 30, but is most often diagnosed in the sixth decade of life. The condition is more common in men than in women. The majority of people with radiologic evidence of Paget's disease are asymptomatic and do not come to medical attention. The condition is therefore often an incidental finding in patients having x-rays for an unrelated reason.

The bones most commonly involved in Paget's disease are the pelvis, spine, femur, tibia, and skull (Figure 69-6), although the distribution of the disease is usually asymmetrical. The extent of skeletal involvement is generally constant within an individual, with previously unaffected bones rarely becoming involved long after diagnosis. The most common presentation is with pain, which may be due to the Pagetic changes in the bone itself or to the effects of skeletal deformity on surrounding structures. The cause of bone pain in Paget's disease may be difficult to determine. It may be due to periosteal stretching, to microfractures, or to direct nerve stimulation by substances released by osteoclasts during bone resorption.

Paget's disease may also cause skeletal deformity, as the affected bones thicken, enlarge, and become more elastic. Classically, this causes frontal bossing of the skull, bowing of the long bones and deformity of the pelvis (protrusion acetabuli). Pagetic bone is more likely to fracture, and fissure fractures may also occur on the outer aspect of bowed long bones.

Thickening of the skull may cause compression of the cranial nerves, particularly the auditory nerves, resulting in deafness. Other cranial nerves are only rarely involved in Paget's disease. The increased vascularity of Pagetic bone may also result in neurologic deficit because of a "vascular steal" syndrome. Softening of the base of the skull may rarely

lead to basilar invagination, causing brainstem compression. Vertebral involvement may result in crush fractures or more rarely spinal cord compression.

A major management problem is the development of secondary degenerative arthritis in joints adjacent to involved bone. This is frequently more disabling than the Paget's disease itself and will not respond to treatment of the underlying bone disease. Other complications of Paget's disease include high output cardiac failure, because of the increased vascularity of the affected bone, which although often described is rarely seen. Sarcomatous change also occurs only rarely but has a poor prognosis.⁸¹

Diagnosis and investigation of Paget's disease

The diagnosis of Paget's disease is reached through a combination of clinical assessment and selected investigations. Although the history rarely leads directly to a diagnosis of Paget's disease, it is important to seek clues to other conditions that may coexist with or masquerade as it. Examination may reveal skeletal deformity, especially of the skull or long bones, which may feel warm to the touch. There may also be signs of associated degenerative arthritis. A full neurologic assessment is advisable in symptomatic patients, though abnormalities other than deafness are not often found.

The diagnosis of Paget's disease is usually confirmed radiologically. x-rays may show an increase in size of affected bones, alteration of bone texture with areas of sclerosis and lucency (see Figure 69-5), skeletal deformity, and evidence of degenerative arthritis in adjacent joints. The radiologic appearances are often said to be pathognomonic, but skeletal metastases from occult carcinoma of the prostate or breast should be considered in the differential diagnosis. Prostate specific antigen should therefore be measured in all men with probable Paget's disease. Rarely, bone biopsy may be required if the diagnosis remains uncertain.

The extent of the bone disease can be assessed by isotope bone scan, although x-rays of areas with increased uptake may be advisable, if there is any doubt about the diagnosis. Serum alkaline phosphatase and biochemical markers of bone resorption are often markedly raised in Paget's disease, reflecting increased osteoblast and osteoclast activity respectively (see Figure 69-5), so they may be used to assess the activity of the condition and its response to treatment.

Treatment of Paget's disease

Treatment of Paget's disease is directed at suppressing the overactivity of osteoclasts, thereby decreasing bone turnover.⁸² Although calcitonin was used for several decades in the management of Paget's disease, bisphosphonates have now become the treatment of choice. These agents are generally used in patients with symptomatic Paget's disease, but their role in asymptomatic individuals is unclear. The PRISM study showed no apparent benefit of intensive bisphosphonate treatment aimed at returning alkaline phosphatase to normal, compared with those given symptomatic treatment for bone pain.⁷¹

BISPHOSPHONATES

Oral antiresorptive therapy for Paget's disease became practical for the first time with the introduction of etidronate in the late 1970s. Disodium etidronate 400 mg daily decreases the biochemical markers of bone turnover by 40% to 60%.⁸²

Unfortunately, prolonged therapy with etidronate leads to impaired mineralization, so courses of treatment should not exceed 6 months. There is also evidence that previous treatment with etidronate decreases the efficacy of subsequent courses of treatment.⁸²

Intravenous infusions of pamidronate decrease the biochemical markers of bone turnover by 50% to 80%, resulting in prolonged remission in many patients with Paget's disease.⁸² Pamidronate may be given by weekly infusion of 30 mg for 6 weeks or by three fortnightly infusions of 60 mg. The intravenous route of administration avoids the potential problems of oral bisphosphonates, such as poor absorption from the bowel, the need to take medication in a fasting condition, and gastrointestinal side effects. These advantages are offset by the need for intravenous infusion and transient flulike symptoms that may follow treatment.

Oral tiludronate 400 mg daily for 3 months decreases the biochemical markers of bone turnover by at least 50% in 70% of patients.⁸³ This may avoid the need for further treatment for at least 18 months. A comparative study in 234 patients with Paget's disease showed that significantly more responded to 3- or 6-month treatments with tiludronate 400 mg daily (60.3% and 70.1%) than to 6-month treatments of etidronate at 400 mg daily (25.3%).⁸⁴ This study also showed an attenuated response to etidronate in patients who had previously received this bisphosphonate.

A North American study compared the effect of risedronate 30 mg daily for 2 months or etidronate 400 mg daily for 6 months in 123 men and women with documented Paget's disease.⁸⁵ At 12 months, alkaline phosphatase decreased into the normal range in 73% of patients who had taken risedronate, compared to 18% with etidronate. Previous treatment with etidronate had no significant effect on the subsequent response to risedronate but resulted in a blunted response to further etidronate. There was a significant reduction in pain with risedronate, whereas etidronate was associated with nonsignificant improvement.

Pooled data from two identical, randomized controlled trials compared a single intravenous infusion of 5 mg zoledronate with a 2-month course of oral risedronate 30 mg daily in 347 patients with Paget's disease.⁸⁶ After 6 months, alkaline phosphatase had returned into the normal range in 88.6% of patients receiving zoledronate, compared with 57.9% in the risedronate group. Although pain scores improved in both groups, there appeared to be greater improvement in quality of life with zoledronate than risedronate.⁸⁶ A subsequent study followed up 296 patients who had responded to treatment with either zoledronate or risedronate for a further 18 months.⁸⁷ In patients treated with zoledronate, the mean alkaline phosphatase remained in the middle of the reference range, whereas it increased in a linear fashion from 6 months with risedronate.

Although bisphosphonates decrease bone pain and reduce the activity of Paget's disease, there is currently no evidence that any treatment will prevent skeletal deformity, fractures, or other complications of the condition.⁷¹ The choice of bisphosphonates for the management of Paget's disease depends on patient preference and tolerability. Despite its low cost, etidronate should no longer be used because it is much less effective than other bisphosphonates. The main choice lies between IV zoledronate or pamidronate infusions and oral risedronate.

CALCITONIN

Calcitonin has a direct, receptor-mediated action on osteoclast function. In vivo studies show that within 30 minutes of calcitonin administration, osteoclasts cease synthetic activity and begin to detach from bone. Recruitment of osteoclasts and fusion of precursor cells is also halted, resulting in a rapid reduction in bone resorption. Calcitonin has a short half-life, so osteoclast activation recommences as soon as local concentrations return to basal levels. Salmon and porcine preparations of calcitonin are also weakly antigenic, and neutralizing antibodies are formed during treatment by some patients, which may limit their long-term efficacy. Nevertheless, subcutaneous or intranasal calcitonin has proved to be useful in the management of Paget's disease, where it decreases bone pain and reduces the biochemical markers of bone turnover.⁸² Calcitonin is now generally only used in patients unable to tolerate bisphosphonate treatment

FRACTURES IN THE ELDERLY

The mechanical properties of an individual bone are determined by the amount of bone present, skeletal architecture, and bone quality. Aging is associated with a reduction in bone mass, disruption of trabecular architecture, and an increased prevalence of disorders such as osteomalacia and Paget's disease, which adversely affect the quality of bone. Nevertheless, the risk of fracture is determined not only by skeletal factors but also by nonskeletal risk factors including postural instability, physical and mental frailty, and conditions associated with falling.^{5,6} It is therefore not surprising that the incidence of fractures increases with advancing age. Whereas fractures in young adults usually occur after extensive trauma, fractures in the elderly may result from minimal trauma, such as falling from standing height. The major fractures occurring in older people are those of the forearm, vertebral body, humerus, pelvis, and hip.^{8,88} The incidence of these fractures increases with advancing age and is higher in women than men because of their lower peak bone mass, different patterns of cortical and trabecular bone loss, smaller skeletal size, and greater risk of falls. Fractures are also more common in older residents of care homes and nursing homes than in community-dwelling people of the same age.⁸⁹ This probably reflects the higher risk of falls and lower BMD in institutionalized older people compared with those living in the community.⁹⁰

There is considerable geographic variation in fracture incidence around the world,⁹¹ which may reflect differences in bone mass due to race, smoking, alcohol consumption, and physical activity. The absolute number of fractures in the elderly is rising rapidly, partly because of the increasing numbers of elderly people and a rising age-specific incidence of fractures.⁹² If present demographic trends continue in the United Kingdom, the number of young elderly will remain reasonably constant over the next few decades, whereas the number of people over the age of 85 will increase considerably. Many of these elderly people will be frail, and therefore at greater risk of falls and fractures. There has been an increase in the age-specific incidence of fractures of the forearm, vertebral body, humerus, and hip over the past few decades,^{93,94} which has been attributed to the increased survival of frail individuals and secular changes in smoking, alcohol consumption, diet, and physical activity. Although

the age-specific incidence of fracture may now be reaching a plateau or even declining,⁹⁵ the aging population means that an increase in the absolute number of fractures is inevitable, in both the developed and developing world.⁹⁶

Forearm fractures

These are the most common fractures before the age of 75.^{8,88} The incidence rises steeply at the menopause in women and then plateaus above the age of 65, whereas the incidence changes little with age in men.⁹⁷ It has been suggested that the rise in incidence at the menopause is due to an increase in postural instability and therefore falls in women at this age.^{98,99} The absence of a further increase in incidence of forearm fractures after age of 65 may be due to the fact that the arm is less likely to be used to break a fall in the elderly. About 50% of postmenopausal women with Colles fracture have evidence of osteoporosis at the forearm, spine, or hip.¹⁰⁰ Forearm fractures are also associated with an increased risk of vertebral and hip fractures in both men and women.^{101–103}

Vertebral fractures

The incidence and prevalence of vertebral fractures is difficult to quantify, as many patients with this fracture do not seek medical attention.¹² The European Vertebral Osteoporosis Study (EVOS) showed that the overall prevalence of vertebral deformity increased in women from 5% at the age of 50 years to 25% at 75 years, whereas the corresponding figures for men were 10% and 18%.¹⁰⁴ The higher prevalence of vertebral deformity in young men compared with women may be due to greater exposure to trauma. There was also a large variation in the prevalence of vertebral fractures across Europe, which may reflect differences in physical activity and other lifestyle factors.¹⁰⁵ Subsequently, the European Prospective Osteoporosis Study (EPOS) showed that the incidence of radiologically apparent vertebral fractures approximately doubles in women every 10 years, from less than 5/1000 person-years at the age of 50 years to about 25/1000 person-years by the late 1970s.¹⁰⁶ In men, the incidence also increases with age, but at a slower rate.¹⁰⁶

In addition to back pain, loss of height, and kyphosis, vertebral fractures may also result in loss of energy, emotional problems, sleep disturbance, social isolation, and reduced mobility.^{12,107} There is also an increased mortality associated with vertebral crush fractures, but this may be due to coexisting conditions associated with osteoporosis rather than the fracture itself.¹⁰⁸ Data from the Study of Osteoporotic Fractures in the United States show that mortality increases with the number of vertebral fractures.¹⁰⁹ It has been estimated that the acute cost of vertebral fractures in the United Kingdom is £12 million/year,¹¹⁰ but the real cost may be substantially higher because of the associated long-term morbidity. Patients with symptomatic vertebral fracture consult their general practitioners 14 times more than control subjects in the year following fracture,¹¹⁰ so they are likely to continue to use health and social service resources at an increased rate. Previous vertebral fracture increases the risk of further vertebral fractures and hip fracture.^{111,112} An incident vertebral fracture is associated with a 20% risk of further vertebral fracture in the next year.¹¹²

KEY POINTS

Metabolic Bone Disease

- Fractures are a major cause of excess mortality, morbidity, and health and social service expenditure in older people.
- The risk of fracture is determined by skeletal and nonskeletal risk factors.
- The incidence of osteoporosis, osteomalacia, and Paget's disease increases with advancing age, contributing to the risk of fracture in older people.
- Treatments are available for osteoporosis, which improve bone density and reduce the risk of vertebral, hip, and other non-vertebral fractures.
- In addition to the increased risk of fracture, osteomalacia, and Paget's disease may also lead to bone pain and skeletal deformity.
- The most common cause of osteomalacia in older people is vitamin D deficiency, which can be corrected by appropriate supplementation.
- Bisphosphonate treatment in Paget's disease reduces bone turnover and decreases bone pain.

Hip fractures

This is the most important fracture in the elderly because it causes greater mortality, higher morbidity, and more expenditure than all other fractures combined. The incidence of this fracture rises steeply with age in both sexes, though it is considerably higher in women than men.^{8,88} The remaining

lifetime risk of a hip fracture in a 50-year-old woman is 11.4% for the hip, whereas the corresponding figure for a 50-year-old man is 3.1%.⁸

The risk of hip fractures is determined not only by BMD but also by nonskeletal risk factors. Studies show an increased risk of hip fracture with causes of secondary osteoporosis, such as oral corticosteroid therapy, thyroid disease, and hypogonadism, and with conditions associated with falling, like previous stroke, Parkinson's disease, and dementia.^{113–117} Hip fractures are associated with a considerable mortality, particularly in individuals with multiple comorbid conditions.¹¹⁸ This excess mortality following femoral neck fractures has been reported to be about 17% over 5 years, though most deaths occur within 6 months of fracture.¹¹⁹ In addition to the excess mortality, femoral fractures are associated with considerable morbidity, with many patients becoming more immobile and more dependent. Between 25% and 50% of individuals are more dependent after fracture, with deterioration occurring more often in women over the age of 75 years, those with a poor clinical result, and those who were already dependent before fracture.^{120–122} It has been estimated that the average cost of hip fracture in the United Kingdom is £12,000, of which £4,800 is due to acute costs.¹¹²

Rheumatic diseases are common in elderly people and are often undiagnosed or undertreated. Elderly patients have similar types of musculoskeletal disorders as those from younger age groups, with some differences in pattern, severity, and effect. Some diseases, particularly osteoarthritis and polymyalgia rheumatica, are more common in elderly people. The main rheumatic diseases of the elderly, summarized in [Table 70-1](#), include inflammatory arthritis, degenerative arthritis, connective tissue diseases, soft tissue rheumatism, and back pain.

Arthritis is the most common cause of disability in people over 75 years of age.¹ One hospital-based survey in London showed 76% of patients admitted to an acute elderly unit had peripheral arthritis, 48% had arthritis directly contributing to their functional disability, and 19% did not volunteer information about their joint disease.² The prevalence of disabling joint diseases increases as people age; osteoarthritis is the dominant problem. A survey from North America³ showed that adults over age 65 years accounted for 37% of arthritis cases in 2005 will account for 50% by 2030. Arthritis in the elderly is a major and growing medical problem.

DISEASE MECHANISMS

Joint inflammation involves many pathologic mediators including T- and B-cell activation, cytokine release, and joint destruction. The key changes are summarized in [Table 70-2](#). A key change is synovial lining cell proliferation, accompanied by increased vascularity in the subintimal layer. At the margins of the synovium the pannus forms overlying cartilage and bone and causes destructive changes.

The causes of rheumatoid arthritis (RA) and other forms of inflammatory arthritis are unknown. One concept is that, in genetically predisposed patients, an infective agent or other stimulus triggers innate immunity by binding to toll-like receptors on dendritic cells and macrophages.⁴ Smoking has been strongly implicated in this process.⁵ This results in a local immune response involving cytokines and other inflammatory mediators together with other components of the innate immune system like complement and neutrophils. Subsequent T-cell activation creates a multimolecular immune/inflammatory cascade. Finally, joint damage, associated with the development of locally invasive “pannus” tissue, occurs through the actions of proteases, growth factors, and activated osteoclasts.

Symptoms and signs of arthritis

Local symptoms include pain, tenderness, swelling, and stiffness in the joints, periarticular tissues, ligaments and tendons, and muscles. Pain is the predominant symptom in inflammatory arthritis as well as in degenerative arthritis.^{6,7} Usually persistent and moderately severe, it is often worse on movement, and it invariably limits patients' lifestyles.

Stiffness is the most characteristic arthritic symptom. It comprises both early morning stiffness and postexercise stiffness. Morning stiffness points toward inflammatory arthritis or polymyalgia rheumatica. It usually lasts longer

than 60 minutes and can be prolonged. Postexercise stiffness points more toward osteoarthritis. Tenderness and swelling of the joints or tendons usually go together and indicate an inflammatory synovitis or tendonitis. They vary from very subtle to gross symptoms. Some elderly patients minimize the extent of their joint swelling, even though it is extensive on examination. Bony swelling of the joints usually indicates osteoarthritis.

Systemic symptoms vary. In rheumatoid arthritis or polymyalgia rheumatica, they can be quite marked and include malaise, anorexia, weight loss, and depression. Low-grade fevers can occur, especially in connective tissue disorders.

Investigations

Investigations range from full blood counts and routine biochemistry to immunologic measures of rheumatoid factor and analysis of synovial fluid for crystals. The main tests are summarized in [Table 70-3](#).

RHEUMATOID FACTOR

Rheumatoid factors are antibodies against the Fc fragment of IgG. Rheumatoid factors react against different species of IgG, including human and rabbit. Rheumatoid factors can involve different immunoglobulin classes, giving IgM, IgG, and IgA rheumatoid factors.⁸ Different subclasses of antibody can also be involved, such as IgA₁ and IgA₂ rheumatoid factors. Most tests detect IgM rheumatoid factor. There is some evidence that IgA rheumatoid factor is more related to joint destruction. Rheumatoid factor positivity goes with worse disease and poorer outcome in rheumatoid arthritis and is associated with subcutaneous nodules, vasculitis, and other extraarticular features. Osteoarthritis, gout, and psoriatic arthritis should all be negative on tests for rheumatoid factor.

Table 70-1. The Main Musculoskeletal Disorders of the Elderly

Type of Disorder	Examples
Inflammatory synovitis	Rheumatoid arthritis Gout Pseudogout Septic arthritis Osteoarthritis
Degenerative arthritis	Polymyalgia rheumatica
Vasculitis and connective tissue diseases	Temporal arteritis Systemic lupus erythematosus
Soft tissue rheumatism	Rotator cuff shoulder lesions Frozen shoulder
Back pain	Mechanical back pain and disc disease Lumbar spondylosis and spondylolisthesis Spinal stenosis Osteoporotic vertebral fracture Spinal malignancy

ANTICYCLIC CITRULLINATED PEPTIDE ANTIBODIES (ANTI-CCP)

These were initially described as antibodies to keratin in buccal mucosal cells and keratinized esophageal cells. They were variously termed antiperinuclear factor, antikeratin antibodies, and antiflaggrin antibodies. They target citrullinated proteins. Citrulline is a nonstandard amino acid. It is formed from arginine by enzymic degradation. Citrullination occurs as part of the inflammatory reaction. A number of enzyme-linked immunosorbent assays can detect antibodies to citrullinated proteins. The second generation assays used cyclic epitopes selected from libraries of citrullinated peptides to provide the most sensitive assays. Anti-CCP

Table 70-2. Key Immunologic Mechanisms

Cytokines and immune regulation	Regulate inflammation and autoimmunity in the joints
Cytokines and bone	Also responsible for osteoclast maturation and activation; hierarchical role for receptor activator of nuclear factor- κ β ligand (RANKL) together with TNF, IL-17, and IL-1
T-cell activation	T-cell activation, particularly toward T helper 1 cells, is associated with the presence of many interleukins in the synovial tissue and drives inflammation
B cells	Critical roles in synovitis via antigen presentation and cytokine release
Macrophages	Macrophage-derived cytokines drive many of the proinflammatory pathways in synovial tissue

Table 70-3. Laboratory Investigations

Class of Test	Category	Example of Abnormality
Hematology	Hemoglobin	Anemia in rheumatoid arthritis
	White blood cell count	Leukocytosis in septic arthritis
	Platelet count	Thrombocytopenia in systemic lupus erythematosus
	ESR	Elevated in polymyalgia rheumatica
Biochemistry	Creatinine	High with involvement in systemic vasculitis
	Uric acid	Elevated in gout
Immunology	Creatine kinase	Elevated in polymyositis
	Rheumatoid factor	Positive in rheumatoid arthritis
	Anticyclic citrullinated peptide antibodies	Positive in rheumatoid arthritis
	Antinuclear antibody	Positive in systemic lupus erythematosus
	C-reactive protein	Elevated in rheumatoid arthritis
	Immunoglobulins	Elevated in Sjögren's syndrome
Synovial fluid microscopy	Complements C3 and C4	Low in active systemic lupus erythematosus
	Crystals	Present in gout and calcium pyrophosphate crystal deposition disease
Culture	Bacteria	Septic arthritis

assays are more sensitive and more specific for rheumatoid arthritis than rheumatoid factor assays.⁹

OTHER IMMUNOLOGIC TESTS

Antinuclear antibodies are more important in connective tissue diseases, although rheumatoid arthritis is a common cause of low-titer positive antinuclear antibodies. There are many types of antinuclear antibodies, and the less specific IgM subclasses are more often seen in RA. Osteoarthritis, gout, and psoriatic arthritis should be negative for antinuclear antibodies.

The other main area of testing is for acute-phase changes. An elevated C-reactive protein level—together with a high erythrocyte sedimentation rate (ESR) and changes in several serum proteins—characterizes active RA. It is termed the acute-phase response. It is mediated by the cytokine network, especially IL-1 and IL-6. The levels of these cytokines can be measured directly, but they are labile and secreted in pulses and thus are poor measures of disease activity in many cases.

IMAGING IN ARTHRITIS

The modalities of imaging are summarized in Table 70-4. Currently plain joint radiographs remain the most widely used method for determining the extent and nature of structural changes in arthritis. The main radiologic changes include periarticular osteoporosis and sclerosis, loss of joint space (reflecting cartilage damage), juxta-articular erosions, marginal osteophytes, joint destruction, and ankylosis.¹⁰ Although joint radiographs offer one of the most objective methods of assessing joint destruction, they are not ideal assessments of disease progression and overall status.

An important development has been the widespread introduction of high-resolution ultrasound.¹¹ This is better than clinical examination and conventional x-rays in diagnosing and assessing joint and bursal effusion and synovitis. It is the imaging modality of choice for tendon pathology. It is also more sensitive in detecting erosions. The main changes seen on ultrasound comprise effusions, synovial swelling indicating synovitis, tendonitis, and tendon rupture and erosions. Doppler ultrasound, particularly power Doppler or color Doppler imaging, allows an assessment of synovial vascularity. It can therefore help distinguish inflamed and nonvascular synovial swelling.

Magnetic resonance imaging (MRI) gives excellent images in arthritis and can show soft tissue changes, cartilage changes, bony erosions, and inflammatory change in the synovium.¹² Gadolinium-based intravenous contrast agents

Table 70-4. Imaging Methods

Modality	Example
Plain radiology	X-rays of hands in rheumatoid arthritis
Magnetic resonance imaging	Imaging of knee joint to show internal derangement
Ultrasound	Imaging shoulder joint to identify rotator cuff tear
Computed tomography	Imaging of sacroiliac joint if infection suspected
Bone scan	Showing active joints in inflammatory synovitis
DEXA	Identifying osteoporosis with inflammatory synovitis

are useful for defining the extent and severity of synovitis. MRI is the most sensitive approach for identifying destructive changes in early arthritis and for defining the benefits of early treatments. It remains more of a research investigation at present.

Physiologic measurements and diagnostic assessments can both be achieved using nuclear medicine techniques and densitometry. Most experience comes from bone scintigraphy, which evaluated a combination of bone blood flow and osteoblastic activity. Its resolution is poor and this is a limiting factor. The three-phase bone scan looks at initial uptake, the blood pool interval, and subsequent localization within the bones.¹³

Densitometry has many advantages for assessing bone changes. It can be either whole-body densitometry or localized views of specific joints, particularly the hand and wrist.¹⁴ Although patients with osteoarthritis often have generalized osteoporosis, they may also have localized bone loss at sites of inflammation.

Drug therapy in arthritis

ANTIINFLAMMATORY DRUGS

Nonsteroidal antiinflammatory drugs (NSAIDs) are a diverse group of drugs; their name distinguishes them from steroids and analgesics. They are one of the most frequently used groups of drugs. However, their benefits must be set against significant risks from gastrointestinal, renal, and cardiac toxicity, which cause a substantial number of deaths each year.^{15–17} NSAIDs can be used locally; they are less effective used in this way but also less likely to cause adverse events. The central effect of NSAIDs is inhibiting cyclooxygenase (COX). Conventional NSAIDs inhibit COX-1, which is responsible for the production of “housekeeping” prostaglandins critical for normal renal, gastric, and vascular function and COX-2, which is responsible for driving inflammation. Newer NSAIDs focus on selectively inhibiting COX-2, with the intention of reducing unwanted adverse effects, particularly gastric ulcers.

Ibuprofen, the first nonaspirin NSAID, was identified in the early 1950s, and by the 1970s it was being widely prescribed for the treatment of arthritis. Subsequently a large number of NSAIDs were identified. NSAIDs such as diclofenac, ibuprofen, and naproxen are well established and have been available for many years. New COXIBs, or COX-2 (cyclooxygenase 2) specific inhibitors, such as celecoxib, have been introduced more recently. The main NSAIDs are summarized in [Table 70-5](#).

NSAIDs reduce the signs and symptoms of acute synovitis and relieve pain and are widely used in RA, osteoarthritis, gout, back pain, and soft tissue rheumatism. They are highly effective in the short term. Their longer-term benefits are less certain.

Adverse effects are the major problem-limiting factor using NSAIDs. The risks increase markedly with age and NSAIDs must be used carefully in the elderly. Minor adverse effects such as dyspepsia and headache are commonplace. Central nervous system side effects, such as drowsiness and confusion, are often underestimated. Hematologic side effects are very unusual. NSAIDs can also exacerbate asthma and cause rashes, though these effects are usually mild. The main adverse effects are shown in [Table 70-6](#).

Gastrointestinal adverse effects are the main problem with NSAIDs. They include dyspepsia, gastric erosions, peptic

Table 70-5. Main Nonsteroidal Anti-inflammatory Drugs

Class	Drug	Common Dose	Comments
Conventional NSAIDs	Diclofenac	75 mg slow release bid	Rapid onset of action but concerns about liver toxicity
	Ibuprofen	600 mg tid	Short half-life giving great flexibility means frequent dosing
	Naproxen	500 mg bid	Effective without major toxicity concerns
COXIBs	Celecoxib	200 mg bid	Reduced gastric toxicity but unresolved concerns about cardiac adverse events
	Etoricoxib	60 mg daily	Reduced gastric toxicity and once daily dosing, but fluid retention makes it unsuitable for patients with cardiac problems

Table 70-6. Adverse Effects of NSAIDs

Type of Adverse Reaction	Example
Gastrointestinal	Indigestion
	Erosions
	Peptic ulcer
	Hemorrhage and perforation
	Small bowel enteropathy
Hepatic	Hepatocellular damage
	Cholestasis
Renal	Acute renal failure
Hematologic	Interstitial nephritis
	Thrombocytopenia
Skin	Neutropenia
	Hemolytic anemia
Chest	Photosensitivity
	Urticaria
Central nervous system	Erythema multiforme
	Bronchospasm
Cardiac	Pneumonitis
	Headache
	Dizziness
	Confusion
Cardiac	Increased risk of myocardial infarctions
	Cardiac failure
	Hypertension

ulceration, bleeding, perforation, hematemesis or melena, small bowel inflammation, occult blood loss, and anemia. Between 10 and 20 out of every 1000 RA patients taking NSAIDs for 1 year will have serious gastrointestinal complications. The mortality risks attributable to NSAID-related gastrointestinal adverse effects are four times that for those not using NSAIDs. Many patients who have serious gastrointestinal complications do not have prior dyspepsia. In the absence of warning signs, there is no way to ascertain if a patient is at the point of developing serious problems. Therefore, if NSAID use is unavoidable, some protective strategy is needed, particularly in those patients at greatest risk. There are several potential options.

One approach is co-prescribing proton pump inhibitors like omeprazole. This is effective and acceptable to

patients. Another approach is to co-prescribe prostaglandin analogues, like misoprostol. This is also effective but causes added side effects such as diarrhea and is less well tolerated than proton pump inhibitors. The final approach is to use a safer NSAID—one of the newer COX-2 drugs. Although COXIBs increase the incidence of gastrointestinal adverse events compared to placebo, the magnitude is substantially less than with standard NSAID therapy.

There have been concerns that NSAIDs and COXIBs increase the risk of heart attacks and strokes. This is an area of controversy.^{18,19} Some trials and some observational studies have found more cardiac problems; other trials have not done so. It is generally recommended that the lowest dose for the shortest period of time is a sensible policy. Patients at risk of cardiac disease should not receive NSAIDs and in particular should avoid COXIBs. As well as cardiac infarctions, some NSAIDs have an increased risk of fluid retention and can cause an increased propensity to cardiac failure.

DISEASE-MODIFYING DRUGS AND IMMUNOSUPPRESSION

Disease-modifying antirheumatic drugs (DMARDs) and immunosuppression are mainly used to treat inflammatory synovitis. The assessment of their effect includes clinical, laboratory, functional, and radiologic approaches. A central theme of therapy—disease control—is based on overcoming the inflammatory synovitis and thus reducing the progression of joint damage.²⁰ The effects of generalized inflammation indicated by the acute-phase response on the progression of RA are well known, as is the association between radiologic progression and acute-phase proteins such as C-reactive protein. However, normalizing an elevated acute-phase response may be insufficient, and only patients who consistently maintain low ESR and C-reactive protein levels have less radiologic progression.

A number of DMARDs are used and they are summarized in Table 70-7. Methotrexate is currently the dominant DMARD. Over half of all patients with rheumatoid arthritis treated with DMARDs who are seen in specialist units are receiving methotrexate. The only other DMARDs used to any appreciable extent are sulfasalazine and leflunomide. A systematic review comparing trials of the main DMARDs concluded that methotrexate, sulfasalazine, and leflunomide all showed similar efficacy.²¹

In patients with definite inflammatory arthritis, DMARDs are usually started as soon as the diagnosis has been made. They are then usually continued unless they have to be stopped for toxicity or loss of effect. In patients who are well controlled on DMARDs, stopping treatment leads to a high risk of flares. DMARD use is similar in all stages of arthritis. Patients need DMARDs in early disease and are equally likely to need them in later stages of the disease.

Table 70-7. Main Disease-Modifying Antirheumatic Drugs

Main Drugs	Minor Drugs	Rarely Used
Methotrexate	Hydroxychloroquine and chloroquine	Cyclosporine
Leflunomide	Injectable gold	Auranofin
Sulfasalazine	Azathioprine	Cyclophosphamide

Conventionally DMARDs were given singly. However, there is extensive evidence that they are also effective in combinations.²² One approach is step-down treatment, which involves starting combinations together and then stopping one or more DMARD. The alternative is step-up treatment, which involves starting one DMARD and then adding another if needed. Combinations can involve two DMARDs, three DMARDs, or DMARDs and steroids. They are also often combined with biologics (discussed later).

DMARDs have a range of adverse events, and these vary between drugs. Gastrointestinal problems are common and include anorexia, nausea, vomiting, and diarrhea. Stomatitis with erythema, painful ulcers, and erosions is often seen. Alopecia is frequent with some drugs, particularly methotrexate, and causes particular concern in women. Skin reactions ranging from rashes to urticaria and cutaneous vasculitis affect many patients. Many DMARDs increase the risk of infections, including opportunistic infections, fungal infections, and viral problems like herpes zoster sometimes. The risks of blood and hepatic toxicity mean many DMARDs require monitoring with blood and liver function tests. Although with modern treatment the risks are minimized and the benefits of monitoring are less certain, it has become part of the standard approach to DMARD treatment. Chest problems are a particular concern with methotrexate and a pretreatment chest X-ray is needed; therapy should be paused or stopped if patients develop chest symptoms such as a cough.

Biologics

These agents have revolutionized the treatment of inflammatory arthritis. Conventional drugs such as DMARDs inhibit small molecules. However, as cytokines are large peptides, they can only be inhibited by large molecules. The biologics that inhibit cytokines are proteins, based on immunoglobulins. It may be possible to replace biologics with small molecules that inhibit intracellular cytokine targets, but so far this aspiration remains unfulfilled.

The dominant biologics are tumor necrosis factor (TNF) inhibitors. Three of these are now available, and these are summarized in Table 70-8. They are effective in rheumatoid arthritis and psoriatic arthritis and also in ankylosing spondylitis.^{23–28} Depending on the biologic, they are either given by infusions or by self-injection every week or fortnight. They are usually given with methotrexate or an equivalent DMARD. They are rapidly effective and improve both synovitis and function. In addition, they reduce erosive damage.

Biologics are usually given only to patients in whom conventional DMARDs have proved ineffective and in whom there is evidence of ongoing synovitis. There is debate about their early use and currently this is not usually recommended.

When a TNF inhibitor is stopped for toxicity, another agent is usually started. There is less certainty when the TNF inhibitor is not effective. Many experts recommend starting an alternative biologic in this situation. It is an area of controversy.

The main alternative biologic is rituximab, which inhibits B cells.²⁹ It is mainly used in patients who have failed TNF inhibitors. A course of rituximab comprises two intravenous infusions 2 weeks apart. It is given with methotrexate. If there is evidence of continued disease activity, another course is given after 6 to 12 months. Some patients have had repeated

Table 70-8. Main Tumor Necrosis Factor Inhibitors

TNF- α Inhibitor	Site of Action	Dosing Schedule	Disease-Modifying Drugs
Adalimumab	Mainly binds soluble and transmembrane TNF- α	Subcutaneous fortnightly	Best to co-prescribe methotrexate
Etanercept	Binds TNF- α and competitive inhibitor of TNF receptor	Subcutaneous twice weekly	Best to co-prescribe methotrexate
Infliximab	Mainly binds soluble and transmembrane TNF- α	IV administration every 4 to 8 weeks	Needs co-prescribed methotrexate or equivalent

courses. Other biologics that inhibit T cells or interleukin-6 have either entered or are about to enter clinical practice. It is an area of rapid development.

Biologics cause local reactions at the injection sites. The main risk is serious and opportunistic infections. Biologics should not be started or should be discontinued when serious infections occur. Tuberculosis is a particular concern. There have been some reports of demyelinating-like disorders and a few cases of pancytopenia and aplastic anemia. Another potential problem is cardiac failure, and patients in whom this is a problem should not receive TNF inhibitors.

Finally there are concerns about the risk of lymphomas. The size of the risk is uncertain because the incidence of lymphoma increases in severe RA irrespective of treatment with immunotherapies. As a result, there is a preexisting increased risk of lymphoma in patients who are likely to receive TNF- α inhibitors.

Steroids

Glucocorticoids, which are invariably termed steroids in routine settings, have been used for more than 50 years to treat arthritis. Their efficacy and toxicity have been known since the 1950s.^{30,31} Although their use extends well beyond rheumatoid arthritis, in other settings such as acute gout there is less evidence supporting their use.³² The long-term side effects of steroids, particularly osteoporosis, remain a substantial obstacle limiting their routine use. Short courses of oral prednisolone or a depot intramuscular injection are often used in active disease when commencing therapy with a DMARD or to control flares of arthritis.

The more prolonged use of oral steroids is advantageous in early disease. There is strong evidence based on the work of Kirwan^{33,34} that steroids reduce erosive progression, particularly when used in early rheumatoid arthritis. In this setting, the benefits of steroids outweigh their risks.

SUPPORTIVE NONDRUG THERAPY

Physiotherapy, occupational therapy, supplying aids, and appliances such as walking sticks, modifying footwear such as fitting insoles and providing surgical shoes, and chiropody all have important roles. Of equal importance is providing patient education and general advice about arthritis, together where possible with simple exercise programs.

RHEUMATOID ARTHRITIS

Epidemiology

Rheumatoid arthritis is a common disorder. We know the incidence of new cases of RA from prospective studies such as the Norfolk Arthritis Register; there will be in the region of 50 new cases of inflammatory synovitis each year per

100,000 population in the United Kingdom.³⁵ Most of these will be due to RA. There is marked geographic variation in the incidence of RA. Its cause is uncertain.

There is also a considerable amount of information about the prevalence of established RA. In Europe, this varies from 0.5% to 2% or more depending on the exact population studied.³⁶ Recent U.K. data suggests the prevalence of RA is relatively static at just under 1% of adults.³⁷ The prevalence of RA increases with age, and it is especially frequent in elderly women. A study in North America in the early 1960s showed that it was rare in men before the age of 45 years and in women before the age of 35 years. In the over-65 age group its prevalence increased to 1.8% in males and 4.9% in females.³⁸

Clinical features of rheumatoid arthritis

Persistent joint inflammation is the central diagnostic feature of RA. The joints are swollen, tender, and stiff. Morning stiffness is prolonged and may last over an hour. The joint involvement is symmetrical and usually involves the hands (proximal interphalangeal and metacarpophalangeal joints), wrists, and feet (proximal interphalangeal and metatarsophalangeal joints). The elbows, knees, and ankles are often involved as well.

The synovitis is accompanied by systemic features of ill health with malaise, weight loss, occasional intermittent fever, and constitutional upset in many cases. As the arthritis progresses there are characteristic destructive changes—for example, ulnar deviation and the Swan neck and Boutonnière deformities of the fingers.

Subcutaneous nodules are a classic extra-articular feature. They are found on extensor surfaces such as the elbows or sites of pressure such as the lower back or in some parts of the hands. There are many other extra-articular features, which are summarized in Table 70-9. Extra-articular disease can occur at any time in the course of RA. Up to 40% of patients may have one or more extra-articular features.³⁹ The most common features are rheumatoid nodules (30-year cumulative incidence, 34%), secondary Sjögren's syndrome (30-year cumulative incidence, 11%), and pulmonary fibrosis (30-year cumulative incidence, 7%). About 10% of patients have severe extraarticular features; these patients have worse outcomes and higher mortality rates.⁴⁰

Clinical assessment

The core dataset, which has been agreed on internationally,⁴¹ is summarized in Table 70-10. The measures give a good overall picture of RA and permit assessment of progression and response to treatment. Disease activity can be assessed by counting the number of active joints. The best joint count has been an area of recent investigation. Prevoo et al⁴² contrasted several available methods. The various

Table 70-9. Extraarticular Features of Rheumatoid Arthritis

Extraarticular Feature	Specific Example
Subcutaneous nodules	Pressure area at elbow In wall of olecranon bursa At sacrum
Pulmonary	Pleural effusion Interstitial fibrosis
Cardiac	Pericarditis Valvular disease
Ocular	Keratoconjunctivitis sicca Episcleritis Scleritis
Neurologic	Carpal tunnel syndrome Mononeuritis multiplex Peripheral neuropathy Cervical myelopathy
Renal	Amyloidosis Drug toxicity
Vasculitis	Nail-fold infarctions Leg ulcers Systemic vasculitis
Hematologic	Anemia Felty syndrome

Table 70-10. Clinical Measures in Rheumatoid Arthritis

Index	Measures
Core data set	Number of swollen joints Number of tender joints Pain assessed by the patient Patient's global assessments of disease activity Physician's global assessments of disease activity Laboratory evaluation of an acute-phase reactant (ESR, C-reactive protein, or equivalent) Disability measure
Disease activity score (DAS28)	Tender joint count Swollen joint count Patient global assessment ESR
Simple disease activity index (SDAI)	Tender joint count Swollen joint count Patient global assessment Physician global assessment C-reactive protein
Clinical disease activity index (CDAI)	Tender joint count Swollen joint count Patient global assessment Physician global assessment

indices had similar reliability and validity, and no joint index was superior for measuring disease activity. The implication is that the simplest index, the 28-joint count, is best. Other studies have also concluded that the 28-joint count gives all the necessary information. Disability is assessed using standard questionnaires. The most widely used is the Health Assessment Questionnaire (HAQ).⁴³

Clinical outcomes

Studies of antirheumatic therapy tend to show that it is successful in the short term, whereas there are poor results in the longer term. Prospective long-term clinical studies show that most patients first seen as inpatients are moderately or severely impaired by 20 years, and the average outpatient has a 30% chance of severe disability.⁴⁴

Rheumatoid arthritis leads to premature death. In hospitalized patients with RA, it is the direct cause of nearly 20% of deaths. Wolfe et al⁴⁵ reported results from a large study examining 922 deaths in 3501 patients with RA. The standardized mortality ratio was 2.3. The causes of death in RA do not differ much from those in the normal population, although there is an increase in infection and lymphatic malignancies as a cause of death. The average shortening of life is in the region of 4 to 5 years. Patients with severe RA are most likely to die early.

Specific problems in the elderly population

Rheumatoid arthritis is increasingly becoming a disease of later life. The most common time for developing the disease is the sixth decade, and as it lasts 10 to 20 years, many patients with RA are over 65 years old. One aspect, the impact of age on disease onset, has been studied in detail. Compared with young-onset RA, elderly-onset patients more frequently have an acute onset, commonly have polymyalgic and constitutional features, usually have higher levels of disease activity when first seen, and are more often male,⁴⁶⁻⁴⁹ confirming a significant influence of age on disease expression at presentation.

When its onset is in old age, it is often overlooked or ignored by patients and physicians. It is difficult to manage complex RA in an elderly person, especially if he or she has other problems with mobility. RA is frequently associated with other diseases, and such comorbidity can be a serious clinical problem. Finally, elderly people have increased risks of adverse effects with antirheumatic drugs such as nonsteroidal antiinflammatory agents, and this makes management more complex.

SERONEGATIVE SPONDYLARTHROSIS

These diseases include ankylosing spondylitis, reactive arthritis, arthritis in Crohn's disease and ulcerative colitis, Reiter's syndrome, and psoriatic arthritis. They are characterized by sacroiliitis, inflammatory back disease, oligoarthritis of large joints, and an enthesopathy. Psoriatic arthritis is the most important seronegative arthritis in the elderly.

Epidemiology

As a group, these disorders are less common than RA.^{50,51} Their prevalence varies across populations in relation to the frequency of HLA-B27; this gene is closely associated with the development of ankylosing spondylitis and, to a lesser extent, other members of this group. Estimates suggest that about 0.3% of adults have psoriatic arthritis, but estimates vary and there may be an underestimation of mild disease.

Clinical features

Most forms of seronegative arthritis involve a small number of large joints, particularly the knee and hip joints. Joint involvement is usually asymmetric. Psoriatic arthritis has a more complex pattern.⁵² In some patients, there is a polyarthritis, which is similar to rheumatoid arthritis. In many patients, there is an oligoarthritis, with two or three joints involved. Some patients have a monoarthritis. A specific variant is a destructive arthritis mainly involving the distal joints. Occasional patients have arthritis mutilans, which is a progressive destructive form of arthritis. These different

patterns change over time, and one form of psoriatic arthritis can merge with the other. The deformities of psoriatic arthritis lead to shortening of digits because of severe joint or bone lysis, with the most severe form being the telescoping of digits. Bony fusion of joints may also occur. Radiologic changes include "pencil in cup" and ankylosis, and there is periosteal reaction, enthesitis, and spinal involvement. Another feature is dactylitis, which is inflammation of an entire digit because of to inflammation affecting both joints and tendons.

The extraarticular features of psoriatic arthritis are very different from those seen in RA. Rheumatoid nodules are absent. Other findings include iritis, mucous membrane lesions, iritis, urethritis, diarrhea, and aortic root dilatation.

OSTEOARTHRITIS

Osteoarthritis (OA) is a heterogeneous condition with a variety of causes and patterns of expression. It is analogous to kidney or heart failure in which similar clinical and pathologic features develop irrespective of the underlying causes and could be considered as "joint failure." Older age is the most significant factor in its development in a general population.⁵³ The joint most commonly affected is the knee, and osteoarthritis of the knee is one of the most common causes of pain and disability in the community. There is a rise in the annual consultation rate for osteoarthritis,⁵⁴ and this may reflect not only an increased incidence of disease but also decreased tolerance of joint problems. Many patients who consult with osteoarthritis have other medical problems, and it is difficult to dissociate which was the main cause of seeking medical advice.⁵⁵

Osteoarthritis can be considered as a synovial joint syndrome rather than a single disease. Pathologically it is characterized by a loss of, and change in, the composition of cartilage proteoglycans leading to failure of normal responses to stress. The results include cartilage fibrillation and loss, bone exposure, and a clinical syndrome of pain and disability. Rare forms of heritable chondrodysplasia lead to premature osteoarthritis but, in most instances, its cause is either excess, inappropriate, or insufficient mechanical demand or traumatic, infective, inflammatory, endocrine, or metabolic disease. There remain idiopathic ("primary") cases in which no cause is demonstrable.

Epidemiology

The prevalence of OA varies depending on how it is defined, which joints are studied, and the features of the population being studied.⁵⁶ All studies show OA prevalence increases steeply with age. Radiologic OA in people over 45 years varies from 20% to 37% in different studies.⁵⁷ Fewer patients have symptomatic OA.

In Europe and North America, there is a similar prevalence, rising from less than 1% of those aged under 35 years to over 30% of those aged over 75 years.^{58,59} Both hand and knee forms of osteoarthritis are more common in women than in men. Hip osteoarthritis is less common, and its prevalence rates in men and women appear to be more similar. The incidence of symptomatic osteoarthritis has been studied less often. One study from North America showed the incidence of knee and hip osteoarthritis was 200 per 100,000 person-years.⁶⁰ Felson et al⁶¹ evaluated 869 patients from the Framingham osteoarthritis study and found rates

of incident disease were 1.7 times higher in women than in men, progressive disease occurred slightly more often in women, but rates did not vary by age. Among women, approximately 2% per year developed incident radiographic disease, 1% per year developed symptomatic knee osteoarthritis, and about 4% per year experienced progressive knee osteoarthritis.

Clinical features

Osteoarthritis is characterized by articular pain, bony enlargement, morning and inactivity stiffness, and associated functional disability and radiography changes. These features are summarized in Table 70-11.

Pain is the predominant symptom in osteoarthritis. It varies in severity and its exact nature both between patients and in individual cases over a period of time. Although pain is more marked in patients with severe joint destruction on x-rays, there is often no close relationship between pain and radiography abnormalities. Causes of pain in osteoarthritis include raised intraosseous pressure, inflammatory synovitis, periarticular problems, periosteal elevation, muscular changes, fibromyalgic amplification, and central neurogenic changes. There is often relatively little relationship between the severity and clinical importance of pain, stiffness, and physical function.⁶²

Most patients with osteoarthritis experience stiffness. "Stiffness" may refer to difficulty initiating movement, problems in completing a full range of movement, or the ache or pain of a joint on movement. It is often present first thing in the morning, but lasts only 10 to 25 minutes in many cases. More characteristically it comes on after inactivity, when it is frequently termed "gelling" of a joint.

Many patients have loss of movement or instability of one or more joints. Sometimes patients note that a joint will suddenly "give way." In some joints, there is a sensation of inflammation due to an associated synovitis and the joint is swollen, tender, and warm.

On examination there is firm or bony swelling around the joint and crepitus on movement. The most characteristic bony swellings are the Heberden's and Bouchard's nodes of hand osteoarthritis. Coarse "crepitations" are usually felt on movement of the involved joint. In severe disease, they can be audible. Effusions occur in some cases, especially in knee osteoarthritis.

There are problems in diagnosing osteoarthritis. Although a set of clinical criteria has been developed,⁶³ these have been criticized for using rheumatoid patients who had not been age- and sex-matched as controls, using osteophytes as

Table 70-11. Clinical and Radiologic Features of Osteoarthritis

Clinical Features	Radiologic Features
Pain	Loss of joint space
Stiffness, including gelling after exercise	Marginal osteophytes
Bony tenderness	Subchondral sclerosis
Bony enlargement	Tibial spiking
Crepitus	Loss of alignment
Normal ESR and negative tests for rheumatoid factor	

a feature of osteoarthritis, for circularity, and for inadequate validation.⁶⁴ Loss of cartilage on x-rays has been reported as the one feature present in all attempted definitions, but these are based on pathologic changes that are not often available to the clinician making the diagnosis. Furthermore, the relationship between the incidence of symptoms and the degree of radiologic change is not clear. Almost all people over the age of 65 years have at least one joint with evidence of radiographic osteoarthritis, but the proportion with symptoms varies with joint, age, and sex.

Clinical subgroups

Osteoarthritis includes several different subgroups that may all have different natural histories, patterns of joints affected, and different rates of disease progression. These include knee/hand osteoarthritis (often known as "generalized osteoarthritis"), inflammatory/erosive osteoarthritis, rapidly progressive osteoarthritis, secondary osteoarthritis, hypertrophic and atrophic osteoarthritis, and destructive osteoarthritis of the elderly.

Set against the classification of osteoarthritis into such distinct subgroups are the findings of Cushnaghan and Dieppe,⁶⁵ who found a strong relationship between age and the number of involved sites. This was thought to be due to the slow addition of new joint sites with age. However, there was no evidence of well-defined clinical subsets of patients. Subsequent follow-up after 3 years⁶⁶ showed most patients reported an overall worsening of their condition, but pain severity did not change. There was an overall increase in disability. Although there were strong correlations between changes in x-ray appearances (joint space, osteophyte, and subchondral bone sclerosis), there were no relationships between radiographic and clinical changes.

Inflammatory osteoarthritis and destructive disease in the elderly deserve special consideration. Destructive osteoarthritis with radiographic findings of rapid severe joint destruction can be a diagnostic problem. The x-ray changes mimic septic arthritis, rheumatoid, and seronegative arthritis. Rapid progression of pain and disability are consistent clinical features. The condition mainly affects the shoulder, knee, and hip.⁶⁷ Progression to complete joint destruction takes only 1 to 2 years. Most patients are elderly women. This disease is a relative rarity.

POLYMYALGIA RHEUMATICA AND GIANT CELL ARTERITIS

Polymyalgia rheumatica and giant cell arteritis, which is also known as temporal arteritis, are related diseases that form two ends of a single spectrum. They are both diseases of the elderly population and their mean age of onset is 70 years, with a range from 50 to 90 years. Their onset is characteristically dramatic, and many patients can give the exact date and hour of their first symptoms. Occasionally the onset is insidious and the symptoms may have been present for months or longer before the diagnosis.

Paulley and Hughes,⁶⁸ in 1962, were the first to link these two conditions, suggesting polymyalgia has many of the manifestations of temporal arteritis. Since then, most authorities recognize the relationship between the two conditions.

Epidemiology

These diseases are relatively uncommon. One study from North America suggested the annual incidence of biopsy-proven giant cell arteritis between 1950 and 1985 in North America was up to 20 in 100,000 people over 50 years of age.^{69,70} It was approximately three times more frequent in women. Studies from Europe suggest an incidence of 16.8 per 100,000.⁷¹ In the United Kingdom, the prevalence of polymyalgic symptoms in people over 65 years of age is approximately 330 per 100,000.⁷²

Clinical features

Both polymyalgia rheumatica and giant cell arteritis are associated with fever, fatigue, anorexia, weight loss, and depression. Occasionally patients present with a fever.

POLYMYALGIA RHEUMATICA

The onset usually involves pain and stiffness in the muscles of the shoulder and neck. There is eventual involvement of the pelvic girdles in some patients. The symptoms are bilateral and symmetric. Stiffness is a predominant feature, especially after rest or in the morning, and usually lasts for longer than an hour. Muscle pain is diffuse, movement accentuates the pain, and it can be worse at night. Muscle strength is usually unimpaired, although the pain makes testing difficult. There is often an associated synovitis especially of the knees, wrists, and small joints of the hands. It is usually transient and mild and erosive changes are unusual. The arthritis may overlap with rheumatoid disease in an elderly person.

GIANT CELL ARTERITIS

Headache is a predominant symptom and is present in a majority of cases. It often begins early in the course of the disease and may be a presenting symptom. Pain is severe and localized to the temple; there may be associated scalp tenderness. Visual disturbance is described in about 25% of cases; visual loss is less common and can involve 5% to 10% of cases, but blindness remains a significant risk owing to involvement of the ophthalmic artery, which is an end artery. Rare features of giant cell arteritis include hemiparesis, peripheral neuropathy, and deafness. Involvement of the coronary artery occasionally leads to myocardial infarction.

GOUT

Gout is one of the most common forms of arthritis affecting the elderly.⁷³ It is caused by an inflammatory response to the formation of urate crystals. These crystals develop secondary to hyperuricemia. Gout can occur in both acute and chronic forms. The hyperuricemia may be due to environmental or genetic factors. Although it most frequently affects middle-aged males, there is an increasing frequency in elderly females taking diuretic tablets. The acute form is usually relapsing and self-limiting. The chronic form is associated with tophus formation and bone and joint destruction.

Epidemiology

Hyperuricemia has been investigated in many populations. In males, the prevalence of hyperuricemia rises steeply after puberty; in females, the prevalence rises after the menopause, although levels in women are usually lower than in men. It

is difficult to determine the precise incidence and prevalence of gout, as it is a remitting and relapsing disease and patients frequently are misdiagnosed. It is rare in children and premenopausal women. It is uncommon in men under the age of 30, and the peak onset in men is between 40 and 50 years. In women it occurs later.

The epidemiology of gout is changing, with an increasing number of females having the disease. This is probably because of changes in lifestyle, drug therapy, and increased longevity. Gout remains the most common inflammatory arthritis in males over 40 years of age.⁷⁴ The prevalence of gout is between 5 and 28 per 1000 males and between 1 and 6 per 1000 females. The plasma urate concentration is the most important determinant of the risk of developing gout.⁷⁵ An important identifiable cause is concomitant thiazide diuretic therapy.

Clinical features

Asymptomatic hyperuricemia is far more frequent than gout. The risk of gout increases with a rising level of serum uric acid. However, many years of hyperuricemia may precede the onset of acute gout, and many individuals with hyperuricemia do not develop the disease. When there is a severe acute overproduction of urate, as, for example, occurs with cytotoxic chemotherapy, there is a high risk of acute gout.

Acute gout is characterized by the rapid onset of pain, its exquisite nature, and the swelling and associated redness around the affected joint. The classic presentation is in the first metatarsophalangeal joint, and in time this is affected in over 80% of patients with gout—this is known as podagra. Many joints may be involved. The lower limbs are involved more frequently than the upper limbs. Redness over the affected joints is a feature that sets gout apart from most other noninfective causes of arthritis. The swelling can be very marked over the entire region. The natural history of acute gout varies: mild attacks may resolve within 1 or 2 days. More severe attacks may last 1 or 2 weeks. Approximately 90% of initial attacks of gout are monoarticular.

Sometimes gout presents early in its course with polyarticular involvement, and it can then be easily confused with other forms of arthritis. In the elderly population, gout is often more indolent and is frequently mistaken for osteoarthritis, which results in a delay in diagnosis. In elderly people, polyarticular gout can be the presenting feature of an attack, especially in elderly women. Acute gout can be precipitated by a variety of factors, including acute illness, trauma, surgery, and alcohol and drugs, which increase the uric acid concentration.

Incomplete resolution of acute gout normally indicates a concurrent arthropathy, especially osteoarthritis. However, a substantial proportion of patients with acute gout go on to develop a chronic phase of the disease. This is characterized by the formation of tophi. These are firm nodular or fusiform swellings that can occur at most sites of the body but are especially common on the hands and feet and around the ear. The inflammatory process in chronic gout is often mild although there can be supra-added acute episodes. Most of the disability is due to the presence of tophi that can become ulcerated and infected. Long-term problems with chronic gout are usually due to the deposition of tophi in the kidney.

Associated disorders

Gout is associated with obesity, hypertension with diuretic therapy and particularly thiazide diuretics, excess alcohol intake, hyperlipidemia, and other vascular disorders. There are also associations with renal impairment, psoriasis, myeloproliferative disorders, and treatment with cytotoxic drugs.

Treatment

Therapy is directed toward controlling the symptoms in acute episodes and preventing further attacks and complications in chronic gout.⁷⁶ Acute attacks of gout can be treated by oral NSAIDs, oral colchicine, or joint aspiration and injection of corticosteroid. Some patients respond to oral or IM steroids (Depo-Medrone). When NSAIDs are used, a conventional drug NSAID such as diclofenac or naproxen should be started as soon as possible, and the treatment should be continued until 48 hours after the attack has resolved. A proton pump inhibitor may be needed for gastric protection. Etoricoxib is an alternative COXIB. When NSAIDs are contraindicated, not tolerated, or have been ineffective in previous attacks, oral colchicine can be used at 500 µg, two to four times a day, until pain is relieved or diarrhea or vomiting occurs. Steroids may be preferable to colchicine.

In patients with recurrent acute attacks, tophi, or radiographic changes of gout, preventive treatment is required. This normally involves allopurinol, which inhibits the enzyme xanthine oxidase. The dosage varies from 100 to 600 mg daily; it is usual to start with a low dose and build up. The initiation of allopurinol may lead to an acute episode of gout, and it is conventional to start allopurinol at the same time as giving NSAID therapy. Allopurinol may make an acute attack of gout worse, so it is used subsequent to control of the joint inflammation with NSAIDs. If allopurinol toxicity occurs, options include other xanthine oxidase inhibitors, allopurinol desensitization, or a uricosuric. The uricosuric benzbromarone is more effective than allopurinol and can be used in patients with mild to moderate renal insufficiency, but it may be hepatotoxic. When gout is associated with the use of diuretics, the diuretic should be stopped if possible. For prophylaxis against acute attacks, either colchicine (0.5 to 1 mg daily) or an NSAID with gastroprotection, if indicated, is recommended.

CALCIUM PYROPHOSPHATE CRYSTAL DEPOSITION (CPCD)

This disease is associated with calcium pyrophosphate dihydrate crystal deposition. Although it is usually sporadic, there are familial forms and it can be associated with other metabolic disturbances. It is predominantly a disease of the elderly population, presenting with an acute self-limiting arthritis that is termed "pseudogout." There is a strong association and overlap with osteoarthritis. It mainly involves the large joints such as the knees and wrists. There is a spectrum of pathology. In some cases, there is only chondrocalcinosis, which is the deposition of calcium in articular cartilage and is usually asymptomatic. In other patients, there is more widespread deposition of pyrophosphate dihydrate, and an associated synovitis develops. Thus, although many patients with pseudogout have chondrocalcinosis, the latter

can occur by itself and be asymptomatic or it may be seen against the background of osteoarthritis.

Epidemiology

Chondrocalcinosis has a female preponderance and is associated with aging. It is rare under the age of 50 years. In those aged between 65 to 75 years, it affects 10% to 15% of the population, and over the age of 85 years it affects up to 60% of the population.⁷⁷ The large population-based radiographic survey from Framingham,⁷⁸ which looked at a population ranging in age between 63 and 93 years, found an overall prevalence of 8%. No epidemiologic data exist for pyrophosphate arthropathy, although it is generally thought to occur in the elderly with a female preponderance. Most studies show that the mean age of presentation is between 65 and 75 years. It is rare in younger cases although occasionally seen. There are many associated conditions, including diabetes, anemia, Paget's disease, and hypothyroidism. The strongest association is with hemochromatosis.⁷⁹

Clinical features of calcium pyrophosphate crystal deposition disease

Pyrophosphate crystal deposition disease can present as an acute synovitis, as chronic arthritis, or as an incidental finding. The classic presentation is the acute synovitis of pseudogout, which is the most common cause of an acute monoarthritis in the elderly population. The typical attack develops with severe pain, stiffness, and swelling maximal between 6 and 24 hours after the onset. The patient often describes the pain as very severe. There may be overlying erythema. Examination shows a tender joint with signs of marked synovitis such as warmth, a large intense effusion, joint line tenderness, and restriction of movement. Fever is common, and this can be marked. Elderly patients often appear unwell and mildly confused. The acute attacks are self-limiting and usually resolve within 1 to 3 weeks.

Chronic pyrophosphate arthropathy is also predominantly found in elderly and female patients. It mainly involves the knees, wrists, and shoulder joints. Presentation is with chronic pain, early morning and inactivity stiffness, reduced movement, and functional impairment. Acute attacks may be superimposed on this chronic history. Symptoms are often restricted to just a few joints, but occasionally multiple joint involvement is observed. Affected joints usually reveal signs of osteoarthritis, such as bony swelling, crepitus, and varying degrees of synovitis. Knee joints may be warm with some tenderness, effusion, and soft tissue thickening.

Examination may show more widespread evidence of osteoarthritis. There may also be occasionally more severe inflammatory features, and the presentation may develop into pseudo-RA, although the infrequency of tenosynovitis and the absence of extraarticular disease normally allows distinction.

Most patients present a benign course, and a majority of patients show stabilization of symptoms.⁸⁰ Occasionally, progressive severe destructive arthritis may occur, especially involving the knees, shoulders, or hips. This is almost entirely confined to elderly women, usually accompanied by severe night and rest pain and associated with a poor outcome.⁸¹

Atypical presentations are commonplace. A notable example is marked shoulder pain and stiffness that suggest

polymyalgia rheumatica. A study from Spain⁸² described 36 patients who met the diagnostic criteria for both polymyalgia and calcium pyrophosphate deposition disease. As a group, these patients were older and had peripheral arthritis more frequently.

Treatment

The aspiration of synovial fluid in acute synovitis associated with calcium pyrophosphate crystal deposition disease can markedly improve the initially severe symptoms. Analgesics and NSAIDs are usually given, and these also rapidly improve symptoms. Colchicine is effective but rarely warranted. For severe polyarticular attacks unresponsive to aspiration and injection, oral steroids may be considered although their efficacy is unproved. Once the synovitis is settling, active mobilization with attention to muscle training is worthwhile.

Unlike with gout, there is no specific therapy for chronic pyrophosphate arthropathy. Treatment of the underlying metabolic disease has little effect on outcome. The main objective is to reduce symptoms and maintain and improve function. Exercise programs, a reduction in obesity, and building up muscle strength are all immensely valuable. If osteoarthritic joint damage is a particular problem, surgical replacement must be considered.

APATITE DEPOSITION DISEASE

Periarticular deposits of calcific material that are predominantly carbonated apatites or intraarticular deposits of a variety of basic calcium phosphates, also predominantly apatites, are observed in a variety of disease settings. Calcific periartthritis and the acute synovitis associated with apatite deposition have different etiologies and clinical courses but are united by the presence of calcium deposits in bone.

The presence of calcific periartthritis has been recognized for many years. However, the relationship between apatite deposition and joint diseases is more recent and was not described in detail until 1976.⁸³

Epidemiology

Calcific periartthritis is relatively common. In one large study of office workers, published in the 1940s, there was a prevalence of 2.7% of shoulder calcification.⁸⁴ Subsequent studies have found relatively similar high levels of shoulder calcification. There have been few studies of the epidemiology of articular apatite deposition, mainly because the relationship between pathologic and radiologic findings and symptoms of arthritis or the presence of an arthropathy or acute synovitis is uncertain. However, the finding of apatite particles in 30% to 60% of osteoarthritic synovial fluids may be of some pathologic relevance.⁸⁵

Clinical features

Calcific deposits around the shoulder and elsewhere are often asymptomatic. They may be associated with a number of clinical syndromes. The most striking presentation is acute calcific periartthritis.⁸⁶ Over 70% of attacks occur around the shoulder, although other sites may be involved. The episode may be preceded by mild trauma or illness but is often spontaneous. Patients present with a sudden onset of severe pain described as "acute hyperalgia." Within hours

there is often associated swelling that might be hot and red. There is extreme local tenderness. Movement around the shoulder is limited. The condition appears to be initiated by a rupture of the calcific deposit leading to crystals being shed into the adjacent periarticular tissues. Sites other than the shoulder that may be involved include the greater trochanter, the epicondyle, the wrist, and around the knee.⁸⁷

In 1981, McCarty et al⁸⁸ described an important large-joint destructive arthropathy associated with apatite deposition. The shoulder is often involved, and the condition is often termed *Milwaukee shoulder*. Patients are usually over 70 years of age, and 90% are female. They present with a short history, over weeks and months, of pain, swelling, and loss of function of a shoulder. Aspiration shows a large quantity of synovial fluid, which may be blood-stained and contains apatite crystals.

Treatment

Acute calcific periarthritis requires high doses of NSAIDs, colchicine or local steroid injections are useful in some patients. Apatite deposition in osteoarthritis requires no specific treatments.

The destructive arthritis associated with Milwaukee shoulder is a difficult management problem. Antiinflammatory drugs, analgesics, and local steroids have all been used, but they are often ineffective. However, as symptoms do appear to be reduced in a majority of patients over a few months,

conservative and simple symptomatic measures may eventually allow a resolution of the symptoms to occur as part of the natural history of the disease. Some centers recommend more intensive treatment such as tidal irrigation, which has been reported to result in considerable benefit.⁸⁹

KEY POINTS

Arthritis in the Elderly

- Arthritis is common in the elderly.
- Over 30% of women over 75 years of age have clinical features of osteoarthritis.
- Over 5% of women over 75 years of age have rheumatoid arthritis.
- Arthritis causes substantial pain and disability and is a major factor in limiting quality of life.
- The treatment of arthritis is similar in elderly and younger people, although drug therapy requires greater caution in the elderly population.
- Intensive treatment of inflammatory arthritis is effective in elderly people, and there is no reason not to prescribe disease-modifying antirheumatic drugs or biologics for these patients.

INTRODUCTION

Connective tissue is found in all the organs of the body, usually forming a supporting scaffold for the cells or blood vessels within the tissue. In addition there are tissues that are composed exclusively of connective tissue. These fall into two major groups: those consisting of cells within an extracellular, collagen-rich matrix (bone, cartilage, fibrous tissue) and those with an internalized, specialized organic “matrix” (smooth, cardiac, and skeletal muscle and fat).

With age, connective tissues change their structure and function. The detailed mechanisms underlying this are dealt with in Chapter 12, but briefly, although there are diverse specific pathogenic mechanisms driving age-related tissue events, there are a number of generic processes that explain the changes seen in most tissues. At the whole body level these include a decrease in the amount of and receptiveness to circulating cytokines and growth factors or trophic hormones (e.g., the GH/IGF-1 axis). At the tissue level these include decreased amounts of tissue (e.g., bone in osteoporosis) and failure of normal responsiveness to load (an important homeostatic element in the biology of connective tissues). At the level of the cell these processes include reduced efficiency and number of stem cells and synthetic ability of increasingly senescent end cells.^{1,2} And at the matrix level they are changes in the structure of matrix molecules (e.g., posttranslational cross-linking of collagen fibers by advanced glycation end products), bringing with it reduced functional efficiency.³

These changes can affect connective tissues anywhere,⁴ not just in those tissues that consist primarily of connective tissue. However, in the latter group the effects can be profound, leading to poor mobility, altered ability to withstand cold, metabolic syndrome,⁵ weakness, and an increased risk of falls, fractures, and age-associated “degenerative” diseases such as osteoarthritis and osteoporosis. As understanding of the causes of altered connective tissue function with age increases, it is becoming clearer that many of the predisposing factors are potential targets for improving quality of life in the elderly.

Diseases of three of the connective tissues—bone (Chapters 19 and 69), articular cartilage (Chapters 19 and 70), and skeletal muscle (Chapter 73)—together with some of the consequences of alterations in the connective tissue components of elements of the cardiovascular system (Chapter 14), blood (Chapters 21 and 93) and skin (Chapter 95), or disorders associated with the increasing prevalence of infection (Chapter 13) and cancer (Chapter 94) are described in detail elsewhere. This chapter concentrates on the common disorders of the connective tissues not already covered, and their associations with aging.

Once osteoporosis, osteomalacia, osteoarthritis, and sarcopenia are accounted for, the number of disorders of connective tissues that characteristically have an onset in the elderly age group (as opposed to those that accumulate throughout life but only present a significant disease burden in the elderly) is surprisingly small. The reasons why certain connective tissue diseases arise in the elderly population are not

known. In this chapter, only those disorders characterized by a peak age of onset in the elderly population are discussed. Coverage cannot be exhaustive or comprehensive, but important issues and diseases affecting elderly people are highlighted.

NONMETABOLIC DISEASES OF BONE

The major nonmetabolic diseases of bone affecting the elderly are fracture, osteomyelitis, and Paget’s disease.

Fracture

There is a higher incidence of both metastasizing epithelial neoplasms and osteoporosis in the elderly population. Both can weaken bone to a point where fracture is more likely to occur under “normal loading,” predisposing the elderly to a higher incidence of pathologic fracture.

In addition, in the elderly there is impoverished fracture healing, probably as a consequence of a complex of diminished numbers of mesenchymal stem cells, poor stem cell maturation, and abnormalities in the humoral pathways that regulate osteoblast differentiation and function.⁶ Poor fracture healing and an increase in the complication rate associated with fracture (e.g., thromboembolism) and illness/surgery/immobilization (e.g., confusion, infection) make even relatively trivial fractures serious events in the elderly, with a high incidence of significant morbidity, institutionalization, and death.⁷

Osteomyelitis

In the general population, osteomyelitis is a bacterial infection of bone marrow that usually reaches the bone by hematogenous spread from a primary site elsewhere. It is most commonly pyogenic, and the most common causal organism is *Staphylococcus aureus*. A second and increasingly common cause of osteomyelitis is consequent on orthopedic interventions such as joint replacement and internal fracture repair.⁸ Joint replacement particularly is increasing in the elderly, and although the procedure is highly successful, a proportion (1% to 5%) of implant sites become infected, which is compounded in the elderly by comorbid conditions such as relative ischemia, diabetes, and reduced innate immunity. An appreciation that low-grade infection can underlie prosthesis failure in the elderly has led to a reassessment of diagnostic modalities⁹ and improved detection of implant-associated osteomyelitis, but diagnosis and treatment remain the most significant problems in orthopedics, particularly in the aging population.

Paget’s disease

Paget’s disease is a disorder of poorly understood etiology that affects one or, rarely, more than one bone.¹⁰ Paget’s disease is believed to develop slowly, manifesting itself predominantly in the elderly population. Initially, perhaps in every case, there is a local decrease in bone mass, which is only later followed by the characteristic osteosclerosis. Usually, clinical features manifest themselves only in the later stages of the disease. The incidence varies widely across the world, being highest in northwest

England where at postmortem as many as 10% of individuals over 70 years of age show changes attributable to Paget's disease.

Histologically there is a generalized increase in bone cell activity that, in severe cases, leads to deposition of woven bone and uncoupling of osteoblastic and osteoclastic activity. Together these two factors lead to the laying down of excessive quantities of weak bone. The bone marrow is very vascular and the normal hematopoietic marrow is replaced by fibrous tissue. By electron microscopy, osteoclasts are seen to contain structures resembling viral particles (Figure 71-1), and modern research techniques, including immunohistochemistry and *in situ* hybridization, have demonstrated the presence of Morbillivirus within bone cells.¹¹ Causative links between the presence of the virus and altered osteoclast activity have given clues to the underlying biology of the disease and placed the osteoclast at the center of the disturbed bone cell biology.¹² There is, however, considerable controversy over the nature of this virus, or even its existence,¹³ and increasingly opinion as to the cause of Paget's disease is moving toward it having a genetic basis.¹⁴

The abnormal bone matrix is weak leading to bone pain and fracture. Increased bone cell turnover predisposes to the development of primary bone malignancies, particularly osteosarcoma, fibrosarcoma, and malignant fibrous histiocytoma making Paget's disease the most common cause of primary bone malignancies in the elderly. Particularly in the elderly where there is a high incidence of impaired cardiac function, the increased vascularity within the affected bone or bones can lead to high-output cardiac failure.

Excessive bone cell activity causes an increase in the serum alkaline phosphatase and urinary collagen breakdown products. As the disease is driven by the osteoclast, symptomatic relief can be obtained by the use of drugs that suppress osteoclast function, notably bisphosphonates and calcitonin.

CARTILAGE DISORDERS

Chondroid tissues are characterized by the expression of the matrix molecules type II collagen and aggrecan and the transcription regulating gene Sox-9. The diversity of tissues expressing these genes is just beginning to be recognized with clear biologic distinctions being drawn between articular cartilage, growth plate, the cartilage of chondroid

Figure 71-1. Osteoclast nucleus containing viral inclusions (arrow) in Pagetic bone ($\times 27,000$).

joints (e.g., costosternal joints), nonskeletal (e.g., nasal, auricular, bronchial) cartilage, structural fibrocartilage of synovial joints, the annulus fibrosus, and nucleus pulposus of the intervertebral disk and the vitreous humor of the eye.

By far the most common symptomatic disorder of cartilage in the elderly is osteoarthritis, which is covered in Chapter 70. Other common disorders include chondrocalcinosis (deposition of calcium pyrophosphate crystals) and degeneration of the intervertebral disk.

Degeneration of the intervertebral disk

Degeneration of the intervertebral disk (IVD) is attracting increasing interest as modern molecular pathology techniques allow the biology of this predominantly human disease to be studied; advances in biologic therapies, tissue engineering, and regenerative medicine offer potential therapeutic modalities; and diskogenic back pain makes an increasingly large impact on health and the economy.

In degeneration there are profound alterations in IVD cell and matrix biology, which include decreased synthesis of aggrecan, a switch in collagen subtype production from type II to type I, increased matrix breakdown by locally produced metalloproteinases, premature cellular senescence, and cell loss through apoptosis. The current view is that these changes are driven by altered cytokine regulation in the IVD, with interleukin 1 (IL-1) and tumor necrosis factor- α (TNF- α) having central roles in the processes leading to degeneration and diskogenic pain.¹⁵ Currently, novel therapies are being developed to reverse the altered biology using cytokine modulators (such as IL-1 receptor antagonist and anti-TNF); replace the damaged tissues (particularly the nucleus pulposus, which is believed to be the seat of the altered cell biology) using disk replacements or biomaterials that have the same properties as the nucleus pulposus; or regenerate the IVD *in vivo* using a combination of stem cell therapy, smart biomaterials, and gene therapy.¹⁶ Until such therapies are developed for widespread use, the treatment for diskogenic back pain in the elderly remains largely symptomatic.

DISORDERS OF FIBROUS TISSUE, LIGAMENTS, AND TENDONS

Disorders of fibrous tissue, particularly the organized fibrous tissues of ligaments and tendons, are common. They include proliferations such as keloid and the fibromatoses; trauma, either to the structure itself or to its insertion into bone (the entheses); myxoid degeneration (e.g., ganglion formation); altered balance of connective tissue components; and metaplasia. Of these, two disorders, Dupuytren's disease and traumatic enthesopathy, are particularly common in the elderly.

Dupuytren's disease

Dupuytren's disease is a disorder in which there is a nodular proliferation of fibroblasts within the palmar fascia and its digital extensions, leading to dense collagen deposition, thickening and contracture within the fascia, and permanent deformity of the adjacent finger.

Many theories have been put forward to explain Dupuytren's disease.¹⁷ They include changes induced by mast cell and epidermal chemical mediators, alterations in the vasculature, and paraneoplastic changes in DNA. None has been unequivocally accepted.

Within the palmar fascia, the fibroblastic proliferation is focal, leading to small nodules of very active fibroblasts (Figure 71-2). The nodular proliferation flits from area to area of the fascia, resulting in a generalized increase in collagen deposition. As the collagen “matures,” internal fiber cross-linking leads to an overall reduction in fiber length and consequent contraction. The patient complains of a slowly progressive, painless nodule in the fascia that, as it worsens, shortens the affected area of tissue, causing further thickening and fascial contraction. Each fascial slip is attached to a finger, and the contraction leads to a permanent flexion deformity of the digit.

The clinical presentation is diagnostic, as are the biopsy appearances. Surgical excision is the treatment of choice, but the potential progression of the disease is not affected.¹⁸

Traumatic enthesopathy

Enthesopathy is the name given to a disparate group of disorders that occur at the entheses. The most striking of these are the inflammatory enthesopathies, seen in ankylosing spondylitis (AS) and rheumatoid arthritis (RA). Active enthesopathic AS is not specifically a disease of elderly people, and RA is discussed in Chapter 70.

There are two other major causes of enthesopathy: hyperparathyroidism and trauma.

Although the incidence of primary hyperparathyroidism peaks in elderly women (Chapter 91), it is usually a mild form of the disease and the abnormal activity of the parathyroid glands is often brought under control by an early resetting of the homeostatic mechanisms while the serum calcium is still within the normal range. There is therefore little of the bone erosion that is seen in classical advanced disease. In more severe disease, hyperosteoclasia at the enthesis can weaken the insertion, leading to pain and ligament failure.

Age-associated changes in collagen in the ligament/tendon and cartilage, weaken the structures in or around the entheses and lead to the increased incidence of partial or complete physical failure encountered during exercise in the increasingly fit elderly population. Trauma at the enthesis leads to a repair process, with development of painful bony outgrowths called “traction spurs,” particularly at sites of maximum load—around the shoulder girdle, at the insertions of the plantar fascia and Achilles tendon into the calcaneum,¹⁹ and the long ligaments of the spine into vertebral bodies.

Figure 71-2. Cellular proliferation within a Dupuytren nodule (H&E ×200).

NEOPLASMS OF CONNECTIVE TISSUE

Although many benign and malignant connective tissue neoplasms are seen in the elderly population, only rare primary connective tissue neoplasms have their peak incidence in this age group. These are all rare and are either benign neoplasms of soft connective tissues or malignant neoplasms of soft connective tissues or bone. The group includes benign neoplasms of soft tissues (spindle cell/pleomorphic lipoma, atypical fibroxanthoma, elastofibroma, cellular angiofibroma), malignant neoplasms of soft tissues (pleomorphic sarcomas of the group that used to be known as malignant fibrous histiocytoma but is now recognized as a spectrum of pleomorphic malignancies that have a similar histologic pattern but different immunophenotype [Figure 71-3], pleomorphic liposarcoma, undifferentiated pleomorphic sarcoma with giant cells, myxofibrosarcoma, and fibrosarcoma), and malignant neoplasms of bone (Pagetic sarcoma, chondrosarcoma).

Elastofibroma

One of these, elastofibroma, is particularly interesting in view of the highly significant age-associated changes that occur in the connective tissue matrix molecule elastin.^{20–22}

Elastofibroma is a benign, slow-growing tumor found mainly in the subscapular area in elderly women. It consists of fibrous tissue containing large numbers of elastin fibers. These can be recognized in conventionally stained sections (Figure 71-4), but stains for elastin are characteristic and show exactly how much elastin is present within the tumor.

The etiology is unknown. There is some evidence that it may be associated with trauma, but the evidence for this is far from convincing and a familial incidence could point

Figure 71-3. Macroscopic image of a pleomorphic sarcoma (arrow) in the lower leg. Diameter approximately 5 cm.

Figure 71-4. H&E stained section of an elastofibroma. Note the wormlike and somewhat ragged edged elastin fibers viewed from the side on in the upper part of the figure and from the end on in the lower part ($\times 300$).

toward a genetic predisposition. There have been studies showing recurrent DNA gains at bands Xq12-q22 and 19,²³ and clonal chromosomal changes have been reported.

Whatever else, the major feature of these tumors is the presence of abnormal elastin. Immunohistochemical, electron microscopic, and molecular studies have shown that the elastin fibers differ only slightly in amino acid composition from normal elastin.²⁴ The changes seem to have resulted from abnormal synthesis rather than some sort of abnormal degradation. The changed amino acid composition leads to morphologic changes in the elastin fibers such that under the electron microscope they appear as irregular, somewhat fern-shaped aggregates of electron-dense material surrounded by and incorporating microfibrils and collagen fibers. Whether this has any relationship to or bearing on the recognized age-associated abnormalities in elastin fiber structure, which have been described as being the one factor that will prevent extreme longevity in humans, is unknown,²⁵ but examination of these tumor cells that are actively overproducing abnormal elastin may be one route to gaining a better understanding of the altered biology of elastin in the elderly.

IMMUNE-MEDIATED CONNECTIVE TISSUE DISORDERS

This group of clinicopathologic entities is characterized by an immune response against "self-antigens," leading to damage to "connective tissues" and blood vessels in multiple organs, notably joints, skin, glomeruli, and large and small blood vessels. Pathogenetically, all of these disorders exhibit immune complex deposition, or formation, within affected organs (usually on basement membranes) and consequent tissue damage. The intriguing thing about these disorders is that the balance of the organs affected by the disease process varies from condition to condition, so that in rheumatoid arthritis the joints are most commonly and severely affected, whereas in polyarteritis nodosa it is the blood vessels, and in systemic lupus erythematosus it is the skin and kidney. Like all autoimmune diseases, they most commonly present in young adult women. Only giant cell arteritis

and polymyalgia rheumatica stand out as being disorders predominantly of the elderly.

Giant cell arteritis and polymyalgia rheumatica

Giant cell arteritis is a relatively uncommon disorder (approximately 1:1000 over 60 years) manifesting as an arterial vasculitis with a predilection for the arteries of the head, particularly the external carotid and the retinal branch of the internal carotid arteries, of elderly women (F:M = 3:1).²⁶ The American College of Rheumatology has proposed diagnostic criteria.

Early in the disorder there is a leukocytoclastic vasculitis, so called because the vessel wall contains viable polymorphs and polymorph debris, evidence of complement activation, and generation of toxic polymorph products. Not only do polymorphs perish in this environment, but so too do the smooth muscle cells of the arterial wall, leading to segmental mural necrosis. Later the distinctive picture of chronic inflammation with giant cells within the wall of the vessel appears. The giant cells are of two types: immune-competent cells, primed to an unknown antigen; and foreign-body type cells that are phagocytosing the internal elastic lamina (Figure 71-5). Thrombus formation is commonly seen. The disease has a focal distribution within the vessel and, in any one location, a short time course. After the inflammation has spontaneously settled, the vessel wall undergoes fibrosis. Extensive fibrosis can be used to indicate earlier destructive inflammation, even in the absence of active inflammation. Care must be taken in interpreting this feature as fibrosis and segmental loss of the internal loss of the internal elastic lamina is a "normal" finding in the elderly population.

The etiology of the vasculitis is not known. There is familial aggregation and association with HLA-DR4. In the serum there are raised levels of IgG, total complement, C3, and C4. Circulating immune complexes have been demonstrated in up to 90% of patients. They have also been seen attached to the internal elastic lamina, perhaps by absorbance. Whether the key role of the elastic lamina in immune complex absorption and its recognition by multinucleate macrophages is another manifestation of the importance of abnormal elastin synthesis in age-associated disorders of connective tissues is not known, but it is certainly intriguing.²⁷

POLYMYALGIA RHEUMATICA

The localized disorder giant cell arteritis is associated with a generalized condition known as polymyalgia rheumatica. It is characterized by low-grade fever, weight loss, ill-defined pain, malaise, fatigue, and stiffness in the shoulder girdle, upper arms, and neck. Movement accentuates the pain, which is at its worst at night. Affected joints, particularly the knees and sternoclavicular joints, are actively inflamed. There is an increase in the number of cells within the synovial fluid and a normochromic, normocytic anemia. The erythrocyte sedimentation rate (ESR) is very high but there is no leukocytosis. Tests for autoantibodies are negative. It responds to steroids.

METABOLIC DISORDERS

Prominent among the metabolic disorders affecting connective tissues in the elderly are disorders in which crystals and abnormal proteins accumulate in the tissues.

Figure 71-5. Artery from a patient with giant cell arteritis. The left panel shows virtual occlusion (arrow) of the lumen (H&E, $\times 10$). The right panel shows inflammation including giant cells (arrow) in the wall (H&E, $\times 150$).

Crystal deposition disease

The main symptomatic crystal deposition diseases affecting the elderly are gout and pseudogout.²⁸

Gout is caused by the precipitation of crystals of monosodium urate in joints. Uric acid, from which urates are formed, is a breakdown product of purine metabolism. Most is excreted by the kidney. Alteration in uric acid excretion, either idiopathic or secondary to diuretic therapy, leads to an increase in monosodium urate in the blood and extracellular fluid and its precipitation in the tissues. Cartilage, particularly articular fibrocartilage and nonarticular hyaline cartilage, and subcutaneous connective tissue are the most common sites of its accumulation. Here aggregates of the crystals induce a macrophage response. These “tophi” may ulcerate. In elderly people, tophaceous or nontophaceous gout occur most commonly consequent upon an idiopathic decrease in urate excretion, generalized deterioration in renal function, or the use of certain diuretics. Therapy can be challenging in the elderly.²⁹

Pseudogout is one of three manifestations of deposition of calcium pyrophosphate crystals in the elderly. The first is chondrocalcinosis, a disorder in which the crystals are deposited in articular tissues, mainly fibrocartilage. Despite being extremely common over the age of 70, it is generally not symptomatic. The second is in osteoarthritis in which calcium pyrophosphate crystals are a common finding in cartilage and synovial fluid and where they are believed to have some pathogenic role in disease progression. The third is pseudogout in which the presence of crystals in the synovial fluid leads to an acute crystal arthritis similar to gout.

Accumulation of abnormal proteins

Two conditions, diabetes and amyloidosis, cause abnormal proteins to accumulate in the elderly at least in part because the molecules are not as readily degraded as their

normal counterparts. In terms of connective tissues, the most significant effects are alteration in structural proteins and thickening of vascular basement membranes leading to altered tissue nutrition. In diabetes a major cause of abnormal proteins to form is hyperglycemia, which leads to the production of advanced glycation end products (AGEs) that in turn induce cross-linking of collagens and other connective tissue matrix molecules.³⁰ In amyloidosis, tissue dysfunction is caused by deposition of molecules that have changed from their conventional structure of an α helix to a β pleated sheet. The greatest interest in amyloids in the elderly has focused on neurodegeneration-associated amyloid deposition in the brain, but amyloids are far more widely spread in the aging

KEY POINTS

Connective Tissue Diseases

- Age-associated disorders of connective tissues are among the most important for determining quality of life in the elderly.
- Connective tissue cells and matrices change structure or function markedly with increasing age. In particular AGE-induced cross-linking and cellular senescence affect tissue function.
- Connective tissue diseases restricted to the elderly population are rare as most connective tissue disorders are ones in which the incidence in the elderly is similar to that in other adults, or are present in the elderly following asymptomatic progression over many years.
- Most of the key connective tissue diseases affecting the elderly are among the most important diseases in the world.
- Elastin is a key matrix molecule for determining pathologic processes in the elderly.
- To fully understand connective tissue diseases in the elderly requires an understanding of the biology of the aging cell and matrix molecules.

population, with one estimate of the incidence of senile systemic amyloidosis (SSA) as 25% of those over 80.³¹ In SSA the major component of the amyloid (AS amyloid) is derived from normal transthyretin (prealbumin). The most common site for age-associated amyloids to accumulate in connective tissues in the elderly is in and around joints and in the walls of arteries. In these sites it is generally benign, but there is an association with osteoarthritis.

SUMMARY

The connective tissues are the most abundant tissues in the body. Diseases of connective tissue can occur at any time of life and most present first during middle age.

Some are specific to the elderly population, including Paget's disease of bone, Dupuytren's disease, elastofibroma, pleomorphic sarcoma, giant cell arteritis, and senile amyloid, discussed here; osteoporosis, osteoarthritis, and vascular disease, which are among the most common non-infective diseases in the Western world, are discussed in other chapters.

INTRODUCTION

Orthopedic care of geriatric patients presents unique challenges. Geriatric patients often have multiple medical comorbidities that affect decisions regarding timing and type of surgery. Bone quality is often substantially inferior to that of younger patients, and many older patients have preexisting arthropathies, making fixation more challenging and sometimes making arthroplasty the favored treatment. Coordination of care with an internal medicine or geriatric team is often helpful to provide the best outcome and to minimize complications. This chapter addresses many of the challenges the orthopedist must deal with when caring for geriatric patients.

Osteoporosis

The World Health Organization has defined osteoporosis as a bone mineral density (BMD) value of 2.5 standard deviations or more below the young adult mean.¹ Patients with known osteoporosis are at a substantial risk for fracture. The majority of patients with a fragility fracture involving the spine, hip, wrist, or proximal humerus, however, do not meet the BMD definition of osteoporosis.² This fact can make it difficult to know which patients should receive pharmacologic treatment to prevent the risk of fracture. This finding also suggests that patients who have had a single fragility fracture should receive treatment for osteoporosis, even if their BMD is not 2.5 standard deviations below the mean.

Despite improvements in pharmacologic treatment, osteoporosis continues to afflict millions of aging Americans and people worldwide. Fragility fractures result in pain, disability, and medical complications and affect as many as 1 in 3 women and 1 in 12 men during their lifetime. It is estimated that worldwide, 323 million people suffer from osteoporosis, and that number is projected to be 1.55 billion by the year 2050.³ It has been predicted that the number of hip fractures in the year 2050 will be 6.3 million.³ The medical expenses following fragility fractures are substantial.⁴ The annual cost of osteoporosis and fragility fractures in Europe is estimated at 13 billion euros.⁴ The majority of that cost results from hospitalization after fracture.

Patients who have sustained a single fragility fracture have a 1.5 to 9.5 times higher risk of sustaining a second fracture than do those who have never had a fracture.⁵ One study found 20% of patients had a second fracture within 1 year.⁶ Despite this risk, many patients who have had a fragility fracture are not started on preventive medication. In one study, only 7% of patients admitted with a fragility fracture were receiving osteoporosis treatment.³ Surprisingly, this number only increased to 11% at the time of discharge. At a minimum, patients should be started on calcium and vitamin D after sustaining a fragility fracture. Antiresorptive medications should also be considered.

Osteoporosis has a dramatic effect on fracture fixation. Traditional nonlocked plates and screws may not achieve adequate purchase in osteoporotic bone. Intramedullary implants or locked plates should be considered to improve fracture fixation and maintain alignment.⁷ Augmentation of

bone with methylmethacrylate cement can enhance screw purchase, but care must be exercised to prevent extravasation into the soft tissues or into the fracture site. In elderly osteoporotic patients, certain fractures may be better treated with arthroplasty rather than open reduction internal fixation.

Several authors have looked at the costs of trying to screen for osteoporosis and institute antiresorptive treatment before the onset of a fragility fracture.^{8–11} A study in Australia looked at 1224 women 50 years old and older and categorized them into age groups.¹² Dual-energy x-ray absorptiometry (DEXA) scanning was performed on all women, and the percentage with osteoporosis was 20% in the 50–59 age group, 46% in the 60–69 age group, 59% in the 70–79 age group, and 69% for those older than 80 years. It was estimated that if all women over 50 years of age were started on antiresorptive medication the risk of fracture would decrease by 50% in those with osteoporosis and by 20% in those without. They calculated the cost per fracture averted in the 50–59 age group at \$156,400 and in the over-80 group at \$28,500. It was concluded that treating all women over age 50 with antiresorptive medication was not financially feasible. The authors also concluded that for women over 60 years of age with osteoporosis, instituting antiresorptive therapy would decrease fragility fractures by 28% and was cost effective.¹²

GERIATRIC TRAUMA

Patients older than 65 years of age account for 28% of all fatal injuries in the United States, although they represent only 12% of the population.^{13,14} Additionally, the population over 65 years of age is the fastest growing segment in the United States. Treatment of fractures in the elderly is often more complicated than in the young, healthy age group as elderly fracture patients often have preexisting medical problems that affect fracture management. One of the most common comorbidities in elderly patients is cardiopulmonary disease, which can limit their ability to tolerate surgery and participate in rehabilitation. Neurologic disorders, such as Alzheimer's disease and Parkinson's disease, are also common. Some patients have residual weakness or contractures from a previous cerebrovascular accident. Any of these disorders can affect gait and balance and limit weight-bearing restrictions that younger patients could comply with. Endocrine problems, particularly diabetes, are common in the elderly. Diabetic patients generally have vascular compromise secondary to small vessel disease and are immunosuppressed. Nonoperative treatment of select fractures may be preferred in these patients, particularly if there is a preexisting diabetic ulcer near the planned operative field.

For multiply injured elderly patients, the injury severity score (ISS) may underestimate the degree of injury. An elderly patient may present with a lower ISS than a young adult and still be unstable or even "in extremis," in the sense that minimal further insult can tip these patients past the point of recovery. At the same time, if their injuries are not rapidly stabilized, these patients may deteriorate beyond the point at which they can survive. It is this tightrope that

Figure 72-1. Grade III C humerus fracture in elderly trauma patient with multiple injuries. Treatment was immediate amputation.

the orthopedic trauma surgeon must walk when treating the elderly patient with multiple fractures. In such cases, simple splinting or external fixation of upper extremity fractures and external fixation of lower extremity fractures may represent the best initial treatment.

Few studies have focused specifically on the impact of orthopedic injuries in elderly trauma patients.^{15–17} One retrospective, multicenter study attempted to define factors associated with increased morbidity and mortality rates in elderly patients who had sustained major trauma.¹⁵ Of 326 patients with an average age of 72.2 years, there was an overall mortality rate of 18.1%. Of patients who required bony stabilization, 77% had this accomplished within 24 hours of admission. The mortality rate for patients who underwent fracture stabilization within 24 hours was 11%, and for those who were fixed after 24 hours it was 18%, but this difference was not statistically significant.¹⁵ The three complications with the highest mortality rates were acute respiratory distress syndrome (ARDS) (81%), myocardial infarction (62%), and sepsis (39%).

For the elderly trauma patient with a mangled extremity, early amputation should be considered. Elderly patients may not be able to withstand the multiple surgeries required to salvage severe, open fractures, especially those with vascular insult. If a severely injured limb becomes infected, the cascade of sepsis and multiple system organ failure can proceed quickly. Although this is often a difficult decision, early amputation in the elderly patient can be a life-saving procedure (Figure 72-1).

ANESTHETIC CONSIDERATIONS

One aspect of orthopedic care in the elderly that should not be underemphasized is pain control. Early stabilization of fractures is one factor in pain control. Once fractures are stabilized, there is a minimization of narcotic use, which can improve respiratory function and mental status. Patients whose fractures are stabilized and have adequate pain control can be weaned from ventilators more easily, can obtain a more upright posture, and have reduced delirium; these are all critical for survival in the elderly. Selective use of nerve blocks or catheters for continuous infusion, such as a femoral nerve block catheter following a femur fracture, can greatly aid in pain relief and minimize narcotic requirements.

Periarticular fractures

Treatment of periarticular fractures in the elderly often differs from treatment in younger patients. Fractures involving the proximal humerus, elbow, hip, and occasionally the knee sometimes fare better with a joint arthroplasty rather than open reduction internal fixation (ORIF) in the elderly. Several studies have compared ORIF to joint arthroplasty for displaced femoral neck fractures in the elderly.^{18–20} The complication rate following ORIF, including need for revision surgery, is substantially higher than it is for the arthroplasty group. Controversy exists as to whether hemiarthroplasty or total hip arthroplasty is the best treatment. Some studies seem to show improved results with total hip arthroplasty.^{21,22} Dislocation rate is a concern with total hip arthroplasty, especially in patients with neurologic disorders such as Parkinson's disease or patients with hemiparesis after a stroke.

Distal humerus fractures are another example of a periarticular injury in the elderly that may have better outcomes with arthroplasty rather than ORIF. Frankle et al reported on a retrospective review of 12 patients who underwent ORIF and 12 who underwent total elbow arthroplasty for distal humerus fractures.²³ The total elbow group performed better on the Mayo Elbow Performance Score with 11 (excellent) and 1 (good) compared to 4 (excellent), 4 (good), 1 (fair), and 3 (poor) in the ORIF group. Muller et al reported on their results with 49 distal humerus fractures in patients older than 65 years treated acutely with total elbow arthroplasty.²⁴ Inclusion criteria included patients who were "high compliance" and "low demand." Average range of motion at follow-up (average, 7 years) was an arc from 24 to 131 degrees. A total of five revision arthroplasties were performed during the follow-up period. They concluded that the procedure is recommended when the appropriate inclusion criteria are met.

For periarticular fractures best treated with ORIF, the advent of locked plates has allowed for improved fixation, especially in patients with osteoporotic bone. Results so far have been encouraging. In one retrospective review of 123 distal femur fractures treated with the Less Invasive Surgical Stabilization (LISS) system, 93% healed without bone graft, the infection rate was 3%, and there was no loss of distal fixation.²⁵ In a prospective study of 38 complex proximal tibia fractures treated with the LISS system, 37 of 38 healed with satisfactory alignment, there were no infections, and the average lower extremity measure (LEM) score was 88.²⁶ Another review of 77 proximal tibial fractures treated with LISS showed 91% healed without complication.²⁷ The overall union rate was 97% with an average time to full weight bearing of 12.6 weeks; the infection rate was 4%.

Acetabular fractures are challenging to treat at any age. Helfet et al was one of the first research teams to report on open reduction and internal fixation of acetabular fractures in the elderly.²⁸ In their review of 18 patients age 60 or older followed for 2 years after ORIF, the mean Harris hip score was 90 points. All fractures healed, and only one patient had loss of reduction. Complications included two pulmonary emboli and one missed intra-articular fragment requiring reoperation. The authors concluded that "open reduction and internal fixation of selected displaced acetabular fractures in the elderly can yield good results and may obviate the need for early and often difficult total hip arthroplasty."²⁸

Figure 72-2. Displaced acetabular fracture in elderly male treated with acute primary total hip arthroplasty.

More recent work has suggested primary total hip arthroplasty may be a viable option for select acetabular fractures in the elderly (Figure 72-2). To perform arthroplasty in the acute setting is challenging and may require internal fixation of the fracture to provide enough stability to hold the arthroplasty. Mears has reported on his results with this approach in 57 patients with a mean follow-up of 8.1 years and mean age of 69 years.²⁹ The mean Harris hip score was 89, and 79% of patients had a good or excellent outcome. He concluded that this is a viable option for patients with a low likelihood of a favorable outcome with fracture treatment alone.

Periprosthetic fractures

As the number of patients with total joint replacements continues to rise, so do the number of patients sustaining periprosthetic fractures. These typically occur from low-energy falls, but the bone quality around the prior implant is often of poor quality making fixation of these fractures challenging. The first step in deciding on the best treatment is to assess the stability of the prior arthroplasty implants. If the implants are

Figure 72-3. Periprosthetic distal femur fracture in osteoporotic bone treated with locking submuscular plate.

loose, then revision arthroplasty with long stem components is typically the best option. The goal is to use stems that extend beyond the fracture by at least two cortical diameters of the bone involved. If the implants are well fixed, then reducing and fixing the fracture is usually the preferred treatment. For certain fractures, such as a supracondylar periprosthetic femur fracture above a total knee replacement, intramedullary (IM) nailing may be employed, provided the knee replacement was cruciate sparing and the femoral component has an open slot for the nail. Other fractures may best be treated with plating. The techniques of plating have advanced to the point most fractures can be treated with indirect reduction to avoid devascularizing the fracture. Plates should overlap the arthroplasty implants to avoid stress risers. Locked plates have provided improved results for many periprosthetic fractures occurring in osteoporotic bone (Figure 72-3).

Prevention of fractures in the elderly

The first step in prevention of fragility fractures is identifying a patient's risk factors. Some risk factors cannot be changed, such as age, family history, rheumatoid arthritis, or a history of hyperthyroidism or hyperparathyroidism. Many risk factors can be modified, however, and include avoiding cigarette smoking, sedentary lifestyle, excessive alcohol use, low body mass index, and lack of dietary calcium vitamin D. Some medications can contribute to osteoporosis, such as glucocorticoids, cyclosporin, methotrexate, heparin, and anticonvulsants.

Multiple approaches to prevent osteoporosis and fragility fractures exist. They include nonpharmacologic means such as well-balanced diet and exercise, adequate sunlight exposure, not smoking, vitamin D and calcium supplementation, and selected use of hip protectors. Adequate exercise seems to be an important modifiable factor in the prevention of fragility fractures. Exercise not only helps prevent osteopenia and osteoporosis, but it also improves balance and aids in fall prevention in the elderly. A multicenter, randomized controlled trial found that group exercise programs were

beneficial in preventing falls and improving physical performance in "prefrail" elderly patients.³⁰ Exercise does not have to be strenuous to achieve results as programs involving the principles of tai chi have been shown to be effective.

Medical treatments include the antiresorptive bisphosphonates such as alendronate, risedronate, and ibandronate. Nasal calcitonin and raloxifene have also been used to limit bone resorption. Teriparatide is an anabolic agent that improves bone density by increasing osteoblast activity. The FDA has withdrawn approval of hormone replacement with estrogen for osteoporosis prevention, except in selected postmenopausal women.³¹

Calcium and vitamin D are relatively inexpensive and do have benefit in the prevention of osteoporosis. The recommended doses for maximal benefit are 800 IU of vitamin D and 1000 to 1200 mg of elemental calcium. One review article recommended that three types of individuals should take vitamin D and calcium supplementation to prevent osteoporosis: (1) patients receiving glucocorticoid treatment, (2) patients with documented osteoporosis, and (3) patients at high risk for calcium or vitamin D deficiency, in particular older men and women.³²

Adequate dietary protein seems to be another factor in the prevention of osteoporosis and fragility fractures. Diets deficient in protein can lead to loss of bone mass and decreased bone microarchitecture and strength.³³ Elderly patients who were given a diet with increased protein following a fragility fracture were found to have decreased postfracture bone loss, increased muscle strength, and reduced medical complications during their hospital stay. One author has stated that dietary protein is "as essential" as calcium and vitamin D for bone health and prevention of osteoporosis.³³ One prospective trial examined soy protein on bone health.³⁴ Soy protein contains phytoestrogens, which are also thought to be beneficial for bone health. Patients were placed on a diet that included 35 mg of soy protein per day. At the 12-week point, the levels of serum alkaline phosphatase had significantly increased and urinary deoxypyridinone had decreased. It was concluded that soy protein "can be effective in protecting bone mass."³⁴

Hip protectors have been proposed as a relatively inexpensive way to limit hip fractures. A meta-analysis of the Cochrane register of controlled trials concluded that hip protectors are an "ineffective intervention" in the home setting, whereas their utility in nursing or residential care settings is "uncertain."³⁵ The main reason for their ineffectiveness seems to be lack of compliance in using them.

FOLLOW-UP

The orthopedist may be the only physician a patient sees after a fragility fracture. Close communication between the orthopedist and the patient's internist is needed to implement osteoporosis treatment after a fragility fracture. In a 2006 survey of 140 orthopedists and internists in the United Kingdom, 45% of the internists believed the orthopedist would refer the patient for osteoporosis treatment if it was indicated.³⁶ When presented with the scenario of a 55-year-old female with a low-energy Colle's fracture, 56% of the orthopedists did not request further investigation for osteoporosis. Better awareness of patients at risk for osteoporosis and better communication between the orthopedist and internist

as to who will initiate further evaluation and treatment are required to limit the growing burden of fragility fractures.

GERIATRIC-ORTHOPEDIC CO-CARE

Several studies have looked at the effectiveness of co-care between orthopedics and geriatrics regarding inpatient care of elderly patients with orthopedic injuries.³⁷⁻³⁹ Most studies have focused on elderly patients with hip fractures. Previous studies have shown mixed results, but many do show some advantages. The keys to success seem to be careful targeting of the population, a proactive rather than a reactionary strategy, and attention to improving specific outcomes rather than just a general geriatric assessment.

A prospective, randomized trial was carried out on 126 patients 65 years and older admitted to a tertiary academic medical center following a hip fracture.³⁹ Patients were randomized to either a proactive geriatrics consultation or usual care. The group receiving the geriatrics consultation had a reduction in the incidence of delirium by one third and a reduction in severe delirium by one half.³⁹ Fisher et al conducted a study on 951 patients 60 years and older admitted with a hip fracture over a 7-year period to a single institution. For the first 3 years of the study, patients did not have routine geriatric medicine evaluation, whereas during the final 4 years, there was routine geriatrics consultation. During the second phase, significant reductions in mortality (4.7% vs. 7.7%, $p < 0.01$) and rehospitalization rates (7.6% vs. 28%) were seen.³⁸

CONCLUSIONS

Orthopedic care of the elderly presents many challenges. Poor bone quality can make the goal of stable internal fixation difficult if not impossible in some patients. Comorbid medical conditions can dictate what types of treatment a patient can tolerate. Rehabilitation of injuries may be limited because of the patient's overall physical condition. For some periarticular fractures, performing a joint arthroplasty rather than trying to reconstruct the fracture may result in a more predictable and functional outcome. Shared care between the orthopedist and the internal medicine or geriatric team seems to improve overall outcomes for many elderly patients. Communication between the orthopedist and the patient's primary care physician is needed to ensure proper osteoporosis management. Each case requires an assessment of both patient and fracture characteristics to determine the most appropriate treatment.

KEY POINTS

Orthopedic Geriatrics

- Approximately 1 in 3 women and 1 in 12 men will sustain a fragility fracture.
- Injury severity scores may underestimate degree of injury for elderly patients.
- Joint replacement may provide the best treatment for some fractures in the elderly.
- Orthopedic and geriatric co-care may improve outcomes for hip fracture patients.

DEFINITION

Irwin Rosenberg defined sarcopenia in 1989 to describe a recognized age-related decline in muscle mass among the elderly.¹ This large and supposedly involuntary loss of muscle tissue in the elderly was considered responsible in part for the age-related decline in functional capacity. Since 1989, various definitions of sarcopenia have evolved as our understanding of the aging process and the changes that occur therein progress along with improved body composition measurement techniques and the availability of large representative data sets. Despite this increasing knowledge and improved technology, a worldwide operational definition of sarcopenia applicable across racial/ethnic groups and populations lacks consensus. One current definition of sarcopenia includes a loss of muscle strength and functional quality in addition to the loss of muscle protein mass.

EPIDEMIOLOGY

After 50 years of age, muscle mass is reported to decline at an annual rate of approximately 1% to 2%, but strength declines at 1.5% per year and accelerates to as much as 3% per year after age 60.² These rates are high in sedentary individuals and twice as high in men as compared to women.³ However, men, on average, have larger amounts of muscle mass and shorter survival than women, which implies that sarcopenia is potentially a greater public health concern among women than men. The current prevalence of sarcopenia in populations varies depending on the definition used, the limitations of past epidemiologic and clinical data from small samples, and mixed information from the different measurement techniques employed. In the New Mexico Elder Health Survey, sarcopenia affects about 20% of men between age 70 and 75 years, about 50% of those over age 80 years, and between 25% and 40% of women have sarcopenia in the same age ranges.⁴ However, Baumgartner later recognized that these estimates, which were based on a bioelectric impedance equation, might be biased and published revised prevalence estimates based on dual-energy x-ray absorptiometry (DEXA) ranging from 8.8% in women and 13.5% men aged 60 to 69 years, and up to 16% in women and 29% in men older than 80 years.⁵ In a healthy elderly community-dwelling population 70 years of age and older in the French Epidemiologie de l'osteoporose (EPIDOS) study, only 10% of the women had sarcopenia⁶ based on the Baumgartner's index, but cut points derived from a different reference group. Using a similar definition, Janssen reported, retrospectively, that 35% of the elderly in the population-based National Health and Nutritional Examination Survey III (NHANES III) had a moderate degree of sarcopenia and 10% a severe degree of sarcopenia.⁷ Findings from a separate study by Melton et al using yet another definition suggests that sarcopenia affects 6% to 15% of persons over the age of 65 years.⁸

OPERATIONAL DEFINITION OF SARCOPENIA

Despite the recognition of the need for a consensus operational definition of sarcopenia since 1995⁹ and the relative

agreement among clinicians and epidemiologists on a theoretic definition of sarcopenia, development of a consensus operational definition useful across clinics, studies, and populations is still lacking.

The quantitative approach

Baumgartner et al⁴ summed the muscle mass of the four limbs from a DEXA scan as appendicular skeletal muscle mass (ASM) and defined a skeletal muscle mass index (SMI) as ASM/height² (as kg/m²). Individuals with a SMI two standard deviations below the mean SMI of a middle-age reference male and female population from the Rosetta study³ were defined as gender-specific cut points for sarcopenia. Several authors have used this definition.^{4,6,8} A limitation may be the ability of DEXA to distinguish water retention or fat tissue infiltration within muscle or soft tissue. There are few published data to date, however, for the impact of variation in these on sarcopenia prevalence estimates. Chen et al¹⁰ and others¹¹ reported strong correlations ($r > 0.94$) between DEXA and magnetic resonance imaging (MRI) measures of skeletal muscle mass, indicating that this increasingly available method is useful for cross-sectional studies and screening. Another potential limitation is that this approach does not account for the joint effects of fat mass or body weight. Most obese adults have increased muscle mass in addition to a high fat mass but a low muscle mass in relation to their total body weight, whereas thin elderly have a high proportion of muscle mass in relation to their total body weight. Thus, the SMI potentially misclassifies the obese elderly with a high SMI and mobility and functional limitations and the thin elderly with a low SMI and none or a few mobility or functional limitations. Some investigators have taken a different approach and tried to build control for fat mass or body weight into the index, rather than adjusting statistically for these when analyzing associations with other variables.^{5,12}

Recently, Janssen et al used data from the National Health and Nutrition Survey III to try to improve prevalence estimates in the United States. In addition, receiver operating curves were used to determine the sex-specific skeletal mass cut point below which the risk of physical disability significantly increased.⁷ Women whose SMI was below 5.75 kg/m² muscle mass had an increased risk for physical disability (OR = 3.31, 95% CI; 1.91–5.73) and men whose SMI was below 8.50 kg/m² had an increased risk for physical disability (OR = 4.71, 95% CI; 2.28–9.74). As note earlier, a limitation of current methods of measuring muscle mass in defining sarcopenia is systematic errors introduced by the age-related increase in fatty infiltration of muscle tissue. Intramuscular adipose tissue infiltration, measured by MRI¹³ and computed tomography (CT), improves our understanding of fat infiltration and muscle tissue impairment, but they are costly and often inaccessible. Ultrasound can accurately measure cross-sectional thicknesses and areas in subcutaneous adipose and muscles tissues,^{14,15} and bioelectrical impedance can provide estimates of muscle mass, but these can have large errors and are sample and population specific.¹⁶ Anthropometry has been used with limited success to detect sarcopenia in ambulatory settings. Changes

in body weight loss are insufficient because an increase in fat mass can obscure a loss in muscle tissue leading to the condition referred to as *sarcopenic obesity*.⁴

The qualitative approach

The main effect from a loss of muscle mass is reduced muscle strength, which is an important factor to consider in defining sarcopenia. Muscle strength is measured with simple and complex equipment. Grip strength is a simple estimator of total muscle strength but is not useful in those with hand arthritis. Leg muscle strength, assessed as maximal lower extremity muscle strength or power, is a good measure of functional status, but it is properly measured with a dynamometer (e.g., Biodex or Kin Com) by a trained technician and is strongly associated with measures of mobility.¹⁷ Including a measure of muscle strength in an operational definition is logical, as several authors have reported that muscle strength, more than muscle mass, is independently associated with physical performance.¹⁸ Moreover, different factors, such as physical activity or hormones, can underlie and contribute in varying degree to the loss of muscle strength and loss of muscle mass. The loss of muscle quality, an important component of the definition of sarcopenia, supposes an assessment of both muscle strength and muscle mass.

Muscle power is strongly related to functional limitation more than muscle mass or muscle strength.¹⁹ Muscle power is strength multiplied by speed, and it is defined as muscle work (muscle strength multiplied by a distance) divided by time. Muscle power declines considerably with aging and at a higher rate than muscle strength. A muscle power assessment is probably closer to a theoretic definition of sarcopenia than muscle strength alone, but muscle power does not include a quantitative measure. Using muscle power to define sarcopenia²⁰ could include muscle contraction speed and a measure of muscle quality in addition to muscle strength. Defining sarcopenia on muscle strength or muscle power only has several other limitations. Osteoarthritis and other comorbidities common with old age can induce underestimates of strength and power from pain affecting individual performance. Loss of muscle strength in the upper or lower limbs can have separate causes and be associated with different outcomes. Moreover, isokinetic, isometric, concentric, and eccentric muscle strength represent different aspects of muscle strength that are probably not affected at the same level during the process of sarcopenia.

Research is needed to validate the parameters (muscle mass, muscle strength, muscle quality) that could be used to define sarcopenia. An operational definition of sarcopenia should include components that contribute to physical function, but these components may be under different mechanisms or treated by different approaches. However, estimates of the prevalence of sarcopenia in populations with complex and variable combinations of muscle mass, strength, and power measurements have not yet been proved. Moreover, a clinical tool may not be useful in epidemiology, and vice versa.

ETIOLOGY OF SARCOPENIA

Multiple risk factors and mechanisms contribute to the development of sarcopenia. Lifestyle behaviors such as physical inactivity, poor diet, and age-related changes in hormones and cytokine levels are important risk factors. Postulated

mechanisms include alterations in muscle protein turnover, muscle tissue remodeling, the loss of alpha-motor-neurons, and muscle cell recruitment and apoptosis.²¹ Genetic susceptibility also plays a role and explains individual and group differences in rates of sarcopenia. The relative influences of these factors on sarcopenia components such as muscle mass, muscle strength, and muscle quality are not well understood.²² Each factor in the etiology and pathogenesis of sarcopenia potentially contributes differently to the loss of muscle mass, strength, or quality.

Lack of physical activity

Inactivity is an important contributor to the loss of muscle mass and strength at any age.^{23–25} Inactivity results from bed rest studies indicate that a decrease in muscle strength occurs before a decrease in muscle mass,²⁶ and low levels of physical activity result in muscle weakness that, in turn, results in reduced activity levels, loss of muscle mass, and loss of muscle strength. Thus, physical activity should be protective for sarcopenia, but some studies suggest that the amount of protection depends on the type of activity.

Loss of neuromuscular function

The neurologic contribution to sarcopenia occurs through a loss of alpha motor-neuron axons.²⁷ Decreased electrophysiologic nerve velocity, related to the dropout of the largest fibers, reduces internodal length and segmental demyelination occurs with the aging process,² but the role of demyelization in sarcopenia seems minor.²⁸ The central drive that contributes to a decrease in voluntary strength is supposed to be preserved. The progressive denervation and reinnervation process observed during aging and resulting in fiber type grouping is the potential primary mechanism involved during the development of sarcopenia. From cross-sectional findings, the decline in motor neurons starts after the seventh decade with a loss of alpha motor neurons in the order of 50%,²⁹ and this affects the lower extremities with their longer axons more than the upper limbs.² The reduction in alpha motor-neuron number and in motor unit numbers results in a decline in coordinated muscle action and a reduction in muscle strength. Reinnervation contributes to the final differentiation of nerve fibers and the repartition between the type I fibers (slow, oxidative fibers) and the type II fibers (fast, glycolytic fibers).

During aging, the number of satellite cells and their recruitment ability³⁰ decrease with a greater decrease in type II than type I fibers. Satellite cells are myogenic stem cells that can differentiate to new muscle fibers and new satellite cells if activated during the process of regeneration,³¹ but this regeneration may lead to imbalance, and the number of type II muscle fibers may decline following damage.

Altered endocrine function

There is evidence linking age-related hormonal changes to the loss of muscle mass and muscle strength. However, controversy persists regarding their respective roles and effects on skeletal muscle in adulthood and old age.

INSULIN

Sarcopenia may be accompanied by a progressive increase in body and intramyocellular fat mass, which are associated with an increased risk of insulin resistance.⁸ Insulin's

role in the etiology and pathogenesis of sarcopenia could be important even if its effect on muscle synthesis remains controversial.^{32–34} Insulin selectively stimulates skeletal muscle mitochondrial protein synthesis,³⁵ but it is unclear if the anabolic effect of insulin on muscle synthesis is impaired with advancing age.

ESTROGENS

There are conflicting data on the effects of estrogens on sarcopenia. Epidemiologic and interventional studies suggest that estrogens prevent the loss of muscle mass,^{22,36} as their decline with age increase the levels of proinflammatory cytokines suspected to be involved in the sarcopenia process such as tumor necrosis factor alpha (TNF- α) and interleukin 6 (IL-6).³⁷ Estrogens also increase the level of sex hormone-binding globulin, which reduces the level of serum-free testosterone, thus hormone replacement therapy (HRT) should decrease rather than increase muscle mass.³⁸ Both these mechanisms may play a marginal role involving estrogen during the development of sarcopenia.

GROWTH HORMONE AND INSULIN-LIKE GROWTH FACTOR 1

Insulin-like growth factor-1 (IGF-1) and growth hormone (GH) decline with age³⁹ and are potential contributors to sarcopenia. GH replacement therapy lowers fat mass, increases lean body mass, and improves blood lipid profile. IGF-1 activates satellite cell proliferation and differentiation and increases protein synthesis in existing fibers.⁴⁰ There is also evidence that IGF-1 acts in muscle tissue by interacting with androgens,⁴¹ but there are conflicting results on its effect on muscle strength despite the apparent increase in muscle mass.^{42,43}

TESTOSTERONE

Testosterone levels gradually decrease in elderly men at a rate of 1% per year, and epidemiologic studies suggest a relationship between low levels of testosterone in elderly men and loss of muscle mass, strength, and function. The increase in sex hormone-binding globulin levels with age results in lower levels of free or bioavailable testosterone. Clinical and experimental studies support the hypothesis that low testosterone levels predict sarcopenia with low testosterone resulting in lower protein synthesis and a loss of muscle mass.⁴⁴ Testosterone induces in a dose-dependent manner an increase numbers of satellite cells, which is a major regulating factor of satellite muscle cell function.⁴¹ When administered to hypogonadal subjects or elderly subjects with low levels, testosterone⁴⁵ increased muscle mass, muscle strength, and protein synthesis. Despite evidence that dehydroepiandrosterone (DHEA) supplementation results in an increase of blood testosterone levels in women and an increase of IGF-1 in men, few studies have reported an effect on muscle size, strength, or function.⁴⁶

VITAMIN D AND PARATHYROID HORMONE (PTH)

With aging, 25-OH vitamin D levels decline. Several cross-sectional studies have reported the association between low 1,25-OH vitamin D and low muscle mass, low muscle strength, decreased balance, and increased risk of falls.^{47,48} One recent longitudinal epidemiologic study reported an independent association between low serum vitamin D and sarcopenia.⁴⁹ Nuclear 1,25-OH vitamin D receptor has been

described in muscle cells,⁵⁰ and low levels of vitamin D have been shown to decrease muscle anabolism. Low vitamin D may also influence muscle protein turnover through reduced insulin secretion. Low levels of vitamin D are associated with raised PTH, but previous studies suggest that high PTH is also independently associated with sarcopenia.^{22,49}

High level of cytokines

Chronic medical conditions, such as chronic obstructive pulmonary disease (COPD), heart failure, and cancer, are highly prevalent in elderly and are associated with an increased serum level of proinflammatory cytokines and loss of body weight, including lean mass. This condition can occur in younger adults or elderly persons and is called cachexia. This acute hypercatabolism differs from the long-term age-related process that leads to sarcopenia. However, aging is also associated with a more gradual, chronic, increased production of proinflammatory cytokines, particularly IL-6 and IL-1, by peripheral blood mononuclear cells. There is some evidence that increased fat mass and reduced circulating levels of sex hormones with aging contribute to this age-related increase in proinflammatory cytokines that constituted catabolic stimuli.⁵¹ Thus, the aging process itself is associated with increased catabolic stimuli, but there is still a lack of evidence for the hypothesis that cytokines predict sarcopenia in prospective studies.^{22,52,53} Nevertheless, sarcopenia is one of the outcomes of cytokine-related aging process.⁵⁴

Obesity is linked to inflammation⁵⁵ and may have an important role in the process leading to sarcopenia.²¹ Being both obese and sarcopenic is a condition named *sarcopenic obesity*.⁵⁶ Sarcopenic obesity has been reported to predict the onset of disability more than sarcopenia or obesity alone. This condition occurs in about 6% of the community-dwelling elderly and to about 29% of men and 8.4% of women over 80 years of age. It has been hypothesized that sarcopenic obesity is associated with increased fatty infiltration of muscle, but confirmatory data are lacking. Fatty infiltration of skeletal muscle is associated with reduced strength^{57,58} and functional status, and it is hypothesized that infiltration affects muscle function.⁵⁸ These findings suggest a role of fat mass in the etiology of sarcopenia.

Mitochondrial dysfunction

The role of mitochondrial dysfunction in sarcopenia is currently controversial.⁵⁹ Mitochondrial function may be affected by the cumulative damage to muscle mitochondrial DNA (mtDNA) observed with aging. This may result in a reduction of the metabolic rate of muscle cell protein synthesis, adenosine triphosphate synthesis⁶⁰ and finally to the death of the muscle fibers and the loss of muscle mass.^{61,62} However, low physical activity could be the primary reason for mitochondrial dysfunction in the elderly. Some investigators report that the decline in mitochondrial functions with aging of can be attenuated by physical activity.⁶³ Others report that mitochondrial impairment is only partially reversed after physical training, but it does not reach the level of improvement observed in young.^{62,64,65}

Apoptosis

Accumulated mutations in muscle tissue mitochondrial DNA are associated with accelerated apoptosis of myocytes, and apoptosis may also be the link between mitochondria

dysfunction and loss of muscle mass. Evidence suggests that myocyte apoptosis is a basic mechanism underlying sarcopenia,⁶⁶ and muscle biopsies of older persons show differences associated with apoptosis⁶⁷ compared with younger subjects. Reports also suggest that type II fibers (those fibers preferentially affected by the sarcopenia phenomenon) may be more susceptible to death via the apoptotic pathway.⁶⁸

Genetic influence

Genetic factors are major contributors to variability in muscle strength and likely contribute to susceptibility to sarcopenic agents. Genetic epidemiologic studies suggest that between 36% and 65% of an individual's muscle strength,⁶⁹ 57% of lower extremity performance⁷⁰ and 34% of the ability to perform the activities of daily living (ADL)⁷¹ are explained by heredity. Sarcopenia and poor physical performance in elderly are also associated with birth weight in both men and women independent of adult weight and height, which suggests that exposures very early in life may additionally program risk for sarcopenia in old age in genetic susceptible individuals.^{72,73}

Few studies have explored potential candidate genes determining muscle strength. In an analysis of the myostatin pathway, a possible muscle mass regulator, linkage was observed to several areas. Several genes were implicated as positional candidate genes for lower extremity muscle strength.^{69,74–76} The actinin alpha 3 (ACTN3) R577X genotype is of interest, as it has been shown to influence knee extensor peak power in response to strength training as has a polymorphism in the angiotensin-converting enzyme (ACE) gene.^{74,77} Also, polymorphisms in the vitamin D receptor (VDR) may be associated with muscle strength because of the relationship between vitamin D and its known effect on both smooth and striated muscle.⁷⁸ Polymorphisms in the VDR have been associated with sarcopenia in elderly men,⁷⁹ muscle strength and body composition in premenopausal women,⁸⁰ and muscle strength in older women.⁸¹

Low nutritional intake and low protein intake

Muscle protein synthesis rate is reported to be reduced 30% in the elderly, but there is controversy as to the extent to which this reduction is due to nutrition, disease, or physical inactivity rather than aging.^{82,83} It is recognized by some that protein intake in elders should exceed the 0.8 g/kg per day recommend intake.⁸⁴ Muscle protein synthesis is also decreased in fasting elderly subjects, especially in specific muscle fractions like mitochondrial proteins,⁸⁵ and thus, the anorexia of aging and its underlying mechanisms contribute to sarcopenia by reducing protein intake.

Muscle protein synthesis is directly stimulated by amino acid and essential amino acids intake,⁸⁶ and protein supplementation has been explored in the prevention of sarcopenia. However, many interventional studies have not reported a significant increase muscle mass or protein synthesis with a high protein diet even when accompanied by resistance training.^{87–89} The lack of effect of protein intake on protein synthesis stimulation may have several explanations.³⁸ A higher splanchnic extraction of dietary amino acids has been already reported.⁹⁰ This could limit the delivery of dietary amino acids to the peripheral skeletal muscle.

CONSEQUENCES OF SARCOPENIA

Increased clinical and epidemiologic interest in sarcopenia is related to the hypothesis that age-related loss of muscle mass and strength results in decreased functional limitation and mobility disability among the elderly (Figure 73-1). Sarcopenia also plays a predominant role in the etiology and pathogenesis of frailty, which is highly predictive of adverse events such as hospitalization, associated morbidity, and disability and death.⁹¹ The annual health care cost attributable to sarcopenia is estimated at \$18 billion in the United States alone.⁹² Several epidemiologic cross-sectional studies have documented associations between low skeletal muscle mass and physical disability⁷ or low physical performance,⁵⁸ with the level of disability two to five times higher in the sarcopenic groups. Sarcopenia also results in decrease in muscular strength and endurance.⁹³ Then, we can speculate that sarcopenia is a predictor of disability in the elderly, but very few longitudinal studies^{7,94,95} have demonstrated that sarcopenia predicts disability and have reported little or no effect of sarcopenia on mobility disability.^{94,95} This weak association between sarcopenia and the risk of disability suggests that disability can result in cases of sarcopenia (see Figure 73-1).

Relationship between sarcopenia and physical performance

Part of the theoretic model for sarcopenia potentially involves the positive association between muscle mass and strength and in improved functional performance and reduced disability. The relationship between muscle mass and strength is linear,⁹⁶ but the relationship between physical performance (such as walking speed) and muscle mass is curvilinear⁹⁷ (Figure 73-2). Thus, a threshold defining the amount of muscle mass under which muscle mass predicts poorer physical performance and physical disability should be detectable, but a specific threshold may exist for each physical task. The relationships among strength, muscle

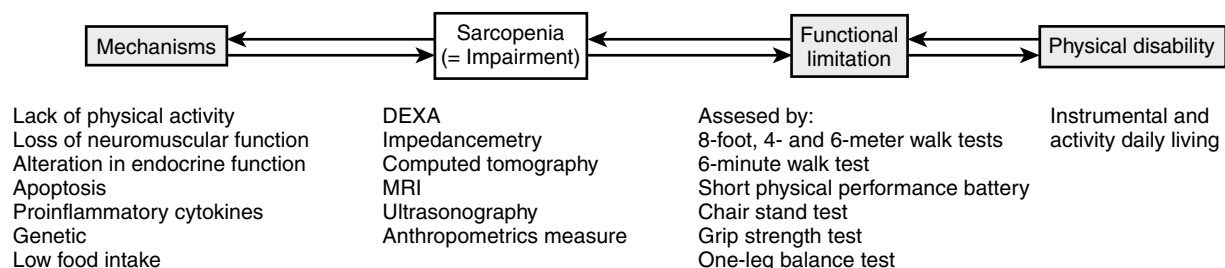

Figure 73-1. Sarcopenia and the disability process.

Figure 73-2. Relationship between muscle mass, muscle strength, and physical performances.

mass, and function have important implications regarding the selection of therapeutic approaches. An increase in muscle mass and strength in the healthy elderly could have little effect on a specific physical performance, but a small increase in muscle mass among sarcopenic elderly could result in a significant increase in physical performance despite a relatively small increase in muscle strength. An increase in muscle mass may have no effect on walking speed in the healthy elderly but a significant impact in very frail. However, differences in functional outcomes and population characteristics are major determinants in the success of interventional studies on sarcopenia, and these differences are attributable, in part, to these methodological considerations.

Treatment and future perspectives

Sarcopenia is treated currently with pharmacologic treatment and lifestyle interventions. Considerable evidence suggests that sarcopenia is a reversible cause of disability and could benefit from intervention, especially at the early stage of sarcopenia.^{98–100} However, the effects and ability of these interventions to improve function and prevent disability and reduce the age-related skeletal muscle decline in elderly are unknown.

In treatment for sarcopenia, it could be argued that improving muscle strength or muscle power is more relevant clinically for the outcomes of disability or mobility than increasing muscle mass; however, increasing muscle mass is more important for other outcomes such as protein stores or thermogenesis. The notion that muscle strength and muscle mass are differentially affected by various treatment modalities is supported by experimental and clinical findings.²² Although behavioral treatments, such as exercise, increase muscle mass and strength, pharmacologic treatments, such as growth hormone, increase mass without a significant change in strength.

Physical activity

No pharmacologic or behavioral intervention to reverse sarcopenia has proved to be as efficacious as resistance training. Muscle mass, strength, and muscle quality (strength adjusted for muscle mass) are reported to improve significantly with resistance training in older people.¹⁰¹ Robust evidence in several studies indicates that resistance training such as weight lifting increases myofibrillar muscle protein synthesis,^{102,103} muscle mass, and strength,^{30,89,104–109} even in the frail elderly. Strength gains result from a combination of improved muscle mass and quality and neuronal adaptation (innervations, activation pattern). However, sarcopenia is observed in master athletes who maintain resistance training activities throughout their lifetimes.^{110,111}

The American College of Sport Medicine (ACSM) and the American Heart Association (AHA) suggested that training at a 70% to 90% of 1-RM (maximal repetition) on two or more nonconsecutive days per week was the appropriate training intensity to produce gains in muscle size and strength, even in frail elderly.^{112,113} Resistance training in elderly increases strength that is low in absolute terms but similar relative to muscle mass, but the increased muscle size is relatively moderate (between 5% and 10%) compared to the increase in muscle strength. Most of the increase in strength is in neural adaptation of the motor unit pathway,² but disuse results in a rapid detraining.¹¹⁴ Several reports suggest that maintaining the benefits from resistance training is possible with as little as one exercise program per week.¹¹⁵

Whether aerobic training can reduce, prevent, or treat sarcopenia is an important practical question because resistance training is less appealing to many sedentary elders. Aerobic exercise does not contribute as much to muscle hypertrophy as resistive exercises, but it stimulates muscle protein synthesis,¹¹⁶ satellite cell activation, and increased muscle fiber area.¹¹⁷ A possible important aspect of aerobic exercises is that they reduce body fatness, including intramuscular fat, which is important for improving the functional role of muscle relative to body weight.

Leisure physical activity is not enough to prevent the decline in muscle mass,¹¹⁸ but aerobic and resistance activities improve balance, lessen fatigue, increase pain release, reduce cardiovascular risk factors, and improve appetite. Thus, promoting an active lifestyle can prevent the functional effects of sarcopenia, but resistance training is the best approach to prevent and treat sarcopenia, although both training modalities contribute to the maintenance and improvement of muscle mass and strength in the elderly.

Nutrition

In malnourished elderly persons, poor protein intake is a barrier to gains in muscle tissue and strength from interventions such as resistance training. Increasing protein intake in elderly and especially in frail elderly can minimize the sarcopenic process.¹¹⁹ However, it is not clear if protein supplementation in the absence of malnutrition enhances muscle mass and muscle strength, as protein supplementation alone or in association with physical training has proved unsuccessful.¹¹³ New approaches, based on specific nutrients, including essential amino acids (leucine),¹²⁰ suggested an anabolic effect.¹²¹ It has been reported that essential amino acids stimulate protein anabolism in elderly, whereas nonessential amino acids had no effect in association to essential amino acids.^{86,122} The acute muscle protein synthesis in response to resistance training and essential amino acids ingestion is similar in old and young subjects but delayed in older subjects.¹²² In supraphysiologic concentration, leucine stimulates muscle protein synthesis,¹²⁰ which may be related to a direct effect of leucine on the initiation of mRNA translation, and amino acid supplements are ineffective for muscle protein synthesis if they do not contain sufficient leucine.¹²³ The quantity and quality of amino acids in the diet are important factors for stimulating protein synthesis, and nutritional supplementation with whey proteins, a rich source of leucine, is a possible safe strategy to prevent sarcopenia.^{124,125} However, caloric restriction can prevent the loss of muscle mass in animal and supposedly some human studies.^{126,127}

The schedule of the protein supplementation is relevant to improve muscle protein synthesis. A large amount of amino acid supplementation in one meal per day is more efficient in increasing the anabolic effect than intermittent protein intake.¹²⁸ The anabolic effect of protein supplementation may be maximized with a large amount of a highly efficient nutritional supplement (such as essential amino acid and especially leucine) once a day. Another way to optimize postprandial protein anabolism is to administer "fast" protein (i.e., quickly digested protein by analogy with "fast" carbohydrate concept), which is an interesting nutritional strategy.^{129,130} However, no randomized clinical trial actually supports the benefits of this specific approach on muscle mass synthesis.

Prevention of sarcopenia should occur throughout life. The possible influence of specific exposures at critical development periods may have a major impact on the risk of sarcopenia in old age.^{72,131} An adequate diet in childhood and young adulthood affects bone development, and calcium maintenance is required throughout life, thus the same appears to be a reasonable lifestyle and treatment regime for sarcopenia.

Testosterone

About 20% of men older than 60 years and 50% of men older than 80 years are considered hypogonadic.¹³² There are conflicting and inconclusive results of the effectiveness of testosterone therapy on muscle mass and muscle strength in elderly. Testosterone increases muscle mass and strength at supraphysiologic doses in young subjects under resistance training,¹³³ but such dose levels are not administered in the elderly. Some interventional studies report a modest increase in lean mass and most report no increase in strength.¹¹³ For the few studies that report an increase in strength, the magnitude was lower than through resistance training. Moreover, the anabolic effect of testosterone on lean mass and strength seems weaker in the elderly than in young.¹¹³ A recent meta-analysis indicated that there is a moderate increase in muscle strength among men participating in 11 randomized studies (with one study influencing the mean effect size).¹³⁴ Studies of DHEA have also reported no change in muscle strength.¹¹³

Testosterone is currently not recommended for the treatment of sarcopenia, and side effects associated with other androgens limit their use also. The potential risks associated with testosterone therapy (e.g., increased level of prostate-specific antigen, hematocrit, and cardiovascular risks) compared to the low level of evidence concerning the benefits on physical performances and function explain the actual recommendations.¹³⁵ High doses of testosterone have not been given in randomized controlled trial (RCT) for fear of prostate cancer,¹³⁶ and sense data from the Baltimore Longitudinal Study on Aging report a positive correlation between free testosterone blood level and prostate cancer.¹³⁷

Growth hormone

GH increases muscle strength and mass in young subjects with hypopituitarism, but in the elderly, who are frequently GH-deficient, most studies report that GH supplementation does not increase muscle mass or strength,¹¹³ even in association with resistance training.^{113,138} GH increases mortality rate in ill and malnourished persons,¹³⁹ and potential serious and

frequent side effects such as arthralgia, edema, cardiovascular side effect, and insulin resistance occur with GH supplementation.⁴³ To date, there is little clinical research support for the use of GH supplementation in the treatment of sarcopenia. Previous observations examining the association of IGF-1 with muscle strength and physical performance in older populations provide conflicting results.¹⁴⁰ Interestingly, in a study among obese postmenopausal women, the administration of GH alone or in combination with IGF-1 caused a greater increase in fat-free mass and a greater reduction in fat mass than those achieved by diet and exercise alone.¹⁴¹ However, safety issues limit the clinical applications of these findings. Some studies have found that IGF-1 correlates with risk of prostate cancer in men, premenopausal breast cancer in women, and lung cancer and colorectal cancer in both men and women.¹⁴²

Myostatin

Myostatin is a recently discovered natural inhibitor of muscle growth,¹⁴³ and mutations in the myostatin gene result in muscle hypertrophy in animals and in humans.^{144,145} Antagonism of myostatin enhanced muscle tissue regeneration in aged mice¹⁴⁵ by increasing satellite cell proliferation. New approaches such as antagonist of myostatin drug may be relevant to the treatment of sarcopenia in the future.^{146–148}

Estrogens and tibolone

A review on the effect of estrogen and tibolone on muscle strength and body composition¹⁴⁹ reports an increase in muscle strength, but only tibolone appears to increase lean body mass and decrease total fat mass. Tibolone is a synthetic steroid with estrogenic, androgenic, and progestogenic activity. HRT and tibolone may both react with the intranuclear receptor in the muscle fibers,^{150,151} and tibolone may also act by binding androgen receptors in the muscle fibers and increasing free testosterone and GH. However, further research is needed to confirm these findings and the long-term safety of these drugs in the elderly population. In fact, no study has currently confirmed the positive findings in older persons.

Vitamin D

Vitamin D supplementation between 700 and 800 IU per day reduces the risk of hip fracture (and any nonvertebral fracture) in community-dwelling and nursing home elderly¹⁵² and the risk of falls.⁴⁸ The underlying mechanism may be the increased muscle strength. Janssen et al reported an histologic muscle atrophy, predominantly type II fibers, in vitamin D deficiency.¹⁵³ Whether vitamin D prevents sarcopenia remains to be proved, but the relationship of vitamin D and calcium on muscle mass and function in the elderly is another important area for research.

Angiotensin II converting enzyme inhibitors (ACE inhibitors)

Growing evidence suggests that ACE inhibitors may prevent sarcopenia.^{119,154,155} Activation of the renin-angiotensin-aldosterone system may be involved in the progress of sarcopenia. Angiotensin II infused in rats results in muscle atrophy,¹⁴⁶ and several mechanisms such as influences on oxidative stress, metabolic, and inflammation pathway have been suggested through epidemiologic and experimental studies. ACE inhibitor reduces the level of angiotensin II in

vascular muscle cell, and angiotensin II may be a risk factor for sarcopenia through the related increase in proinflammatory cytokine production. ACE inhibitors may also improve exercise tolerance via changes in skeletal muscle myosin heavy chain composition.¹⁵⁶ The ACE gene polymorphism also affects the muscle anabolic response and muscular efficiency after physical training.¹⁵⁷

Cytokine inhibitors

The age-related inflammation process is supposed to be an important factor in the development of sarcopenia, and anti-inflammatory drugs may delay its onset and progression. Cytokine inhibitors, such as thalidomide, increase weight and lean tissue anabolism in AIDS patients.¹⁵⁸ TNF- α produces muscle tissue atrophy in vitro. Anti-TNF- α antibodies, a treatment provided to rheumatoid arthritis patients, may also be an alternative therapeutic opportunity for sarcopenia.¹⁵⁹ However, the benefit/risk balance of these drugs is a major limitation that has not yet been tested in sarcopenic patients. Epidemiologic data also suggest that fatty fish consumption rich in the anti-inflammatory actions of omega-3 fatty acid may prevent sarcopenia.¹⁶⁰

Genes

Many genetic factors contribute to muscle mass and strength.^{161,162} Treatment based on the basic physiopathology of sarcopenia can be expected in the future.¹⁶³ Understanding the fundamental pathways leading to sarcopenia, such as the expression pattern of genes and proteomics, will probably determine future treatment strategies.

Apoptosis

Our understanding of the mechanisms of apoptosis suggests that caspase inhibitors may represent a possible future therapy.¹⁶⁴ Apoptosis may be reversible. For instance, exercise training reverses the skeletal muscle apoptosis and caloric restriction reduce apoptosis pathway stimulated by TNF- α .^{127,165} Redox modulators such as carotenoids¹⁶⁶ seem to be important factors in influencing loss of muscle strength, functional limitation, and disability. Interest in all these molecules is actually suggested by basic research but may be studied in future clinical researches.

CONCLUSION

Improved understanding and treatment of sarcopenia would have a dramatic impact on improving the health and quality of life for the elderly, reducing the associated comorbidity and disability and stabilizing rising health care costs. However, continued research is needed to develop a consensus operational clinical definition of sarcopenia applicable in clinical management and clinical and epidemiologic

research across populations. Sarcopenia is a complex multifactorial condition, the interrelated underpinnings and onset of which are difficult to detect and poorly understood. Thus, a comprehensive approach to sarcopenia requires a multimodal approach. Reducing the loss of muscle mass and muscle strength is relevant if the decrease in physical performances and increase in disability are affected. Defining target elderly populations for specific treatments in clinical trials is an important issue if the findings and their interpretation are to be inferred to other groups and populations of elderly individuals. An important clinical end point should be the prevention of mobility disability along with reducing, stopping, or reversing the loss of muscle mass, muscle strength, or muscle quality.

Currently, resistance strength training is the only treatment that affects the muscle aspects of sarcopenia. There are no pharmacologic approaches that provide definitive evidence in the ability to prevent the decline in physical function and sarcopenia. Current and future pharmacologic and clinical trials and epidemiologic studies could radically change our therapeutic approach to understanding and treating mobility disability in elderly.

KEY POINTS

Sarcopenia

- Definition of sarcopenia includes a loss of muscle strength and functional quality in addition to the loss of muscle protein mass.
- Sarcopenia affects about 20% of men between age 70 and 75 years, about 50% of those over age 80 years, and between 25% and 40% of women have sarcopenia in the same age ranges.
- A consensus operational definition of sarcopenia that is useful across clinics, studies, and populations is still lacking.
- Multiple risk factors and mechanisms contribute to the development of sarcopenia.
- Lifestyle behaviors, poor diet, and age-related changes in hormones and cytokine levels are important risk factors.
- The relationships among strength, muscle mass, and function have important implications in research and clinics.
- Evidence suggests that sarcopenia is a reversible cause of disability and could benefit from intervention.
- Muscle mass, strength, and muscle quality improve significantly in older people who participate in resistance training.
- No pharmacologic approaches provide definitive evidence in the ability to prevent sarcopenia.

With population aging continuing to accelerate, particular attention must be paid to the multiple and complex disorders that impair functional independence and compromise quality of life of older adults. One of the most important and sometimes overlooked topics is that of proper foot health and function. Estimates of the prevalence of foot pain among community-dwelling older adults range between 36% and 70%, depending on definitions and populations studied.¹ Foot pain can easily jeopardize an individual's ability to perform many of the important instrumental activities of daily living, including cooking, shopping, housekeeping, doing laundry, and using transportation. Even so, as few as one third of older adults with disabling foot pain report receiving professional foot treatment.²

Foot pain in older adults may be caused by changes in gait, hereditary problems, or previous foot conditions that were not treated or treated inadequately. Changes in mental status, nutritional deficiencies, systemic and local disease, hospitalization and confinement to bed, polypharmacy, and other common elderly life situations may complicate the picture.

The myriad of changes associated with aging results in a diminished homeostatic reserve, commonly manifested with loss of ambulation. The ability of an individual to remain ambulatory may be the only dividing line between institutionalization and remaining an active and viable member of society.

Proper foot care must be provided for elderly patients in an attempt to promote pain-free ambulation. The consequences of immobility in this age group (bladder infections, pulmonary problems, and venous thrombosis) certainly underscores this point. Podiatric problems are often preventable or readily treatable. Podiatric care is just part of the comprehensive and interdisciplinary nature of geriatric medicine. Of note, it is coming under the same scrutiny as other areas, with a controlled trial of a multifaceted podiatry intervention now under way.³

In this chapter, the diagnosis, treatment, and prevention of common pedal problems are discussed.

ORTHOPEDIC/BIOMECHANICAL DISORDERS

Lower extremity joint impairment and painful foot disorders also represent major causes of treatable gait disturbances. Heel pain is a common complaint of older individuals, especially as the older population exercises more. Recent weight gain, increased walking or standing activities, hard floors or surfaces, and biomechanical abnormalities are the factors that predispose to the development of plantar calcaneal pain. Plantar calcaneal spurs (diagnosed by a lateral radiograph of the foot) are often aggravated by an atrophied fat pad. Conservative treatment includes rest, stretching exercises, nonsteroidal anti-inflammatory drugs (NSAIDs), and biomechanically sound footwear, such as a sneaker or running shoe, with a thick shock-absorbing insole. Viscoelastic heel cushions or heel cups (available commercially) can be inserted into existing shoes to provide cushioning. Prescription custom-made orthoses may be indicated to support

the arch and to reduce traction of the plantar fascia from its origin on the calcaneus. Accordingly, shoe modification and orthoses are prescribed for the long term. Stretching of the Achilles tendon and plantar fascia may help diminish symptoms more rapidly. Recalcitrant cases may require a series of local injections (local anesthetic combined with a corticosteroid) into the area of maximum tenderness (usually the anteromedial tubercle of the calcaneus). Acute plantar heel pain can become a chronic condition, especially in patients who are overweight or have bilateral symptoms.⁴ When appropriate therapy fails to achieve expected results (especially within 3 to 6 months), one should consider systemic disease as a possible cause of heel pain. Diseases such as rheumatoid arthritis, ankylosing spondylitis, psoriatic arthritis, and Reiter's syndrome can also cause heel pain.

Another common musculoskeletal problem in elderly people, which is often misdiagnosed, is posterior tibial tendon dysfunction. Suspect this problem in a presentation of sudden asymmetry in arch height. There may be swelling and tenderness on palpation of the tendon insertion around the medial and plantar aspect of the navicular, and these findings often extend along the course of the tendon proximally behind the medial malleolus. If not already present, an actual tear or even rupture of the tendon may result. Orthotics can control minor cases, but depending on the level of activity of the patient and the degree of discomfort, custom-made braces or surgical correction may be the best option.

The joints of the feet are also prone to osteoarthritis. Diagnosed by limited and painful range of motion with or without crepitation, this condition usually responds well to conservative measures. Joint space narrowing on radiographs is often a late finding. Shoe modifications such as balanced inlay orthoses and a forefoot rocker sole angled to follow the progression of gait provide good local treatment. Topical preparations such as capsaicin (Zostrix) cream have been shown to relieve pain caused by degenerative joint disease and may augment NSAID therapy, which is the mainstay of treatment.

Joint pains from hallux valgus, hammer toes, and mallet toes are also common lower extremity problems in elderly people (see [Figure 74-1](#); see also [Color Plate 74-1](#)). The myth that these are caused by ill-fitting shoe gear is disproven by the studies of populations in the world who typically live their lives unshod. The same incidence of these deformities occur, pointing to a more biomechanical/genetic cause. Indeed, shoes aggravate these conditions and make them painful, with the development of corns and adventitious bursae. A hammer toe is one in which there is a flexion contracture at the proximal interphalangeal joint. An extensor contracture at the metatarsophalangeal joint may coexist. A mallet toe is contracted at the distal interphalangeal joint, and a claw toe is contracted at both. The most common problem associated with these deformities is the formation of corns dorsally over areas of prominence and medial and lateral, and interdigitally. If the above-mentioned conservative measures fail to alleviate the pain, surgical correction may be considered. Foot surgery can provide improvement of function and quality of life, even in the presence of chronic illnesses. Of course, a

Figure 74-1. A bunion deformity with hammer toe of the second digit. Note preulcerative lesion over proximal phalangeal joint of second toe secondary to shoe pressure.

prudent comprehensive surgical work-up in conjunction with the primary care physician, and an anesthesiologist, would be obligatory. Fortunately, many forefoot procedures require only local anesthesia and are done on an ambulatory basis.

Your examination should always include watching the patient walk. Gait disturbances are a common sequela of age-related changes in the central and peripheral nervous systems (see Chapter 105). Features of pathologically induced gait disturbances are frequently nonspecific and overlap with those of senile ataxia, giving little clue as to the primary pathology. In Parkinson's disease and cerebellar atrophy, gait characteristics are specifically helpful in establishing the diagnosis. Shuffling and abducted gaits also produce increased stress and pressure on the soft tissues leading to dermal lesions (see Dermatology section below).

It is important to search for an underlying cause in the physical assessment because approximately 25% of gait disturbances in older adults have a treatable cause.⁵ Serum studies may reveal vitamin B₁₂ deficiency, hypothyroidism, osteomalacia, or drug toxicity. Radiographic studies assist in excluding bone disease. Remember that stress fractures may not be evident at the time of injury. If signs and symptoms are consistent with fracture, treat as such and repeat the radiograph in 10 to 14 days. Computed tomography, magnetic resonance imaging, myelography, and electrophysiologic studies may offer a definitive diagnosis in cases of primary central nervous system pathology. Common causes of gait disorders include neurologic (cerebrovascular accident, dementia, Parkinson's disease, etc.), musculoskeletal (arthritis, osteoporosis, myopathy, etc.), vascular, endocrine (hypothyroidism, diabetes), psychological (depression, fear of falling), and medications. Demonstration of poor gait, difficulty with chair transfer, and a loss of balance when standing on tip-toes suggests an underlying neurologic or musculoskeletal disorder.⁶

DERMATOLOGIC DISORDERS

Hyperkeratotic lesions (corns and calluses) are the most common podiatric complaints of elderly people. They frequently arise in areas of increased pressure or friction

and over bony prominences. Although these conditions are common among all age groups, degenerative joint disease, atrophy of the plantar fat pad, and decreased pain threshold predispose elderly people to increased frequency of complaints. Depending on their depth and severity, there may be an associated adventitious bursa formation. Treatment consists of aseptic débridement and weight or pressure dispersion. Lesions on the plantar aspect of the foot should also be treated with a shock-absorbing insert to disperse the weight-bearing forces and augment an atrophic or displaced plantar fat pad.

It is especially important to débride chronic hyperkeratotic lesions in patients with vascular or neurologic impairment because untreated lesions may give rise to soft tissue breakdown, ulcerations, and bone infection. As noted earlier in this chapter, sneakers or running shoes are ideal foot-gear for biomechanical and dermatologic problems. A wide and high toe box is important for preventing pressure on the digits, and abundant cushioning on the sole of the foot is required to mitigate the excessive plantar pressures that cause the hyperkeratotic lesions.

Well-cushioned shoe gear is also required to mitigate the consequences of atrophied subcalcaneal or submetatarsal fat pads. When the natural fat found on the plantar aspect of the feet atrophies, the underlying bony structures become more prominent and cause pain. When such pain occurs under the plantar aspect of the metatarsal head, it is called metatarsalgia. The complaint is frequently a callus or inflammation of the area (bursitis). Diagnosis can be made by clinical examination, and radiographs may reveal underlying bone pathology. Treatment consists of débridement of hyperkeratotic lesions with padding to disperse the weight. Long-term treatment includes the use of soft tissue supplements such as plastizote, which can be added to foot orthotics or inserted directly into the shoe.

Expensive custom-molded shoes are often unnecessary for all but the most severe foot deformities. If they are indeed indicated, they should include a high, wide toe box, a bunion last, and an extra depth feature to accommodate weight-dispersive orthoses. Surgical correction should always be considered as the last resort, after all conservative measures have failed.

Maceration and fissuring of the interspaces is another common dermatologic finding in the elderly population. Vision and dexterity loss make it difficult to examine and care for the feet, and digital deformities precipitate moisture accumulation between the toes. The dark and moist environment between the toes predisposes the area to fungal and bacterial infection, which range from a mild annoyance to a severe debilitating infection. A Wood's light can be used to detect coral red fluorescence suggestive of *Corynebacterium minutissimum*, which is usually treated with topical erythromycin. Macerated toe web spaces may also be due to a fungal or yeast infection that can be treated with ciclopirox (Loprox) or clotrimazole solution (Lotrimin, Mycelex) applied interdigitally twice daily for 2 to 4 weeks. Of course, meticulous cleaning and drying of the area while bathing is also necessary. If lamb's wool or gauze is used to separate the toes, never encircle a digit; such dressings may become constrictive and severely compromise the circulation.

Interdigital tinea pedis (described previously), inflammatory tinea pedis, and chronic dry scaly tinea pedis are the three main categories of pedal dermatophyte infections.

Inflammatory tinea pedis, which is an acute vesicular eruption that has a particular predilection for the long arch, is caused by the dermatophyte *Trichophyton mentagrophytes*. It is usually severely pruritic, it may weep, and the severest of cases may require bed rest in addition to topical and/or oral antifungal therapy. The chronic form of tinea pedis, usually caused by *Trichophyton rubrum*, has a predilection for the arch as well, but is mainly confined to the lateral surfaces of the sole. Sometimes the entire plantar aspect is involved in what is classically described as a moccasin distribution. In contrast to the inflammatory type, these lesions are scaly and erythematous, and commonly display an arcuate shape.

There is also a decrease in skin hydration as aging progresses. Combined with diminished sebaceous and eccrine activity, dry, scaly, and hyperkeratotic skin often results. Peripheral heel hyperkeratosis is very common, but when fissures occur, severe pain and infection may ensue. This is a serious problem in the face of arterial insufficiency. Management includes débridement of the tissue, hydration of the skin, and avoidance of backless footwear. Chemical cautery with silver nitrate is often necessary to close a bleeding fissure. It is momentarily painful but works very effectively. Heel fissuring is more prevalent in the obese, and tends to be a chronic problem. In patients who have had total joint replacement, the presence of heel fissures should not be trivialized (see Figure 74-2).

Ulcerations of the leg, feet, and toes are also seen frequently in the geriatric population. The differential diagnosis of pedal ulcers includes arteriosclerosis obliterans, neurotrophic ulcers, chronic pernio, gout, mycobacterium tuberculosis, Raynaud's disease/phenomenon, scleroderma, and neoplasms, in addition to those caused by biomechanical, iatrogenic, or patient-induced diseases.⁷

Ischemic ulcers typically occur on the distal aspect of digits and over bony prominences. Symptoms include severe pain, often worse at night and relieved by dependency. They are characterized by poor granulation tissue, poor color of tissue (cyanotic, gray, or black), and poor bleeding upon débridement.

Neurotrophic ulcers commonly occur beneath pressure points or hyperkeratotic lesions. There is usually no pain because the patient is typically neuropathic. The ulcers are characterized by punched-out lesions with a red granular base and white fibrotic rim. Due to the high incidence of diabetic ulcers and their coexisting morbidity, this topic will be discussed thoroughly in a separate section within this chapter.

Figure 74-2. Severe xerosis causing fissuring of the heels.

Venous stasis ulcerations often follow chronic stasis dermatitis, which is secondary to incompetent venous circulation in the leg, as further described in Chapter 47. Poor arterial circulation is an added risk that will impair healing and increase the chance of infection.

Treatment of these ulcers must address their cause, and therefore requires a multidisciplinary approach. An ischemic ulcer requires a vascular consult as soon as possible, with possible revascularization. Neurotrophic ulcers require weight dispersion, débridement of devitalized tissue, and use of antibiotics when appropriate. Edema can be reduced with elevation of the foot (above heart level), and with compressive boots and stockings. Individuals with a history of venous stasis ulcers should wear elastic supports daily. Wound care must be performed regularly to ensure a clean, moist granular bed of the ulcer. Aerobic and anaerobic cultures must be performed if infection is suspected, followed by the appropriate antibiotic coverage.

It is important to keep in mind that a chronic ulceration, especially if it is not responding to appropriate therapy, has the potential for malignant degeneration. This is especially true for the common venous stasis ulcer. Any suspicious ulcer should be biopsied to include the most ominous border, along with normal skin for comparison.

NAIL DISORDERS

Identification of a fungal nail infection is easily performed with a KOH prep and fungal culture. The PAS (periodic acid-schiff stain) test is also used to detect the presence of viable or degenerating fungus organisms, and its sensitivity may be higher than that of the KOH test. Mycotic nail infections tend to respond poorly to topical therapy. The advent of safer oral agents such as Sporanox (itraconazole, Janssen Pharmaceutica) and Lamisil (terbinafine hydrochloride, Novartis) may help to achieve a cure in some patients, although the success of systemic agents is directly related to the vascular supply to the nail bed. A new topical antifungal, Penlac solution, 8% (ciclopirox, Dermik Laboratories), was approved by the U.S. Food and Drug Administration in 2000, and is indicated for mild to moderate onychomycosis due to *Trichophyton rubrum*. Older patients usually do well with serial nail débridement, which not only maintains comfort but decreases the chance of soft tissue infection, infected ingrown toenails, and subungual corns or ulceration.

It is important to differentiate mycotic nail infections from nail dystrophies secondary to systemic disease, vascular insufficiency, and trauma. For example, poor nutritional status can lead to toenails that are atrophic, thin, brittle, and lackluster, with possible longitudinal ridges. Other systemic diseases associated with common nail dystrophies include diabetes mellitus, syphilis, psoriasis, Reiter's syndrome, ischemia, gout, rheumatoid arthritis, and systemic lupus erythematosus.

Although patients invariably attribute periungual pain as being secondary to an ingrown or incurvated nail, it is important to rule out ischemia as the cause of the nail pain. Ischemic changes of the digit can often mimic nail pain and mislead both patient and physician.

Nail fold infections often exhibit adjacent chronic granulation tissue. In chronic infections, it may be prudent to biopsy such lesions. We are aware of patients in whom Kaposi's sarcoma,

amelanotic melanoma, and squamous cell carcinoma of the nail groove have given the appearance of a pyogenic granuloma.

Subungual hematomas are not uncommon in older individuals, and usually result from microtrauma secondary to improperly fitting shoe gear. However, it is prudent to consider any subungual hyperpigmented lesion a melanoma until proved otherwise. In such cases, débride the nail plate as proximal as possible: many times part of the nail can be removed to reveal subungual debris consistent with previous hemorrhage or fungal infection. If a melanotic process is suspected, a biopsy must be performed.

FOOT PROBLEMS IN PATIENTS WITH DIABETES

Neuropathy, peripheral vascular disease, and immunopathy all play a role in the development of foot pathology in patients with diabetes. These three factors, combined with the reduced vision and mobility that impair the ability of older patients to inspect and care for their feet, can have disastrous consequences. When left unrecognized and therefore untreated, many minor foot problems (such as corns and calluses) progress to ulcerations and infections, producing the well-known morbidity associated with diabetes. Risk factors for diabetic foot ulcers include sensorimotor and autonomic neuropathy, peripheral vascular disease, limited joint mobility, high plantar pressures, bony deformities, history of previous ulceration, and visual or functional impairment.

Chronic sensory neuropathy is one of the most common long-term complications of diabetes mellitus. Symptoms frequently include numbness, dysesthesia, lancinating pain, burning, and hypersensitivity. Sensory loss is typically in a stocking-glove distribution and is often of insidious onset. In its early stages, patients may be unaware that a decrease in sensorium even exists. In those patients without diabetes, pedal neuropathy may be secondary to alcoholism, a herniated nucleus pulposus, heavy metals, vitamin deficiencies, and collagen diseases, among other systemic conditions.

Sensory neuropathy is often accompanied by a motor component. In the foot of a patient with diabetes, loss of motor fibers may lead to intrinsic muscle atrophy and imbalance between flexor and extensor muscles. Clawing of the toes, prominent metatarsal heads, and anterior displacement of an already atrophied plantar fat pad may increase the patient's risk for pressure-induced lesions.^{8,9} Glycation of collagen leads to thickening and increased cross-linking of collagen bundles, resulting in thin, tight, and waxy skin and further restriction of joint movement.¹⁰ Dry and atrophic skin is also caused by the autonomic neuropathy, which leads to denervation of the sweat glands. Cracks and fissures violate the skin defenses, leaving the patient vulnerable to bacterial infection.

Ulcerations may be caused by an acute event or repetitive minor trauma. It has been shown that constant pressure of 5 to 7 lb/square inch over a bony prominence can cause ischemic necrosis in less than 7 hours.¹¹ If an ulcer is indeed caused by pressure or a biomechanical problem, it will never resolve if weight is not dispersed from the affected area, regardless of how much débridement of local wound care is given.

Peripheral vascular disease is 20 times more common in patients with diabetes than in nondiabetic individuals.¹²

Microvascular and macrovascular disease puts the patient at risk for gangrene and ulceration by reducing the perfusion pressure where tissue ischemia occurs. Diabetic occlusive disease has a predilection for the tibial and peroneal arteries, and tends to be bilateral and multisegmental. Ankle brachial pressure index (ABPI) and pulse volume recordings may be of questionable value in assessing peripheral circulation in patients with diabetes, but they are useful if they are low.¹⁰ In general, be suspicious if the ABPI is greater than 1.0. A reading of less than 0.5 indicates serious arterial compromise and poor healing potential.

The best treatment for the foot of a patient with diabetes is patient education and thorough, frequent foot examinations. The foot examination should be a regular part of each office visit. Both shoes and socks should be removed and the feet should be checked for trophic and pretrophic skin changes, thickened or incurvated nails, and hyperkeratosis. Hemorrhage within a callus may be suggestive of ulcer formation. The interspaces should be carefully inspected for maceration or fissuring. Legs and feet should be evaluated for diabetic skin markers, such as bullous diabeticorum, diabetic dermopathy, and necrobiosis lipoidica, some of which may herald vasculopathy and retinopathy.

The neurologic examination should include evaluation of deep tendon reflexes, sharp/dull discrimination, light touch, proprioception, vibratory sensation using a 128 Hz tuning fork, and protective threshold using the Semmes-Weinstein monofilament. In fact, patients can do monofilament tests themselves. Vibratory sensation and proprioception, both carried by the posterior columns, are the first to be affected by diabetic neuropathy. Keep in mind that decreased vibratory sensation may also occur as part of normal aging. Diminished or absent knee and ankle jerk reflexes are also common with aging, and in the absence of other pathology do not require further evaluation. Autonomic neuropathy can be recognized clinically by the absence of sweating, a relatively fixed heart rate, and postural hypotension.

A palpable popliteal pulse may be an unreliable indicator of circulation in the lower extremity, as 40% of patients with diabetes having distal gangrene also have a popliteal pulse.¹³ Similarly, a palpable dorsalis pedis or posterior tibial pulse is an unreliable indication of circulation in the toes. Twenty percent of patients with diabetes with palpable pedal pulses have significant small-vessel disease. Temperature gradient, capillary filling time, rubor on dependency, and pallor on elevation are useful adjunctive tests for assessing distal lower extremity circulation.

The pain of diabetic neuropathy is another common complaint of patients with diabetes. It is difficult to control, especially in patients with poor glucose control. Topical capsaicin (Zostrix) applied two or three times a day may provide some relief. Tricyclic antidepressants and nonsteroidal antiinflammatories may also prove advantageous, as are new drugs on the horizon.

Patients play an important role in preventing their foot problems. The following recommendations should be made at each office visit: stop smoking, inspect feet daily for cuts and blisters, inspect the inside and outside of shoes for foreign objects, do not walk barefooted, cut toenails straight across, avoid temperature extremes on the feet, and notify a physician of any problems immediately.

Summary of Management Algorithm

Diabetic Foot Ulcers

1. Evaluation
 - a. Clinical appearance
 - b. Depth of penetration
 - c. X-rays to detect
 - 1) foreign body
 - 2) osteomyelitis
 - 3) subcutaneous gas
 - d. Location
 - e. Biopsy
 - f. Blood supply (noninvasive vascular studies)
2. Débridement, radical
3. Bacterial cultures (aerobic and anaerobic)
4. Metabolic control
5. Antibiotics
 - a. Oral
 - b. Parenteral
6. Do not soak feet
7. Decrease edema
8. Non-weight-bearing
 - a. Bed rest
 - b. Crutches
 - c. Wheelchair
 - d. Special sandals
 - e. Contact casting
9. Improve circulation (vascular surgery)

SUMMARY

Successful patient management must extend beyond diagnosis and disease treatment and include promotion of function and prevention of decline.¹⁴ The podiatrist can be a valuable team member in the multidisciplinary approach of geriatric assessment; he or she can deliver proactive and preventive care that maintains or improves quality of life for older

patients. The simple ability to ambulate comfortably is critical for our patient's feelings of overall well-being, self-esteem, and ability to interact in society. In addition, elderly people have become increasingly engaged in athletic activities, making them more prone to overuse, repetitive motion, and traumatic injuries. It is therefore necessary to prevent and treat the pedal manifestations of vascular, neurologic, musculoskeletal, and metabolic disorders to improve quality of life and ambulatory ability, while reducing pain and foot morbidity.

KEY POINTS

Podiatry

Orthopedic/biomechanical disorders:

- Heel pain
- Posterior tibial tendon dysfunction
- Osteoarthritis
- Digital deformities
- Pathologic gait

Dermatologic disorders:

- Hyperkeratotic lesions
- Bacterial infections
- Tinea pedis
- Xerosis/fissuring
- Ulcerations

Nail disorders:

- Fungal nail infections
- Nail dystrophies

Foot problems in patients with diabetes:

- Neuropathy
- Ulcerations
- Peripheral vascular disease

Geriatric Dentistry: Maintaining Oral Health in the Geriatric Population

Andrea Schreiber
Robert Glickman

INTRODUCTION

Whereas dental textbooks address the management of medically compromised, older patients (generally including a review of the basic pathophysiology of a disease, the clinical signs and symptoms of the condition, common therapeutic interventions, and how either the disease itself or the medications for it might impact on planned dental care) in general, medical textbooks, even those on geriatric medicine, do not address the impact of oral health on the overall systemic health of a patient. The fact is that physicians are uniquely situated to screen elderly patients for common oral diseases.

Older adults tend to have low use rates of dental services, due perhaps to a lack of insurance coverage for these services or limited access to care secondary to infirmity. Although more than 90% of adults over the age of 75 seek medical care on a regular basis, only approximately a third of these individuals seek dental care.¹

In a pilot study² investigating the physicians' role in the diagnosis and management of oral diseases in a geriatric population, four primary care physicians and four geriatricians were asked to identify oral conditions on 30 color slides. The rate of correct diagnosis was 55%, and appropriate treatment decisions were made 70% of the time.

In another study³ performed to assess hospital physician knowledge and views concerning oral health in elderly patients, 70 respondents completed a survey and were asked to diagnose 12 different oral conditions demonstrated on clinical slides. Although 84% of respondents felt that it was important to examine the oral cavity, only 19% reported that they did so. Fifty-six percent of responding physicians did not feel confident in examining the oral cavity and 77% felt that they had insufficient training to do so. Two of the 70 physicians (3%) were able to correctly identify all 12 oral conditions depicted in the slides.

The focus of this chapter will be on the maintenance of oral health for the geriatric patient and how physicians and dentists can ensure this goal. Topics to be covered include the definition of oral health, how oral health is measured, the changing dental needs of the geriatric population due to advances in medicine and dentistry, the impact of oral health on systemic health, recognition and management of common oral conditions in the elderly population and access to care issues for both community dwelling older adults and residents of long-term care facilities. Prevention and management of oral diseases will improve systemic along with oral health.⁴

Definition of oral health

Any discussion concerning the maintenance of oral health as a goal, must start with a definition of the term.⁵ Mouradian⁶ defined it as "...encompassing all of the immunologic, sensory, neuromuscular and structural functions of the mouth and craniofacial complex. Oral health influences

and is related to nutrition and growth, pulmonary health, speech production, communication, self-image and societal functioning." Although the author was addressing the oral health needs of the pediatric population, this definition of oral health appears to apply to the population in general and to the geriatric population in particular. Conditions that adversely affect the oral and maxillofacial complex are common and pervasive in the elderly and can affect an individual's general health and quality of life.

Measures of oral health and function

Common measures of oral health include the number of teeth present in the mouth, the presence of caries (Figure 75-1, see also Color Plate 75-1) and restorations, and the presence or absence of periodontal disease (infection of the gingiva and tooth supporting structures) (Figure 75-2, see also Color Plate 75-2) and oral mucosal lesions (Figures 75-3 through 75-6, see also Color Plates 75-3 through 75-6). Many attempts have been made to quantify the effect of these parameters on oral function and the relationship of adequate oral function to an individual's quality of life. In a literature review⁷ focused on determining the relationship between dentition and oral function, four specific areas were investigated: overall masticatory function, aesthetics/psychosocial ability, posterior dental occlusal stability and support, and other functions, including taste and phonetics. Eighty-three articles met inclusion criteria for review. Satisfactory masticatory function was linked to the total number of teeth present—specifically 20 teeth with 9 to 10 dental contacts (upper and lower teeth in occlusion). Patients with fewer teeth and/or fewer contacts demonstrated limited masticatory function. Dental aesthetics and psychosocial satisfaction was linked to the loss of anterior teeth with variations in satisfaction noted between age groups, cultures, and socioeconomic status. Occlusal stability

was noted with three to four posterior units in individuals with a symmetrical pattern of tooth loss and five to six posterior units in those with a nonsymmetrical pattern of bone loss. Patients did not attribute a high value to either phonetics or taste. The conclusion of the authors was that the World Health Organization goal of maintaining 20 natural teeth throughout life as a means of assuring an acceptable level of oral function is supported by current literature.

Measures of oral health-related quality of life (OH-QoL) assume functional and psychosocial impacts on the quality of life but exactly what is being measured by a variety of instruments designed for this purpose still remains to be clearly elucidated.⁸

Many efforts are underway to verify the validity of the quality of life assessment tools used to measure the impact of oral health on quality of life, or to add subscales to current tools to aid in quantifying a qualitative question.^{9,10} In a survey study investigating the association between tooth

loss, chewing ability, and association with oral and general health-related quality of life issues, two survey instruments were used (the Oral Health Impact Profile and the EuroQoL Visual Analogue Scale). In addition to the patient survey, functional tooth units were assessed by calibrated dentists on more than 700 Australians over the age of 50. The number of functional tooth units was positively related to chewing ability and general health, thereby reflecting the importance of oral health to general well-being.¹¹

The aim of the Ontario Study of Oral Health of Older Adults (OSOHOA) was to document the natural history of oral diseases and disorders in older adults and to document the impact on physical, functional, and psychological well-being.¹² This was an observational cohort study of a random sample of adults who were over the age of 50 when recruited. The study consisted of a baseline phase and 3- and 7-year follow-ups. The ability to chew was assessed using an index of six different foods. Descriptive statistics were used to measure changes in chewing ability over time. The proportions of individuals experiencing increased chewing problems rose from 24% at baseline to 33.8% over the 7-year period. An increased prevalence and severity of chewing dysfunction was most noted for edentulous patients.

Other studies have noted that approximately one third of older adults have trouble biting some foods and that this percentage increases with advancing age and number of teeth missing.¹³ Chewing ability or lack thereof can influence food choices and result in malnutrition in both community-dwelling and long-term care residents (Figure 75-7, see also Color Plate 75-7). Weight loss and poor nutrition in long-term care facilities have been linked to chewing problems.^{14,15}

The changing need for dental care in geriatric patients

Advances in dental research have resulted in a lower incidence of tooth loss and caries in the general population as a result of the widespread use of fluoride, patient education,

and dental hygiene programs.¹⁶ Simply put, people are living longer with more teeth. The fully edentulous octogenarian is and will continue to be less frequently encountered in the twenty-first century. However, edentulous patients, despite the absence of teeth, may have a host of problems that can adversely affect oral and systemic health, including denture- or nondenture-related soft tissue lesions, oral candidiasis, malnutrition from ill-fitting dentures (Figure 75-8, see also Color Plate 75-8), or lack of thereof, resorption under existing dentures (Figure 75-9, see also Color Plate 75-9), gastrointestinal problems, masticatory insufficiency, swallowing disorders, and aspiration pneumonia. They are still susceptible to mucosal diseases (Figures 75-3 and 75-4, see also Color Plates 75-3 and 75-4) and oral cancers (Figures 75-5 and 75-6, see also Color Plates 75-5 and 75-6) despite the absence of teeth. The surgeon general's report on Oral Health in America in 2000 cited 30,000 new diagnoses of

Figure 75-7. Angular cheilitis caused by loss of dentition, poor diet, and candidiasis. (Reprinted with the permission of Mirriam Robbins, DDS, New York University College of Dentistry.)

oral cancer each year, mainly in individuals with the median age in the sixth decade of life.¹⁷

The types of problems encountered by a dentate or partially edentulous geriatric patient may include dental caries, chronic facial pain and/or temporomandibular dysfunction, and benign or malignant lesions of the oral mucosa or jaws. Periodontal disease, an inflammatory disorder that results in alveolar bone loss and chronic tissue inflammation (Figure 75-10, see also Color Plate 75-10) is a primary cause of tooth loss in the elderly, which has been shown to have strong associations with the pathophysiology of certain systemic diseases including cardiovascular disease, cerebrovascular disease, and diabetes mellitus.¹⁸ In fact, patients with periodontal disease are up to twice as likely to develop cardiovascular disease.¹⁹ Medications taken for comorbid conditions may result in decreased salivary flow, which in turn impacts on the ability to chew, swallow, and cleanse the oral cavity. Additionally, xerostomia may be accompanied by painful or burning sensations. Finally, maxillofacial trauma as a result of gait disturbance, neuromuscular disease or in some cases elder abuse, is another factor affecting oral health in the geriatric population.⁵

As advances in medical research result in increasing patient life span, older adults have become the fastest growing portion of the population. In the United States, population projections indicate that by the year 2030 more than 20% of the population will be 65 years old or older.²⁰ Since concurrent advances in dental research have resulted in less tooth loss in older adults, these patients will require an increased need for dental care in the future, most especially with the advent of dental implants leading to less reliance on conventional dentures as a primary form of treatment. Although the trend is toward less tooth loss in older adults, there are still regional demographic variations, with higher levels of edentulism in areas of lower socioeconomic status. With increased tooth retention comes the continued risk of recurrent and cervical caries. The pattern of caries differs in the geriatric versus the general population in that coronal (chewing surface) caries

Figure 75-10. Severe periodontal bone loss. (Reprinted with the permission of Mirriam Robbins, DDS, New York University College of Dentistry.)

are less frequent than root caries. Root or cervical caries (Figure 75-11, see also Color Plate 75-11) are characterized by rapid progression and increased difficulty in restoration, often necessitating extraction (Figure 75-1, see also Color Plate 75-1).^{20,21}

Dentists are now challenged with treating an increasing number of community dwelling older adults with chronic but stable systemic diseases, along with caring for the dental needs of the more debilitated and frail elderly with both physiologic and cognitive impairments. According to the surgeon general's report in 2000, more than 20% of homebound or institutionalized elderly require emergency dental care annually. As this population increases, so too will the need for care.¹⁷

Oral health impact on systemic health

The well established links between oral and systemic diseases have served as a "wake-up" call to improve oral hygiene and access to dental care for elderly patients in long-term care facilities.^{22,23} One such risk is aspiration pneumonia, which has long been recognized as a common cause of death in infirm homebound and long-term care facility residents. Bacterial pneumonia is directly linked to aspiration as a result of dysphagia and/or poor oral hygiene and the elevated numbers of respiratory pathogens within oropharyngeal secretions. Attention to improved oral hygiene is a method or strategy to decrease the incidence of bacterial pneumonia in susceptible populations.²⁴

The main causes of community-acquired pneumonia are *Streptococcus pneumoniae* and *Haemophilus influenzae*. The organisms more frequently associated with hospital-acquired pneumonia are *Staphylococcus aureus* and *Pseudomonas aeruginosa*. Hospital-acquired pneumonia commonly occurs in the frail elderly with compromised immune systems.

Aspiration is most likely to occur in patients with functional dependence on oral care and feeding.^{25,26} Studies have demonstrated increased levels of bacteria in the oral secretions of institutionalized versus home-dwelling seniors.²⁷ Aspiration occurs most frequently with feeding or during sleep. The risk of developing an infection subsequent to aspiration depends on the state of the individual's host defenses—cough reflex, mucociliary adequacy, and cellular immunity—and on the type and volume of aspirate. The

Figure 75-11. Severe cervical decay. (Reprinted with the permission of Mirriam Robbins, DDS, New York University College of Dentistry.)

higher the bacterial load of the aspirate and the lower the host defenses, the greater the risk.²⁸

Oral care for functionally dependent elderly patients in long-term care facilities has been documented as being sorely lacking in numerous studies.^{29,30} Poor oral hygiene leads to the proliferation of dental plaque, which is a biofilm responsible for dental and periodontal disease (Figure 75-2, see also Color Plate 75-2). As the biofilm matures, organism shedding is facilitated. Reduced salivary flow in the elderly as a consequence of medications, aging, or disease may also enhance microbial growth in the oral cavity. Similarly, long-term use of broad-spectrum antibiotics may contribute to the overgrowth of certain organisms in the oral cavity.

A study by Adachi et al³¹ investigated the incidence of fevers greater than 37.8° C and aspiration pneumonia in the residents of two nursing homes for 2 years. Patients who received professional oral health care were compared with patients who did not. The prevalence of fevers and the rate of aspiration pneumonia was significantly lower in the patient group who received professional oral health care, than in the group who did not. It has been demonstrated that improved oral hygiene efforts in long-term care facilities has resulted in a decreased incidence of fevers and pneumonia deaths. Effects of improved oral health care on other systemic diseases, such as cerebrovascular accident, diabetes mellitus, and myocardial infarction have yet to be fully investigated.

Desvarieux et al³² investigated the relationship between periodontal disease and tooth loss with subclinical atherosclerosis. Subjects received comprehensive periodontal examination, a carotid scan, and evaluation of cardiovascular disease risk factors. A significant association was noted between observed prevalence of carotid plaque formation and the number of teeth missing. Approximately 60% of individuals missing more than 10 teeth demonstrated carotid artery plaque, and this association was greatest among patients over the age of 65. The mechanisms underlying the relationship between periodontal disease and cardiovascular disease are not well understood but are likely due to chronic bacteremia and elevated inflammatory markers. Interestingly, in a follow-up study, gender variations were noted in the relationship between periodontal disease, tooth loss, and subclinical atherosclerosis, with men being affected more frequently than women.³³

The relationship between cardiovascular disease/stroke and periodontal disease has been the object of numerous studies in the last decade, most focusing on the role of inflammatory markers, such as C-reactive protein (CRP), interleukin, and tumor necrosis factor. Periodontal disease results in elevations of CRP and interleukins, but a clear link between periodontal disease and the pathogenesis has yet to be elucidated. The therapeutic implications for such an association are significant given the prevalence of periodontal disease in the general population and the relative ease with which oral hygiene improvement can be accomplished. Other risk factors for the development of cardiovascular disease, such as gender, hypertension, obesity, hyperlipidemia, and smoking, are less readily addressed and modified. Animal studies indicate that chronic infections lead to increased systemic inflammation and the accelerated development of atherosclerotic plaque.³⁴

The results of the meta-analysis of five prospective cohort studies involving more than 85,000 patients indicated that

patients with periodontal disease had a 1.14 times higher risk of developing cardiovascular disease than those patients without periodontal disease. The highest risk (1.24) was assigned to individuals with less than 10 remaining teeth. The meta-analysis of five case control studies involving more than 1400 individuals demonstrated an even higher risk of individuals with periodontal disease developing cardiovascular disease.³⁵

Issues facing community dwelling versus long-term care facility residents

Ohru³⁶ studied more than 400 Japanese nursing home residents evaluating the relationship between dental status and mortality. Participants were divided into three groups: individuals with adequate dentition, edentulous individuals who wore full dentures, and individuals without adequate dentition and without dental prosthesis. All groups were followed for 5 years. The 2- and 5-year risks for mortality were greater for the functionally edentulous individuals than for the other groups. Ohru concluded that the dental status of institutionalized elderly should be systematically evaluated and optimized.

Elderly patients with dementia may demonstrate difficulty with activities of daily life including oral care, and as such, they pose unique challenges to caregivers in the community and within institutions. Connell and McConnell³⁷ evaluated changes in the nursing home environment that could foster improved oral health care. The changes included modification of the physical environment to compensate for cognitive defects and physical incapacity and staff instruction on cues to overcome cognitive and noncognitive deficits. Improved visual cues, single step cues, and closing doors to decrease distractions all resulted in improved oral hygiene status. Improved wheelchair access to sinks, access to mirrors, and change from conventional toothbrushes to those designed with better grip handles also resulted in improved oral hygiene.

A study of 192 nursing home residents investigating oral health status, cognitive function, and the need for dental treatment as assessed by dental professionals and nursing staff was performed by Nordenram et al.³⁸ The results indicated that dentate status coupled with a loss of cognitive function was predictive for the need for oral treatment. The patients with the best cognitive function were found to have better chewing ability. Thirty percent of patients were found to have a functional chewing deficit based on lack of dentures, ill-fitting dentures, or poor dental status. Assessment of need by staff versus dental practitioners was compared, as clinical dental function and oral hygiene were assessed by both groups. The two groups varied widely in their assessment of the oral health status of the nursing home residents, as the dentists found that 93% of residents required oral hygiene assistance, whereas the nursing assessment was that only 11% of the population required such aid. Such disparity in findings between nursing home staff and dentists clearly indicates the need for improved training in the recognition of oral hygiene neglect and related oral health conditions.

Physical disability, cognitive impairment, or a combination of the two can result in making nursing home residents who are no longer functionally independent vulnerable to poor oral health. Numerous studies have documented the need for improved oral health care for both long-term care

residents and homebound elderly. Reports of severe periodontal disease, untreated root caries, and poor oral hygiene on remaining teeth and on dentures abound in the literature. Frenkel et al³⁹ reported that more than 70% of nursing home residents had not seen a dentist in 5 years and that more than 20% reported untreated dental problems.

Murray et al⁴⁰ observed soft tissue lesions and dry mouth in 6% of their nursing home population. Oral hygiene, as measured by the amount of calculus on crowns of teeth or on dentures, increased with patient age and length of time of denture wear. Less than a quarter of nursing home patients demonstrated minimal or no calculus present.

In an article reviewing the prevalence and consequences of poor oral health care or lack of care in geriatric patients in long-term care facilities, Pino et al⁴¹ concluded that the effects on the general health and well-being of these patients was far-reaching. Poor oral hygiene or oral health neglect may result in problems that range from socially embarrassing to life threatening. Systemic complications, including deep fascial space infections, endocarditis, cavernous sinus thrombosis, and brain abscesses, are well documented in both dental and medical literature. Nutritional status, conversing, smiling, and eating are all dependent on adequate oral health.

The institutionalized elderly are not the only individuals at risk. Studies of oral health status in the United States and Europe document the need for attention to oral health care in the elderly. Tooth loss results in masticatory insufficiency that can result in swallowing and digestive disorders, in addition to poor diet due to the need to alter food choices. Periodontal disease may present clinically with erythematous, edematous gingival tissue associated with bleeding, tooth mobility, and fetid oris locally (Figure 75-2, see also Color Plate 75-2), and aspiration pneumonia and local and distant spread of infection systemically.⁴¹

In a study evaluating functional tooth number (greater or less than 10) and overall mortality in more than 500 individuals aged over 40 who were followed for 15 years, Fukai et al⁴² found that adults aged over 80 demonstrated increased mortality and decreased functional tooth number in comparison to the other groups. An increased risk of malnutrition was assessed on 130 community dwelling older adults in Japan using the Mini Nutritional Assessment tool (MNA). Factors affecting increasing risk of malnutrition were found to include cognitive impairment, physical disability, poor oral health status, and difficulty with meal preparation resulting in unbalanced diets. Twelve percent of participants were found to be at risk for malnutrition.⁴³

Recognition and management of common oral conditions in the elderly population

CARIES AND PERIODONTAL DISEASE

Although the incidence of caries (tooth decay) is highest in children and young adults, dentate geriatric patients are not immune from the development of these lesions. To the contrary, cervical or root caries and recurrent caries under existing restorations are common in elderly dentate patients. Cervical caries tend to progress more rapidly than caries on occlusal surfaces, and restoration of teeth with cervical caries is often more difficult, leading ultimately to extraction. Partially edentulous elderly adults often alter their diets to softer consistency foods, which are high in carbohydrates

and which increase the chance of caries formation, especially when coupled with inadequate home care. The CDC estimates that 30% of adults over the age of 65 have untreated caries and that 94% of adults with one or more natural teeth have experienced caries.⁴⁴

Periodontal disease is a chronic inflammatory process involving the gingiva and alveolar bone, which ultimately results in gingival erythema, edema, bleeding, recession, and loss of alveolar bone resulting in tooth mobility and ultimately tooth loss.

In a study of more than 300 patients aged 65 to 95, Stabholz et al⁴⁵ found that caries accounted for 30% of extractions and periodontal disease accounted for 65% of extractions performed. In another study that followed 179 geriatric patients at three long-term care facilities over a period of 30 months, a logistic regression demonstrated that the relative risk of a worsening periodontal condition or loss of teeth was twice as high for those patients not enrolled in a preventive program than for those that were.⁴⁶ The benefit of an oral health preventive program in the severely frail elderly or terminal patient appears to demonstrate no significant improvement.⁴⁷

EDENTULISM, PARTIAL EDENTULISM, DENTURES, AND IMPLANTS

Caries and periodontal disease, left untreated, are the primary causes of tooth loss.

Although the number of teeth present is a common tool used in evaluating oral health and masticatory function, evaluation of functional tooth units, which involves description of the arrangement and number of remaining teeth, is perhaps a more reliable tool to evaluate masticatory function in the elderly population. Hildebrandt et al⁴⁸ found that a low number of functional tooth units resulted in food avoidance patterns and swallowing of coarser boluses of incompletely chewed food.

The fabrication of full or partial dentures has long been the primary method of ensuring masticatory sufficiency in adults with missing teeth. Long-term use of these prostheses often leads to resorption of alveolar bone and associated soft tissue changes including ulcerations and hypertrophic areas. This ultimately results in the need for dentures to be continuously refitted. In some cases, resorption may be so severe as to obviate the fabrication of stable prostheses. The advent of dental implants (Figure 75-12, see also Color Plate 75-12) and the ability to provide implant supported bridges and dentures have improved the masticatory capabilities, diet, and nutrition of countless adults in the last 2 decades. The greatest benefit appears to be for patients with the most ridge resorption.⁴⁹ Implant supported prostheses may demonstrate secondary benefits, such as improvements in facial esthetics and lip support that complement improvements in masticatory function.⁵⁰

In a survey of 125 patients, loss of function was the most common complaint of wearers of full dentures, whereas patients with fixed prostheses demonstrated fewer complaints.⁵¹

Before the advent of implants for treatment of full or partial edentulism, removable dental prostheses were the primary means of oral rehabilitative care. Full and partial dentures did and do provide for improvements in mastication, swallowing, speech, and facial aesthetics. Implant supported prostheses

Figure 75-12. Dental implants: before fabrication of prosthesis/bridge. (Reprinted with the permission of Mirriam Robbins, DDS, New York University College of Dentistry.)

provide a more comfortable, functional, and stable alternative to conventional dentures. A study⁵² was conducted of 15 patients over 60 years of age who were treated with implant supported lower dentures and then evaluated for impact of this treatment on their quality of life. The reported benefits of this treatment included improvements in eating, speaking, and social interactions.

Dental implants to treat either full or partially edentulous conditions have become a common treatment option, with more than 90% success rate reported at 10 years. Neither advanced age nor systemic disease are absolute contraindications to implant placement.⁵³ Some studies appear to have demonstrated an increased risk of implant failure associated with diabetes mellitus, smoking, oncologic treatments (including chemotherapy and head and neck radiation), and postmenopausal hormone therapy.⁵⁴ Patients should be evaluated as candidates for implants based on the level of control of their systemic diseases, their ability to withstand surgical stress, life expectancy, and quality of life.⁵⁵ Evidence of implant failure due to systemic disease is not prevalent.⁵⁶

Grant and Kraut⁵⁷ placed 160 implants in the maxillas and mandibles of 47 patients all aged over 79 and with a median age of 89 years. All but one of the implants healed successfully. The authors concluded that geriatric patients in stable medical condition are suitable implant patients. It appears that concerns about the success of osseointegration in elderly patients as regards to bone remodeling and resorption and decreased soft tissue response may not be entirely warranted. There is no strong body of evidence to support an increased failure rate of implants based on advanced patient age. A review of the literature regarding the success of implants in elderly patients revealed that old age, in and of itself, is not a significant concern.⁵⁸ Al Jabbari⁵⁹ concluded that even limitation in oral hygiene capacity in old age is not a contraindication to implant placement. Treating dentists need to first consider if the patient is in optimal condition to withstand the procedure and be less concerned about whether osseointegration is likely to occur in the elderly patient.

SALIVA AND SALIVARY GLANDS

Xerostomia may occur with medication use, chemotherapy, radiation therapy for head and neck cancer, or as a symptom of Sjögren's syndrome. Common sequelae include an inability to tolerate a dental prosthesis, difficulty swallowing, alteration of nutritional status, and increased incidence of dental caries because of changes in the dental plaque biofilm. The decreased ability to chew comfortably can result in malnutrition, and decreased enjoyment of food and the social interaction of meals.⁶⁰ Dry mouth is a common complaint in the elderly, possibly secondary to polypharmacy for multiple comorbid conditions. It is more common among patients who take several medications, especially if antipsychotics are included.⁶¹

Dry mouth or xerostomia has a number of possible causes including smoking, use of alcohol or caffeinated beverages, mouth breathing, and a host of medications. Some drugs may cause the sensation of dry mouth, whereas others may result in measurable hyposalivation.⁶² The drugs that are most commonly implicated in dry mouth are antipsychotics, tricyclic antidepressants, β -blockers, antihistamines, and atropine.⁶³ Advancing age and medication use were shown to be related to objective evidence of hyposalivation, whereas female gender and psychiatric issues were strongly correlated to subjective complaints of oral dryness.⁶⁴

No specific medication has been singled out as being more xerogenic, but polypharmacy does increase the likelihood of dryness. Severity of dryness complaint appears to be increased with female gender and antianginal, antiasthma, and antidepressant medications.⁶⁵

Drugs can affect salivary flow rate or composition by antagonizing or mimicking any of the regulatory aspects of salivation. The mechanism of action of xerogenic drugs may be due to an anticholinergic action mediated by parasympathetic (M3 muscarinic receptors) neurotransmission to the salivary glands.⁶⁰ Tricyclic antidepressants have been shown to reduce salivary flow whereas selective serotonin release inhibitors do not. This lower incidence of dry mouth complaint is thought to be related to the lower anticholinergic effects of this group of medications. Approximately one quarter of patients on tricyclics develop a complaint of dry mouth. Muscarinic receptor antagonists, such as oxybutynin, which are used to treat the overactive bladder symptoms of frequency and urgency with or without incontinence, are nonspecific for the bladder and also cause dry mouth. Tolterodine demonstrates *in vivo* selectivity for the bladder over the salivary glands and may be a good choice for elderly patients who are taking other xerogenic medications.

Anticholinesterase inhibitors such as donepezil, used in the treatment of Alzheimer's disease, may also induce dry mouth. Many antihypertensive agents including β -blockers, ACE inhibitors, and α -methyl dopa have been associated with complaints of dry mouth.

A study of 175 home-dwelling elderly patients⁶¹ who were hospitalized for an acute change in health status were compared with 252 outpatients. The parameters evaluated included medical diagnosis, prescribed medications, oral examinations, and analysis of saliva samples. Sixty-three percent of hospitalized and 57% of outpatients complained of dry mouth, whereas 13% of hospitalized and 18% of outpatients complained of burning mouth. There were no

differences in the biochemical analysis of the saliva between the two groups. The complaint of dry mouth was associated with polypharmacy, whereas this was not the case for the complaint of burning mouth. Dry mouth and burning mouth were rarely reported simultaneously.

The management of dry mouth is challenging, and saliva substitutes have been the mainstay of treatment for many years along with alcohol-free mouth rinses, increased water intake, lubricating gels, and alteration of food consistency (blenderized diet). Since dentate patients diagnosed with xerostomia are prone to an increased incidence of caries, a comprehensive and aggressive caries monitoring protocol should be instituted including fluoride treatments, sealants, and use of sugar-free lubricating gum. Stimulation of salivary secretion with Yohimbine, an α_2 -adrenoreceptor antagonist has been somewhat effective in patients being treated with psychotropic drugs. Another strategy, for patients on multiple medications, is for physicians to evaluate the xerogenic potential of each of the medications prescribed for an individual and to alter the medication regimen if at all possible. A persistent dry mouth may necessitate alteration of drug dose or prescription.⁶¹

ORAL LESIONS

Oral mucosa possesses an essential protective function, which is presumed to diminish with age as the tissue becomes more permeable. This theory appears to be supported by the reported increased incidence of oral lesions with advancing age.⁶⁶ However, Wolff and Ship⁶⁷ found that the incidence of oral mucosal lesions in healthy adult seniors was not significantly higher than that of the general population. Other factors contributing to the development of oral mucosal lesions include general health and nutrition status, medication usage, and the presence of ill-fitting dentures.

Common oral mucosal conditions of elderly denture wearers include candidiasis (Figure 75-13, see also Color Plate 75-13), epulis fissuratum (soft tissue hyperplasia), traumatic ulcers, angular cheilitis (Figure 75-7, see also Color Plate 75-7), and coated tongue. Although the majority of oral mucosal lesions appear to be benign, premalignant and malignant lesions are also present, usually in the form of

Figure 75-13. Oral candidiasis: note striae throughout indicative of fungal infection. (Reprinted with the permission of Mirriam Robbins, DDS, New York University College of Dentistry.)

leukoplakias (Figure 75-4, see also Color Plate 75-4), erythroplakias, and squamous cell carcinomas (Figure 75-6, see also Color Plate 75-6).

Denture stomatitis is a generally asymptomatic, inflammatory process found on mucosal surfaces underlying full or partial removable dentures (Figure 75-8, see also Color Plate 75-8), with a commonly reported prevalence of 10% to 75% of denture wearers.⁶⁸ Causal factors for the development of denture-related stomatitis include trauma from ill-fitting dentures, poor oral hygiene, reduced vertical dimension (atrophy), continuous use of prosthesis, unstable occlusion, hyposalivation, and nutritional deficiency. The increased incidence of lesions was associated with a greater number of years of denture use. Interestingly, advanced age and high alcohol consumption did not correlate with incidence of these lesions.⁶⁹

A retrospective study of 4098 adults, investigating the prevalence of oral lesions and association of those lesions with age, dentures, tobacco, or alcohol use, found that the overall prevalence of oral mucosal lesions appeared to be linked to risk behaviors and age. More than 27% of the male adults and 22% of the female subjects were noted to have a mucosal lesion. The use of alcohol and tobacco appeared to be linked to the incidence of leukoplakia, nicotinic stomatitis, and frictional lesions. Denture-related lesions, in the form of candidiasis and traumatic and frictional lesions, appeared to be the most prevalent.⁷⁰

The incidence of oral mucosal lesions⁷¹ in a Thai population of 500 adults over the age of 60 was investigated in relationship to type of lesion, age, sex, and presence or absence of dentures. The incidence of oral mucosal lesions in this study population was 83.6%, with no significant gender difference. The incidence of oral mucosal lesions appeared to increase with advancing age and denture use. The three most prevalent oral mucosal conditions were traumatic ulcers, fissured tongue, and lingual varices. Premalignant lesions were detected in 5% of subjects, and squamous cell carcinoma was detected in less than 1% of the subjects.

In one study,⁷² older patients, especially females, appeared to be at increased risk of developing malignant lesions, and curiously, those who never smoked appeared to be at greater risk. Oral squamous cell carcinoma most commonly occurred on the ventral and lateral tongue, floor of the mouth, and retromolar regions.

Angular cheilitis is characterized by cracking fissures at the commissures of the lips, which may be caused by saliva accumulation in this region secondary to ill-fitting dentures, candida infections, or vitamin deficiencies (B) (Figure 75-7, see also Color Plate 75-7). Discomfort with eating and speaking are often attendant complaints. Treatment is aimed at the cause and may include topical antifungal ointments, vitamin supplements, dietary changes, and denture adjustments—or in some cases the fabrication of new dentures or implant supported prostheses.

Poor oral hygiene, immune compromise, or both can lead to an overgrowth of candida on dentures, resulting in denture stomatitis and oral-pharyngeal candidiasis (Figure 75-13, see also Color Plate 75-13). It is frequently asymptomatic and found on routine examination. On occasion, complaints of a painful or burning sensation may be elicited. Common clinical characteristics include erythema or pinpoint hyperemic areas in denture-bearing locations. Frank fungal colonies are also

sometimes observed. If the affected region is limited to the denture-bearing areas, dentures should be routinely brushed and may be soaked in chlorhexidine or a dilute hypochlorite solution. In more extensive areas, oral antifungal troches are administered. Denture stomatitis may occur in up to one half of edentulous patients who wear full dentures.³⁹

Oral cancer occurs most frequently in the older population, usually in or after the sixth decade of life, with more than 95% of cases occurring in individuals over the age of 45.^{17,73} These cancers account for approximately 3% of all cancers in the United States. The National Institute of Dental and Craniofacial Research estimates that more than 28,000 Americans will be diagnosed and that 7000 individuals will succumb to oral cancer this year. Oral cancer affects men more frequently than women by a ratio of approximately 2:1. Tobacco and alcohol use remain primary risk factors for the development of oral cancers, the risks increasing with increased usage of either or both substances. The 5-year survival rate remains at 59%.⁷⁴

Early detection remains the key to improved prognosis. Common clinical signs and symptoms include nonhealing ulcers and areas of leukoplakia, erythroplakia, or mixed lesions. Lesions that do not resolve upon removal of a suspected irritant or within a few weeks of detection should be biopsied because histologic evaluation is necessary to determine if any dysplastic or malignant changes are evident. If a malignancy is detected, treatment is then predicated on the staging of such lesions and may involve surgical ablation, chemotherapy, radiation therapy, reconstruction with vascularized grafts, and oral rehabilitation.

CONCLUSION

Compromised oral health may result in a variety of illnesses and conditions that can adversely impact an individual's quality of life or life span. Engaging in conversation, enjoying a good meal, kissing a loved one, smiling and laughing—many of life's "little pleasures"—require a functioning and esthetically acceptable dentition. The ability to engage in these activities improves socialization, self-esteem, and the quality of life of all but the most infirm and cognitively impaired individuals. Additional benefits of good oral health on an individual's systemic health include improved diet and nutrition and decreased frequency of aspiration pneumonia in the frail elderly population. The association between

periodontal disease and cardiovascular disease, stroke, diabetes, and myocardial infarction may prove to have the most far-reaching health benefit.

The key to maintaining oral health in the geriatric population remains timely access to care. Community dwelling dependent seniors, homebound frail elderly, and long-term care facility residents face many more obstacles to receiving dental care than do healthy, independent seniors. Therefore, physicians play a primary and crucial role in ensuring adequate oral health of these individuals. Familiarity with common oral conditions afflicting both dentate and edentulous elderly adults is the first and most basic step in assuring improved oral health in these patients.

KEY POINTS

Maintaining Oral Health in the Geriatric Population

Definition of Oral Health:

- Conditions that adversely affect the oral and maxillofacial complex are common and pervasive in the elderly and can affect an individual's general health and quality of life. Physicians are in a unique position to screen elderly patients for common oral disorders. Impact on Quality of life.
- Poor oral health and loss of teeth adversely affect nutritional status and gastrointestinal health by limiting food choices secondary to masticatory insufficiency. In addition, socialization and psychologic well-being may also be affected. Oral Health Impact on Systemic Health.
- The link between oral and systemic disease has been reinforced in recent years, specifically in relationship to cardiovascular disease. The risk of aspiration pneumonia in nursing home residents has been demonstrated to be decreased with improvements in oral hygiene care. Recognition and management of common oral diseases of the elderly.
- Improvement of oral health hinges on recognition of common conditions, including caries, periodontal diseases, partial or complete edentulism, salivary gland dysfunction, benign and malignant lesions of the mucosa, and bony structures.

Symptoms of gastrointestinal disorders are frequently mentioned by older Americans during visits to the doctor, and the digestive diseases producing these symptoms are among the most common hospital discharge diagnoses for elderly patients in the United States.^{1,2} As the elderly population expands and the demand by older individuals for medical care grows, it becomes increasingly important for physicians to be acquainted with the manifestations of diseases of the upper gastrointestinal tract in members of this age group.

THE ORAL CAVITY

The most proximal of the digestive organs traditionally is considered to be the esophagus; patients with complaints thought to originate within the oral cavity or pharynx are referred to a dentist or a specialist in disorders of the ear, nose, and throat. The oral cavity, however, is examined easily by the general practitioner and may reveal the cause of unexplained or apparently unrelated abnormalities; thus evaluation of the upper gastrointestinal tract should begin with the mouth.

The mouth and nutrition

Changes in the oral cavity occasionally limit the ability of elderly people to eat and enjoy a normal diet. Problems with eating sometimes are severe enough to cause malnutrition and prompt a search for a wasting illness.³ The number of general oral health problems has been shown to be a strong predictor of involuntary weight loss in elderly people.⁴

A variety of abnormalities of oral structure and function may contribute to malnutrition. The muscles of mastication may become impaired during aging as the result of a decrease in (lean) body mass.⁵ Eating occasionally becomes difficult because of tooth loss as a result of periodontal disease, poor dentition, or loosening of dentures caused by resorption of mandibular bone.⁶

A reduction in food intake by elderly individuals is sometimes related to a change in taste perception. The number of taste buds decreases after age 45, resulting in a decrease in taste sensation, especially the ability to appreciate salty and sweet foods.⁷⁻⁹ Diminished perception of sour and bitter tastes is associated with palatal defects and typically occurs in patients who wear dentures. Taste sensation may also be altered directly by medications or indirectly affected by a drug's unpleasant flavor. Agents associated with abnormal taste perception (dysgeusia) include tricyclic antidepressants, sulfasalazine, clofibrate, L-dopa, gold salts, lithium, and metronidazole. Medications with anticholinergic properties interfere with taste by reducing salivary gland secretions and producing xerostomia. Age alone, however, is not associated with a reduction in stimulated saliva flow in nonmedicated subjects.¹⁰

Although abnormal perception may lead to deficient nutrition, some primary nutritional disorders may be responsible for dysgeusia and glossitis. For example, vitamin B₁₂ and niacin deficiency are associated with a "bald" or magenta-colored tongue, respectively. Taste sensation and eating

habits also are disturbed by processes that interfere with the sense of smell, which typically is diminished substantially by age 70.¹¹

Vascular lesions

Diminutive vascular lesions of the upper gastrointestinal tract are poorly understood and rarely reported. The nomenclature for these lesions is confusing, and the terms *arteriovenous malformation*, *vascular ectasia*, *angiodyplasia*, and *telangiectasia* are usually used interchangeably with little regard as to their true meanings.

The lips are a frequent site of senescent vascular lesions resembling those of hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu disease), and involvement often includes the upper gastrointestinal tract. In addition to this form of small vascular abnormality, patients often have sublingual varices, or "caviar lesions" (Figure 76-1). The walls of these dilated vessels are thick, but the endothelial lining is hypoplastic.¹² In males, sublingual varices may be associated with the occurrence of capillary phlebectasias, or Fordyce lesions, of the scrotal skin (Figure 76-2).

Because vascular abnormalities are often responsible for cryptogenic gastrointestinal bleeding, their presence in the mouth should suggest that similar lesions elsewhere in the gastrointestinal tract may be responsible for blood loss in such cases.¹³ Not every individual, however, with bleeding vascular lesions of the gastrointestinal tract has involvement of oral structures, and the presence of oral lesions does not preclude existence of an unrelated distal bleeding lesion.

The oral mucosa

A number of abnormalities of the oral mucosa are encountered in elderly patients. These changes may be the result of medical therapy, signify the presence of a systemic disease, or represent premalignant changes.

Candidiasis

Candidiasis is usually caused by the fungus *Candida albicans*. This organism is part of the normal gastrointestinal flora, and its presence is not sufficient by itself to produce disease. Mucosal candidiasis occurs only after a change in other constituents of the normal flora or in the presence of an immunologic abnormality. In elderly patients, the widespread use of antibiotics and immunosuppressive chemotherapy for malignancies is most often responsible for the development of mucosal candidiasis.

The typical oral lesions of candidiasis are soft, white plaques that resemble cottage cheese. Characteristically, these plaques can be peeled from the mucosa, leaving the underlying surface raw and bleeding. This observation is important because most other white, plaque-like lesions, for example, leukoplakia, cannot be stripped off the mucosa.

A diagnosis of candidiasis is made by smearing scrapings of the lesion on a glass slide, macerating them with 20% potassium hydroxide, and examining this preparation under a microscope for the presence of typical hyphae. A definitive diagnosis can be made by culture on selected media.

Therapy usually consists of reestablishing the normal microbiologic flora by discontinuing antibiotics. In the immunocompromised host and the individual with significant morbidity, topical therapy with nystatin suspensions or troches is usually successful, although treatment with absorbable oral agents such as fluconazole may be required. Antifungal agents may be supplemented by the use of topical anesthetics to provide symptomatic relief (see later discussion).

Stomatitis

Cancer patients treated with radiation or chemotherapy frequently develop painful inflammation and erosions of the oropharyngeal mucosa. Stomatitis complicating cancer therapy is the direct consequence of drug and radiation toxicity to susceptible, rapidly dividing cell populations of the upper gastrointestinal tract and the indirect consequence of neutropenia, which impairs regeneration of injured tissues. Radiation to the head and neck also causes xerostomia secondary to fibrosis of the salivary glands. An absence of lubrication by saliva further aggravates mucosal damage,

and a lack of salivary IgA permits overgrowth of bacteria and fungi. Oral lesions may become infected, contributing to persistent injury, discomfort, and poor nutrition and posing a risk of more widespread infection in immunocompromised individuals.

The initial therapy for stomatitis is promotion of good oral hygiene. Brushing and flossing are contraindicated in neutropenic patients because of the risk of disseminated infection. Instead, mouthwashes containing dilute hydrogen peroxide or a salt and soda solution are used to reduce mucosal bacterial and fungal colonization.

A number of therapeutic mouthwash "cocktails" have been recommended to relieve symptoms, promote healing, and treat superficial mucosal infection in patients with stomatitis.¹⁴ Some of these cocktails have been tested in controlled trials, but the use of most is empirical, based on the known analgesic, antibiotic, and protective effects of widely available liquid medicines. Viscous lidocaine (2%) is frequently used as a topical anesthetic, as is diphenhydramine, which is often mixed with oral antacids or kaolin-pectin. Many recipes include sucralfate suspension because it coats damaged epithelium and promotes the production of mucus and protective prostaglandins. Antibiotics used alone or in combination in mouthwash cocktails to treat superficial infection include chlorhexidine gluconate, nystatin, tetracycline, neomycin, vancomycin, and clindamycin. Hydrocortisone and other glucocorticoids also have been added to reduce inflammation, but rapid absorption across the denuded oral mucosa into the systemic circulation may compromise the patient's immune defenses. Artificial saliva replacements (Salivart, Moi-Stir, Xero-Lube) are also available for patients with xerostomia.

Hairy tongue

"Hairy tongue" is characterized by hypertrophy of the filiform papillae of the tongue and a lack of normal desquamation. In this condition, the color of the tongue varies from yellow to brown or black, depending on staining by exogenous substances, such as tobacco or food, and on the presence of various chromogenic microorganisms.^{15,16} Hairy tongue is frequently seen in patients who have had extensive radiotherapy to the head and neck. Although these individuals are usually asymptomatic, some complain of nausea, dysgeusia, and halitosis. On occasion, the lingual papillae reach such considerable length that they brush against the soft palate, gagging the patient.

Many organisms have been cultured from papillary scrapings from this entity; there is, however, no proof of a cause-and-effect relationship with any microorganism, and invasion of the lingual epithelium has not been demonstrated. Species of microorganisms that have been isolated are, in all probability, simply colonizing an already abnormal, excessively papillated tongue.

Therapy for this disorder consists of vigorous brushing of the tongue to promote desquamation and to remove accumulated debris. In extreme cases, topical treatment with podophyllin, an alcoholic extract of the mayapple, may result in a dramatic response.

Leukoplakia

The term *leukoplakia* was introduced by Schwimmer in 1877 to describe any white plaque. Today, some authors use this term to refer to histologic zones of hyperkeratosis, acanthosis, and

chronic inflammation, whereas others reserve it to describe malignant dyskeratosis and epithelial atypia. Although leukoplakia is considered by many clinicians to be a premalignant condition, its natural history is uncertain because of a lack of uniform definition in case selection. The term should be abandoned because of its lack of specificity. Any persistent white lesion of the oral mucosa should be biopsied in an attempt to make a specific histologic diagnosis.

Leukoplakia is more common in men than in women, and most often occurs during the sixth and seventh decades.¹⁷ It can be found anywhere in the oral cavity, although it is most common on the buccal mucosa, tongue, and floor of the mouth. Leukoplakia varies in appearance, partly depending on the age of the lesion. Some investigators consider verrucous patches to be of higher malignant potential than smooth plaques, whereas others believe that granular pinkishgray to red islands, also called erythroplakia, are most likely to be associated with carcinoma in situ or even invasive malignancy. Such controversy stresses the importance of taking a biopsy in the management of all such lesions. Approximately 10% of patients with leukoplakia have or will develop invasive carcinoma in the lesion.¹⁷⁻¹⁹

Once the diagnosis of leukoplakia has been substantiated by microscopic examination of a biopsy specimen, therapy is initiated. When dysplasia is present, or when the lesion fails to resolve after a source of physicochemical trauma has been eliminated, treatment consists of ablation.

Epidermoid carcinoma

Approximately 5% of human cancers arise in the mouth; 95% of oral malignancies are epidermoid carcinomas.^{18,19} The lower lip is the most common site of malignancy in the area of the oral cavity. Epidermoid carcinoma of the lip occurs almost exclusively in elderly men; causal factors include actinic radiation, syphilis, and tobacco use, especially pipe smoking.

Carcinoma of the lip varies in clinical appearance and may be bulky or ulcerated. It metastasizes slowly, usually to the ipsilateral submental or submaxillary lymph nodes. Surgical resection or radiation therapy produces equally good results, with cures in approximately 80% of affected individuals. Successful treatment depends on the duration of symptoms, size of lesion, and presence of metastases.

Within the oral cavity, one half of epidermoid carcinomas originate in the tongue, and the rest arise with equal frequency in the palate, buccal mucosa, floor of the mouth, and gingiva. The disease is seen mainly in older individuals and occurs most often in males. Factors suspected of contributing to the development of oral cancer include tobacco, alcohol, nutritional deficiencies, syphilis, and miscellaneous forms of physicochemical trauma, such as irritation from pipe stems and dentures. Almost 90% of patients have a combination of predisposing factors.

Intraoral epidermoid carcinomas display a considerable amount of histologic variation, although lesions tend to be moderately well differentiated. Early carcinomas arising in the tongue typically are painless, even though they may ulcerate. Pain develops later, as the lesions grow, especially if they become secondarily infected. Tumors are usually located on the lateral or ventral surface of the tongue. The site of the primary lesion is of prognostic importance because cancers of the posterior aspect of the tongue tend to

be more aggressive. Nodal metastases are located on either or both sides of the neck. Tumors also spread by direct invasion. Early detection is mandatory if patients are to survive more than a year after diagnosis.

Keratoacanthoma is a spontaneously resolving benign lesion often mistaken for epidermoid carcinoma.²⁰ It occurs most frequently in adults 50 to 70 years of age, involves the upper and lower lips equally, and usually presents as a painful umbilicated lesion seldom more than 1 to 1.5 cm in diameter. It initially appears as a small nodule, which reaches full size within 4 to 8 weeks. It persists as a static lesion for another 4 to 8 weeks, after which the keratin core is expelled and the mass resorbed over a period of 6 to 8 weeks. Recurrence is rare.

THE OROPHARYNX

The oropharyngeal phase of swallowing is exceedingly complex, requiring the participation of multiple distinct structures in the mouth, pharynx, and esophagus coordinated by six cranial nerves and orchestrated by the swallowing center of the central nervous system. After food has been masticated and moistened with saliva, the tongue initiates swallowing by thrusting the food bolus into the oropharynx. The soft palate prepares for the arrival of the bolus by elevating, so that material from the mouth cannot enter the nasal passages. The glottis also shuts, and the epiglottis tilts downward to prevent the bolus from entering the trachea. Relaxation of the upper esophageal sphincter in association with contraction of the pharyngeal muscles allows propulsion of food into the esophagus.²¹

Striated muscle involved in the oropharyngeal phase of swallowing, like the muscles of mastication, may be impaired during aging by a decrease in lean body mass. A radiographic study of 100 individuals beyond the age of 65 suggested that 22 had pharyngeal muscle weakness along with abnormal cricopharyngeal relaxation with pooling of barium in the valleculae and pyriform sinuses.²² Several individuals also were noted to have tracheal aspiration of barium. All the subjects, however, were asymptomatic. Thus, although functional changes in the oropharyngeal phase of swallowing may occur with aging, these changes have not been identified as a cause of morbidity in elderly people.

Oropharyngeal dysphagia

Patients with oropharyngeal (cervical or "transfer") dysphagia complain of difficulty shifting food from the front of the mouth into the back of the throat, or of trouble initiating a swallow once the food bolus has been positioned in the oropharynx. Symptoms may be most severe when the patient attempts to swallow liquids. Signs of transfer dysphagia include nasal regurgitation or aspiration of oral contents during swallowing as a result of a failure to seal the nasopharynx or the trachea by appropriate muscle contraction. Inasmuch as oropharyngeal dysphagia may be due to a neuromuscular disorder, the patient may display other signs of neuromuscular dysfunction, including dysarthria, nasal speech, cranial nerve dysfunction, weakness, or sensory abnormalities.²³

A variety of conditions interfere with the transfer of food from the mouth to the esophagus (Table 76-1).²⁴ Mechanical lesions, including tumors, abscesses, and strictures, may block passage of the food bolus or disrupt structures that

Table 76-1. Causes of Oropharyngeal Dysphagia in Elderly People

Postoperative—laryngectomy
Medications
Motility disorders of the upper esophageal sphincter

directly mediate the oropharyngeal phase of swallowing. A neoplasm, infection, or cerebrovascular accident may damage the central nervous system, producing brain stem or pseudobulbar palsy and associated transfer dysphagia. The initiation of swallowing also may be impaired by degenerative diseases of the central or peripheral nervous system, the motor end plate, or the muscle itself. Finally, oropharyngeal dysphagia is often caused by a failure of upper esophageal sphincter function. Many of these problems are encountered in older individuals.

Cricopharyngeal achalasia

The term *cricopharyngeal achalasia*, partly derived from the Greek word meaning "absence of slackening," is a misnomer, as the cricopharyngeus muscle of patients with this disorder is capable of relaxing. The problem in cricopharyngeal achalasia is failure of the muscle to function in synchrony with other elements of the swallowing mechanism. As a result, the pharyngeal muscles propel all or part of the food bolus against a closed sphincter, producing symptoms of cervical dysphagia.

Cricopharyngeal achalasia is usually encountered in elderly individuals. Many disorders may cause this problem, but central nervous system diseases predominate. The clinical features are those of oropharyngeal dysphagia in general. Depending on the cause, the onset of symptoms may be sudden, as with a cerebrovascular accident, or intermittent, as with more insidious disorders such as diabetic neuropathy. The natural history of cricopharyngeal achalasia is also variable, again probably reflecting its many causes: dysphagia may diminish, remain unremitting, or follow a relapsing, remitting course. Most individuals with this disorder have more difficulty swallowing liquids than solids. Many patients have a pulmonary presentation with laryngitis, bronchitis, recurrent pneumonia, bronchiectasis, and pulmonary abscesses as the sequelae of otherwise quiet cricopharyngeal dysfunction.²⁵ In some patients, symptoms result in such a fear of eating that weight loss, malnutrition, and psychological problems overshadow the motility disorder.

Postintubation dysphagia

Special mention must be made of cervical dysphagia occurring as a sequela of endotracheal intubation. Unilateral vocal cord weakness is a common complication of endotracheal intubation and because the vocal cords are important to the formation of a tight laryngeal seal during the oropharyngeal phase of glutition, patients with vocal cord weakness may experience coughing and aspiration with swallowing. Individuals who have undergone a tracheostomy also may develop symptoms of oropharyngeal dysphagia. Scar

Figure 76-3. Oblique view of a barium-filled esophagus showing a small Zenker's diverticulum (*arrow*) proximal to a hypertrophied cricopharyngeus. (Reproduced from Brandt L.J. *Gastrointestinal disorders of the elderly*. Lippincott-Raven, 1986, New York.)

formation from a tracheostomy occasionally prevents normal elevation and anterior rotation of the larynx, causing decreased pharyngeal contraction and incomplete upper esophageal sphincter relaxation during swallowing.

Management of oropharyngeal dysphagia depends only in part on its cause. Any underlying disorder, such as parkinsonism, should be treated. If dysphagia persists despite such therapy, or if significant complications result from impairment of the swallowing mechanism, treatment can be directed at the esophagus itself.

Bougienage of the upper esophageal sphincter with mercury-weighted rubber dilators is beneficial to some patients but often gives only temporary relief. This technique is contraindicated by the presence of a pharyngoesophageal diverticulum because of the high risk of perforation (see later discussion).

Many individuals with cricopharyngeal achalasia benefit from surgical interruption of the upper esophageal sphincter.²⁶ Failure to respond is observed most often in patients with central nervous system disease or peripheral neuropathy, although even these individuals are occasionally relieved of symptoms by this procedure. Serious complications following cervical myotomy are rare. Botulinum toxin injection and balloon dilation also have been employed. Gastroesophageal reflux or severe distal esophagitis indicating reflux is an absolute contraindication to cricopharyngeal myotomy unless the lower esophageal defect is corrected first.

Pharyngeal diverticula ZENKER'S DIVERTICULUM

Zenker's diverticulum (Figure 76-3) is a posterior herniation of the hypopharynx through the triangular area just above the upper esophageal sphincter where the oblique and transverse fibers of the cricopharyngeus muscle join. It is seen once in every 1000 routine upper gastrointestinal series and is more frequent in males. Approximately 85% of cases occur in individuals over the age of 50.²⁷

Symptoms of Zenker's diverticulum usually develop insidiously. An annoying irritation in the back of the throat is an early complaint, which may be followed later by the more

classic symptoms of oropharyngeal dysphagia. Occasionally, an affected individual complains of a noise like the "roar of the ocean" or a "washing machine" during swallowing. Post-cibal and nocturnal regurgitation of undigested food are common complaints. Obstructive symptoms may be caused by associated cricopharyngeal achalasia or, rarely, by compression of the esophagus by a large diverticulum.

Incoordination and incomplete relaxation of the upper esophageal sphincter during swallowing have been described in association with Zenker's diverticulum, lending support to the theory that cricopharyngeal dysfunction leads to high pharyngeal pressures, which result in the formation of hypopharyngeal diverticula. Many patients with a Zenker's diverticulum, however, have normal function of the upper esophageal sphincter or even reduced upper esophageal sphincter pressure, suggesting that high pharyngeal pressures may be due to stiffening of the pharyngeal muscles with loss of compliance.²⁸

Zenker's diverticula most often are seen during x-ray examination but when small may be missed in the posteroanterior view because of superimposition over the main column of barium in the esophagus; this problem can be avoided by rotating the patient during the study (Figure 76-3). Endoscopic examination of the upper gastrointestinal tract in the presence of a hypopharyngeal diverticulum may be associated with an increased risk of perforation; however, this danger is minimized by passage of the instrument under direct vision.

Complications include compression and obstruction of the distal esophagus by a large diverticulum, respiratory difficulties caused by aspiration of diverticular contents, and diverticulitis with perforation. Rarely, carcinoma may develop in a Zenker's diverticulum.²⁹ Worsening of dysphagia, weight loss, and the appearance of blood in regurgitated material suggest the development of a malignant neoplasm.

The therapy for a symptomatic Zenker's diverticulum includes surgical excision alone or cricopharyngeal myotomy with or without removal of the diverticulum.³⁰ Endoscopic techniques for the treatment of Zenker's diverticulum also have been described.³¹

Lateral pharyngeal diverticula

Lateral pharyngeal diverticula, or pharyngoceles, occur with increased frequency in elderly people and are especially common in men.³² They develop in the gap between the superior and middle pharyngeal constrictors. Symptoms are the same as those of a Zenker's diverticulum. In addition, patients may complain of a neck mass that enlarges with a Valsalva maneuver. Increased intrapharyngeal pressure may be an important causal factor, as exemplified by the frequency of this entity in muzzins and wind instrument players. Surgical repair is safe and effective.

THE ESOPHAGUS

The muscularis propria of the esophagus is composed of striated muscle fibers proximally and smooth muscle fibers distally. The central nervous system governs the activity of the striated muscle by means of sequential activation of extrinsic nerves. In humans, the dominant mechanism for control of the smooth muscle of the esophagus is unknown; both central and intramural neural pathways have been demonstrated.

Orderly peristaltic contractions of esophageal muscle are necessary for normal esophageal function.

Although no information is available about the effects of aging on the regulation of esophageal muscle activity, alterations in esophageal muscle function have been identified manometrically in elderly individuals. These changes were described first in 1964 by Soergel et al,³³ who referred to motility disturbances in the elderly as "presbyesophagus." Soergel and his co-workers studied 15 subjects beyond the age of 90 and found a variety of abnormalities; 13 of their patients, however, had diseases known to affect esophageal motility. Subsequent studies have confirmed that, in the absence of other disorders, esophageal motility may be abnormal in elderly individuals, but the only manometric change identified in all the published work is a reduction in the amplitude of muscle contraction after a swallow.³⁴⁻³⁶

Elderly people also may be noted to have disordered motility, or "tertiary contractions," during a barium esophagogram, but this finding is rarely associated with symptoms.³⁷ Because motility changes that develop with aging do not appear to have clinical importance, the diagnosis of presbyesophagus should be abandoned. Elderly patients with dysphagia should be evaluated for the presence of disease processes involving the esophagus, and complaints should not be ascribed to motility changes occurring as a result of age alone.

Dysphagia and heartburn

Dysphagia and heartburn (pyrosis) are the principal symptoms of esophageal diseases; patients with esophageal disorders, especially elderly people, also may complain of respiratory difficulties, painful swallowing (odynophagia), chest pain resembling the pain of myocardial ischemia, regurgitation, and vomiting.³⁸⁻⁴⁰

Dysphagia is caused by impaired passage of food through the esophagus and is experienced immediately after the act of deglutition. Patients often complain that food "sticks on the way down." Since sensation in the esophagus is referred proximally, lesions at the gastroesophageal junction often appear as symptoms experienced at the level of the sternal notch. When a patient has symptoms apparently originating in the area of the proximal esophagus, evaluation of the entire esophagus, often with both esophagoscopy and barium radiography, is required.

The pattern of dysphagia frequently suggests the nature of the underlying disease.⁴¹ Schatzki observed that a correct diagnosis can be made after taking a careful history in up to 85% of patients with this complaint.⁴² Thus intermittent dysphagia connotes a motility disorder or a pliant mechanical obstruction such as an esophageal web. Progressive dysphagia often represents a neoplasm. Individuals who experience difficulty in swallowing liquids and solid food usually have a primary neuromuscular abnormality and disordered esophageal motility, whereas dysphagia produced only by solid foods is associated with mechanical obstruction of the esophagus.

Heartburn is a manifestation of the reflux of gastric contents into the esophagus and, as its name suggests, is described as being a hot sensation behind the sternum or in the left parasternal area. Pyrosis is relieved by antacids and intensified by bending at the waist or lying supine, especially when the stomach is full. Pyrosis also may be aggravated

by some medications, smoking, and ingestion of alcohol, fruit juices, caffeine, chocolate, or peppermint. Discomfort is often accompanied by regurgitation of gastric contents, belching, vomiting, or secretion of saliva (water brash). The nature or extent of esophageal abnormalities associated with gastroesophageal reflux and heartburn cannot be predicted on the basis of the intensity of symptoms, especially in elderly people; severe reflux disease as evidenced by esophageal ulcers may be present in the absence of substantial symptoms.⁴³

Esophageal motility disorders

After individuals with structural lesions have been excluded, more than 50% of adults of all ages with a complaint of dysphagia are found to have esophageal motility disorders.^{44,45} These abnormalities may be primary or secondary and are classified according to their manometric signatures. Most often, adults with dysphagia have disordered motility with nonspecific and inconsistent manometric features.

NONSPECIFIC SECONDARY MOTILITY DISORDERS

In elderly people, nonspecific disorders of esophageal motility frequently are secondary to a systemic disease. Examples of generalized disorders sometimes responsible for esophageal dysmotility are myxedema, amyloidosis, connective tissue diseases, and diabetes mellitus.

Approximately 50% of patients with diabetic neuropathy have abnormal esophageal motility. Findings in these individuals include a decrease in the amplitude of muscle contraction, delayed esophageal emptying, esophageal dilation, and reduced lower esophageal emptying sphincter pressure. In patients with diabetes, the severity of motility changes correlates with the severity of other neuropathic complications; however, affected individuals usually do not have significant dysphagia. For this reason, esophageal symptoms in a diabetic must be fully evaluated and not simply attributed to diabetes.

PRIMARY AND SECONDARY ACHALASIA

Primary achalasia is the second most common motility disorder diagnosed in patients with nonstructural dysphagia, but it is rare in elderly people.⁴⁶ In persons beyond the age of 50, achalasia is most often secondary to gastric adenocarcinoma (Figure 76-4); pancreatic adenocarcinoma, oat cell carcinoma, reticulum cell sarcoma, and anaplastic lymphoma are responsible for isolated cases.^{47,48} Manometric findings in secondary achalasia are identical to those in the primary disorder: absence of esophageal peristalsis, usually in association with elevation of resting lower esophageal sphincter pressure and failure of the lower esophageal sphincter to relax following an appropriate stimulus. The elevation of resting lower esophageal sphincter pressure typical of achalasia is less pronounced in elderly people, who also experience less chest pain in association with this disorder than do younger patients.⁴⁹ Pneumatic dilation typically is the treatment of choice for patients with primary achalasia.

Patients with both primary and secondary achalasia may experience progressive difficulty in swallowing. Food collects in the esophagus, which may become distended and tortuous even when the patient has an underlying carcinoma. In the absence of proximal dilation of the esophagus, a diagnosis of malignancy is favored. When the patient reclines, pooled food flows out of the esophagus back into

Figure 76-4. Barium esophagram showing tapering of the distal esophagus simulating achalasia. The subtle presence of a mass in the gastric fundus (arrows) suggested a diagnosis of carcinoma. (Reproduced from Brandt LJ. *Gastrointestinal disorders of the elderly*. Lippincott-Raven, 1986, New York.)

the pharynx, resulting in coughing and aspiration. Affected individuals, therefore, may have aspiration pneumonia. In addition to an infiltrate, a chest x-ray may reveal an air-fluid level in the esophagus and absence of the gastric air bubble. Because the presentations of primary and secondary achalasia may be identical, malignancy must be excluded in an elderly patient with this syndrome. Computed tomographic x-rays of the chest and upper abdomen, and endoscopy with biopsy of the distal esophagus, are recommended.⁵⁰ Endoscopic ultrasound may be helpful in differentiating primary from secondary achalasia.

The pathogenesis of secondary achalasia is unknown. Submucosal infiltration of the distal esophagus by tumor has been noted in some cases and normal histologic appearance in others.⁵¹ It is possible that, in the absence of tumor infiltration, the motility disorder reflects a paraneoplastic neuropathy; manometric and roentgenographic abnormalities may disappear after resection of a gastric carcinoma or therapy for a lymphoma.^{52,53}

DIFFUSE ESOPHAGEAL SPASM

Although primary esophageal motility disorders usually occur in middle-aged individuals, manometric recordings in elderly persons with intermittent dysphagia occasionally display the pattern of diffuse esophageal spasm.³⁸ In this motility disturbance, the patient has simultaneous, repetitive muscle contractions of prolonged duration occurring spontaneously or after a swallow. Normal peristalsis is present most of the time, explaining the intermittent nature of symptoms, which may be triggered by hot or cold food, pills, or carbonated beverages. The pathogenesis of diffuse esophageal spasm is obscure; on the basis of case reports,

some have speculated that in some cases this disorder represents a stage in the development of achalasia.

"NUTCRACKER" ESOPHAGUS AND NONCARDIAC CHEST PAIN

It is usually assumed that in persons free of significant coronary artery disease with chest pain resembling the pain of myocardial ischemia, symptoms are due to an esophageal motility disorder. Such patients, however, rarely have chest pain during esophageal manometry, and provocative testing may be used to precipitate symptoms. Provocative testing with intravenous edrophonium chloride and infusion of acid into the esophagus causes chest pain in about 30% of subjects with a history of noncardiac chest pain.⁵⁴ A similar number of patients with noncardiac chest pain have been found to have an esophageal motility disorder, but only 25% of these individuals have symptoms during provocative testing.⁴⁴ It is often difficult, therefore, to prove that the esophagus is the source of the patient's complaints.

The most common motility disorder found in patients with noncardiac chest pain is "nutcracker" esophagus.⁴⁴ This abnormality is characterized by peristaltic muscle contractions of extremely high amplitude and long duration in the distal portion of the esophagus. A defect in esophageal transit can be demonstrated in many affected patients using a radio-nuclide marker. In one large series of individuals with noncardiac chest pain, 50% of patients with a motility disorder had nutcracker esophagus; other symptomatic individuals were found to have diffuse esophageal spasm.⁴⁴ A causal role for these motility defects in the production of chest pain has not been proved. In recent studies, many patients with noncardiac chest pain were found to have musculoskeletal disorders.

A number of medications have been used to treat primary esophageal motility disorders, especially diffuse esophageal spasm and nutcracker esophagus. Nitrates, anticholinergics, calcium channel blockers, or sedatives are occasionally effective in relieving symptoms of dysphagia and chest pain; their benefit in this setting, however, has never been evaluated in an appropriately designed trial. Some patients also obtain relief from dysphagia after bougienage.

Hiatus hernia

The incidence of hiatus hernia (Figure 76-5) increases with each decade of life from less than 10% of those under age 40 to approximately 40% in the sixth and seventh decades and 70% in patients beyond the age of 70. Symptoms such as pyrosis and regurgitation formerly attributed to the hernia are now known to be due to lower esophageal sphincter dysfunction. Sphincter dysfunction and gastrointestinal reflux are independent of the presence of a hiatus hernia, and the common "sliding" hiatus hernia is not considered by itself to be pathogenic.

One type of hiatus hernia that deserves special mention is the paraesophageal hernia (Figure 76-6), an uncommon hernia that occurs most often in persons between the ages of 60 and 70. Paraesophageal hernias often result in significant complications and therefore are of major importance. These hernias are frequently asymptomatic or cause only nagging discomfort until mechanical entrapment occurs. Such a catastrophe is associated with progressive distention of the incarcerated segment, vascular embarrassment, hemorrhage, gangrene, and perforation. In the absence of contraindications, a paraesophageal hernia demands surgical repair.

Figure 76-5. A small hiatus hernia sliding in (A) and out (B) of the thorax. The esophagogastric junction is seen above the diaphragm. (Reproduced from Brandt L.J. *Gastrointestinal disorders of the elderly*. Lippincott-Raven, 1986, New York.)

Figure 76-6. Barium esophagogram demonstrating a paraesophageal hernia with the gastric fundus above the diaphragm. The esophagogastric junction is at the level of the diaphragm. (Reproduced from Brandt L.J. *Gastrointestinal disorders of the elderly*. Lippincott-Raven, 1986, New York.)

Reflux esophagitis

The only notable change in the lower esophageal sphincter seen with aging is a reduction in the amplitude of postdeglutitive contraction or relaxation. Nevertheless, because the secretion of gastrin, which potentiates contraction of the lower esophageal sphincter, increases with age, and because gastric acid secretion declines with age in many individuals, it is unusual for reflux

esophagitis to appear for the first time in elderly people.⁵⁵ The nature or extent of esophageal injury associated with gastroesophageal reflux cannot be predicted on the basis of the intensity of symptoms in older patients.⁴³ Complications of chronic, asymptomatic reflux such as stricture formation may be the initial clinical presentation of esophagitis in about 20% of affected elderly patients. When an aged individual complains of the recent onset of pyrosis, other causes of esophageal symptoms, such as candidiasis, must be considered. The therapy of reflux in elderly patients is the same as in younger patients, however, attention must be paid to the potential development of adverse effects of medications (see later discussion).⁵⁶

Barrett's metaplasia

In patients with Barrett's metaplasia, the lower esophagus is lined for a variable distance by columnar, rather than the usual stratified squamous, epithelium.⁵⁷ The metaplastic columnar epithelium may be continuous with the columnar epithelium of the stomach and extend in tongues into the distal esophagus, or it may be present in islands surrounded by normal squamous epithelium. The importance of Barrett's metaplasia lies in its association with reflux esophagitis, (deep) esophageal ulcers, (high) esophageal strictures (Figure 76-7), and adenocarcinoma. The metaplastic columnar lining is believed to develop as a consequence of prolonged gastroesophageal reflux. Esophageal squamous epithelium damaged by exposure to gastric contents is replaced by a specialized columnar epithelium (intestinal metaplasia), a junctional type of epithelium, or a gastric fundic type of epithelium. Each of these three cell types may be seen alone or in combination with the others.

Most cases of Barrett's esophagus probably occur between the ages of 50 and 70; the exact incidence is unknown. The most common symptoms are those related to the reflux of stomach contents, and the entity is diagnosed best by esophagoscopy with multiple biopsies. The presence of

specialized columnar epithelium establishes the diagnosis of Barrett's esophagus.⁵⁷ If the columnar epithelium in the biopsy specimen is one of the other two types, the biopsy must have been taken at least 3 cm above the gastroesophageal junction to make the diagnosis. Intestinal metaplasia can be recognized *in situ* by staining with Alcian blue.

Stricture and neoplasia are long-term complications of Barrett's esophagus. There is increasing evidence that cancer arises only in the specialized columnar epithelium. By careful screening using esophagoscopy with a directed biopsy every 1 to 2 years, premalignant dysplastic changes can usually be detected.^{58,59} The development of severe dysplasia or carcinoma *in situ* requires resection of the involved esophagus. Thermal ablation of Barrett's epithelium with multipolar electrocoagulation, laser coagulation, or argon plasma coagulation has been investigated. Destruction of the Barrett's epithelium by these techniques is successful initially, but recurrence of the Barrett's tissue may occur. Therapy of reflux usually results in symptomatic improvement, but regression of the columnar epithelium does not occur without surgery.

Lower esophageal ring

A lower esophageal or Schatzki ring (Figure 76-8) is a thin, annular ridge of mucosa projecting perpendicularly into the esophageal lumen at or near the squamocolumnar

Figure 76-7. Barium esophagogram revealing a stricture of the esophagus at the level of the aortic arch in a patient with Barrett's esophagus. A hiatus hernia is also present. (Reproduced from Brandt L.J. *Gastrointestinal disorders of the elderly*. Lippincott-Raven, 1986, New York.)

Figure 76-8. A Schatzki ring prevents passage of a barium pill in a patient with intermittent dysphagia. (Reproduced from Brandt L.J. *Gastrointestinal disorders of the elderly*. Lippincott-Raven, 1986, New York.)

junction.^{60–62} A Schatzki ring may be asymptomatic, found incidentally during evaluation of the upper gastrointestinal tract for unrelated reasons, or it may cause intermittent episodes of dysphagia and an uncomfortable sticking or pressing sensation as a result of food lodging above the ring. Episodes commonly occur during hurried meals, meals requiring a great deal of mastication, or meals consumed with alcohol, hence the appellation “steakhouse syndrome.” As the lumen of the ring diminishes to less than 12 mm (0.047 in.) in diameter, attacks become more frequent. Attacks usually last several minutes or more until the patient regurgitates the food bolus or flushes it into the stomach with a beverage.

Total obstruction of the esophagus secondary to food impaction frequently brings patients to the emergency department. Relaxation of the esophagus by administration of a small dose of intravenous benzodiazepine or 1 mg of glucagon is occasionally effective in relieving the impaction. Pepsin solution (meat tenderizer) should not be used to try to digest the meat because its use has been associated with esophageal perforation. If the impacted bolus does not pass, it must be removed by esophagoscopy. Alternatively, it may be gently nudged into the stomach if a patent lumen can be seen distally, the esophageal mucosa is intact, and there is no bone or other sharp object present. Multiple biopsies to disrupt the ring or dilation with bougies are techniques used to treat symptomatic rings.

Dysphagia aortica

Degenerative changes in the aorta may produce compression of the esophagus and dysphagia. Obstruction of the upper esophagus is occasionally caused by a thoracic aneurysm, while the distal esophagus may be squeezed between an atherosclerotic aorta posteriorly and the heart or esophageal hiatus anteriorly. Most patients are women beyond the age of 70.^{63–65} Symptoms are usually prevented by having the patient thoroughly masticate solid food, but occasionally the obstruction is severe enough to warrant surgical mobilization of the esophagus at the hiatus.⁶⁶

Medication-induced esophageal injury

Esophageal injury can occur as a result of the local caustic effects of medications.^{67,68} The most frequent offenders are antibiotics, especially tetracyclines, potassium chloride, ferrous sulfate, nonsteroidal anti-inflammatory drugs, alendronate, and quinidine.

Most patients with medication-induced esophageal injury have no underlying esophageal disorder. Some individuals, however, have nonspecific, asymptomatic disorders of esophageal motility, peptic strictures, esophageal compression from left atrial enlargement, a prominent aortic knob, or mediastinal adhesions following thoracic surgery. Pills commonly lodge in the esophagus at the level of the aortic knob or the lower esophageal sphincter without the patient's knowledge. Many cases of pill-induced esophageal injury probably remain unrecognized with full recovery. The most frequent symptoms of medication-induced esophageal injury are odynophagia and retrosternal pain. Symptoms usually resolve within 6 weeks of stopping the medication or changing it to a liquid formulation; damage, however, may result in esophageal stricture formation or, occasionally, hemorrhage or perforation. Pills should always be taken with a generous amount of water, and elderly

patients should not take pills immediately before bedtime because a decrease in salivation and esophageal motor activity accompanies sleeping.⁶⁹

Esophageal diverticula

Diverticula of the esophagus are much less common than diverticula of other parts of the gastrointestinal tract. In a review of 20,000 barium studies on the upper gastrointestinal tract, Wheeler noted only six midesophageal (traction-type) and three epiphrenic (pulsion-type) diverticula, as compared with 1020 duodenal diverticula.⁷⁰ The terms *traction* and *pulsion* refer to commonly accepted theories regarding the pathogenesis of esophageal diverticula. Traction diverticula are thought to be caused by the effects of fibrotic disease in structures contiguous with the esophagus, whereas pulsion diverticula are hypothesized to result from increased intraluminal pressure. Pseudodiverticulosis of the esophagus also has been described.

MIDESOPHAGEAL DIVERTICULA (TRACTION DIVERTICULA)

Traction diverticula occur most commonly in the middle third of the esophagus, where a large group of lymph nodes lies in direct contact with the esophageal wall. Nodal inflammation of this area may lead to periesophagitis, fixation of the esophagus to the lymph nodes, and distortion of the esophageal wall. In the past, tuberculosis was the most common cause for this process; any infection with lymph node involvement, however, may lead to the formation of a traction diverticulum.

Traction diverticula usually occur in patients of middle age or older and are slightly more common in men. They rarely cause symptoms, perhaps because they are small, have a broad neck, and can contract and empty because they contain all the layers of the esophageal wall including muscle.

EPIPHRENIC DIVERTICULA (PULSION DIVERTICULA)

Pulsion diverticula are found in the lower 10 cm of the esophagus, usually on the right wall. Like traction diverticula, they contain all the layers of the esophageal wall; the muscular layer, however, may be quite attenuated.

Epiphrenic diverticula usually develop in males during middle age. Patients may complain of dysphagia or chest pain, but symptoms are probably due to an associated esophageal motor abnormality, such as achalasia or diffuse esophageal spasm.⁷¹ The occurrence of an epiphrenic diverticulum without an underlying motility disorder or a hiatus hernia appears to be rare.

Many epiphrenic diverticula are asymptomatic, and in these instances no therapy is required.⁷² Treatment of esophageal reflux or an underlying, motility disorder may afford the patient symptomatic relief.^{73,74} In cases of larger diverticula, surgical resection may be necessary.⁷⁵

INTRAMURAL PSEUDODIVERTICULOSIS

In esophageal pseudodiverticulosis, dilation of the excretory ducts of submucosal glands causes multiple small (1 to 3 mm) invaginations of the esophageal wall.^{76,77} These defects involve all, or segments of, the esophagus in a circumferential fashion. Pseudodiverticula are best detected by barium contrast studies; their roentgenographic appearance is quite

Figure 76-9. Intramural pseudodiverticulosis with multiple outpouchings (arrows) on a barium esophagogram. (Reproduced from Brandt LJ. *Gastrointestinal disorders of the elderly*. Lippincott-Raven, 1986, New York.)

characteristic (Figure 76-9). Pseudodiverticulosis is usually diagnosed during the seventh decade of life in patients with dysphagia. In at least 20% of cases, gastroesophageal reflux, a motility disorder, or a malignancy is found, and in approximately one half of patients, smears or cultures of the esophageal mucosa reveal *Candida albicans*. Stenoses, or areas of reduced distensibility, are found in up to 90% of cases of pseudodiverticulosis and preferentially seem to involve the upper esophagus. Surprisingly, there is no fixed relationship between the narrowed area and the segment involved with pseudodiverticula.

The cause of pseudodiverticulosis is unknown. The term *adenosis* has been used to refer to this entity because the number of deep esophageal mucous glands is markedly increased. Therapy consists of treatment of associated abnormalities. Coexisting strictures should be evaluated to ensure that they are benign.

Esophageal candidiasis

Infection of the esophagus is rare in patients without acquired immunodeficiency syndrome, with the exception of infection with *C. albicans*. *C. albicans* is a normal inhabitant of the

alimentary tract; the yeast form is found in almost 50% of oral washings and 80% of stool samples.⁷⁸ The population of *C. albicans* is suppressed in healthy adults by other intestinal flora. Comparison of fecal specimens from subjects aged 70 to 100 with those of individuals aged 20 to 69 have revealed fungi to be more common in the elderly group. This finding may be explained by a diminution in esophageal peristalsis, a reduction in gastric acid secretion, and age-related alterations in cellular and humoral immunity.

In the absence of antibiotic therapy or an underlying immune disorder, esophageal candidiasis is a disease of elderly people. Most cases in this age group, however, occur in association with predisposing conditions, including malignancy, therapy with immunosuppressive or cytotoxic drugs, diabetes mellitus, malnutrition, and treatment with broad-spectrum antibiotics.^{79,80}

In the proper clinical setting, dysphagia, odynophagia, substernal burning, or an awareness of food passing down the esophagus should suggest the possibility of candida infection, although even in the presence of infection with *C. albicans*, up to one half of patients may be asymptomatic. Esophageal candidiasis often results from the extension of oral lesions, and a careful examination of the oral cavity is important in any debilitated patient complaining of esophageal symptoms.

A diagnosis of candida esophagitis may be suggested by an abnormal barium esophagogram, although a normal study does not exclude the presence of this organism. Esophagoscopy is the best method for detecting candida infection; raised white plaque, hyperemia, ulceration, and friability are characteristic. The gross appearance of candida esophagitis may be confused with that of exudative esophagitis, and therefore the diagnosis must be confirmed by brushings and by taking biopsies. Typical hyphae are revealed under the microscope in scrapings placed on a glass slide and macerated with 20% potassium hydroxide.

In the appropriate setting, a trial therapy may be initiated without attempting an invasive diagnosis. As in oral and vaginal candidiasis, therapy usually consists of promoting the reestablishment of normal microbiologic flora by discontinuing antibiotics. In an immunocompromised host or in an individual with significant morbidity, fluconazole is considered the drug of choice. Odynophagia can be treated with viscous lidocaine or with a "swish-and-swallow" preparation of the type used to treat stomatitis (see previous discussion). Failure to respond to simple treatment necessitates endoscopic confirmation of the diagnosis and often systemic therapy with additional antifungal agents.

Esophageal neoplasms

Esophageal cancer (Figure 76-10) occurs most frequently after age 55 and is three times more common in males than in females in the United States, and two times more common in males than in females in the United Kingdom.¹ In the United States, it accounts for approximately 2% of all reported cancers. Factors associated with the development of esophageal cancer include alcohol and tobacco use, thermal irritation, poor oral hygiene, and esophageal stasis.^{1,81,82} Furthermore, an association has been noted with certain esophageal diseases, notably achalasia, Barrett's esophagus, lye stricture, and Plummer-Vinson syndrome, and with previous gastric surgery.⁸³⁻⁸⁵

Figure 76-10. Barium esophagogram demonstrating an ulcerating esophageal carcinoma. (Reproduced from Brandt LJ. *Gastrointestinal disorders of the elderly*. Lippincott-Raven, 1986, New York.)

Surveillance, epidemiology, and end results (SEER) data show an increase in adenocarcinoma from 8% to 18% of all esophageal cancers during the years 1973–1984; it now represents the most rapidly increasing malignancy in the United States.⁸⁶ Esophageal adenocarcinoma is either cancer of the gastric fundus or a malignancy that has developed in a segment of Barrett's esophagus. Squamous cell carcinoma most commonly involves the middle third of the esophagus. Local spread occurs early and because the esophagus dilates so readily, dysphagia, the most common complaint at the time of diagnosis, is a late symptom.

In elderly people an important manifestation of esophageal cancer is an achalasia-like syndrome. Primary achalasia is uncommon in patients beyond the age of 50. Elderly individuals who have symptoms of achalasia of less than 1 year's duration associated with notable weight loss should be suspected of having a malignancy, most often gastric adenocarcinoma. The pathogenesis of secondary achalasia is unknown; in some cases the lower esophagus is infiltrated with tumor cells, but in other cases achalasia may reflect a paraneoplastic process.

The prognosis for esophageal cancer is dismal. Management is directed at relieving progressive obstruction.^{87–89} Surgical resection and radiation are the accepted modes of treatment. Surgical resection offers the only chance for long-term survival, but fewer than half of all patients having esophageal cancer have a resectable lesion. If there is evidence of nodal or distant metastases, a thoracotomy should be avoided. Thoracic radiation, while useful, may be followed by the development of esophagitis, usually within 3 weeks of initiating therapy and continuing for several weeks after its completion. Chemotherapy may result in symptomatic improvement but does not substantially prolong survival. New chemotherapeutic agents should be administered under an investigational protocol. Combined modality therapy may offer advantages over more traditional approaches. Palliative therapy with endoscopically placed stents, lasers, or photodynamic therapy is often very useful and has improved the quality of life for many patients, albeit without prolonging survival.

THE STOMACH

Aging is associated with alterations in both the motor and secretory functions of the stomach but, as in other parts of the gastrointestinal tract, changes in gastric physiology attributable to age alone rarely are responsible for symptoms.

The motor activity of the stomach allows it to behave as two individual, albeit coordinated, organs: one that processes liquids and another that processes solids. The fundus and proximal body of the stomach serve as a reservoir for liquids. In contrast, the distal gastric body and the antrum grind solids into small particles and pump them into the duodenum. The activities of both the proximal and distal stomach are controlled by complex neural and hormonal mechanisms. Studies employing food labeled with radioactive isotopes suggest that gastric emptying of liquids is prolonged in elderly persons, whereas emptying of solids is unaffected by age.^{90,91}

Changes in gastric secretion also occur in individuals as they grow older. In the past, almost every study on gastric acid production showed a decline in basal and stimulated acid output with advancing age.⁹² Work by Goldschmiedt et al,⁹³ however, suggests that in the absence of *Helicobacter pylori* infection, aging is actually associated with an increase in gastric acid secretion. Previous confusion about the effect of aging on gastric acid secretion is probably related to the high incidence of *H. pylori* infection and chronic atrophic gastritis with secondary achlorhydria in older individuals (see later discussion).⁹⁴

Gastric and duodenal mucosal injury

Advances in our understanding of the pathobiology of gastric and duodenal mucosal injury, and improvements in our ability to examine the upper gastrointestinal tract and detect diseases responsible for mucosal injury, make it important for physicians to use descriptive and diagnostic terminology carefully in clinical practice.^{95,96} Unless diagnostic findings are reported with a precision that accurately reflects current understanding of mucosal injury, the benefits of medical advances made during the past few decades may be lost to patients.

In usual cases of gastric or duodenal mucosal injury, endoscopic inspection often reveals the presence of gross epithelial defects. Small epithelial defects, or erosions, do not penetrate the muscularis mucosae. Ulcers are defined as being larger than 3 mm in diameter and extend a variable distance through the muscularis mucosae, in some instances freely perforating into the peritoneal cavity or penetrating into an adjacent organ. A typical ulcer is composed of four layers or zones: a superficial layer of fibrinopurulent debris overlying a zone of inflammation, a layer of granulation tissue, and, at its base, a collagenous scar. Both erosions and ulcers may be sources of bleeding.

Diffuse mucosal erythema, a common finding at endoscopy, in most instances represents microvascular congestion and, although it is interpreted by many endoscopists as indicating the presence of "gastritis," this conclusion is unjustified. Mucosal erythema due to microvascular congestion is caused by a variety of factors and is without any specific causal significance or clinical association.⁹⁶ Conversely, patients often have histologic gastritis without the presence of mucosal erythema.

The term *gastritis* implies the presence of inflammation and should not be used unless examination of a biopsy specimen has revealed typical mucosal inflammatory changes, including infiltration of the lamina propria with polymorphonuclear leukocytes and mononuclear cells. Neutrophils are seen early in the course of inflammation (acute gastritis). With the passage of time, mononuclear cells, mainly plasma cells, and eosinophils appear in increasing numbers (chronic gastritis). Most patients with gastritis have a predominance of mononuclear cells in the lamina propria with a lesser number of neutrophils (chronic active gastritis).⁹⁷ The inflammatory changes of gastritis are accompanied by signs of cell injury and regeneration. Cell damage and death cause submucosal hemorrhage and edema and lead to development of epithelial defects. Hemorrhage and edema may be visible grossly at endoscopy and evident on microscopic examination of biopsy specimens, as are erosions and ulcers. In response to injury, the epithelium regenerates by proliferation and differentiation of mucous neck cells, a process that leads to elongation and tortuosity of the gastric pits (foveolar hyperplasia). The vast majority of cases of gastritis are caused by infection with *H. pylori* (type B gastritis). Gastritis also may be due to other less common bacterial infections, granulomatous disease, autoimmune disease (type A gastritis), and hypersensitivity reactions.

Other agents of gastric injury damage the mucosa without exciting an inflammatory response. This gastropathy is sometimes referred to as type C gastritis, an unfortunate misnomer given the noninflammatory nature of the process.⁹⁸ Microscopic examination of biopsy specimens from patients with gastropathy typically reveals vascular congestion and edema of the lamina propria, hypertrophy of the muscularis mucosae, and mucosal regenerative changes with foveolar hyperplasia.⁹⁹ As in gastritis, cell damage and death are accompanied by submucosal hemorrhage and edema and lead to the development of epithelial defects. The latter changes are all often grossly visible on endoscopy. The most common causes of gastropathy are ingestion of nonsteroidal anti-inflammatory drugs (NSAIDs) and ethanol.

***Helicobacter pylori*, gastritis, and peptic ulcer disease**

Infection with *H. pylori*, a spiral gram-negative microaerophilic rod, is the most common chronic bacterial disease in humans. This organism attaches to receptors on the surface of gastric

mucous neck cells and is also found on metaplastic gastric epithelium in the duodenum but not on the duodenal mucosa itself or on metaplastic duodenal mucosa in the stomach (Figure 76-11).¹⁰⁰ *H. pylori* causes alterations in cell structure and function, inflammation, metaplasia, and cell death.¹⁰¹ A number of virulence factors, including urease, make it possible for the organism to colonize the stomach and produce disease.¹⁰²

H. pylori infection is the most common cause of chronic gastritis (type B antral gastritis) and is one of the two principal causes of peptic ulcer disease, the other being ingestion of NSAIDs. More than 90% of patients with duodenal ulcer and more than 75% of patients with gastric ulcer also have *H. pylori* infection and chronic active gastritis.¹⁰² The relationship between ulcer disease and gastritis was recognized long before the causal role of *H. pylori* in the pathogenesis of peptic ulcer disease was understood. *H. pylori* infection also has been linked to the development of gastric cancer, another gastritis-associated disease.¹⁰³

Infection with *H. pylori* is usually acquired during childhood and occurs most often in persons living under conditions of poverty, crowding, and inadequate sanitation.¹⁰⁴ The prevalence of *H. pylori* infection in the United States and in the nations of western Europe increases with advancing age, a result of the poorer living conditions in these countries during the early years of the twentieth century.¹⁰⁵ Thus regardless of present socioeconomic status, infection is most prevalent in older individuals. The incidence of peptic ulcer disease also increases progressively with advancing age, reflecting the age-related increase in *H. pylori* infection.

Under experimental conditions, acute infection with *H. pylori* causes transient dyspeptic symptoms accompanied by the development of active antral gastritis.¹⁰⁶ Mucosal

Figure 76-11. Gastric biopsy showing *H. pylori* in the surface mucous layer (Giemsa stain, 1000x). (Courtesy of Sumi Mitsu.)

inflammation apparently may resolve spontaneously in the minority of patients or become chronic, gradually spreading proximally into the body and fundus of the stomach. As the disease progresses, inflammation extends into the deeper, glandular part of the epithelium containing the gastric secretory cells. These include parietal cells, which make hydrochloric acid and intrinsic factor; chief cells, which make pepsin; pylorocardiac gland cells, which make mucus; and endocrine G cells, which make gastrin. Normal glands are gradually destroyed and replaced by metaplastic glands (intestinal metaplasia) or by atrophic gastric mucosa (atrophic gastritis), a process that takes many years. Atrophic gastritis often is associated with low serum gastrin levels and antibodies to gastrin-secreting cells. Patients with chronic active gastritis frequently also have submucosal hemorrhage, edema, epithelial erosions (erosive gastritis), and peptic ulcers.

Individuals with active gastritis and gastric mucosal atrophy are usually asymptomatic but may complain of intermittent dyspepsia, abdominal pain, distention, nausea, and vomiting (nonulcer dyspepsia). The relationship, if any, between symptoms of nonulcer dyspepsia and gastritis is unclear (see later discussion); many persons with dyspepsia do not have gastritis, and many persons with gastritis do not have dyspepsia.¹⁰⁷ Dyspeptic symptoms may be due to the development of a gastric or duodenal ulcer, although at least 50% of patients with acute ulcers are asymptomatic.

H. pylori infection may be diagnosed by a transendoscopic pinch biopsy of the stomach. Microscopic examination of biopsy specimens from infected individuals reveals chronic active gastritis and typical spiral gram-negative rods in the mucus coating the surface epithelium (Figure 76-11). The absence of gastritis strongly argues against *H. pylori* infection, whereas its presence suggests that a failure to identify *H. pylori* is due to sampling error. Tissue also may be implanted in commercially available agar plates containing urea and a pH indicator. If *H. pylori* is present in the tissue specimen, bacterial urease will split the urea into bicarbonate and ammonia, raising the pH and producing a color change. Because infection may be patchy, testing several specimens obtained from different parts of the stomach improves the sensitivity of the assay.

Noninvasive diagnosis of *H. pylori* infection can be made by detecting serum antibody to bacterial antigens. This method of diagnosis is satisfactory, presuming there is no indication for endoscopy if the patient has not previously been treated with antibiotics to which *H. pylori* is sensitive. Antibody titers decrease gradually after eradication of infection, but qualitative serology remains positive for a number of years, leaving what has been referred to as an "immunologic scar." The presence of an immunologic scar makes it impossible to use antibody testing to assess the effectiveness of therapy or the occurrence of reinfection. This problem is avoided by using the urea breath test, which is positive only in a setting of active infection. In the urea breath test, the patient is given an oral dose of urea labeled with either a stable (¹³C) or unstable (¹⁴C) isotope of carbon. If the patient is infected with *H. pylori*, the urea will be metabolized by bacterial urease to ammonia and bicarbonate, and bicarbonate containing the isotopic tracer will be converted to CO₂ and expired. The presence of labeled CO₂ in samples of expired gas indicates active *H. pylori* infection. A stool assay for detection of *H. pylori* also is available commercially.

Simultaneous treatment with a combination of two antibiotics and a proton pump inhibitor is the most consistently effective means of curing *H. pylori* infection.¹⁰⁸ *H. pylori* is sensitive to a variety of antimicrobial agents, including metronidazole, tetracyclines, macrolides, some quinolones, β -lactams, bismuth preparations, and proton pump inhibitors. The most commonly used regimen is a combination of amoxicillin, clarithromycin, and a proton pump inhibitor. Regimens containing metronidazole are limited by the frequent occurrence of bacterial resistance to this agent. Because of the morbidity caused by *H. pylori* infection, the National Institutes of Health Consensus Development Panel has published guidelines mandating treatment of all *H. pylori*-infected ulcer patients, including those currently without an active ulcer crater or dyspeptic symptoms.¹⁰⁹ The significant treatment failure rate makes it desirable to document a cure by conducting a urea breath test 4 weeks after the completion of therapy. In addition to antibiotic therapy for *H. pylori* infection, patients with acute ulcers should be treated with an antisecretory agent to promote ulcer healing.

Nonsteroidal anti-inflammatory drugs, gastropathy, and peptic ulcer disease

Nonsteroidal anti-inflammatory drugs (NSAIDs) are among the most frequently prescribed medicines in the world. Approximately 3 million people in the United States, or 1.2% of the population, take at least one NSAID daily. Uncounted others regularly use over-the-counter NSAID preparations, including aspirin. As a result, NSAID-related morbidity is exceedingly common; each year 2% to 4% of chronic NSAID users have a serious drug-induced complication involving the gastrointestinal tract.¹¹⁰ The use of NSAIDs and complications of NSAID use are most prevalent in elderly people.¹¹¹⁻¹¹³ In the United Kingdom, NSAID prescription rates for the entire population increased steadily from 1967 to 1985 and did so in direct proportion to the age of the recipient, with progressively more prescriptions being written for progressively older patients.¹¹⁴ Thus in 1985, an astonishing 1400 NSAID prescriptions were written for every 1000 women in the United Kingdom aged 65 years or older. These chronic NSAID users are estimated to have a twofold to threefold greater mortality rate than nonusers because of drug-related gastrointestinal complications.

Each and every nonselective NSAID is capable of injuring the gastrointestinal mucosa and does so in a dose-dependent fashion roughly proportional to its anti-inflammatory effect. Virtually 100% of patients who take a NSAID preparation, including aspirin, develop acute gastropathy during the first 1 to 2 weeks of therapy.¹¹⁵ This gastropathy has the typical histologic features described above and characteristically is associated with submucosal hemorrhage and some degree of edema, both of which are often grossly visible at endoscopy. Many NSAIDs, such as aspirin, are weak acids that remain nonionized as the tablets break up and are dispersed in low-pH gastric secretions. Because they are nonionized, NSAIDs move easily across the membranes of epithelial cells and then ionize at the neutral pH of the cytoplasm. In the ionic form, they interact with cell constituents and cause cell damage and death.¹¹⁶ Dead epithelial cells leave shallow mucosal defects (erosions), which may bleed. Patients often have dyspeptic symptoms during this acute phase of injury.

In a significant minority of chronic NSAID users, mucosal defects enlarge and form true ulcers; approximately 12% to 30% of patients develop a gastric ulcer, and 2% to 19% of patients develop a duodenal ulcer.¹¹⁷ Elderly people seem to be particularly vulnerable to the harmful effects of NSAIDs. In a study of peptic ulcer disease in persons aged 65 and older, Griffin et al¹¹⁸ found that almost 30% of ulcers diagnosed in these individuals may have been caused by NSAIDs. The principal mechanism by which NSAID use leads to the development of peptic ulcers is dose-dependent systemic inhibition of prostaglandin synthesis. Prostaglandins protect the upper gastrointestinal mucosa by stimulating the secretion of bicarbonate and mucus, increasing mucosal blood flow, and promoting a number of cellular processes crucial to mucosal defense and repair. A decrease in prostaglandin synthesis tips the balance between defensive and aggressive factors in the upper gastrointestinal tract in favor of those that injure the mucosa, leading to the formation of ulcers and the possible development of complications, including hemorrhage, obstruction, perforation, and penetration into an adjacent organ.

The cyclooxygenase-2 (COX-2) specific agents have been shown to be equally efficacious as nonselective NSAIDs in the treatment of both osteoarthritis and rheumatoid arthritis, but with significantly fewer gastrointestinal side effects. These agents have a greater affinity for COX-2 as compared with COX-1; COX-2 is induced in response to inflammation, whereas COX-1 is a constitutive enzyme that functions in a variety of maintenance and housekeeping roles. Many studies have demonstrated a decreased incidence of both gastric and duodenal ulcers in patients taking COX-2 selective agents as compared with those using nonselective NSAIDs. The use of COX-2 selective agents is associated with ulceration rates in the gastrointestinal tract that are no different than a placebo.¹¹⁹ Some COX-2 specific agents have been withdrawn from the market because of adverse side effect profiles; celecoxib remains available in the United States as of 2009.

A variety of treatment strategies for preventing the development of gastric and duodenal ulcers in patients on chronic NSAID therapy have been tested.¹²⁰ Many commonly used medicines are without any demonstrable prophylactic benefit in this setting. Ranitidine and omeprazole have been shown to prevent duodenal but not gastric ulcers in arthritis patients taking NSAIDs.¹²⁰⁻¹²² Similar results were obtained by Taha et al¹²³ in arthritis patients treated with prophylactic famotidine; however, in the same study, high-dose famotidine reduced the incidence of both duodenal and gastric ulcers.¹²³ An alternative approach to ulcer prevention in patients who require chronic NSAID therapy is prostaglandin replacement with an oral synthetic prostaglandin E₁ analog. The prostaglandin E₁ analog, misoprostol, like famotidine, has been shown to prevent development of both duodenal and gastric ulcers.¹²⁴ This agent also reduces the incidence of bleeding, perforation, and gastric outlet obstruction in patients on chronic NSAID therapy.¹¹² The use of misoprostol has been limited by its tendency to cause loose stools, abdominal cramps, and flatulence in a significant minority of individuals during initiation of treatment.

The large number of eligible patients makes it impossible to prescribe prophylactic famotidine or misoprostol for every NSAID user, or to use COX-2 selective agents in all. Instead, an effort should be made to identify and treat those

who both require chronic NSAID therapy and are at greatest risk for developing a significant NSAID-related complication. Included in this high-risk group are elderly people and persons with a history of peptic ulcer disease or previous upper gastrointestinal bleeding, individuals also taking steroids, and patients with cardiovascular disease.^{112,113} Once an ulcer develops, a serious complication is often the first sign of its presence. Approximately 50% of persons with ulcers have no dyspeptic symptoms. Patients taking NSAIDs who have dyspeptic symptoms require evaluation for ulcer disease and possible *H. pylori* infection, and those with ulcers should be treated with an anti-secretory agent and also antibiotics, if indicated.

Peptic ulcer disease in elderly people

Ulcer disease, whether due to *H. pylori* infection, NSAID use, or some other less common cause, frequently exhibits a virulent course in elderly people with more complications and higher mortality than in the young.¹²⁵⁻¹²⁷ A duodenal ulcer occurs two to three times more frequently than a gastric ulcer, but the latter is responsible for two of every three deaths from peptic ulcer disease in older individuals, and the death rate increases with advancing age.

The presentation of ulcer disease in elderly people tends to be acute, often with bleeding or perforation, but symptoms may be subtle; this is particularly true of gastric ulcers. Gastric ulcers produce chronic blood loss more commonly than duodenal ulcers, and resultant anemia may lead to cardiac or neurologic symptoms. Weight loss and fatigue suggesting malignancy may be the only complaints, a presentation characteristic of giant ulcers. So-called geriatric ulcers (Figure 76-12) high in the cardia may cause misleading symptoms such as dysphagia mimicking esophageal neoplasm or

Figure 76-12. Upper gastrointestinal series revealing a large benign "geriatric ulcer" high on the lesser curvature. (Reproduced from Brandt LJ. *Gastrointestinal disorders of the elderly*. Lippincott-Raven, 1986, New York.)

chest pain suggesting angina. A history of NSAID use is commonly obtained from elderly patients with peptic ulcer disease.

The complication rate of peptic ulcer disease rises progressively from 31% in patients 60 to 64 years of age to 76% in those 75 to 79 years of age. Surgery should not be withheld or delayed solely because of advanced age because it is often life-saving in older patients. Bleeding, the most common complication, accounts for one half to two thirds of all fatalities (see later discussion). Perforation is the second most common complication of peptic ulcers in elderly people. The presentation of a perforated ulcer is subtle in this age group, delaying the correct diagnosis and contributing to the high mortality rate. Gastric outlet obstruction complicates ulcer disease in 10% to 15% of patients beyond 60 years of age, generally occurring in those with a long history of disease; an obstructing malignant lesion must be excluded in such patients.

Duodenal ulcers greater than 2 cm in diameter were once considered a distinct entity because of their poor prognosis, but it is probable that most of these "giant" duodenal ulcers are caused by either *H. pylori* infection or NSAID use, just like smaller lesions. Giant duodenal ulcers occur most often in men over 70 years of age who have no prior history of peptic ulcer disease. The most frequent complaint is of abdominal pain radiating to the back or right upper quadrant, suggesting pancreatic or biliary disease. Pain may be relieved by antacids, but aggravated by eating, and is often accompanied by significant weight loss. The ulcer crater is so large that it sometimes is mistaken for the duodenal bulb on an upper gastrointestinal series (Figure 76-13). Although giant duodenal ulcers were often fatal 30 years ago, today they usually respond to therapy with histamine antagonists or proton pump inhibitors and with antibiotics when indicated by the presence of *H. pylori* infection.

Giant gastric ulcers have a diameter of more than 3 cm.^{128,129} They also are most likely caused by either *H. pylori* infection or NSAID use. Giant gastric ulcers are slightly more

common in males and are usually seen in patients over 65 years of age. Pain is not a prominent complaint, but only about 10% of patients are completely free of pain. Pain may radiate to the chest, periumbilical region, or lower abdomen. Morbidity and mortality rates are high, with hemorrhage being the most common complication. These ulcers are usually benign and can be treated with histamine antagonists or proton pump inhibitors and with antibiotics when there is documented *H. pylori* infection. Patients should be followed carefully with endoscopy to demonstrate healing. Candidiasis of the ulcer crater may delay healing and requires adjunctive antifungal therapy.

A number of potential problems must be considered in prescribing acid-suppressive therapy for elderly patients with peptic ulcer disease. Many antacid preparations contain large amounts of mineral salts, which may produce undesirable effects, such as fluid retention, diarrhea, or constipation. Aluminum hydroxide forms insoluble chelates with a number of drugs, including digoxin, quinidine, and tetracycline, interfering with their absorption. Histamine antagonists variably inhibit the oxidative metabolism of many drugs, prolonging their duration of action. Cimetidine impairs the elimination of lidocaine, nifedipine, phenytoin, propranolol, quinidine, theophylline, and warfarin, to mention a few. Ranitidine is a less potent inhibitor of mixed-function oxidases than cimetidine, and alterations in drug metabolism caused by ranitidine are usually not associated with pharmacologic effects. Famotidine has no effect on the oxidative metabolism of drugs. Intravenous administration of cimetidine in elderly patients with impaired renal function may produce mental confusion in a dose-related fashion. Cimetidine may also cause a mild elevation of serum creatinine levels unassociated with impairment of renal function. Ranitidine is a rare cause of hepatitis, and ranitidine and famotidine may cause headache. Sucralfate frequently causes constipation in elderly individuals. The National Institutes of Health Consensus Development Panel has published guidelines mandating antibiotic treatment of all ulcer patients infected with *H. pylori*, including those without an active ulcer crater or dyspeptic symptoms.¹⁰⁹

Nonulcer dyspepsia

Patients with nonulcer dyspepsia suffer from chronic, recurrent upper abdominal pain and nausea, which may or may not be related to meals and which occurs in the absence of an ulcer crater.¹³⁰ Nonulcer dyspepsia is at least twice as common as true peptic ulcer disease. Most patients with this problem have no recognizable pathologic abnormality, although many have histologic gastritis.¹⁰⁷ Nonulcer dyspepsia is further defined by the absence of reflux esophagitis, disease of the biliary tract or pancreas, or most symptoms of irritable bowel syndrome. The criteria used to select patients for inclusion in clinical studies of nonulcer dyspepsia are very inconsistent, perpetuating confusion about this diagnosis among physicians and patients.¹³¹

The cause of nonulcer dyspepsia is unknown; numerous explanations have been proposed for this syndrome, including psychosocial factors, altered sensation, abnormal gastrointestinal motility and compliance, and *H. pylori* infection.^{130,131} Gas washout studies show that individuals with nonulcer dyspepsia do not have increased gas in their digestive tracts, and therefore complaints of bloating are probably explained

Figure 76-13. Upper gastrointestinal series demonstrates a giant duodenal ulcer resembling the duodenal bulb (arrows). (Reproduced from Brandt LJ. *Gastrointestinal disorders of the elderly*. Lippincott-Raven, 1986, New York.)

by sensitivity to normal volumes of gas; in some, the transit of infused gas is abnormal, suggesting a motility disorder. Gastric antral hypomotility and impaired gastric emptying of solids have been observed in 40% to 50% of patients with nonulcer dyspepsia, and treatment with drugs that affect upper gastrointestinal motility relieves symptoms in many patients.^{132–134} Thirty to 50% of patients with symptoms of nonulcer dyspepsia have chronic active gastritis, even when the gastric mucosa appears grossly normal at endoscopy. It has been suggested that nonulcer dyspepsia is part of the spectrum of disease caused by *H. pylori*, which includes chronic active gastritis, duodenitis, and peptic ulcer disease. The successive development of nonulcer dyspepsia, duodenitis, and duodenal ulcer disease has been termed Moynihan's disease.¹³⁵ *H. pylori* infection, however, has not been shown to be the cause of nonulcer dyspepsia, nor has a definite relationship between nonulcer dyspepsia and peptic ulcer disease been proved.¹³⁶

In practice, therapy for nonulcer dyspepsia is the same as for peptic ulcer disease, despite the fact that in double-blind, placebo-controlled trials, histamine antagonists, and proton pump inhibitors are only a little better than a placebo in treating this disorder, and the role of gastric acid hypersecretion in nonulcer dyspepsia is unproved by formal measurements of basal and peak acid outputs.^{137,138} Peptic ulcer disease, NSAID use, *H. pylori* infection, and gastric cancer must be excluded in elderly patients who have dyspeptic complaints.

Upper gastrointestinal bleeding

Thirty-five percent to 45% of all cases of acute upper gastrointestinal hemorrhage occur in patients beyond age 60, and of these, half are caused by peptic ulcer disease.^{139–141} Other important causes of gross upper gastrointestinal bleeding in elderly people are gastric erosions and esophagitis; these two entities in combination with peptic ulcer disease account for 70% to 80% of hospital admissions for upper gastrointestinal bleeding in older patients.

It is unclear whether elderly patients with upper gastrointestinal hemorrhage frequently have a long history of underlying acid-peptic disease, for example, chronic peptic ulcer disease, or whether they usually bleed from newly developed lesions. In one series, 36% of older individuals admitted to the hospital with acute upper gastrointestinal bleeding gave no history of preceding symptoms.¹³⁹ Alternatively, some patients complain of prior epigastric pain, pain in other parts of the abdomen, anorexia, dyspepsia, pyrosis or, simply, weight loss. Elderly patients with acute upper gastrointestinal bleeding usually have hematemesis, although 30% of patients have only melena.¹³⁹ Hemorrhage is often seen in persons with chronic medical illnesses, the most common being degenerative joint disease. Therapy with NSAIDs for rheumatologic and other problems has been found to be an important cause of upper gastrointestinal bleeding in elderly patients.^{141,142} Other causes include disease found in younger patients, and entities seen almost exclusively in older individuals. Geriatric ulcers and giant duodenal ulcers are not associated with an unusually high incidence of hemorrhage, whereas giant gastric ulcers frequently do bleed.¹²⁹

Aortoenteric fistula is an uncommon cause of gastrointestinal hemorrhage seen most often in men during the seventh and eighth decades of life. The most common cause

is rupture of an arteriosclerotic abdominal aortic aneurysm. Other causes of aortoenteric fistulas include graft-enteric fistula, aortitis, mycotic aneurysm, carcinoma, trauma, foreign body, and peptic ulceration.^{143,144} The overwhelming majority of fistulas between the aorta and the alimentary tract occur in the duodenum and, as a result, usually produce upper gastrointestinal bleeding. Other reported sites of communication include the esophagus, stomach, distal small bowel, and colon. Most patients experience an initial self-limited or "sentinel" bleed, followed hours to days later by massive hemorrhage. Mortality rate is very high but may be reduced by early endoscopic detection of the fistula during investigation of the cause of bleeding. An elderly patient with an aortic graft who has upper gastrointestinal bleeding, no matter how trivial, must undergo immediate endoscopy because of the possible presence of a graft-enteric fistula.

Another rare cause of massive upper gastrointestinal hemorrhage in elderly people is a dilated gastric artery with an overlying mucosal defect, typically located within 2 cm of the cardioesophageal junction. This lesion, called exulceratio simplex, or the ulcer of Dieulafoy, often requires surgical therapy, although it has been treated effectively with electrocautery, laser, argon plasma coagulation, and banding.^{145,146}

Occasionally, vascular abnormalities of the type found in Osler-Weber-Rendu syndrome (hereditary hemorrhagic telangiectasia) may also be responsible for upper gastrointestinal bleeding in elderly people. There may be no history of childhood epistaxis and no family history of similar occurrences, although typical telangiectatic lesions are often found in the oral cavity, lips, nailbeds, and skin.

The hospital course of elderly patients with upper gastrointestinal bleeding is similar to that of younger patients with respect to duration, amount of blood transfused, and frequency of surgery.^{147,148} Older patients, however, suffer significantly more morbidity than do younger patients; complications include cardiac, neurologic, and renal disease; sepsis; and reactions to medications and transfusions. Elderly patients are more likely than young patients to die during a hospital admission for gastrointestinal bleeding, especially if peptic ulcer is the cause.

The evaluation and treatment of upper gastrointestinal bleeding in elderly people are the same as in younger individuals. Age per se is not a contraindication for surgery; the decision to operate on an individual patient must be made in the context of the clinical setting. Early surgery should be contemplated for elderly patients who have bled from ulcers, who have signs of major hemorrhage (e.g., hypotension), and when endoscopic findings imply a significant risk of recurrent bleeding.

Volvulus of the stomach

Volvulus of the stomach is a relatively rare condition occurring most often after age 50 and requires relaxation of the gastric ligaments for its development.^{149,150} Gastric volvulus may be responsible for chronic abdominal symptoms or may be manifested acutely with strangulation and gangrene.

Gastric volvulus is classified according to the axis around which the stomach rotates: torsion about a longitudinal axis formed by a line connecting the cardia and pylorus is known as organoaxial volvulus; rotation about a vertical axis passing through the middle of the lesser and greater curvatures is

Figure 76-14. An organoaxial volvulus of the stomach identified on upper gastrointestinal series. (Reproduced from Brandt LJ. *Gastrointestinal disorders of the elderly*. Lippincott-Raven, 1986, New York.)

referred to as mesenteroaxial volvulus. Approximately 60% of affected patients have the organoaxial type, 30% have the mesenteroaxial type, and 10% have a combination form. Rotation may be partial or complete; complete twists often severely impair gastric blood flow and may cause gangrene, whereas partial twists may be asymptomatic or responsible for chronic symptoms.

Organoaxial volvulus usually has an acute presentation and often is associated with the presence of a large paraesophageal hiatus hernia or eventration of the diaphragm. Patients complain of the abrupt onset of upper abdominal or lower thoracic pain. Vomiting gives way to retching, and it is difficult to pass a nasogastric tube beyond the gastroesophageal junction. This group of symptoms and signs has been referred to as the Borchart's triad. Roentgenograms may reveal a gas-filled viscus in the chest or an "upside-down stomach" in the upper abdomen (Figure 76-14). Gangrene ensues in approximately 5% of cases, mostly in individuals with a traumatic diaphragmatic hernia. Organoaxial volvulus usually requires surgical correction.

Mesenteroaxial volvulus is often intermittent and incomplete. Affected persons complain of chronic postprandial pain, belching, bloating, vomiting, and early satiety; strangulation is rare. Diagnosis is made by barium roentgenogram. Decompression with a nasogastric tube may return the stomach to its normal position. Surgery is indicated for persistent symptoms. Some patients have been successfully treated by fixation of the stomach with two percutaneous endoscopic gastrostomy tubes; these are removed after adhesions fix the stomach to the anterior abdominal wall.

Benign gastric tumors

The incidence of benign gastric tumors increases with age. A hyperplastic polyp accounts for 75% to 90% of such growths and typically is a small, solitary lesion at the junction of the gastric body and antrum.¹⁵¹ Hyperplastic polyps

are not considered true neoplasms and are not premalignant. They rarely produce symptoms and thus are found incidentally in an evaluation of the upper gastrointestinal tract. In contrast, adenomatous polyps are true neoplasms and account for 10% to 25% of gastric polyps. The mean incidence of malignant change in gastric adenomas is reported to be anywhere from 6% to 75%, probably reflecting their heterogeneity in size, age, and histology (tubular, villous, or mixed).

Gastric polyps may occur in some gastrointestinal polyposis syndromes, but the only one appearing in older individuals is the Cronkhite-Canada syndrome. This disorder is acquired, not inherited, and is characterized by diffuse gastrointestinal polyposis, protein-losing enteropathy, and ectodermal abnormalities, including hyperpigmentation, alopecia, and dystrophic nail changes. Polyps in this syndrome are hamartomas composed of tubules and mucus-filled cysts.

Mesenchymal tumors, including leiomyomas, fibromas, and tumors of neural origin, account for a significant percentage of benign gastric tumors. Symptoms of these tumors are usually related to their size and not their type. Pain and bleeding are the most common manifestations.

Malignant gastric tumors

GASTRIC ADENOCARCINOMA

Inexplicably, the incidence of gastric cancer is decreasing in elderly people, while relatively more cases are being diagnosed in younger patients.¹⁵² Nevertheless, the vast majority of gastric cancers occur in patients beyond 60 years of age.¹ Carcinoma of the stomach is usually incurable by the time symptoms appear because symptoms often do not develop until the tumor is large. Initial symptoms are often mild and nonspecific. The tendency to treat dyspepsia in older patients without a diagnostic evaluation prompted Sir Heneage Ogilvie to say in the early 1900s, "in carcinoma of the stomach, alkalis are the undertaker's best friend."

Vague epigastric discomfort, anorexia, early satiety, and weight loss are the most frequent symptoms of gastric cancer. Physical examination may reveal enlarged left axillary and supraclavicular lymph nodes, an umbilical nodule, or a hard palpable left hepatic lobe. Rarely, the patient develops acanthosis nigricans, dermatomyositis, or an explosive outbreak of skin tags or keratotic lesions (sign of Leser-Trélat), raising the suspicion of a visceral neoplasm.

Laboratory abnormalities are nonspecific. Surgical excision is the only potentially curative treatment. Seventy percent to 90% of patients with gastric cancer are considered suitable for laparotomy, but only half are found to be eligible for potentially curative resections and death occurs in most of these individuals within 1 year. Five-year survival rates are 5% to 15%. Combined chemotherapy and irradiation may be of some benefit, but irradiation alone is ineffective except for palliation of bone pain from metastases.

GASTRIC LYMPHOMA

The stomach is the most frequent site of primary, extranodal lymphoma and accounts for one half to three fourths of patients with lymphoma of the gastrointestinal tract. Gastric lymphoma produces nonspecific symptoms, but epigastric pain with weight loss and a palpable mass in a

Figure 76-15. Upper gastrointestinal series showing a gastric lymphoma with antral narrowing mimicking an adenocarcinoma. (Reproduced from Brandt L.J. *Gastrointestinal disorders of the elderly*. Lippincott-Raven, 1986, New York.)

patient who is otherwise well is typical. Radiographically, lymphoma resembles carcinoma in up to two thirds of cases (Figure 76-15). Large, ulcerated masses, hyperrugosity, polypoid lesions, or antral narrowing suggests lymphoma. A definitive diagnosis cannot be made from gastroscopic brush cytology and biopsy, and laparotomy may be necessary. Therapy is wide excision followed by radiation and leads to a 5-year survival rate of about 40% to 50%.

SYSTEMIC DISEASES

Diabetes mellitus

Patients with long-standing diabetes mellitus often have profound abnormalities of gastrointestinal motility, including delayed gastric emptying of solids.¹⁵³ Such abnormalities are frequently without clinical manifestations, although difficulty controlling plasma glucose, due to an inconstant and unpredictable rate of gastric emptying, may be a subtle indication of gastroparesis. Gastric atony may be manifested by a gradual onset of upper abdominal fullness, satiety, and vomiting. Gastroparesis and accompanying hypochlorhydria probably underlie the

development of gastric bezoars and bacterial and fungal overgrowth in this population.

Diabetic gastroparesis is caused by an abnormality of the autonomic nervous system almost always associated with peripheral or autonomic neuropathy. Metoclopramide has been used to improve gastric motility and relieve symptoms but causes intolerable central nervous system effects in many patients.

Amyloidosis

The gastrointestinal tract is involved in 50% to 75% of patients with amyloidosis, and in approximately one half of these cases the stomach is affected. It is unusual for signs and symptoms of gastrointestinal involvement to be directly attributable to the amyloidosis per se. Outlet obstruction may be caused by an obstructing mass of amyloid in the distal stomach. Amyloid may also diffusely infiltrate the gastric wall, making surgery difficult, and may be associated with giant gastric ulcers resistant to medical therapy. Prognosis is related to that of the primary disease.

KEY POINTS

The Upper Gastrointestinal Tract

- Evaluation of the upper gastrointestinal tract should begin with the mouth; changes in the oral cavity, such as candidiasis, stomatitis, leukoplakia, and vascular lesions, may limit the ability of elderly people to enjoy a normal diet.
- Oropharyngeal, or transfer, dysphagia is an important problem in the elderly, caused by uncoordinated muscular contractions that are the result of a wide spectrum of disorders including stroke and Parkinson's disease.
- Dysphagia, or difficulty swallowing, in the elderly should not be ascribed to aging alone and should prompt a search for the presence of disease processes involving the esophagus, such as gastroesophageal reflux disease, esophageal motility disorders, structural abnormalities including rings and webs, and neoplastic disorders.
- Aging is associated with alterations in both the motor and sensory functions of the stomach, but changes in physiology related only to aging rarely account for dyspeptic symptoms.
- Peptic ulcer disease in the elderly is very common, largely due to the frequent use of NSAIDs for arthritis and pain, and often is associated with severe complications including bleeding and perforation.

BACKGROUND

The pancreas is a retroperitoneal organ located deep to the stomach and has both endocrine and exocrine functions. Some knowledge of its development and structure is necessary as a foundation on which to base an understanding of the diseases that affect it and its changes with age.

Development of the Pancreas

The pancreas begins to develop at day 26 as dorsal and ventral endodermal buds arising from their respective aspects of the primitive tubular foregut. The ventral bud arises together with the embryonic bile duct, and it then migrates posteriorly around the duodenum. Late in the sixth week, the two pancreatic buds fuse to form the definitive pancreas (Figure 77-1). The dorsal pancreatic bud gives rise to part of the head, the body, and the tail of the pancreas, whereas the ventral pancreatic bud gives rise to the uncinate process and the remainder of the head. The two ductal systems fuse, and the proximal end of the dorsal bud duct usually degenerates leaving the ventral pancreatic duct as the main duct opening at the ampulla. The opening of the dorsal duct, if it persists, forms the accessory duct. The pancreatic endoderm of each bud develops into an epithelial tree that will form the duct system draining the exocrine products manufactured in the acini. Endocrine cells arise separately from the ducts and aggregate into the islets.¹

A failure of migration or fusion of the early pancreatic buds can result in pancreas divisum (this occurs in about 7% of people); alternatively, the pancreas can surround the duodenum resulting in an annular pancreas. Abnormal development of the ventral duct can result in a common channel whereby the junction of the biliary and pancreatic ducts is outside the wall of the duodenum allowing reflux and mixing of bile and pancreatic juice; this can result in damage to the bile duct in the fetus resulting in a choledochal cyst or damage to the pancreas causing acute pancreatitis.

Anatomic Relationships

The adult pancreas is a retroperitoneal structure 12 to 15 cm long extending from the duodenum to the hilum of the spleen. The neck of the pancreas lies anterior to the superior mesenteric vein and the uncinate process curls around the vein to lie on its right and the posterior border. Posterior to the head and uncinate process is the inferior vena cava. The splenic artery and vein pass deep to the upper border of the pancreas and provide much of its vascular supply. The right-hand border of the head is closely applied to the concavity of the duodenum, and its superior part is related to the portal vein.

Histology

The pancreas has a lobulated structure and there are intralobular ducts penetrating the secretory acini, which are flask-shaped structures consisting of typical zymogenic cells. The larger interlobular ducts contain some nonstriated smooth muscle.

The million or so islets of Langerhans are distributed throughout the adult pancreas and consist of endocrine

cells. The alpha cells constitute 15% to 20% of the islet cells and produce glucagon. The insulin-secreting beta cells constitute about 65% to 80%; delta cells (3% to 10%) produce somatostatin. The PP cells (3% to 5%) produce pancreatic polypeptide, and the epsilon cells (<1%) produce ghrelin.

Exocrine function

The pancreas secretes 1400 mL per day of an alkaline, bicarbonate-rich solution containing proenzymes that are converted into active enzymes (proteases, lipases, and glycosidases such as amylase). In the gut, a proenzyme, like trypsinogen, is converted into trypsin by enterokinases; trypsin then, in turn, releases more trypsin from trypsinogen.

Enzyme secretion is stimulated by cholecystikinin released by the duodenum in response to the presence of food. Secretin, also released from the gut wall, controls the secretion of water and electrolytes, most of which is secreted from the ducts of the pancreas.²

Pancreatic exocrine function deteriorates with age; the secretion of bicarbonate and enzymes have been found to be reduced in a group of subjects with average age 72 years compared with a group with average age 36 years.³ However, 80% to 90% of pancreatic function must be lost before malabsorption becomes apparent, and this happens only occasionally in the elderly where other causes of malabsorption are more common.⁴

Endocrine function

Synthesis and release of insulin from the beta cells of the pancreas is controlled by the level of glucose in the beta cells, which will reflect the plasma level. However, overall control of pancreatic function is the result of many complex interrelated feedback loops. Somatostatin, for example, secreted from the delta cells in response to an increasing blood sugar level, inhibits enzyme release and decreases gut motility. The full complexity of the hormonal control of glucose in the body is as yet not fully elucidated; however, it is clear that there are some functional changes with age.⁵

Age changes

Besides the age-related changes in pancreatic function, there are morphologic changes; after the age of 60 the pancreas shrinks and can become more fatty.⁶ Patchy fibrosis can also occur in the pancreas from the seventh decade onward, but without the other changes of chronic pancreatitis this age-related focal lobular fibrosis is associated with ductal papillary hyperplasia, which can be premalignant.⁷

TUMORS OF THE PANCREAS

Adenocarcinoma is the most common pancreatic tumor, accounting for 90% of all tumors in the pancreas; it is a malignant tumor with a poor prognosis. Many of the remaining 10% are cystic, often with a more benign behavior but malignant change cannot be ruled out. Truly benign tumors such as fibromas, lipomas, and hemangiomas do occur but are exceedingly rare.

Figure 77-1. Embryology of the pancreas. A, The two pancreatic buds form at 26 days of development. B, Rotation of the ventral pancreas. C, At 45 days, the final position is reached and the ventral and dorsal pancreases have fused.

CYSTIC TUMORS

These tumors are often an incidental finding on imaging, but once they have been detected, determining the exact nature of a cystic lesion in the pancreas is difficult in spite of modern computed tomography (CT), magnetic resonance imaging (MRI), and ultrasound (US) by both transcutaneous and endoscopic techniques. It is often difficult to distinguish an inflammatory lesion from a neoplasm.^{8,9} Biopsy is often difficult or inconclusive, and the general advice is to err on the side of resection.¹⁰ Although these tumors tend to occur more commonly in the young or middle aged, they also occur up to the seventh and eighth decades and they are more likely to be malignant in patients older than 70 years, when resection should be considered.¹¹

Solid-pseudopapillary neoplasm

These occur most commonly in young women and are generally benign but can undergo malignant change. They should be treated by resection, which results in an excellent prognosis.¹²

Serous cystadenoma

This is sometimes known as a serous microcystic tumor. The mean age of presentation is in the sixth decade, and 70% occur in females. The vast majority are benign, only a handful of cases of malignant serous cystic tumor of the pancreas have been reported.¹³

Mucinous cystic neoplasm

This neoplasm accounts for 50% of cystic tumors and is either malignant or potentially so. It is most common in middle-aged women and it should be treated by resection of the affected part of the pancreas.¹⁴

Intraductal papillary mucinous neoplasm (IPMN)

This tumor is twice as common in males as in females and has a mean age at presentation in the seventh decade. It is characterized by copious mucous draining at a patulous ampulla from a dilated duct. It has a favorable prognosis following appropriate resection.^{15,16}

Lymphoepithelial cyst of the pancreas

This is a rare epithelium-lined cystic lesion similar histologically to a branchial cyst.¹⁷

Cystic islet cell tumors

This tumor results from cystic degeneration of a solid endocrine tumor. Although it is rare, it is important to consider this diagnosis when evaluating a cystic lesion in the pancreas and test for endocrine activity in order to exclude a functioning tumor, although the majority of these tumors are in fact nonfunctioning.

Von Hippel-Lindau syndrome

This is rare genetic condition with autosomal dominant inheritance. Several types of pancreatic tumor can occur in this condition including serous cystadenoma, multiple cysts, and endocrine tumors.¹⁸

SOLID TUMORS

Adenocarcinoma

EPIDEMIOLOGY AND AGE INCIDENCE

Pancreatic cancer is the sixth most common cause of cancer death in the United Kingdom and the fourth most common in the United States. In 2005, the number of deaths from pancreatic cancer in the United Kingdom was 7238, with a rate of 12.1 per 100,000 population; for the United States in 2004, the death rate was 9.24 per 100,000 population.^{19,20}

The incidence of pancreatic cancer in the United Kingdom increases sharply with age and the average age at presentation is 69 years.^{19,21} (See Figure 77-2.)

Pancreatic ductal adenocarcinoma has the lowest 5-year survival rate for all cancers for both men and women at 2% in the United Kingdom and 5% in the United States. The mortality rate is 94% of the incidence rate.^{20,22} The mortality rate for pancreatic cancer remained static across most of the world from 1992 to 2002.²³

Risk factors for pancreatic adenocarcinoma include chronic pancreatitis, diabetes mellitus, smoking, possible relation to increased body mass index (BMI), and genetic (BRCA2, Peutz-Jeghers, von Hippel-Lindau and hereditary nonpolyposis colorectal cancer).^{24,25}

PRESENTATION

Approximately 85% of patients present with disseminated or locally advanced disease, and symptoms frequently include epigastric or back pain, anorexia, weight loss, and obstructive jaundice.²⁶

NUMBER OF DEATHS BY SEX AND AGE IN THE UK 2005

Figure 77-2. Death rate from pancreatic cancer in the United Kingdom in 2005. (Derived from Cancer Research UK 2008 data.)

PAIN Pain can be caused by tumor compression of surrounding structures, tumor size, invasion of pancreatic nerves, and invasion of the anterior pancreatic capsule. Pain intensity at presentation has been found to correlate with survival (29 months for patients without pain, 9 months for those with severe pain).²⁷ Back pain may predict unresectability and shortened survival after resection.²⁸

WEIGHT LOSS Weight loss is a common presenting symptom and can be due to anorexia, catabolic metabolism, or malabsorption; however, weight loss is also a common symptom in the elderly and can be nonspecific.

JAUNDICE Sixty percent to 70% of pancreatic adenocarcinoma affect the head of the pancreas, and these patients often present with obstructive jaundice resulting from compression of the biliary tract.²¹

OTHER Tumors of the body and tail of the pancreas are frequently associated with late presentation and inoperability. When an older patient presents with a new diagnosis of diabetes mellitus, then the presence of an underlying pancreatic cancer should be borne in mind especially if the patient has other suggestive symptoms. Tumor has been found to be the underlying cause in 1% of patients over 50 years old diagnosed with diabetes.²⁹ Other presentations may include acute pancreatitis and acute upper gastrointestinal or retroperitoneal hemorrhage.²¹

DIAGNOSIS

The investigations performed in suspected pancreatic cancer are undertaken with the following aims:

- Establishing the diagnosis
- Locating the tumor
- Staging the tumor
- Assessing resectability
- Obtaining a tissue diagnosis

Blood Tests

SERUM ANTIGENS

Carbohydrate antigen 19-9 (CA 19-9) is a glycoprotein synthesized by pancreatic cancer cells as well as being produced by normal epithelial cells of the pancreas, bile ducts, stomach, and colon.³⁰ It has been found to have a sensitivity of 70% to 90% and specificity of 75% to 90% for pancreatic cancer, but it is also elevated in obstructive jaundice, chronic pancreatitis, and biliary and gastrointestinal cancers.^{30,31} Other tumor markers such as carcinoembryonic antigen (CEA) and carbohydrate antigen 125 (CA 125) have limited use because of lower sensitivity and specificity.³¹ Although tumor markers cannot actually confirm a diagnosis, they are particularly useful later in the patient's management when a rise in CA19-9, especially if it originally decreased after treatment, may indicate a recurrence. It is of no use as a screening test.³²

Imaging

TRANSABDOMINAL ULTRASOUND

Transabdominal ultrasound (US) is frequently the first-line imaging investigation performed in the elderly patient presenting with upper abdominal symptoms. The results are variable and dependent on the operator, the patient's body habitus, and the presence of overlying gas-filled bowel loops. The sensitivity of diagnosing pancreatic cancer with ultrasound ranges from 44% to 95%,^{30,33,34} with the very high sensitivities in groups where patients were not scanned on an intention to treat basis and difficult scans were excluded from the analysis.

COMPUTED TOMOGRAPHY

Computed tomography (CT) is considered the imaging modality of choice in pancreatic cancer as it can give additional staging information by imaging the chest, abdomen, and pelvis, and more detailed information regarding

the resectability of pancreatic tumors. Helical CT has been found to be effective in detecting and staging adenocarcinoma, with sensitivity of up to 97% for detection and up to 100% accuracy in predicting unresectability, although it is not as good at predicting resectability.³⁵ When directly compared with endoscopic ultrasound (EUS) and MRI in a cohort of patients deemed fit for surgery, CT had the highest accuracy in assessing the extent of the primary tumor (73%), locoregional extension (74%), vascular invasion (83%), and tumor resectability (83%).³⁶ Multidetector CT used with an appropriate protocol for timing the injection of contrast agent can provide images in both venous and arterial phases, and the data can then be reformatted in transverse, coronal, and sagittal planes allowing for improved precision in assessing any vascular involvement.²¹ The value of CT in predicting resectability, however, can be as low as 38%, with patients predicted to have resectable disease on CT found to be unresectable at laparotomy, with the most common causes of unresectability including small peritoneal or liver metastases and vascular involvement of the tumor.³⁵ The contrast material used for CT is potentially nephrotoxic, and patients must be well hydrated and serum creatinine checked; this may be a problem in the elderly, in whom renal impairment is more common.

MAGNETIC RESONANCE IMAGING

MRI has the advantage of demonstrating the anatomy of the biliary tree better than CT, but in comparison to multidetector CT, MRI is not thought to offer any diagnostic advantage with respect to the pancreas.³⁷ Magnetic resonance cholangiopancreatography (MRCP) has been shown to be as diagnostically effective as endoscopic retrograde cholangiopancreatography (ERCP) in patients with symptoms suggestive of pancreatic cancer (84% sensitivity and 97% specificity).³⁸ MRCP has the added advantage of fewer complications, compared with ERCP, although a number of elderly patients are unable to tolerate the confined space in an MRI scanner.

ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY

In the diagnosis of cancer of the pancreas, ERCP has a sensitivity and specificity of 70% and 94%³⁸ and offers the opportunity to obtain a cytologic diagnosis by sampling bile or taking brushings. The value of such sampling can be questionable, however, as a sensitivity of only 60% has been reported with a specificity of 98%.³⁹ ERCP carries a significant rate for serious complication such as pancreatitis, cholangitis, hemorrhage, and death.

ENDOSCOPIC ULTRASOUND

Endoscopic ultrasound (EUS) is rapidly growing in importance. The high-frequency ultrasound probe positioned in the stomach and duodenum allows high-resolution imaging of the pancreas and surrounding tissue. The accuracy of EUS in evaluating tumor and nodal status was found to be 69% and 54%, respectively,⁴⁰ and EUS has been found to be at least as valuable as CT⁴¹ and equal if not superior to CT in evaluating vascular invasion.⁴² EUS also offers the opportunity of performing fine needle aspiration of the tumor to aid diagnosis, but in potentially resectable patients this should generally only be performed via the duodenum rather than the stomach as the duodenum will be removed during resection and

there have been concerns regarding seeding malignant cells in the needle track.

POSITRON EMISSION TOMOGRAPHY

Positron emission tomography (PET) exploits the increased glucose metabolism observed in malignant tumors by administering a radioactive glucose analogue and scanning for increased uptake by tumor cells. PET images may be captured with coincident CT images to aid in localizing any accumulation of tracer. There is still uncertainty about the ability of PET scans to distinguish between inflammatory and malignant lesions.⁴³ PET is useful in diagnosing small (<2 cm) tumors and has sensitivity and specificity as good as EUS, ERCP, and US and is particularly useful in detecting distant metastasis—for example, cervical nodes.⁴⁴

Management

RESECTABLE DISEASE

The only curative treatment for pancreatic cancer is surgical resection; however, only 15% of patients presenting with pancreatic cancer are considered to be resectable.²⁶ Preoperative imaging is useful for determining clearly inoperable tumors, but at operation a further proportion will be found to be inoperable because of local or distant involvement of other tissue.

To be considered as resectable on imaging, there should be no involvement of the superior mesenteric artery or celiac axis, a patent superior mesenteric vein (SMV) and portal venous confluence and no evidence of distant metastasis. At the time of surgery, findings including previously unidentified metastasis or a tumor that cannot be dissected of the SMV would preclude progression to resection.

Surgical options for resecting cancer of the head of the pancreas include the traditional Whipple pancreaticoduodenectomy or a pylorus-preserving pancreaticoduodenectomy (PPPD). PPPD involves dividing the bile duct close to the liver hilum, dividing the duodenum 2 cm beyond the pylorus, dissecting the pancreas off the superior mesenteric vein, and dividing the pancreas between the head and neck and dividing the small bowel at the duodenal-jejunal flexure. The reconstruction then involves three anastomosis: restoring gut continuity by a pylorus-jejunal anastomosis, connecting the stump of the bile duct to the jejunum just distal to the pylorus-jejunal anastomosis, and finally a pancreatic anastomosis. This last anastomosis is the Achilles' heel of the operation and there is much debate about the technique.⁴⁵ The authors prefer a pancreaticogastric anastomosis rather than the alternative pancreatojejunal anastomosis. Most surgeons use the technique that in their hands gives them good results; however, the published leakage rate is up to 10% in some series.⁴⁶

The Whipple procedure differs in that a distal gastrectomy is also performed, although it would be expected to cause possible long-term morbidity because of gastric dumping, marginal ulceration, and bile reflux gastritis when compared to the PPPD. There have been questions regarding adequacy of resection in a PPPD, but a Cochrane review in 2008 has demonstrated no significant difference between a Whipple and PPPD in terms of in-hospital mortality, overall survival, and morbidity rates.⁴⁷

The overall complication rate for PPPD is around 39% with a mortality rate ranging from 0 to 7%.^{47–49} Early complications including postoperative bleeding and bile leak

are quoted at rates of 4.8% and 1.2%, respectively, in a meta-analysis.⁴⁷ Other significant early complications that are of particular importance in the elderly because of pre-existing comorbidities include cardiac and respiratory complications, and the elderly have been shown to be treated for significantly more cardiac events following PPPD (13% versus 0.5%).⁵⁰ The overall mortality for pancreatic cancer resections in octogenarians is over twice that for younger patients (15.5% vs. 6.7%).⁵¹ Late complications related to the nature of the operation include delayed gastric emptying, which occurs in 21% of PPPD patients, and pancreatic fistula in 11%.⁴⁹ Pancreatic endocrine function is generally maintained,⁵² and pancreatic exocrine function should be assessed by measuring fecal elastase, as malabsorption will result in malnutrition postoperatively.⁵³

Surgery for cancer of the body and tail of the pancreas is less frequently performed, as patients usually have only non-specific symptoms and a diagnosis is often only made when the tumor is inoperable. However, when a distal pancreatectomy is possible, it involves dissecting the pancreas off the SMV, dividing the pancreas, and then oversewing the cut end. A splenectomy is also performed in cancer operations to ensure as much clearance as possible.

The question of the appropriateness of performing surgery of such magnitude in an elderly patient is an important one. The patient should be evaluated on an individual basis with regard to comorbidities and fitness for anesthetic, possibly using assessments such as Physiological and Operative Severity Score for the enUmeration of Mortality and Morbidity (POSSUM), a multifactorial scoring system⁵⁴ and cardiopulmonary exercise testing (CPX) (which defines the physiologic stress level at which the patient becomes anaerobic).⁵⁵ Patients must be made fully aware that their short-term function, and nutritional condition may be compromised after a major pancreatic resection.⁵⁰

It has been demonstrated that patients older than 75 years of age, when compared with patients younger than 75 years of age, undergoing pancreatic surgery for cancer have increased mortality rates (10% compared with 7%), are more frequently admitted to the intensive care unit unplanned (47% compared with 20%), are treated for more cardiac events (13% compared with 0.5%), are more likely to have a compromised nutritional and feeding status, and are more likely to be transferred for further nursing care before the discharge home.⁵⁰ The operative mortality rate for pancreatic cancer surgery has been shown to increase with advancing age: 7% at 65 to 69 years, 9% at 70 to 79 years, and 16% at 80+ years.⁵¹ However, when looking at significant predictors of survival, some studies have not found age to be an independent variable.^{56,57}

UNRESECTABLE DISEASE For patients with unresectable disease, the three most important symptoms for palliation are pain, jaundice, and gastric outlet obstruction. A multidisciplinary team consisting of representatives from surgery, medical oncology, gastroenterology, radiology, and palliative care medicine is essential for the optimal palliation of symptoms.⁵⁸

PAIN

The World Health Organization approach to pain management in patients with advanced cancer is still recommended,⁵⁹ and analgesics should be titrated according to the three-step analgesic ladder: (1) nonopioids, including nonsteroidal

anti-inflammatory agents, (2) weak opioids, and (3) strong opioids. Attention should be paid to the route of administration in pancreatic cancer patients, as gastric outlet obstruction may be present and absorption of oral analgesics may be unpredictable.

In patients with severe pain, a celiac plexus block (CPB) with neurolytic solutions may provide analgesia by interrupting visceral afferent pain transmission from the upper abdomen. This can be performed percutaneously, surgically (at the time of laparotomy or bypass), or under EUS guidance. In a prospective, randomized, double-blinded, placebo-controlled trial percutaneous CPB with absolute alcohol has been shown to significantly improve pain relief in patients with unresectable pancreatic cancer, compared with opioids although CPB did not affect quality of life or survival.⁶⁰ The major complications from percutaneous CPB include lower extremity weakness, paresthesia, lumbar puncture, and pneumothorax, and they have been quoted at a rate of 1%. The technique of EUS-guided CPB has therefore developed in popularity recently and has been found to be safe and effective in pancreatic cancer.^{61,62}

JAUNDICE

Jaundice can have severe consequences, including intolerable itching, liver dysfunction, and eventually hepatic failure caused by bile stasis and cholangitis,⁶³ relief of the jaundice has been shown to result in a dramatic increase in quality of life.⁶⁴ Biliary drainage can be achieved by endoscopic or percutaneous placement of a biliary stent or by a surgical biliary-enteric anastomosis. Biliary stents are plastic (Teflon and polyethylene) or made of an expandable metal meshwork. Plastic stents are associated with a higher complication rate including migration, blockage, and infection, although they can be replaced and are cheaper, whereas metal stents have a significantly longer time to first blockage but cannot be removed and are not recommended for patients with a prognosis greater than 2 years because of metal fatigue.^{63,65}

Percutaneous stenting is often performed if endoscopic stent placement was difficult or impossible in patients with hilar obstruction, bilateral or multiple strictures, or previous upper gastrointestinal tract surgery. In the case of metal percutaneous stenting, it provides good palliation with a procedure-related morbidity rate of 9%.⁶⁶ The choice of an endoscopic or percutaneous approach may depend on local expertise.

A Cochrane review of palliative biliary stents for obstructing pancreatic carcinoma concluded that based on meta-analysis, endoscopic stenting with plastic stents appears to be associated with a reduced risk of complications but with a higher risk of recurrent biliary obstruction before death when compared with surgery. No trials comparing endoscopic metal stents to surgery were identified.⁶⁷

GASTRIC OUTLET OBSTRUCTION

A number of patients with unresectable pancreatic cancer will develop functional or mechanical gastric outlet obstruction (GOO); this can be caused by a dysfunction of gastric or duodenal motility as a result of celiac nerve plexus infiltration by tumor or duodenal blockage caused by tumor infiltration of the wall and lumen. These cases should be fully assessed radiologically with a video contrast meal to assess both motility and the existence of tumor blockage before planning management. For mechanical blockage, surgical gastrojejunostomy can be performed either laparoscopically

or at open operation. It should, however, be performed at the time of laparotomy if the intended resection of a pancreatic cancer is found to be not possible and it may be combined with a biliary bypass. This method of preempting GOO was studied by comparing two groups that underwent either single bypass (hepaticojejunostomy) or double bypass (hepaticojejunostomy and retrocolic gastrojejunostomy) and researchers found that there was a significantly higher incidence of GOO in the single bypass group (41% as compared to 5%) with no significant difference in length of stay, survival, or quality of life.⁶⁸

It is, however, pointless to trying to drain a stomach that is paralyzed. Pharmacologic agents such as metoclopramide or erythromycin may occasionally be helpful in this situation.

Endoscopic palliation with a self-expanding metal duodenal stent is an option in GOO. It has been found to be simple and effective with no complications related to the insertion or the stent, and a 93% reported improvement in symptoms.⁶⁹ Subsequent stent obstruction was observed, however, in 11% of patients.

CHEMORADIO THERAPY Chemotherapy with or without radiotherapy can be used as an adjuvant treatment in patients following attempted curative resection for pancreatic cancer or as a primary treatment in advanced or metastatic pancreatic cancer. The decision to recommend chemotherapy or chemoradiotherapy for an elderly patient with pancreatic cancer should be made after careful evaluation of the patient's health status, comorbidities, and quality of life, and consideration that physiologic decline and alterations in pharmacodynamics may make the older patient more susceptible to cytotoxic medication.⁷⁰

The role of adjuvant chemotherapy following curative resection for carcinoma of the pancreas still remains controversial. A recently published meta-analysis of randomized controlled trials estimated a prolongation of median survival time of 3 months for patients in the chemotherapy group, but there was no difference in the 5-year survival.⁷¹ A randomized controlled trial specifically looking at the impact of gemcitabine in patients following gross complete resection of pancreatic cancer demonstrated an improved disease-free survival of 7.5 months with no difference in overall survival or quality of life.⁷²

A Cochrane review evaluated various chemotherapeutic regimens used in advanced inoperable pancreatic cancer and concluded that chemotherapy (5-fluorouracil [5-FU] combination regimens), when compared with best supportive care, resulted in improved mortality at 1 year.⁷³ There was no significant difference in outcomes when chemotherapeutic regimens (mostly including 5-FU and gemcitabine) were compared with each other, although current trends seem to favor gemcitabine as it is clinically more acceptable.⁷³ The evidence for the use of chemoradiotherapy was less convincing, and the authors suggest that although there may be benefit from using chemoradiotherapy over supportive care or radiotherapy alone, the potentially greater toxicity needs further review.⁷³

The evidence for chemo- and chemoradiotherapy specifically in an elderly population with advanced pancreatic cancer is limited to retrospective evaluations of patients who had been considered suitable for therapy. Chemotherapy with gemcitabine-based regimens was found to be as acceptable in patients over 70 as in those under 70 with no difference in overall survival, but more elderly patients required dose

reduction and experienced increased toxicity.⁷⁴ Chemoradiotherapy (5-FU and radiotherapy) was also found to be acceptable in the over-70s, with no difference in toxicity and an actual increase in median survival for elderly patients (11.3 months versus 9.5 months).

NEUROENDOCRINE TUMORS

Pancreatic neuroendocrine tumors (pNET) are rare with an incidence of 1 to 2 per 1 million population.⁷⁵ They have a median age of presentation of 57 years.⁷⁶ pNETs are a heterogeneous group of tumors that can be classified according to functionality, tumor localization, rate of proliferation, and metastatic disease.⁷⁷ The World Health Organization (WHO) classification defines three types of pNET: well-differentiated neuroendocrine tumor (WDT), well-differentiated neuroendocrine carcinoma (WD-Ca), and poorly differentiated neuroendocrine carcinoma (PD-Ca).⁷⁶ This classification is useful in estimating prognosis with 5-year survival rates quoted as WDT, 95%; WD-Ca, 44%; and PD-Ca, 0%.⁷⁶

Management is controversial involving surgery, chemotherapy, octreotide therapy, interferon- α , and peptide receptor radionuclide therapy. The main goal of surgery is curative resection of tumor, but other indications include relief of symptoms from hormone-secreting tumors or obstruction.⁷⁷

ACUTE PANCREATITIS

Acute pancreatitis is an acute inflammatory process of the pancreas with variable involvement of the other regional tissues or remote organs.⁷⁸ It is a potentially fatal disease, and the incidence in the United Kingdom is increasing although the mortality has decreased. The incidence and mortality increase with age.⁷⁹ (See Figure 77-3.)

Etiology

Acute pancreatitis has multiple causes. Gallstone disease (44% to 54%) and alcohol (3% to 19%) are the predominant causes in the United Kingdom, although in the elderly population gallstones is the most common cause.⁷⁹ Drugs are responsible for a small proportion (about 5%) of cases of acute pancreatitis, and as the elderly are more likely to

Figure 77-3. Rate of acute pancreatitis by age group in the United Kingdom, 1987–1998. (Data derived from Goldacre MJ, Roberts SE. Hospital admission for acute pancreatitis in an English population, 1963–98: database study of incidence and mortality. *BMJ* 2008;328:1466–9.)

be prescribed medications such as furosemide, nonsteroidal anti-inflammatory drugs, steroids, some antibiotics, and cancer drugs, this should be considered as a possible etiologic factor. Other causes include hypertriglyceridemia, hyperparathyroidism, trauma, and infection. There is accumulating evidence that the underlying cause of acute pancreatitis is premature intracellular activation of trypsin.⁸⁰

Presentation

Abdominal pain and vomiting are the most common presenting symptoms of acute pancreatitis, and an elevation of plasma amylase (to four times normal) will often confirm the diagnosis. The serum amylase level peaks early and then declines over 3 to 4 days; in a patient presenting late, this peak may be missed. A raised serum lipase is more specific for pancreatitis and persists for slightly longer. The amylase level may be increased for other reasons, such as acute gastrointestinal ischemia, gastrointestinal perforation, or a leaking abdominal aortic aneurysm; it should be noted that these conditions are also more common in the elderly.⁸¹

Assessment

Immediate assessment should include clinical evaluation, blood tests (including complete blood count; liver, bone, and renal profiles; blood glucose), a chest x-ray, and any other tests necessary because of comorbidities present in an elderly patient. It is important to determine the severity of an attack of acute pancreatitis in order to help predict outcome and manage the patient in a suitable setting; care in a high-dependency unit is recommended for patients with severe acute pancreatitis.⁸² There are several methods for assessing severity: Ranson⁸³ and Imrie or Glasgow⁸⁴ are specific acute pancreatitis scoring systems based on a range of factors; a score of 3 or more predicts a severe attack (Table 77-1). APACHE II is based on an assessment of Acute Physiology and Chronic Health. It is more complicated to calculate than Imrie or Ranson scores but can give an accurate initial prediction of severity; a score greater than 8 predicts a severe attack.⁸² Additionally, it may be used repeatedly to assess the progress of a patient.⁸⁵ Trypsinogen activation peptide (TAP)⁸⁶ and C-reactive peptide (CRP)⁸⁷ are based on the assay of a single marker and are useful adjuncts to assessing severity. The British Society of Gastroenterology (BSG) guidelines recommend that APACHE II is performed on admission and the Glasgow score be calculated at 48 hours.⁸²

Abdominal ultrasound is useful in acute pancreatitis to confirm the presence of gallstones or bile duct dilatation. Gas-filled loops of bowel overlying the pancreas will often diminish the value of these images; contrast-enhanced ultrasound may, however, be more helpful.⁸⁸ Early CT is

occasionally indicated for diagnosis if clinical or biochemical findings are inconclusive and alternative diagnoses need to be excluded. Abdominal contrast-enhanced CT is most useful in acute pancreatitis between 6 and 10 days after admission to look for pancreatic necrosis in patients with persisting organ failure, signs of sepsis, or clinical deterioration.⁸²

Management

Approximately 75% of acute pancreatitis is *mild* and is usually self-limiting, requiring simple supportive management.⁸⁹ *Severe* acute pancreatitis, however, can produce a systemic inflammatory response syndrome (SIRS) and subsequent multiorgan dysfunction syndrome (MODS). The principles of management in severe acute pancreatitis (SAP) are, therefore, to support each organ system and establish appropriate monitoring to detect deterioration or the onset of complications, which may need some form of intervention. Elderly or obese patients should also be managed in a high-dependency unit.⁹⁰

RENAL

Adequate and timely intravenous fluid (IV) replacement lowers the risk of developing renal insufficiency and failure. Rapid or aggressive fluid resuscitation can be difficult in the elderly patient who may well have underlying cardiac or respiratory compromise.⁹¹ Hemofiltration or hemodialysis can be necessary if renal failure develops.

RESPIRATORY

Respiratory failure is the most frequently encountered single organ malfunction in SAP, and all patients should receive oxygen therapy and monitoring with oxygen saturation, arterial blood gas sampling, clinical evaluation, and radiologic investigation. Intervention with positive pressure ventilation may be required, and in severe cases high-frequency ventilation may be indicated.

CARDIAC

Cardiac failure is more commonly seen in those with pre-existing cardiac problems including hypertension, myocardial infarction, and atrial fibrillation and is therefore more common in elderly patients. Inotropic support is often needed in these patients.

GUT

Gut anoxia and the inflammatory syndrome can result in intestinal barrier failure and subsequent bacterial translocation, which has been suggested as a factor in the development of infected pancreatic necrosis. Enteral nutrition is recommended by the BSG guidelines (2005) as it may help preserve gut mucosal barrier function.⁸² Enteral feeding may be nasojunal or, if the stomach is emptying, nasogastric. If the stomach is, however, not draining, nasogastric aspiration should be used to manage the gastric stasis.⁹²

GENERAL

The inflammatory response alters capillary permeability and results in edema and hypovolemia.⁹³ As already mentioned, aggressive IV fluid replacement should be initiated in the patient with SAP,⁹⁴ and cardiovascular response should be monitored with, for example, central venous pressure

Table 77-1. The Glasgow Scoring System Includes a Point for Each of These Parameters

Albumin	< 32 g/l
WCC	> 15,000/mm ³
LDH	> 600 units/L
AST/ALT	> 200 units/L
Glucose	10 mmol/L
Calcium	< 2 mmol/L
Urea	> 16 mmol/L
PO ₂	< 8 KPa

measurement, Swan-Ganz catheter or the pulse contour computer (PiCCO),⁹⁵ and urinary output measurement. There is no consensus as to whether prophylactic antibiotics should be administered.⁹⁶

The elderly patient is more likely to have pre-existing organ dysfunction and so the capacity to tolerate an insult such as SAP is limited; this is reflected by the higher incidence in development of organ failure in the elderly (64% compared with 48%).⁹⁷

MANAGEMENT OF PANCREATIC NECROSIS

Nonperfusion of the pancreas on contrast-enhanced CT implies pancreatic necrosis and indicates a poor prognosis.⁹⁸ The Atlanta Classification provided a definition of necrosis, but it has not been strictly adhered to and a more recent classification has been suggested.^{78,99} It is important to determine if the necrosis is infected, as sterile necrosis can be left to resolve.¹⁰⁰ Infection may be confirmed by CT-guided needle aspiration. Untreated, infected necrosis is almost always fatal and the necrosis must be débrided and drained at open operation or by a minimally invasive technique.^{89,90}

MANAGEMENT OF FLUID COLLECTIONS

Fluid collection can occur within or adjacent to the inflamed pancreas (i.e., within the lesser sac) or elsewhere in the abdomen, remote from the pancreas. There is much controversy in the literature concerning the nomenclature and management of these collections.^{78,99} In essence, sterile collections will often resolve, whereas an infected collection (a pancreatic abscess) will need drainage by open operation, endoscopy, or a minimally invasive technique; the choice often depends on local expertise and preference.⁸²

CONCLUSIONS

Pancreatitis is more likely to be severe in the elderly, and this contributes to the higher mortality rates observed in elderly patients: 2.7 deaths per 100 patients in the 45- to 54-year-old age group compared with 18.9% in those 75 years or older.¹⁰¹ Patients with SAP, especially the elderly in whom there may be complicating comorbidities, should be managed in a specialist unit by experienced intensivists and pancreatic surgeons. Those patients who survive long-term management of complications such as diabetes and malabsorption caused by destruction of the pancreas will require specialist management. Attempts must be made to determine the cause of the pancreatitis to try to prevent further attacks. Patients with gallstone pancreatitis will require either cholecystectomy or ERCP and duct clearance.

CHRONIC PANCREATITIS

Chronic pancreatitis is an inflammatory disease resulting in progressive, irreversible destruction of the pancreatic parenchyma affecting exocrine and endocrine function. Onset is typically in the fourth decade with a strong male predominance, and presentation in those over 65 years is rare.¹⁰² Chronic pancreatitis shortens life expectancy by 10 to 20 years and is therefore not typically a disease of the elderly.¹⁰²

In up to 80% of cases of chronic pancreatitis (CP), the etiology is alcohol related,¹⁰³ and long-term alcohol consumption (>35 years) increases the risk of developing CP.¹⁰⁴ The

remaining 20% of cases of chronic pancreatitis can be attributed to tropical CP, hereditary CP, pancreatic strictures, pancreas divisum, pancreatic trauma, or idiopathic CP. Idiopathic senile chronic pancreatitis is a subtype of idiopathic CP that presents after the age of 50 and is more prevalent in the elderly.¹⁰⁵ Various theories have been proposed as to the mechanism of cell destruction, inflammation, fibrosis, and atrophy seen in CP, but this is still controversial.

The predominant symptoms of CP include pain, typically remitting and relapsing; exocrine dysfunction characterized by weight loss and malabsorption secondary to steatorrhea; and endocrine dysfunction manifesting as diabetes mellitus. Patients often present with symptoms related to the complications of chronic pancreatitis, which include pseudocysts, ductal calculi, distal bile duct strictures, pancreatic duct strictures, and duodenal stenosis.

The diagnosis of chronic pancreatitis can be difficult, but clinical history and examination, biochemical investigations, and radiologic investigations should be used in combination. Fecal elastase is a useful test to confirm pancreatic exocrine failure and has increasing sensitivity with increasing severity of disease. Other pancreatic exocrine function tests are possible but are more unreliable and generally not used.

The role of imaging in CP is both diagnostic and therapeutic. Ultrasound can be used to demonstrate changes in pancreatic tissue and the ductal system; however, CT has greater sensitivity in identifying pancreatic atrophy, pancreatic calcification, dilatation of the pancreatic duct, and pseudocysts, which are typically seen in chronic pancreatitis. MRCP is a useful, noninvasive method of imaging the biliary and pancreatic ductal system, especially if the pancreatic duct is dilated, and the administration of secretin can improve duct visualization. ERCP can provide similar images and has the advantage of offering therapeutic interventions such as sphincterotomy, dilatation of strictures, extraction of calculi, and stenting, although these procedures do carry a complication rate of 5% to 10%.¹⁰⁶ EUS has become a useful tool in the diagnosis of CP, particularly in the early stages,¹⁰⁷ and is useful therapeutically in celiac

KEY POINTS

The Pancreas

Pancreatic Adenocarcinoma

- The incidence increases with age.
- It has the lowest 5-year survival for all cancers.
- Most patients present with advanced disease.
- It is managed with surgery, chemotherapy, or palliation.

Acute Pancreatitis

- It is most commonly caused by gallstones in the elderly.
- Severity scoring is important to indicate prognosis and guide management.
- Management is supportive according to BSG guidelines with input from intensivists.
- It results in a higher incidence of organ failure and death in elderly.

Chronic Pancreatitis

- It is not typically a disease of the elderly.
- It is often caused by alcohol.
- It is characterized by pain and pancreatic insufficiency.

plexus blockade, drainage of pseudocysts, and obtaining a tissue diagnosis. The incidence of pancreatic cancer is increased in chronic pancreatitis. Radiologic imaging may be utilized to distinguish between the two diseases, although this can be difficult and the conclusion is often equivocal,¹⁰⁸ many patients will be found to be inoperable when they are diagnosed.

Management of patients with CP initially involves symptom control and the goal should be to improve quality of life. Pain should be initially treated with analgesics according to the analgesic ladder, but if this becomes intractable, then celiac plexus block can be considered—operatively, percutaneously, or endoscopically.

The main indications for surgery in CP are intractable pain, suspicion of malignancy, and involvement of adjacent organs. It is recommended that surgery should be individualized according to pancreatic anatomy (small or large duct), pain characteristics, exocrine and endocrine function, and medical comorbidity.¹⁰⁹ In an elderly patient, careful consideration should be given to the risks and benefits of

what is potentially major and complicated surgery. Options include gastrojejunostomy, feeding jejunostomy, PPPD, Whipple procedure, total pancreatectomy, lateral pancreaticojejunostomy (Puestow procedure), duodenum-preserving pancreatic head resection (the Beger's procedure), and local resection of the pancreatic head with longitudinal pancreaticojejunostomy (the Frey's procedure).

The nutritional status of a patient with CP should be carefully assessed and addressed with appropriate feeding and supplements, and exocrine insufficiency should be managed with enzyme supplements. Endocrine dysfunction may require referral to a specialist diabetologist.

The prognosis for patients with CP is poor, with a 20-year survival rate of 45% and a significantly worse survival for older patients and those with alcoholic CP.¹¹⁰

STRUCTURE

Decline in liver mass and a reduction in hepatic blood flow are commonly cited features associated with increasing age. A reduction in liver volume both in absolute terms and in relation to total body mass is known to occur after the age of 50,¹ and studies using ultrasound have estimated that total hepatic volume declines somewhere between 20% and 40% across the lifespan in humans.² Postmortem data suggest that livers of subjects older than 60 years exhibit increased hepatocyte volume despite decline in total liver size.³ However, other studies using liver scintigraphy have suggested that total hepatic mass in elderly subjects is not diminished, but that the mass of functional hepatocytes is decreased.⁴ Aging in the liver is also associated with reduction in hepatic blood flow of the order of 30% to 50%. Both total and functional hepatic flow decrease with age, and this reduction is particularly evident after the age of 75.⁵ The effects of aging on hepatocyte structure are less clear. There is an increase in the binuclear hepatocyte index and polyploidy, and decreased hepatic concentration of smooth endoplasmic reticulum.⁶ Within hepatocytes, mitochondrial volume increases, yet the number of mitochondria per hepatocyte is decreased with age.⁷ There are reports of thickening of the endothelial lining by 60% and an 80% decline in the number of endothelial cell fenestrations with increasing age.⁸ The resultant implications of these changes are impairment of sinusoidal blood flow and hepatic perfusion, as well as reduced uptake of macromolecules such as lipoproteins from the blood,² which may contribute to hyperlipidemia and vascular disease.⁹ The term *brown atrophy* is used to describe the macroscopic change seen in the liver with advancing age. This is due to age-related accumulation of the brown pigment lipofuscin within the lysosomes of hepatocytes. Studies in rodents have demonstrated that this may contribute to hepatocyte dysfunction by impairing metabolism, secretion, or excretion.⁹

FUNCTION

The structural changes with increasing age observed in human and animal studies do not appear to directly reflect any functional degeneration of the elderly liver. Certainly, there are no liver diseases specific to advancing age, and compared to other systems such as the musculoskeletal and cardiovascular systems, the liver appears to be less affected by aging.¹⁰ Elderly patients with abnormal liver biochemical tests should be investigated in the same way as younger patients as these changes cannot be attributed to an aging liver. Serum concentrations of liver enzymes remain unaltered, with albumin concentrations and synthesis rates remaining stable in old age.¹¹ The exception is alkaline phosphatase (ALP), which has been reported to increase by approximately 20% between the ages of 20 and 80,¹² probably as a result of bone ALP leakage into blood. Values for serum bilirubin in some reports have been shown to be slightly decreased with increasing age, perhaps explained

by an effect of reduced cellular muscle mass and decreased hemoglobin concentration.¹³ Hepatic secretion of cholesterol has been shown to increase with age, whereas bile flow and bile salt formation are reduced by 50%.¹⁴ The hepatic clearance of high-density lipoprotein has also been found to be reduced with increasing age in humans.² The increased incidence of cholesterol gallstones in elderly patients may be explained by some of these changes. Kupffer cells—macrophages with a major role in the removal of endotoxins—have impaired phagocytic activity with increasing age and could explain the susceptibility of elderly patients to sepsis because of intra-abdominal infection.¹⁰ It has also been reported that there is a 50% age-related decline in DNA base excision repair in mouse hepatocytes.¹⁵ The DNA damaged by free radicals or other insults therefore undergoes repair at a slower rate in older animals, increasing the likelihood of cell dysfunction. In animal studies, it has been extensively reported that the liver has a decreased capacity to recover from severe hepatic injury with increasing age. Although the rate of regeneration is slower, the overall capacity for regeneration seems to be preserved.² These changes appear to demonstrate that hepatic function declines with age; however, the significance of this in relation to clinical practice remains unclear.

DRUG AND ALCOHOL METABOLISM

The effect of age on hepatic drug metabolism, unlike renal drug excretion, remains controversial although it is widely perceived that there is a decline in the rate of clearance of drugs undergoing liver metabolism with increasing age. Reduction in liver blood flow and mass with increasing age has been consistently shown to correlate with the reduction of metabolism of rapidly cleared drugs such as propranolol, amitriptyline, verapamil, and morphine.¹⁶ Total hepatic enzyme activity is adversely influenced by changes in liver size, enzyme mass, and activity, yet metabolism of drugs such as phenytoin and warfarin, cleared in this manner, are unchanged with age.¹⁷ Animal studies have demonstrated impaired enzyme activity with a reduction in microsomal content of cytochrome P-450 during aging in mice; however, this has not been reproduced in most human studies.¹⁶ The clearance of drugs that undergo phase I metabolism appears to be unchanged in older people.¹⁸ However, drugs that undergo phase II metabolism are affected by age. Clearance of drugs such as ibuprofen, many benzodiazepines, imipramine, and more recently ropinirole and citalopram have been shown to be reduced by 10% to 50% with increasing age.¹⁹ Differentiation between frail and healthy elderly must be considered when interpreting data on drug metabolism. It has been demonstrated that clearance of paracetamol per unit body weight is significantly reduced in the frail elderly when compared with age matched fit subjects.²⁰ In addition, a reduction in the clearance of metoclopramide has also been described in frail but not in healthy subjects older than 65 years.²¹ Influence of disease states, environmental factors,

and co-administration of other drugs have been postulated as important factors affecting variance of hepatic drug metabolism with aging.¹⁹ The physiologic effect of alcohol on the aging body differs to that in the young.²² Reduced hepatic blood flow and fewer hepatocytes result in a prolonged effect of alcohol and comparably higher serum levels in the elderly despite a similar or reduced alcohol intake to that of younger subjects.²³ Ethanol is distributed almost completely in the body's water space, which is reduced with advancing age thus partially explaining increased blood alcohol concentration after intravenous administration in the elderly.²⁴ Animal experiments on older rats have revealed decreased alcohol elimination rates and reduced alcohol dehydrogenase activity within the liver.²² In addition, animal studies have demonstrated an age-dependent reduced activity of cytochrome P4502E1, an important enzyme in the metabolism of alcohol, but to date, this has not been reported in humans.²⁵

INVESTIGATIONS

Liver function tests (LFTs) refer to measurements of serum bilirubin, alkaline phosphatase (ALP), aspartate aminotransferase (AST), alanine aminotransferase (ALT), gamma glutamyl transpeptidase (GGT), and albumin, but they should also include the prothrombin time (PT). In general, conditions affecting the liver cell (hepatitis) cause a rise in AST and ALT, whereas biliary tree disorders (cholestasis) cause raised ALP and GGT. It is important to recognize that these enzymes are also present in other sites of the body, and when interpreting isolated elevation extrahepatic sources should be considered (Table 78-1). Raised liver enzymes often overlap between hepatitis and cholestatic patterns in clinical practice. Aminotransferases (AST, ALT) can also be elevated in both intra- and extrahepatic cholestasis.²⁶ Extrahepatic biliary obstruction causing irritation and secondary inflammation of hepatocytes results in mildly raised serum transaminases, and hepatitis can lead to a degree of cholestasis with consequent rise in ALP and GGT. In practice, when faced with this situation, it is helpful to recognize the pattern of the so-called dominant distribution of raised enzymes.²⁷ If the serum bilirubin is elevated to greater than twice the upper limit of the normal reference range, then the patient will be clinically jaundiced. Bilirubin can be raised in most types of hepatobiliary pathology,²⁷ often with an associated rise in liver enzymes. Initial evaluations should determine whether the hyperbilirubinemia is conjugated (direct) as seen in most types of liver disease, or unconjugated (indirect).²⁸ A low-serum albumin level and prolonged prothrombin time (PT) are sensitive indicators of impaired hepatic synthetic function, occurring in both acute and chronic liver disease, and are important prognostic indicators. When interpreting the serum albumin in elderly patients it must be taken into account that other factors may result in low levels of albumin. A prolonged PT may also arise from a deficiency of vitamin K, which is required for synthesis of clotting factors II, VII, IX, and X in the liver. This may be of particular significance in the elderly as dietary insufficiency can exhaust hepatic stores of vitamin K after just 4 weeks. Vitamin K deficiency can be excluded by giving intravenous replacement of 10 mg of vitamin K and then repeating the PT.

In chronic liver disease, blood loss from gastrointestinal bleeding as a result of upper gastrointestinal pathologies such

Table 78-1. Interpreting LFTs in the Elderly

Abnormality in Liver Enzymes	Consider
Elevated ALT and AST	Hepatitis A, B, C, and E Alcoholic liver disease Nonalcoholic fatty liver disease Autoimmune hepatitis Hereditary hemochromatosis Medications (e.g., NSAIDs, herbal drugs) Congestive cardiac failure and ischemic hepatitis Celiac disease
Elevation of AST only (normal ALT)	Nonhepatic source Cardiac, skeletal muscle, kidneys, brain, pancreas, lungs, leukocytes, and red blood cells ²⁹
Elevated ALP and GGT	Intrahepatic cholestasis (e.g., primary biliary cirrhosis); drugs (e.g., co-amoxiclav, erythromycin); sepsis Extrahepatic cholestasis (e.g., biliary obstruction), stones, strictures, malignancy Hepatic infiltration (e.g., malignancy)
Elevated GGT only (normal ALP)	Excess alcohol consumption Enzyme-inducing drugs (e.g., barbiturates, phenytoin) ²⁶ Fatty liver, obesity, type II diabetes, hypercholesterolemia Renal failure Chronic obstructive pulmonary disease Pancreatic disease Myocardial infarction ³⁰
Elevated ALP only (normal GGT)	Extrahepatic source—bone Malignancy without liver or bone involvement (e.g., lung) ³¹ Amyloid, leukemias, granulomas
Isolated raised bilirubin (normal LFTs)	Unconjugated—hemolysis Inherited disorders (e.g., Gilbert syndrome)
Elevated PT only (normal LFTs)	Warfarin Vitamin K deficiency Malabsorption
Low albumin only (normal LFTs)	Malabsorption Malnutrition Urinary and gastrointestinal losses Acute illness ³¹

as bleeding varices, can lead to iron deficiency anemia. This may be exacerbated by coagulopathy and thrombocytopenia secondary to the splenic enlargement seen in portal hypertension. Hypersplenism can also result in leukopenia and a mild anemia. A raised mean corpuscular volume (MCV) suggests excessive alcohol intake because of its direct toxic effect on the bone marrow. In addition, macrocytosis is also seen in patients with chronic liver disease due to failure of bone marrow to produce erythrocytes and reduced erythrocyte survival. In elderly patients, poor nutrition, particularly lack of dietary folic acid, can lead to hematinic deficiencies and may contribute to difficulties interpreting hematologic tests when there is underlying liver disease.

The true prevalence of abnormal LFTs in the elderly has yet to be clarified. However, research from the early 1980s showed 17% of elderly hospitalized patients had abnormal LFTs when screened without clinical indication.³² In the United Kingdom, there is evidence that liver disease may be missed in all age groups as abnormal LFTs are often not investigated.³³ A thorough history is a mandatory part of a "liver screen" and should include the patient's

alcohol consumption, current or recent drug use (prescribed or otherwise), risk factors for viral hepatitis, the presence of autoimmune diseases, family history of chronic liver disease, and factors such as diabetes, obesity, and hyperlipidemia. Elderly patients with elevated LFTs should be investigated initially with noninvasive serologic tests²⁸ (Table 78-2). It excludes Wilson's disease, which is rarely diagnosed over the age of 40. Liver disease in those with homozygote α_1 -antitrypsin deficiency tends to become apparent in the age group of 50 to 60 years but is probably worth including as part of the screen. Serologic screening tests for celiac disease could also be included as this condition is recognized as causing asymptomatic elevation of transaminases, which subsequently normalize on a gluten-free diet.³⁴ There are several causes of LFT derangement in patients with a negative liver screen including drugs, sepsis, and other comorbidities. Many of the medications used in elderly patients can cause abnormal LFTs.³⁵ This should be borne in mind when reviewing a patient's drug history. In a district general hospital study of hospitalized patients with jaundice, the second commonest cause after cancer was found to be sepsis/shock.³⁶ A study of liver function tests in bacteremia not of hepatobiliary origin demonstrated significant elevations in levels of GGT and ALP, and reduced albumin levels.³⁷ Other possible causes to consider include alcohol excess, fatty liver, obesity, diabetes, thyroid disease, and Addison's disease, which may also cause mild derangement of LFTs. Some expert reviews suggest that where there is a negative screen to treat the most likely cause of the abnormal LFTs—that is, alcohol (by abstinence), hepatotoxic drugs (by drug cessation), and nonalcoholic fatty liver disease (by weight reduction and diabetes control)—before more detailed investigation if LFTs remain abnormal after a period of observation.²⁸

RADIOLOGY

The role of *abdominal ultrasound* is well established in the evaluation of the liver and biliary tree. It should be the first-line investigation in patients with any abnormality in liver function tests or where there is a suspicion of liver disease. It is safe and noninvasive and therefore an ideal investigation for use in elderly patients. The images require no adaption in interpretation compared to younger patients; the only change seen in the liver in increasing age is reduction in liver volume. It is particularly useful in the detection of focal liver lesions, when performed by an experienced operator.²⁷ The advent of contrast-enhanced ultrasound has been shown to improve the detection and differentiation of these focal lesions.³⁸ Detection of fatty liver is also possible, although ultrasound is unable to accurately quantify the amount of fat present.²⁶ Ultrasound is also useful in chronic liver disease, particularly evaluation of liver texture and size, and for assessing other upper abdominal organs including the spleen. Doppler facilities to detect blood flow provide useful information about vascular structures and in portal hypertension, reversed portal vein flow, and development of collateral vessels can be demonstrated. *Spiral computed tomography (CT)* can provide extra detail and is particularly effective in further characterization of focal liver lesions. It can also be used to detect diffuse liver disease because of fat, iron deposition, and cirrhosis as well as providing further information about other abdominal organs. There are no protocol adaptations

Table 78-2. Initial Serologic Tests in Elderly Patients with Abnormal LFTs

Screening Test	Disease	Other Clues
Hepatitis A IgM	Hepatitis A	Travel to endemic areas
Hepatitis B surface antigen (HBsAg)	Hepatitis B	Intravenous drug usage Blood transfusion
Hepatitis C virus antibody (HCV antibody)	Hepatitis C	Intravenous drug usage Blood transfusion
Hepatitis E IgM	Hepatitis E	Travel to endemic areas
Antimitochondrial antibody (AMA)	Primary biliary cirrhosis	Pruritus Female sex Presence of other autoimmune disorders
Smooth muscle antibody (SMA)	Autoimmune hepatitis	Presence of other autoimmune disorders
Liver kidney microsomal antibody (LKM)		Female sex
Transferrin saturation	Hemochromatosis	Diabetes Joint symptoms
Ferritin		
Serum Alpha-fetoprotein	Hepatocellular carcinoma	Known chronic liver disease
α_1 -Antitrypsin level	α_1 -Antitrypsin deficiency	Coexisting lung disease
Anti-TTG antibody	Celiac disease	Gastrointestinal symptoms of malabsorption
Lipid profile	Nonalcoholic fatty liver disease	Comorbidities (e.g., diabetes)
Serum glucose		

that need to be specifically undertaken in elderly patients when undergoing CT scans of the liver; however, the intravenous contrast agent can cause renal failure in patients with underlying reduced creatinine clearance. Even elderly patients with a degree of cognitive impairment may be able to cooperate well with CT scanning, as examinations are now quicker; for example, the entire liver and pancreas can be imaged in one single breath hold.³⁹ Unenhanced *magnetic resonance imaging (MRI)* of the liver is comparable to enhanced spiral CT in the detection of focal liver lesions, while avoiding the disadvantage of radiation exposure and the potential nephrotoxic effect of iodinated contrast agent.⁴⁰ It has improved the characterization of underlying nodules and fibrotic changes in patients with cirrhosis, particularly when there is sideroblastic nodular regeneration.⁴¹ MRI is also particularly useful in quantifying hepatic iron concentration and has a positive and negative predictive value of 100% in the detection of hemochromatosis.⁴⁰ Magnetic resonance cholangiopancreatography (MRCP) is the modality of choice for noninvasive assessment of the pancreatic duct,⁴² giving further views of the biliary tree. It may even demonstrate common bile duct (CBD) stones not seen on endoscopic retrograde pancreatography (ERCP).⁴²

LIVER BIOPSY

The need for further investigation of persistently abnormal LFTs in the elderly must depend on clinical context, considering the risks and benefits of the procedure and whether the findings will dictate further management. Liver biopsy is not specifically contraindicated in elderly patients, but a

25-year audit from Australia found that increasing age was a risk factor for major complications following the procedure, particularly in those age over 50.⁴³ The patient should be able to understand and cooperate with instructions given by the person performing the liver biopsy and be able to give informed consent.⁴⁴ Midazolam can be used as sedation in the very anxious, but this must be used with caution in elderly patients. It is important to correct clotting abnormalities prior to biopsy to minimize the potential risk.⁴⁴ The indications for liver biopsy can be broadly subdivided into the diagnosis of parenchymal disease and focal lesions. In parenchymal liver disease, biopsy is indicated in the diagnosis and classification of chronic viral hepatitis and is useful for planning treatment decisions. In hemochromatosis, it is recommended that liver biopsy is undertaken to define or exclude the presence of cirrhosis.⁴⁴ In autoimmune hepatitis, where 25% of patients are diagnosed over the age of 65,⁴⁵ liver biopsy is indicated in both diagnosis and follow-up.⁴⁶ It is not usually indicted for primary biliary cirrhosis or routinely in alcoholic liver disease, and its role in nonalcoholic fatty liver disease has not yet been clearly established. Liver biopsy may be useful in the investigation of acute liver dysfunction where routine serologic tests are unhelpful or there is an unusual course or severity of illness. It may also be of use in suspected drug reactions, especially herbal medicines. For the assessment of focal liver lesions, the indications for liver biopsy depend largely on the clinical picture.⁴⁴

LIVER DISEASES

Liver disease in clinical practice can be classified into acute liver failure (ALF) and chronic liver disease. ALF is the term used to describe a clinical syndrome of sudden loss of hepatic function in a patient with no prior history of liver disease.⁴⁷ Chronic liver disease is caused by long-standing liver damage and commonly presents with the complications of cirrhosis. There are a number of recognized etiologies of acute and chronic liver disease as summarized in Table 78-3. As chronic liver disease is more commonly seen in the elderly population, this will be discussed first.

Liver injury caused by *chronic liver disease* of any etiology can result in cirrhosis, defined histologically as a diffuse process with fibrosis and nodule formation. As there are no diseases specific to liver aging itself, older patients are affected by the same conditions and have similar clinical manifestations as younger age groups.⁴⁸ However, older patients may present with more advanced disease and prognosis is poorer with increasing age.⁴⁹ It is important to recognize that there is a

greater mortality rate from other diseases unrelated to the liver, especially pneumonia, in those age 80 or over with underlying cirrhosis.⁴⁹ Cirrhosis has a varied clinical presentation from an asymptomatic individual with abnormal LFTs to advanced decompensated liver disease indicated by the presence of complications such as jaundice, ascites, and portal hypertension with variceal bleeding. There are several recognized stigmata of chronic liver disease which include palmar erythema, Dupuytren's contracture, clubbing, spider nevi, and gynecomastia.

The prevalence of *chronic hepatitis B (HBV) infection* is declining worldwide, but it is still high in elderly people of Asian origin. Although acute cases are rare, the natural history of HBV infection appears to be altered in the elderly with a higher risk of progression to chronic infection.⁵⁰ HBV in the elderly can present as chronic hepatitis, but more often as cirrhosis with older patients more likely to have advanced liver disease compared to younger ones.⁵¹ HBV causes liver injury via an immune response against virus-infected hepatocytes. The aim of treatment is to reduce inflammation and fibrosis by preventing replication of the virus. Antiviral treatments (e.g., interferon- α , lamivudine) are available and indicated in patients of all ages with chronic HBV who also have markers of active viral replication (i.e., detectable HBV DNA), elevated aminotransferase levels, and chronic hepatitis on liver biopsy. The decision to treat must consider the presence of other comorbidities and the patient's overall general health, as the advantages of treatment of HBV in the elderly remain unspecified. That said, most elderly patients with chronic HBV infection even with advanced liver disease have no evidence of ongoing viral replication and therefore are not candidates for antiviral treatment.⁵¹ The increased rate of adverse effects seen with interferon in older patients may render lamivudine as the treatment of choice, but these decisions should always be led by a specialist center. Screening for hepatocellular carcinoma is of importance where there is long duration of viral infection as it develops mainly in patients over age 50 with cirrhosis, although development may occur in those with either chronic hepatitis or simple HBsAg carriage.⁵¹

Chronic hepatitis C (HCV) can cause liver disease in the elderly, and in some southern European countries it is estimated that as many as one in two or three people over age 80 are infected.⁵² It is anticipated as the population ages over the next few decades, so will the prevalence of HCV in older patients. Most of the elderly with HCV infection have previously acquired it from blood transfusions. The American Association for the Study of Liver Diseases (AASLD) recommends that anyone who received blood transfusion or blood products before 1992 be screened for HCV infection.⁵³ Chronic HCV develops in 55% to 85% of individuals initially infected with HCV,⁵⁴ and the progression of fibrosis is more rapid in those who acquire the infection at an older age.⁵⁵ The mechanism of this rapid progression in elderly patients has not been fully established, although factors such as a higher prevalence of the more aggressive genotype 1 and impaired immunity have been suggested.⁵⁶ Among HCV-infected individuals, cirrhosis becomes more prevalent with age,⁵⁶ with studies showing a mean age of 65.4 years for those with cirrhosis.⁵⁷ Accordingly elderly patients are more likely to present with a complication of cirrhosis or hepatocellular carcinoma (HCC).⁵⁸ HCC develops in 1% to

Table 78-3. Common Causes of Acute and Chronic Liver Disease Presenting in the Elderly

Causes of Acute Liver Failure	Causes of Chronic Liver Disease
Acute viral hepatitis A, B, C, and E	Chronic hepatitis B and C
Drug induced	Alcoholic liver disease
Ischemic hepatitis	Nonalcoholic fatty liver disease
Autoimmune hepatitis	Autoimmune liver disease—autoimmune hepatitis, primary biliary cirrhosis,
Portal or hepatic vein thrombosis	primary sclerosing cholangitis
	Hemochromatosis

2% of patients with cirrhosis because of chronic HCV and the interval between infection and diagnosis of HCC may be shorter when the infection is acquired at an older age.⁵⁹ The current treatment of choice for active HCV infection is pegylated interferon- α and oral ribavirin.⁵³ The goals of treatment are to clear the virus and to prevent complications, such as cirrhosis and HCC. Only patients who have at least moderate inflammation and necrosis on liver biopsy and a significant risk of cirrhosis during their estimated life expectancy should be considered as candidates for therapy.⁵⁶ Treatment in elderly patients is controversial as they are more likely to experience adverse effects including lethargy, confusion and behavioral change,⁶⁰ but guidelines do not stipulate an upper age limit for antiviral therapy. Therapy is contraindicated for patients with reduced life expectancy from severe hypertension, heart failure, coronary artery disease, poorly controlled diabetes, or obstructive lung disease.⁵³ Adherence to therapy, which is essential to achieving a virologic response, may be suboptimal in older patients.⁶¹ Studies have also shown that increasing age is an independent predictor of poor response to treatment, although sustained response rates of 45% have been observed in patients above 65 years.⁶² Whether this benefits overall survival in the elderly population remains to be seen and the decision to treat must therefore encompass an individual's risks and benefits.

Alcoholic liver disease (ALD) is becoming an increasing problem among elderly individuals. Alcohol consumption is common in the elderly, and the prevalence of alcohol abuse probably underestimated.⁶³ Reasons for increased alcohol consumption may be explained by associated psychosocial problems, such as loss of spouses, loneliness, and mental health problems that occur with increasing frequency.²² Although data suggest that most patients with severe ALD present in the fifth or sixth decade of life, a study from the United States reported the peak incidence of alcoholic cirrhosis in the seventh decade among white men.⁶⁴ An increased rate of complications and severity of disease at presentation is one important difference in the elderly population and the presence of other comorbidities may result in the increased capability of alcohol to cause a harmful effect.⁶⁵ This has implications for overall prognosis, which is dependent on the severity of disease at presentation. Those over the age of 70 years with alcoholic cirrhosis have been shown to have a mortality rate of 75% at 1 year.⁶⁶ Patients are living longer because of better therapeutic strategies, and therefore HCC is emerging as a major complication in later life.²³ In the elderly, the spectrum of symptoms and signs of ALD do not differ from those seen in younger adults and include jaundice, acute liver failure, and decompensated liver disease with portal hypertension. Nonspecific symptoms of ALD including general malaise and anorexia are more common.⁶⁷ Chronic alcohol ingestion can result in alcoholic fatty liver, which can be reversible even in the elderly with abstinence.²² Patients are usually asymptomatic but may have hepatomegaly on examination. Alcoholic hepatitis may result from continued or increased alcohol intake, as well as recommencing drinking after a period of abstinence. Severe alcoholic hepatitis results in a potentially life-threatening illness, with deep jaundice, encephalopathy, ascites, and coagulopathy. Underlying cirrhosis may coexist, and signs of decompensated liver disease are common. The

prognosis of alcoholic hepatitis is variable; however, ongoing alcohol abuse, the presence of cirrhosis, and severe malnutrition are important factors.²²

A raised GGT supports a diagnosis of alcohol-related liver disease when serum AST:ALT levels are elevated at a ratio of 2:1, particularly in the presence of a raised MCV.²⁹ Bilirubin is a useful prognostic indicator and correlates well with the degree of histologic change in alcoholic steatohepatitis.²² A careful alcohol history should be taken in all elderly patients and the opportunity for advice and counseling utilized, as alcohol abstinence is beneficial at any stage of ALD. Studies suggest that these brief interventions reduce hazardous alcohol consumption in the elderly similar to younger populations.⁶⁸ Withdrawal from alcohol in elderly subjects should be supervised by a health care professional.⁶⁹ Few clinical studies directly support or refute the hypothesis that withdrawal symptom severity, delirium, and seizures increase with advancing age, but several observational studies suggest that adverse functional and cognitive complications during alcohol withdrawal do occur more frequently in elderly patients.²³ Benzodiazepines such as chlordiazepoxide and diazepam are used, based on validated alcohol withdrawal protocols with dose and frequency individualized. Older hospital in-patients with concurrent serious illness may have increased sensitivity to adverse effects.⁷⁰ β -Blockers, clonidine, carbamazepine, and haloperidol may be used to treat withdrawal symptoms not controlled by benzodiazepines in the elderly. Attention to nutrition and replacement of B vitamins via an intravenous route are of great importance to prevent Wernicke's and Korsakoff's syndromes. For acute alcoholic hepatitis, intensive care management may be indicated. Selected patients may gain benefit from steroid therapy or pentoxifylline, an inhibitor of TNF- α .⁷¹ Management of complications and continued encouragement of abstinence is the mainstay of treatment in alcoholic cirrhosis with liver transplant the ultimate therapy.

Nonalcoholic fatty liver disease (NAFLD) represents a spectrum of disorders characterized by predominantly macrovesicular hepatic steatosis that occur in individuals in the absence of consumption of alcohol in amounts considered harmful to the liver.⁷² This spectrum includes fatty liver and nonalcoholic steatohepatitis (NASH) with inflammation and fibrosis, which can lead to cirrhosis. It is the probable cause of "cryptogenic cirrhosis" in many elderly individuals.⁷³ Risk factors for underlying NAFLD include obesity (particularly abdominal adiposity), diabetes and insulin resistance, rapid weight loss, drugs including amiodarone, and elevated triglycerides. Older age (>40 years) is an independent risk factor for more advanced liver disease in NAFLD.⁷⁴ For patients with the metabolic syndrome and NASH-associated cirrhosis, liver failure is the main cause of morbidity and mortality rather than cardiovascular disease.⁷⁵ It is estimated that 20% to 30% of the U.S. population is affected by NAFLD,⁷⁶ with 3.5% to 5% prevalence of NASH.⁷⁷ NAFLD commonly presents between the ages of 46 and 57 years,¹⁰ and one study from Israel has reported a prevalence of NAFLD, as determined by ultrasound criteria, as high as 46% in a group of patients older than 80 years.⁷⁸ Prospective studies are few, but it is thought 10% to 15% of patients will progress to advanced fibrosis and cirrhosis.⁷⁹ The overall progression to cirrhosis is slow, but once developed, complications will occur in 45% within 10 years.⁷⁶ Elderly patients are therefore likely

to constitute a considerable proportion of this cohort. Many patients are asymptomatic; however, initial symptoms can include fatigue, malaise, and right upper quadrant pain. The diagnosis can usually be made on the basis of a negative "liver screen," mild elevation of transaminases (ALT:AST ratio < 1), evidence of fat on abdominal ultrasound, or features of the metabolic syndrome.⁷⁴ Excess alcohol consumption must be excluded. A liver biopsy is the only way to determine the stage of NAFLD. No therapy has yet been proved to be of benefit although initial management should focus on lifestyle modification and the reversal of conditions associated with NAFLD.⁸⁰ There is a growing consensus that only patients with NASH require pharmacologic treatment.⁸¹ Slow weight loss by dietary modifications and exercise are recommended to achieve weight loss and improve insulin sensitivity,⁷² although this may prove to be challenging in the elderly with reduced mobility. Drug treatments for weight loss appear promising, but there may be issues with long-term tolerability relevant to elderly patients. Improvement of insulin resistance with metformin and thiazolidinediones have shown potential, but further randomized placebo-controlled trials are needed to assess efficacy and safety of these drugs.⁸⁰ Lipid-lowering drugs, antioxidants, angiotensin-converting enzyme inhibitors, and angiotensin receptor blockers are also the subject of ongoing studies.

Autoimmune hepatitis (AIH) is a chronic necro-inflammatory disease of the liver which can silently progress to cirrhosis.⁴⁵ It is characterized by hypergammaglobulinemia (usually IgG) circulating autoantibodies and morphologic changes of interface hepatitis.⁷ Although it was initially thought to affect young women, it is now known to have a bimodal distribution with another peak between 50 and 70 years of age.⁸² Studies have agreed that approximately 25% of cases of AIH present in those over 65 years of age.⁴⁵ It may present acutely, but commonly in the elderly presents in a more indolent form. However, patients over the age of 60 have been observed to have a higher rate of cirrhosis at presentation. Symptoms can be subtle and may include fatigue, upper abdominal pain, anorexia, and polymyalgia, but a lower rate of arthralgia when compared to younger patients.⁴⁵ Autoantibodies such as antinuclear (ANA), anti-smooth muscle (SMA), antiliver kidney microsomal (LKM) and antisoluble liver/pancreas (SLA/LP) antigens may be positive but are nonspecific. AIH in the elderly is almost always characterized by ANA and SMA antibodies, classified as type 1 (classic) disease; other pathologic autoantibodies occasionally seen in this population are anti-SLA/LP and antiactin.⁸³ The outcomes for elderly people with AIH appear to be no worse than they are for younger ones,⁵⁰ including those who are untreated.⁸⁴ It was traditionally believed that elderly patients had a milder disease course and controversy existed as to whether treatment was beneficial; however, it is now widely thought that these patients have an excellent prognosis if remission is induced. Treatment failure occurs less commonly in patients older than 60 years compared to younger adults, but it must be recognized by careful monitoring. The preferred initial treatment for severe AIH in the elderly is prednisolone in combination with azathioprine.⁸⁵ If there is relapse after remission, low-dose prednisolone or azathioprine as maintenance is used although sustained long-term remission free from medication is still possible after relapse and retreatment.⁸⁴ However, in the elderly, azathioprine is

less well tolerated and use of prednisolone alone in a higher dose is associated with greater frequency of adverse effects. Bone protection must be instituted early. A recent study from Japan suggested ursodeoxycholic acid may be an effective drug for management of older patients with AIH.⁸⁶

Primary biliary cirrhosis (PBC) is an autoimmune disease classically affecting middle-aged women, but it may be present in patients older than 65 years in 30% to 40% of cases.⁵⁰ Data from the 1990s revealed that in England, more than one third of patients with PBC were older than 65, with a median age at diagnosis of 62 to 63 years.⁸⁷ Symptom severity at first presentation does not differ in older subjects, although age is known to be an independent adverse prognostic risk factor in PBC when symptoms and complications of liver disease arise.⁸⁸ Diagnosis can be made in the presymptomatic stage, where antimitochondrial antibody (AMA) is detected in the serum but LFTs are normal. In the asymptomatic phase, patients have detectable AMA and abnormal LFTs (elevated ALP and GGT) but no clinical features of disease. However, up to 50% have established cirrhosis at diagnosis. When symptoms arise, lethargy and pruritus are characteristic. In late presentation, symptoms and signs of decompensated liver disease can dominate the clinical picture. Jaundice does not become apparent until late in the disease, and serum bilirubin is an important prognostic indicator. Other autoimmune diseases, especially Sjögren's syndrome, Raynaud's syndrome, or rheumatoid arthritis, may be present. Helpful investigations include raised immunoglobulins, particularly IgM and raised serum cholesterol. In the presence of investigations highly suggestive of the disease, some hepatologists believe a liver biopsy to be unnecessary, especially in elderly and frail patients, where management will not be affected.⁴⁴ Liver transplantation is the only effective treatment for patients with end-stage disease.⁸⁹ Immunosuppressants such as steroids are of no benefit. Ursodeoxycholic acid (UCDA) can improve LFTs and symptoms; however, it does not improve overall survival.⁹⁰ For pruritus, cholestyramine is the most commonly used agent, but other drugs such as rifampicin, naltrexone, and sertraline can be of benefit. Patients who have marked cholestasis are at risk of malabsorption of fat-soluble vitamins A, D, E, and K and should receive replacement where this occurs. Bone disease such as osteopenia, osteomalacia, and osteoporosis can complicate PBC, and prophylaxis is indicated.⁹¹

Hemochromatosis is an inherited disorder of iron metabolism. Liver damage results from progressive iron deposition, which also affects the pancreas, heart, endocrine organs (pituitary, occasionally thyroid, and adrenals), and joint synovia.²⁷ The gene for hemochromatosis (HFE) is located on chromosome 6, with 90% of cases associated with homozygous substitution of tyrosine for cysteine—the C282Y mutation.⁹² It is characteristically diagnosed in men between 40 and 50 years, but in women, because of the protective effect of menstruation, presentation is classically a decade later. Raised serum ferritin and raised transferrin saturation (>60%) are suggestive of the diagnosis. Genetic testing for the HFE gene is now widely available, and, as already mentioned, MRI can be useful. Liver biopsy is recommended to define or exclude the presence of cirrhosis, in cases where biochemical and genetic testing do not give a clear diagnosis and where other causes of liver disease need to be excluded.⁴⁴ Presentation can be with symptoms and signs of the complications of chronic

liver failure, especially if HCC has developed. The risk of HCC is particularly high in hemochromatosis, estimated at 30%.²⁶ Venesection should be performed once or twice weekly to remove 500 mL of blood (200 to 250 mg of iron) until serum ferritin is less than 50 mg/L. However, elderly patients with underlying heart failure may need smaller volumes of blood removed or less frequent phlebotomy. The aim of treatment is to prevent the onset of cirrhosis, and thus HCC. Life expectancy is similar to that of the healthy population if treatment can be achieved before the onset of cirrhosis or diabetes.⁹² Transplantation for liver failure remains a viable option, although survival in this group is lower than in those transplanted for other indications.⁹³ Genetic screening of all first-degree relatives of any age is recommended given the effectiveness of early treatment in preventing complications that significantly reduce life expectancy.

Primary sclerosing cholangitis (PSC) can be diagnosed at any age but is commonly a disease of young males. There is a close association with inflammatory bowel disease, particularly ulcerative colitis. There is also increased risk of developing cholangiocarcinoma. LFTs usually show cholestasis, and AMA is negative. Other autoimmune markers including ANCA are nonspecific. Endoscopic Retrograde and Magnetic Resonance Cholangio-Pancreatography demonstrate multiple irregular strictures and dilatation of the biliary tree. Management involves symptomatic relief of cholestasis, bone disease prophylaxis, and replacement of fat-soluble vitamins. Where there are acute episodes of cholangitis, antibiotic treatment is indicated. Balloon dilatation or stenting may be undertaken if there is a focal obstructive biliary stricture. Liver transplantation remains the only effective treatment, although there is a high risk of subsequently developing colon cancer in those with ulcerative colitis.

COMPLICATIONS OF CIRRHOSIS

Portal hypertension results from cirrhosis of any cause but can occur acutely following portal vein thrombosis or occlusion of the hepatic vein (*Budd-Chiari syndrome*). Although rare in the elderly, Budd-Chiari syndrome is a recognized complication of myeloproliferative diseases resulting in a hypercoagulable state. The development of *varices* in cirrhosis has important prognostic implications for the patient, as 30% will bleed from their varices, irrespective of age, within 2 years of diagnosis. The mortality rate for each bleeding episode is 30% to 50%.⁹⁴ Immediate survival rate after variceal bleeding is similar in elderly and younger cirrhotic patients, although midterm and long-term survival rates appear to be worse for the older group.⁵⁰ Initial management of a significant bleed requires stabilization of the patient, with care not to precipitate congestive cardiac failure in older individuals. Terlipressin (a vasopressin analogue) to reduce portal blood flow should be used with caution in the elderly as it may precipitate an ischemic event, which can either be cardiac, mesenteric, or peripheral⁹⁵ and is contraindicated in documented ischemic heart disease. Upper gastrointestinal endoscopy should be arranged urgently; endoscopic treatment using sclerotherapy, or preferably band ligation, has a high success rate of approximately 90% across all age groups.⁹⁵ If bleeding cannot be controlled endoscopically, balloon tamponade with either a Sengstaken-Blakemore tube or Minnesota tube can be

undertaken. If there is continued bleeding despite endoscopic intervention, transjugular intrahepatic portal systemic shunt (TIPSS) can be employed. Following TIPSS there is a greater risk of encephalopathy in elderly patients, and it is recommended that careful assessment be undertaken so the risk of encephalopathy does not outweigh the benefit.⁹⁶ It also increases cardiac preload and may precipitate cardiac failure in those with heart disease.⁹⁷ Propranolol, a nonselective β -blocker for primary and secondary prevention, has been shown to be effective in lessening rebleeding and mortality by reducing portal pressure.⁹⁵ It should be used with caution in the elderly, as they are less tolerant to β -blockers and coexisting heart failure may increase the likelihood of adverse effects.

Ascites and peripheral edema are often the first signs of decompensated liver disease,⁹⁵ occurring in over half of all patients with cirrhosis over a 10-year period.⁹⁸ In a patient with known liver disease, it should not be presumed that the underlying cause of the ascites is cirrhosis. Patients should undergo an ascitic tap, and fluid should be sent for albumin and protein levels, culture and sensitivity, neutrophil count, and, if there is clinical suspicion, amylase and cytology. Patients with cirrhosis generally have low levels of protein or albumin in the ascites. Treatment is aimed at addressing the key underlying factors in the pathogenesis of ascites in cirrhosis formation—portal hypertension and sodium retention. Bed rest is no longer recommended for the treatment of uncomplicated ascites.⁹⁸ The risk of muscle atrophy, particularly in the elderly, and other complications can result in prolonged in-patient stays. However, salt restriction is important, and dietary salt should not exceed 90 mmol per day. Food with very low salt content in a hospital setting can be unpalatable⁹⁵ and reduces patient compliance; therefore, recognition and avoidance of malnutrition is important. There is controversy over the role of fluid restriction. Despite sodium retention, some patients have hyponatremia because of impaired free water clearance. Recently updated guidelines⁹⁸ recommend that water restriction be reserved for those who are clinically euvoletic with severe hyponatremia, who are not taking diuretics and only where there is a normal serum creatinine. In situations where the sodium is <120 , diuretics should be stopped. Diuretic therapy remains the mainstay of treatment in ascites. Spironolactone, an aldosterone antagonist, is the first-line drug of choice, but amiloride or eplerenone are alternatives. If spironolactone alone does not achieve adequate diuresis, a loop diuretic such as furosemide may be added. Careful monitoring of fluid loss by recording body weight, together with serum urea and electrolytes should be undertaken particularly in the elderly.⁹⁵ Large volume paracentesis is reserved for patients who initially present with tense ascites. To prevent circulatory dysfunction, volume expansion with intravenous salt-poor human albumin is given. Although there are no data on the hemodynamic changes seen during paracentesis specific to elderly patients, it is reasonable to suggest that they should be carefully monitored. TIPSS is a highly effective treatment for refractory ascites; however, it may precipitate encephalopathy, and whether it has a positive impact on overall survival remains to be clarified.

Even with early diagnosis and prompt treatment, *spontaneous bacterial peritonitis (SBP)* carries a mortality rate of 20%.⁹⁹ It is diagnosed when the ascitic fluid neutrophil count is

>250 in the absence of a precipitating cause, such as an intra-abdominal and surgically treatable source of sepsis.⁹⁸ It is commonly caused by coliforms; however, culture can be negative. The symptoms are usually nonspecific, especially in the elderly where there may be a poor systemic and laboratory response to infection.⁹⁵ It should be suspected if there is abdominal pain, fever, or encephalopathy in a patient with ascites or deterioration in blood tests. Intravenous cefotaxime is the antibiotic of choice and will attain high ascitic fluid concentrations.¹⁰⁰ In a third of patients, renal impairment develops and this is a significant cause of mortality. Treatment with intravenous albumin has been shown to be associated with improvement in circulatory function compared with equivalent doses of fluid as colloid.¹⁰¹ Continuous prophylactic antibiotics with oral norfloxacin or ciprofloxacin is recommended after an episode of SBP because of the cumulative recurrence rate of 70% at 1 year.⁹⁸ SBP is an indicator of poor prognosis and referral for liver transplantation should be considered.

Hepatorenal syndrome (HRS) is a serious complication in patients with advanced cirrhosis either alone or in association with SBP. Intense vasodilatation of the splanchnic circulation causes a relatively low and insufficient cardiac output with effective hypovolemia.¹⁰² Marked vasoconstriction of the renal circulation results in "functional" renal failure with no structural damage to the kidneys.¹⁰³ Vasoconstrictors such as terlipressin together with albumin infusions are recommended as first-line treatment of HRS. Treatment should continue until there is reversal of HRS, defined as reduction in serum creatinine below 1.5 mg/dL, commonly seen in week 2,¹⁰⁴ although the optimum duration of treatment is unknown. In most studies of HRS, the incidence of ischemic side effects with terlipressin is approximately 13%,¹⁰² although many studies exclude high-risk patients with ischemic heart disease or arterial disease and also the elderly.¹⁰⁵ TIPSS is an alternative treatment in HRS; however, the long-term survival benefits remain unknown.¹⁰³ Overall survival in HRS is poor, and liver transplantation again remains the treatment of choice.¹⁰⁶

The exact underlying pathophysiology of *hepatic encephalopathy (HE)* remains poorly understood, but it is believed that failure to detoxify gut-derived toxins that are normally cleared by the liver is one of the main factors. Elevated circulating levels of ammonia, alteration in neurotransmitter systems, including increased levels of the neuroinhibitor GABA, decreased neuroexcitation, and an altered blood-brain barrier are all thought play an important role.¹⁰⁷ HE is characterized by the development of mental slowing, memory loss, disorientation, worsening somnolence, and occasionally coma in advanced stages.⁹⁵ Clinical examination findings include asterixis (liver flap), fetor hepaticus, increased reflexes, or muscular rigidity. Chronic persistent encephalopathy may result where there have been recurrent episodes of acute encephalopathy. Dysarthria, ataxia, dementia, and extrapyramidal signs in this context may be difficult to assess in elderly patients with underlying neurologic disorders. In its subclinical form, estimated to affect over 60% of patients with compensated cirrhosis,⁹⁵ diagnosis is challenging—in particular in elderly patients where it may be confused with cognitive impairment or early dementia. In addition, elderly patients with subdural hematoma, meningitis, or sepsis from urinary tract infections, cellulitis, or pneumonia may appear

to be encephalopathic. It has also been described that a significant proportion of elderly patients with documented liver disease and a presumptive diagnosis of HE had coexisting treatable extrahepatic conditions.⁴⁸ When appropriate treatment was administered, including standard therapy for HE, 67% of these patients showed improvement in their encephalopathy. There are also a number of factors that can precipitate HE, and careful identification and treatment of these are important. They include gastrointestinal bleeding, electrolyte disturbance, dehydration, drugs including diuretics, infection, and constipation—especially if elderly patients are noncompliant with laxatives. There is no laboratory test to confirm the diagnosis, ammonia levels may be raised but do not correspond to the severity of symptoms, and electrophysiologic tests are rarely used outside of research. The drawing of a five-pointed star is often useful as constructional apraxia is a common feature of HE and should be assessed at the bedside. General treatment measures include short-term protein restriction to reduce the gut protein load, although in the elderly this should be instituted with caution as many have borderline nutrition to begin with.⁹⁵ Lactulose is the mainstay of drug therapy. It lowers colonic pH, dissuading replication of ammonia-producing bacteria and reducing absorption of ammonia, and increasing fecal nitrogen elimination by producing osmotic diarrhea.¹⁰⁸ Adverse effects such as diarrhea and abdominal cramps may make it difficult to tolerate in elderly, especially outside the hospital setting. Antibiotics such as neomycin can also be effective; however, long-term risks such as ototoxicity and nephrotoxicity limit their use. Chronic persistent HE is also an indication for liver transplantation.

Hepatocellular carcinoma (HCC) is a common complication of liver cirrhosis affecting the elderly,¹⁰⁹ with 35% to 40% of patients diagnosed over the age of 70 years.¹¹⁰ An aging society and increased survival because of better treatments of the complications of cirrhosis are the likely explanations. HCV infection contributes to a greater risk of HCC in the elderly, because of its long natural history,¹¹¹ and is responsible for the rise in incidence of HCC seen in Western countries.¹¹² Five-year survival is poor in all age groups. HCC typically presents on a background of known cirrhosis, and it should be suspected in any patient with sudden decompensation. An elevated serum Alpha-fetoprotein (AFP) with characteristic radiologic imaging especially in the presence of cirrhosis is widely recognized as diagnostic. The potential risk of needle track spread should contraindicate biopsy when surgical resection is a viable option. Six-monthly assessment of AFP and imaging such as ultrasound or CT is indicated in patients with cirrhosis to screen for HCC,¹¹³ as early diagnosis is vital in determining a favorable outcome, especially in older patients. Options in the treatment of HCC in cirrhotic patients include liver transplantation, surgical resection, and local ablation techniques. Previously, the role of resection surgery in HCC in elderly patients was uncertain because of the high operative mortality and high tumor recurrence rate. However, one paper¹¹⁴ reported a low mortality rate for major hepatic resection in elderly cirrhotic patients and early surgical outcomes comparable to those of younger patients. Data on HCC in patients greater than 80 years¹¹⁵ have shown that it is the advanced stage of HCC and not the patient's age or comorbidities that has the greatest impact on survival rate.

ACUTE LIVER FAILURE

As *acute liver failure (ALF)* is rare in the elderly, little is known specifically about the underlying causes, clinical course, and outcomes.¹¹⁶ Despite extensive medical investigation, in some cases the etiology remains undiscovered. It often results in multiorgan failure, with cerebral edema and sepsis being the leading causes of death.¹¹⁷ ALF commonly presents initially in a nonspecific manner with malaise or nausea. Jaundice then develops, followed by features of hepatic encephalopathy, and many patients evolve to coma within 1 week or less.⁴⁷ Elderly patients with ALF have been described as having a more protracted disease course,¹¹⁶ and increasing age has been identified as an independent risk factor of mortality from all causes.¹¹⁸ The presence of other coexisting diseases and smaller functioning liver mass is believed to render them more easily susceptible to succumbing to a lesser degree of hepatic necrosis.¹¹⁶ Impaired regeneration, as described previously, can result in prolonged hepatocyte damage. The spontaneous survival rate for ALF is poor and has been reported as less than 50% for adults of any age.¹¹⁹ In one study from Japan, incidence of ALF in autopsy cases of those more than 65 years of age was 0.2%.¹¹⁶ The mortality rate of ALF in the elderly patients in this study was found to be 85%.

A variety of viral agents can cause acute liver disease. *Acute hepatitis A (HAV)* infection usually begins with a prodromal illness, before the appearance of jaundice. It is typically a self-limiting disease that resolves in the majority of patients within 6 weeks. Although rare in this age group, patients over 65 years are more susceptible to severe infections and are more likely to have serious complications.⁵⁰ ALF occurs in less than 0.35% of younger adults with HAV; however, in elderly patients this figure is higher. In addition, the mortality rate is increased, with the U.K. census data for 1979 through to 1985 demonstrating a mortality rate approaching 15% in those older than 75.¹²⁰ *Acute hepatitis B (HBV)* and *C (HCV)* infection is also rare over the age of 65 in the Western world, due in part to the lack of risk factors such as intravenous drug use and high-risk sexual behavior and the routine screening of donated blood for these viruses. However, sporadic cases and rare outbreaks may still occur.⁵⁰ Data from the United States have shown acute HBV still accounts for 3% of all adult ALF cases.¹²¹ *Hepatitis E (HEV)* has emerged as an important cause of acute hepatitis in the elderly throughout the world. It has an overall mortality rate of between 0.5% and 4%. In a U.K. study of sporadic HEV, the majority of cases affected elderly males,¹²² and data from Hong Kong suggest that older patients affected by HEV have a more severe illness leading to a higher mortality rate than patients with hepatitis A.¹²³ In a recent French study of patients with severe ALF resulting from acute HEV, the mortality rate for those older than 70 years was 71%.¹²⁴ It is possible that underlying liver disease from other etiologies may be a factor in the poor prognosis observed in these patients. Other viruses such as cytomegalovirus, Epstein-Barr virus, and yellow fever are rare but recognized causes of ALF.

Drug-induced ALF occurs with increased frequency in the elderly, because of either increased drug use and polypharmacy, but also accidental or intentional overdose. Worldwide, the major causative drugs include antituberculous drugs, antibiotics, nonsteroidal medication, and paracetamol

(acetaminophen).¹²⁵ Anesthetic drugs of the halothane family cause hepatic failure and death more commonly in older compared to younger patients.¹²⁶ Although paracetamol poisoning is predominantly seen in adolescents and young adults, the majority of paracetamol-related deaths occur in the older population,¹¹⁸ and it is widely held that older age is an independent risk factor for both development of ALF and subsequent death. In addition, accidental overdose and late presentation are seen more commonly in the elderly and are individual risk factors associated with poor prognosis.¹¹⁸ *N-acetylcysteine (NAC)* is an effective therapy in the treatment of paracetamol overdoses, and when given within 24 hours of overdose it has been shown to decrease the risk of liver injury.¹²⁷ It can be used safely in elderly patients.

Ischemic hepatitis is thought to be more likely with older age. One U.K. study demonstrated the condition occurring in 1% of elderly patients acutely admitted to hospital with a variety of other conditions.¹²⁸ It is often difficult to recognize, as the classical signs of liver failure are not prominent. It is thought to be associated with an episode of hypotensive liver anoxia, which is usually the result of a significant drop in blood pressure.¹²⁹ In the absence of any other causes, a striking and reversible rise in serum transaminases (in the order of 10- to 20-fold) is generally accepted as diagnostic in the appropriate clinical setting.¹³⁰ A retrospective analysis has indicated that all patients with a clinical diagnosis of ischemic hepatitis had evidence of cardiac disease, usually right sided, suggesting underlying hepatic congestion may be an important part of the pathophysiologic process.¹³⁰ Prognosis in ischemic hepatitis is influenced by the underlying condition; in one U.K. study, the mortality rate was found to be one third in the elderly.¹²⁹

Autoimmune hepatitis (AIH) can present as an acute severe hepatitis. Belgian data have demonstrated an acute presentation with pronounced jaundice and a biopsy showing severe necrotizing hepatitis present in 19% of the elderly population studied (4% of the total study group).⁴⁵ AIH should be considered in all elderly patients with acute liver failure as it typically responds favorably to corticosteroid treatment.⁴⁷

If the liver has been severely damaged by any of the preceding conditions, emergency transplantation can be considered. Artificial liver-assist systems have not yet been proven to affect survival in ALF,¹³¹ but the next generation of systems are being developed using hepatocyte cell-based therapy. These are promising developments for the future. At present, the mainstay of treatment is supportive, to allow time for the liver to recover from the acute insult and eventually regenerate.

LIVER TRANSPLANTATION

There is growing evidence to suggest that in end-stage chronic liver disease, advanced age should not be considered a contraindication to liver transplantation. More than 10% of patients undergoing liver transplantation in the United States in 2000 were over the age of 65 years.¹³² Recently published data from the United Kingdom¹³³ demonstrated no significant difference in survival between age groups within the first 5 years after liver transplant. In addition, patients over 65 years were found to have lower rejection rates, probably because of reduced immune function, and have excellent graft survival. After 5 years, survival is

significantly worse in older recipients. At this time point, one study showed a survival rate of 52% in those over 60 years compared to 75% in younger patients, with more deaths from malignancy in the older group.¹³⁴ In particular, good survival rates have been observed in those over 65 years who received transplants for PBC as their primary indication.¹³³ Chronologic age alone should not form the basis of refusal for liver transplantation; it is the overall general health of the patient that appears to be of greater importance.

FOCAL LIVER LESIONS

Pyogenic liver abscess is a disease of elderly patients, most often diagnosed after the sixth to seventh decades.¹³⁵ Untreated it is invariably fatal. Biliary tract disorders, such as cholangitis and portal pyemia from intra-abdominal sepsis, are common sources of liver abscess; however, few papers have remarked on etiologies in relation to age. Data suggest there are no age-related differences with regard to symptoms or laboratory data at presentation.¹³⁵ Classical presentation includes abdominal pain, fever, nausea, and vomiting. Examination findings may include a tender liver. Laboratory investigations may reveal an elevated white blood cell count, elevated liver enzymes (especially ALP), raised inflammatory markers, and a low serum albumin. Centrally necrotic liver metastases may sometimes be indistinguishable from abscess on conventional as well as contrast-enhanced ultrasound.³⁸ Blood cultures can be negative; abscess cultures are often of greater yield, with *E. coli* the most frequently isolated organism across all age groups. Treatment of pyogenic liver abscess is by complete percutaneous drainage of the abscess, either by needle or indwelling catheter. This is in combination with intravenous antibiotics, which should be continued for 14 days, followed by oral treatment for a minimum of 4 weeks depending on clinical response. A broad-spectrum cephalosporin with metronidazole is usually adequate, but advice from a microbiologist is useful. Surgery is rarely indicated. Progress can be monitored by serial ultrasound, and the search for the underlying cause should be attempted and treated if possible. Active management is well tolerated in the elderly, and there appears to be no appreciable difference in mortality rates compared with younger patients.¹³⁵

Liver metastases are common in elderly patients, particularly of gastrointestinal origin; for example, 35% of those with colorectal carcinoma have liver metastases at presentation.¹³⁶ Weight loss, general malaise, and nonspecific abdominal

discomfort are common presenting features. However, the finding of metastatic disease can be incidental. Liver biopsy may be indicated where the nature of the primary neoplasm is unknown, and with new immunohistochemistry techniques it may help to indicate the likely primary site and guide further treatment. Lymphoma, for example, resembles hypervascular metastases on ultrasound scanning³⁸ but has good prognosis if treated. However, if there is a history of a known primary malignancy, liver biopsy is often not required. Where surgical resection of the metastasis is under consideration, liver biopsy should not be undertaken. Colorectal metastases have the potential to be cured by liver resection, and increasing numbers of elderly patients are being referred for surgery. A recent U.K. study¹³⁷ has confirmed that low perioperative morbidity and mortality rates as well as good long-term outcomes can be achieved with an aggressive strategy in elderly patients with colorectal liver metastases.

Benign liver lesions include simple cysts, hemangiomas, and focal nodular hyperplasia (FNH), which can present in all age groups. There is no potential for malignant transformation, and patients can be reassured that no treatment is required. The majority of patients are asymptomatic, and these lesions are found incidentally on abdominal imaging. In cysts and hemangiomas, rupture or hemorrhage can occur, causing right upper quadrant discomfort. Mass effect from large lesions can also result in pain, but other causes of pain should be excluded first.¹⁴

KEY POINTS

The Liver

- There are no liver diseases specific to old age.
- Abnormal liver function tests in the elderly should be fully investigated, in the first instance with serologic tests.
- Alcoholic liver disease and chronic hepatitis C infection are becoming more prevalent in the aging population worldwide.
- No treatment of liver disease is contraindicated by age alone, only by the individual's frailty and comorbidity.
- Liver transplantation for chronic liver disease in selected elderly patients is achieving improved outcomes.

Biliary Tract Diseases

Elias Xirouchakis
Andrew K. Burroughs

Jaundice, or icterus, is the yellow discoloration of sclerae, mucous membranes, and skin caused by accumulation of bilirubin: clinically, it is not obvious until the bilirubin concentration in the blood exceeds 51 $\mu\text{mol/L}$ (3 mg/dL).

The appearance of jaundice is also related to the circulatory status and any accompanying edema. Particularly in elderly people, paralytic and edematous limbs tend not to have the typical pigmentation and it is possible to observe a one-sided icterus in patients with hemiplegia.

Jaundice can be classified in different ways, depending on the following:

- Prevalent form of bilirubin detectable in serum: it is divided into unconjugated, mixed, or conjugated hyperbilirubinemia.
- Site of impairment in bilirubin production or excretion pathway: it is classically divided into prehepatic, hepatocellular, and obstructive.

From a practical point of view, it is useful clinically to consider conditions that lead to icterus under the following categories:

- Isolated disorders of bilirubin metabolism
- Liver disease
- Obstruction of the bile ducts

ISOLATED DISORDERS OF BILIRUBIN METABOLISM

In these conditions, there is an increase in bilirubin production (hemolysis, ineffective erythropoiesis, blood transfusion, resorption of hematomas) or decreased hepatocellular uptake or conjugation (congenital hyperbilirubinemias). Liver function is otherwise normal and hyperbilirubinemia is often characterized by a predominant elevation in unconjugated bilirubin.

Jaundice resulting from hemolysis is usually mild with a serum bilirubin of 68 to 102 $\mu\text{mol/L}$ (or 4 to 6 mg/dL), as normal liver function can easily handle the increased bilirubin derived from excessive breakdown of red blood cells. Unconjugated bilirubin is not water soluble and therefore will not pass into the urine, hence the term *acholuric jaundice*. Urinary urobilinogen is increased. Causes of hemolytic jaundice are those of hemolytic anemia. Investigations show raised unconjugated bilirubin but normal serum alkaline phosphatase, transferase, and albumin, and serum haptoglobins are low.

Most of the congenital and inherited defects are diagnosed in young people; the only condition that could incidentally be found in older patients is Gilbert's syndrome, the most common familial hyperbilirubinemia. It is asymptomatic and is usually detected as an incidental finding of a slightly raised bilirubin 17 to 102 $\mu\text{mol/L}$ (or 1 to 6 mg/dL) on a routine check. No signs of liver disease are present. There is a family history of jaundice in 5% to 15% of patients.

Hepatic glucuronidation is approximately 30% of normal, resulting in an increased proportion of bilirubin monoglucuronide in bile. Most patients have reduced levels of UDP-glucuronosyl transferase activity, the enzyme that conjugates bilirubin with glucuronic acid. Evidence¹⁻³ has shown mutations in the gene encoding this enzyme with an expanded nucleotide repeat consisting of two extra bases in upstream 5' promoter element. The abnormality appears to be necessary but is not in itself sufficient for the phenotypic expression of the syndrome.⁴ Among the most relevant drugs that undergo glucuronidation are morphine, acetaminophen, chloramphenicol, and transplant immunosuppressants such as cyclosporine A and tacrolimus, but also the widely used antitumor drug metabolite of irinotecan SN-38.

The major importance of establishing this diagnosis is to inform the patient that it is not a serious disease and to prevent unnecessary investigations. Tests show only a raised unconjugated bilirubin, which is further raised on fasting, during mild illnesses or infections, after surgery, or during consumption of large amounts of alcohol; the reticulocyte count is normal. No treatment is necessary.

LIVER DISEASE

Primary sclerosing cholangitis (PSC) is a rare (8 to 13 cases per 100,000 persons) chronic cholestatic disease characterized by chronic inflammation and progressive obliterating fibrosis of the intra- or extrahepatic biliary ducts. It affects primarily caucasian men during their fourth or fifth decade of life.⁵ Etiology is unknown: both immune (genetic) and nonimmune (infections, toxins, ischemic damage) mechanisms have been postulated. A genetic predisposition to PSC has been described, and there is a strong association between PSC and inflammatory bowel diseases (IBD). Coexisting IBD is seen in 50% to 80% of PSC patients, more commonly ulcerative colitis (UC) than Crohn's disease; in 2% to 10% of IBD patients, PSC is also present.⁶ However, there is no correlation between severity of PSC and IBD, nor a temporal relation between the onset of the diseases. Furthermore, therapy of IBD has little effect on the course of PSC and vice versa. Other less common disease associations are thyroiditis, ankylosing spondylitis, and celiac disease.

Typical symptoms on presentation are pruritus and fatigue, but asymptomatic cases are being diagnosed more frequently because of routine testing monitoring of liver function tests particularly in IBD patients. One third of patients have episodes of acute cholangitis, with recurrent attacks; in advanced disease, jaundice is constantly present.

Liver enzymes and especially serum alkaline phosphatase levels are raised in the majority of patients; perinuclear antineutrophil cytoplasmic antibodies (pANCA) may be detected in 26% to 85% of PSC cases, but they lack specificity for diagnosis. Overlap syndromes with other forms of liver diseases have been described. PSC with autoimmune hepatitis-like features has been referred to as autoimmune cholangitis. These patients usually present with high serum alanine aminotransferase (ALT) levels, modest or no

elevations in serum alkaline phosphatase, high titers of anti-nuclear (ANA) and anti-smooth muscle antibodies (SMA), and liver histologic findings typical of autoimmune hepatitis. Corticosteroid therapy may lead to improvements in symptoms and liver enzyme abnormalities.

The differential diagnosis for a patient with chronic cholestatic symptoms includes all the secondary causes of bile duct abnormalities, particularly biliary obstruction resulting from pancreatic, biliary, or metastatic malignant obstruction; strictures resulting from previous surgery; and malignant transformation and lymphomas. Rare causes are cryptosporidiosis and cytomegalovirus in patients with immunodeficiency.

Although endoscopic retrograde cholangiopancreatography (ERCP) has been the gold standard diagnostic technique in diagnosing PSC for many years, magnetic resonance cholangiopancreatography (MRCP) has replaced ERCP for diagnosis of PSC.^{7,8} Typical findings are multifocal strictures of the biliary tree alternating with normal segments and ectatic ducts; liver biopsy shows fibro-obliterative ductal lesions in one third of cases. There is no correlation between histologic severity and radiologic findings.

The estimated median survival for PSC is about 12 years: for symptomatic patients, there is a significant reduction in life expectancy with a mean survival just under 10 years.⁹ Cholangiocarcinoma develops in 6% to 20% of patients at a rate of 1% to 5% per year and can occur before the onset of cirrhosis, especially in patients with coexisting UC¹⁰ as these patients have a higher risk of developing colorectal cancer. Hepatocellular carcinoma can develop in those with cirrhosis.

Different drugs including antifibrotic agents such as methotrexate or colchicine, penicillamine, and ursodeoxycholic acid (UDCA) have been used, but none of them has been shown to improve histology, liver function tests, symptoms, or survival. However, a few studies have emerged reporting improved liver enzymes and a possible survival benefit with high doses of UDCA (30 mg/kg/day).¹¹⁻¹³ Bone density and liposoluble vitamin deficiency should be monitored and treated appropriately, particularly in patients with advanced disease.¹⁴ Preliminary reports suggest that UDCA therapy decreases the risk of colon cancer,^{15,16} but further investigation is needed. Currently liver transplantation is the only life-extending treatment available, with 5-year survival rates of 75% to 85%. However, disease recurrence has been reported in up to 47% of cases, with the presence of IBD being the most important independent predicting factor.¹⁷

OBSTRUCTION OF BILE DUCTS

Obstruction can be mechanical or anatomic and is commonly due to stones, intrinsic disorders of the biliary tree (e.g., cholangiocarcinoma), or extrinsic compression, usually by pancreatic carcinoma.

Clinically, there is a considerable rise of serum conjugated bilirubin, alkaline phosphatase (ALP), and cholesterol. In contrast to what happens in cirrhosis, serum bilirubin levels rarely exceed 600 $\mu\text{mol/L}$, with a trend to a plateau, as, when conjugated bilirubin concentration increases, glomerular filtration and excretion also increase. In complex cases with prolonged partial obstruction, hepatocyte function is also affected, thus producing a mixed biochemical picture, with elevation of circulating unconjugated bilirubin. Patients do

not usually have signs of chronic liver disease but may have signs indicating malignancy, and pruritus is usual.

On examination, in the presence of obstructive jaundice a palpable gallbladder may be found; this is due to malignant obstruction of the biliary tree, usually pancreatic head carcinoma (Courvoisier's sign) or to a stone impacted in Hartman's pouch, leading to a mucocele or an empyema (Mirizzi's syndrome).

Signs of infection such as fever, abdominal pain, and chills are common. Steatorrhea is responsible for weight loss and malabsorption of fat-soluble vitamins A, D, E, and K and calcium.

Gallstones

Diseases affecting the gallbladder and bile ducts occur commonly in elderly people. By the age of 70, cholelithiasis and choledocholithiasis are found in 13% to 50% of the population, and the figures rise to 38% to 53% in persons above the age of 80. There is geographic variation: gallstones are rare in the Far East and Africa and very common in native North Americans and in Chile and Sweden. They occur twice as frequently in women as in men, but this difference decreases with increasing age.

Gallstones can be distinguished in three types, depending on the major constituents: pure cholesterol, pure pigment (which can be black or brown), and mixed. Cholesterol stones are by far the most frequent, accounting for 80% to 90% of all gallstones in the West. They contain more than 70% cholesterol, often with some bile pigment and calcium. Cholesterol is slightly soluble in aqueous media and is transported in bile mixed with bile salts and phospholipids in the form of micelles and vesicles. These later become saturated when cholesterol cannot be solubilized any further. Therefore cholesterol supersaturation could result from (1) hepatic hypersecretion of biliary cholesterol (often observed in obese patients with gallstones), (2) decreased rates of bile salt or phospholipid secretion into bile (non-obese patients with gallstones, ileectomy, diseases of the ileum such as Crohn's disease, or surgical bypass of the ileum), or (3) a combination of cholesterol hypersecretion with hyposecretion of the solubilizing lipids (found in both American Indians and whites with gallstones, which could be the result of diminished 7-hydroxylation of cholesterol).¹⁸

With the passage of time and in the presence of a heterogeneous pronucleating agent, usually mucin gel in gallbladder bile, cholesterol supersaturation leads to precipitation of cholesterol monohydrate crystals from a phase of separated liquid to a crystalline phase, followed by agglomeration and growth of the crystals into mature and macroscopic stones.

Several factors have been reported to influence gallstone formation. More rapid crystallization of cholesterol in bile of patients with gallstones suggests that lithogenic bile may contain components (i.e., pronucleating agents) that accelerate crystallization or alternatively that normal bile may contain components (i.e., antinucleating agents) that inhibit crystallization. Mucin was the first biliary protein shown to promote cholesterol crystallization. Subsequently, it was shown that many glycoproteins that bind reversibly to concanavalin A-Sepharose also speed up cholesterol crystallization.¹⁹ Two roles in the formation of gallstones have been proposed for mucins: (1) as a pronucleating/crystallizing agent for the nucleation/crystallization of cholesterol from

saturated bile and (2) as a scaffolding for the deposition of crystals during growth of stones. Despite evidence that mucin overproduction is critical in the pathogenesis of gallstones, the mechanisms triggering mucin production during gallstone formation are still unclear. Furthermore, mucin secretion and accumulation in the gallbladder are determined by multiple mucin genes. Although the regulation of gallbladder mucin secretion and accumulation and its role in gallstone pathogenesis have been intensively studied *in vivo* and *in vitro*, no information is available on how individual mucin genes contribute to cholesterol gallstone formation and whether the epithelial mucins influence susceptibility to cholesterol gallstone formation.¹⁹ Other nucleating factors such as nonprotein components of bile also expedite cholesterol crystallization. A low-density particle composed principally of lipids is a potent promoter of crystallization. Calcium bound to micelles and vesicles in bile may accelerate cholesterol crystallization by promoting fusion of cholesterol-rich vesicles.

Antinucleating factors include apolipoproteins AI and AII, and secretory immunoglobulin A and its heavy and light chains.¹⁹

Impaired gallbladder motility could precede gallstone formation. The stasis induced by the hypofunctioning gallbladder would provide the time necessary to accommodate nucleation of crystals and growth of gallstones within the mucin gel in the gallbladder.

Intestinal factors including decreased large bowel transit time, increased colonic gram-positive anaerobic bacteria, increased bile acid metabolizing enzymes, and higher intracolonic pH values compared to stone-free controls have also been documented. Together, these changes lead to increased deoxycholic acid formation, solubilization, and absorption.

Black pigment stones contain calcium salts of bilirubin, phosphate, and carbonate in addition to bilirubin polymers and mucin glycoproteins. The biliary lipids are normal. These stones form in the gallbladder and are seen in patients with chronic hemolysis (e.g., hereditary spherocytosis and sickle cell disease) where there is an increase in bilirubin, and also in cirrhosis.

Brown pigment stones have layers of cholesterol, calcium salts of fatty acids (mainly palmitate), and calcium bilirubinate. They form in the common bile duct as a result of stasis and infection, usually in the presence of *E. coli* and *Klebsiella* spp., which produce β -glucuronidase that converts soluble conjugated bilirubin back to the insoluble unconjugated state, which is prone to precipitation with calcium. They are also found with biliary strictures, sclerosing cholangitis, and Caroli's syndrome.

The most common presentation of gallstone disease is biliary pain. This occurs in the epigastrium and right hypochondrium, and it does not fluctuate but persists from 15 minutes up to 24 hours, subsiding spontaneously or with opioid analgesics; it may radiate round to the back in the interscapular region.

Complications of gallstones

ACUTE CHOLECYSTITIS, COMMON DUCT STONES, AND CHOLANGITIS

Acute cholecystitis occurs when a gallstone impacts in the neck of the gallbladder or in the cystic duct, leading to distension and inflammation. The inflammation is usually sterile,

but within 24 hours gut organisms can be cultured from the gallbladder. Infections are polymicrobial in 30% to 80% of the episodes. Occasionally inflammation may be mild and quickly subside, sometimes leaving a gallbladder distended by mucus (mucocele). More commonly, the inflammation is severe, involving the whole wall and giving rise to localized peritonitis and acute pain. The gallbladder can become distended by pus (empyema) and, rarely, an acute gangrenous cholecystitis occurs with perforation and a more generalized peritonitis.

The patient is usually ill with fever and shallow respirations. Right hypochondrial tenderness is present, being worse on inspiration (Murphy's sign). There is guarding and rebound tenderness.

The presentation of biliary colic in the elderly patient with diabetes and diabetic neuropathy is obfuscated and atypical. In such patients, a condition as serious as gangrenous cholecystitis can present with minimal temperature increases, without significant leukocytosis and few, if any, abdominal complaints. Consequently, clinically significant cholecystitis can be interpreted as an episode of mild biliary colic.

At ultrasound (US) examination, with the detection of gallstones alone is insufficient for a diagnosis of acute cholecystitis. Additional criteria are as follows:

- Sonographic Murphy's sign (focal tenderness directly over the visualized gallbladder)
- Distention of gallbladder
- Presence of biliary sludge
- Pericholecystic fluid
- Gallbladder wall thickening (but not specific for acute disease)

Common bile duct stones are frequently found in elderly patients who present with concomitant cholecystitis. In the general population, 5% of patients presenting with cholecystitis have coexisting bile duct stones, but this figure rises to 10% to 20% in elderly people. Presentation can be with one or all of the triad of abdominal pain, jaundice, and fever. The pain is usually severe and situated in the epigastrium and right hypochondrium, and it may be accompanied by vomiting; it usually lasts for a few hours and then clears up, only to return days, weeks, or even months later. Between attacks the patient is well.

The jaundice is variable in degree, depending on the amount of obstruction. Urine is dark and the stools are pale. High fever and rigors indicate cholangitis. The liver is enlarged if the obstruction lasts for more than a few hours. Prolonged biliary obstruction or repeated attacks lead to secondary biliary cirrhosis, but this is now rare.

US examination reveals a dilated common bile duct, but stones are detected in only about 75% of cases. MRCP is very useful as an additional diagnostic test, particularly if the bowel hinders good visualization of the common bile duct, and is better than ultrasound in detecting stones in the lowest part of the common bile duct. Endoscopic ultrasound, when available, is a more accurate method of detecting a stone with a sensitivity and a specificity of more than 80% and 95%.

Acute cholangitis is due to bacterial infection of the bile ducts and is always secondary to bile duct abnormalities. The most frequent causes are common duct stones, biliary

strictures, neoplasms, or following ERCP in the presence of large duct obstruction.

Symptoms are fever, often with a rigor, upper abdominal pain, and jaundice. Older patients can present with collapse and gram-negative septicemia and renal failure.

Initial therapy of acute cholecystitis and cholangitis is directed toward general support of the patient, including fluid and electrolyte replacement, correction of metabolic imbalances, and antibacterial therapy. In all but mild cases, pain relief with an opiate is required. In the absence of vomiting, the patient can soon tolerate oral fluids, and nasogastric aspiration is not often required.

Antimicrobial therapy is usually empirical. Initial therapy should cover the Enterobacteriaceae, in particular *E. coli*, and anaerobes, especially in elderly people and in patients with previous bile-duct–bowel anastomosis. In patients with moderate clinical severity, monotherapy with a ureidopenicillin—mezlocillin or piperacillin—is more effective than the combination of ampicillin with aminoglycoside. Additionally, in the most recent years quinolones have proved their efficacy and as they can also be administered orally, many clinicians use them as the first choice of therapy in biliary tract infections. Patients who are septic or who have a previous biliary stent in place may benefit from the addition of ampicillin as further coverage against *Enterococcus*. Therapy with aminoglycosides when necessary, mostly for *Pseudomonas aeruginosa*-related infections, should not exceed a few days because the risk of nephrotoxicity increases during cholestasis.²⁰ Relief of biliary obstruction is mandatory,²¹ even if there is clinical improvement with conservative therapy, because cholangitis is most likely to recur with continued obstruction.

Endoscopic techniques are effective for removing bile duct stones by sphincterotomy and stone extraction and should be the first therapeutic approach because it is safer than surgery in elderly people²² as the associated morbidity and mortality of endoscopic therapy is unchanged regardless of age. Stent insertion with bypass of common bile stones may be needed if stones cannot be removed or sphincterotomy is unsafe or as part of a two-stage procedure with delayed sphincterotomy. Sometimes endoscopic nasobiliary drainage may be required as a first step to relieve obstruction in the presence of sepsis, again followed by a second therapeutic endoscopy to remove stones.

Cholecystectomy^{23,24} is the treatment of choice for virtually all patients with gallbladder stones and symptoms. Since the late 1990s, laparoscopic cholecystectomy has been the operation of choice.²⁵ In patients aged 65 to 69 years, mortality rates are comparable with those reported in the younger patients (0.3%), and patients can leave hospital in 24 to 48 hours. Accordingly, the complication rate is low and includes wound sepsis, bile duct injury (0.2%), and retained gallstones in the common bile duct.²⁶ In patients older than 70 years, complications can increase up to 13%, mostly represented by chest infections, whereas the mortality rate can increase up to 2%, especially when concomitant cholangitis or other comorbidities coexist. In addition, postoperative stay is significantly higher.²⁷ Laparoscopic cholecystectomy is not superior to the small incision cholecystectomy, and some surgeons prefer this “mini-laparotomy” approach, with a small surgical incision, because the length of stay in

hospital and return to full activity is similar to that of laparoscopic surgery.^{28–32}

Malignant obstruction

Obstructive jaundice can result from neoplasms of the gastrointestinal tract, arising from the biliary tree or most frequently from the pancreas. The usual presentation of this syndrome in the elderly consists of the insidious development of cholestasis and jaundice.

PANCREATIC CARCINOMA

Pancreatic carcinoma is the most common cause of malignant biliary obstruction. In the United States, pancreas cancer develops in approximately 30,000 patients per year, with about the same number in Europe and about 20,000 annual cases in Japan. Although it represents a rare form of cancer with age-adjusted rates in most countries, ranging from about 5 to 10 new cases per 100,000 persons per year, it is so lethal that it ranks fourth as a cause of death from cancer.³³ Usual presentation is in the sixth and subsequent decades of life.

PRIMARY ADENOCARCINOMA OF THE GALLBLADDER

Primary adenocarcinoma of the gallbladder represents less than 1% of all cancers; it occurs chiefly in patients over 70 years of age, more commonly in women, and has striking genetic, racial, and geographic characteristics, with an extremely high prevalence in Native Americans and Chileans. Gallstones are usually present, but a definite relationship is uncertain. Polyps that are larger than 1 cm, single, sessile, and echogenic are associated with a higher risk of malignancy. Anomalous junction of pancreaticobiliary ducts, chronic bacterial infections, certain occupational and environmental carcinogens, hormonal changes, and possibly a porcelain gallbladder are additional factors that predispose to cancer. Occasionally a mass can be palpable in the right hypochondrium.

The majority of cases are discovered during exploration for presumed gallstone disease, and cholecystectomy is performed if possible. The overall 5-year survival is 5%, and the 1-year mortality is 88%.

CHOLANGIOCARCINOMA

Cholangiocarcinoma is the most common primary tumor of the biliary tree; it is less common than hepatocellular carcinoma, representing less than 3% of gastrointestinal cancers, but is rapidly increasing in incidence in several countries.^{34,35} There is no association with cirrhosis or viral hepatitis, whereas in the Far East it may be associated with infestation with *Clonorchis sinensis* or *Opisthorchis viverrini*. Primary sclerosing cholangitis, as described earlier, is an important risk factor.³⁶

It usually develops at the hepatic hilum, from the junction between right and left hepatic ducts; more rarely the tumor arises from the common bile duct or intrahepatic ducts. Despite the central site of obstruction, the two hepatic lobes can present different degrees of dilatation of the biliary ductal system, with the left lobe usually more involved. Local invasion and proximity of vital structures within the porta hepatis contribute to the difficulty in achieving complete resectability, so that curative surgical resection is rarely possible: only one third of cases are suitable after staging.

Patients usually die within 6 months.^{37–39} Even for resectable disease, 5-year survival rate is between 20% to 40%.

Liver transplantation alone is not a current option because of an almost universal likelihood of recurrence.⁴⁰ A protocol for treatment of unresectable disease combining external beam radiation therapy (EBRT) with brachytherapy, 5-fluorouracil chemosensitization, then liver transplantation has been used.⁴¹ The most recent published survival following this regime, published in 2006, of 65 patients with a mean follow-up of 32 months was 91% at 1 year and 76% at 5 years.⁴²

AMPULLARY TUMORS

Malignant tumors of the ampulla present with cholestatic jaundice, which may occasionally be intermittent. They may ulcerate and produce gastrointestinal hemorrhage or chronic anemia. The diagnosis is usually made at ERCP. Carcinoma of the ampulla can sometimes be resected, with a 5-year survival rate of 40%.

MANAGEMENT OF PANCREATICOBILIARY MALIGNANCY

The main goal in treating patients with malignant biliary diseases, presumed to be unresectable, is to provide palliation of jaundice, to avoid early liver failure caused by chronic obstruction, and improve the patient's nutritional and immunologic status. Surgical therapy consists of either attempting a curative resection of the tumor or performing a palliative operation. Unfortunately, the surgical cure rate of these tumors is less than 5%.

Staging techniques should be used in elderly people in order to select carefully those patients who are likely to have resectable disease. Multislice computed tomography scanning should be routine. Endoscopic ultrasound (EUS) is the most sensitive diagnostic modality currently available for predicting resectability.^{43,44}

Palliative surgery is directed toward relieving jaundice by creating a biliary-enteric anastomosis. However, given the morbidity and 30-day mortality (up to 20%) for bypass procedure, nonoperative techniques of palliation are preferred in aged populations unless there is a concomitant or impending duodenal obstruction. Alternatively, stenting of duodenal obstruction with self-expanding metal stents that can be deployed endoscopically or placed radiologically can obviate the need for surgery. These stents do not preclude endoscopic management of pancreatic or biliary problems.

Endoscopic relief of jaundice has been used successfully for over 20 years, and endoscopic techniques have a high rate of success (up to 90% to 95% of cases). Greater success is achieved when treating distal bile duct obstruction, as complications occur less frequently. With tumors affecting the bifurcation of the hepatic ducts (Klatskin tumors), several stents can be placed into both the right and left intrahepatic ducts to provide decompression.

Plastic stents placed endoscopically have a propensity to clog or occlude within 6 months of placement, thus requiring exchange. Expandable metal stents seem to delay stent occlusion, but they are not removable and are more expensive than plastic stents. However, with a limited life span in many patients, metallic stents offer a one-step procedure with excellent palliation. A recent meta-analysis of seven randomized controlled trials confirmed a significantly

reduced relative risk of stent occlusion at 4 months for metal compared to plastic stents⁴⁵ but reported no significant difference between the two stent types in terms of technical success, therapeutic success, 30-day mortality, or complications. Covered metallic stents that can be removed are now available, and these may offer a further advantage in patients with malignant obstruction and in those with benign strictures for whom surgery carries too high a risk.

INVESTIGATIONS OF THE BILIARY TRACT

Liver ultrasound

This is the imaging technique of choice in the evaluation of jaundice. In acute jaundice, if the clinical history and laboratory tests suggest an obstructive etiology, liver ultrasound should be the first imaging modality and can be considered as the "stethoscope" of the hepatologist. It can demonstrate changes in size and shape of the liver. Fatty changes and fibrosis produce a diffuse increased echogenicity. In established cirrhosis, there may be marginal nodularity of the liver surface and distortion of the arterial vascular architecture. The patency and diameter of the portal and patency of hepatic veins can be evaluated. The sensitivity of abdominal ultrasonography for the detection of biliary obstruction in jaundiced patients ranges from 55% to 91% and the specificity from 82% to 95%. US can demonstrate cholelithiasis and space-occupying lesions in the parenchyma greater than 1 cm in diameter, as well as enlargement of pancreatic head suggestive of carcinoma. The Achilles' heel of the visualization is the very low common bile duct. Ampullary carcinomas are usually too small to be directly visualized, but they can be suspected when a simultaneous dilatation of pancreatic and biliary duct is found without any other abnormality ("double duct sign"). Dilatation of the common biliary duct, which usually indicates biliary tract obstruction, is also common in patients who have undergone previous cholecystectomy. The major advantages of ultrasound are that it is noninvasive, portable, and relatively inexpensive. The major disadvantages are that it is operator dependent, and the images may be difficult to interpret in obese patients or patients with overlying bowel gas.

Computed tomography of the abdomen

This is useful in all hepatobiliary problems and is complementary to US. Pancreatic disease, enlargement of regional lymph nodes, and lesions in the porta hepatis can be visualized. Abdominal computed tomography (CT) permits accurate measurements of the caliber of the biliary tree. Using spiral (helical) CT and the multidetector channel row (MDCT) scanner technology, with a single breath-hold multiple thin slices can be obtained and reconstructed by a computer analysis program, giving very high quality images. Recently for the detection of choledocholithiasis, sensitivities of 88% to 96% and specificities of 92% to 96% have been reported.⁴⁶ Moreover helical CT improves diagnostic accuracy in relation to space-occupying lesions of the liver: it involves rapid acquisition of a volume of data during or immediately after intravenous contrast injection. Data can thus be acquired in both arterial and portal phases of enhancement, enabling more precise characterization of a lesion and its vascular supply. It remains the main imaging technique for the study of the liver, including screening for focal lesions, as it can detect nodules

as small as 5 mm, differentiating benign masses from malignant and helping in staging hepatocellular carcinoma (HCC) in patients undergoing hepatic resection. In the case of cholangiocarcinoma, accuracies for arterial, portal, and biliary involvement of 92.7%, 85.5%, and 84% have been reported.⁴⁷

CT is not as operator dependent as US and provides technically superior images in obese patients in whom the biliary tree is obscured by bowel gas. CT is not as accurate as US in detecting cholelithiasis, because only calcified stones can be seen clearly. Other considerations in the use of abdominal CT in patients with jaundice are its lack of portability, requirement for intravenous contrast, and expense.

Magnetic resonance imaging

MRI is a very useful investigation of hepatobiliary disease, especially in diagnosing and staging malignant disease. Alteration in weighting of the image leads to prominence of the ductal system in the biliary tree and pancreas, known as magnetic resonance cholangiopancreatography (MRCP). The basic principle of MRCP is to utilize T2-weighted images in which stationary or slowly moving fluid, including bile, has high signal intensity and all surrounding tissues including retroperitoneal fat and solid visceral organs are lower in signal. MRCP provides detail of the liver parenchyma and biliary tree; it can be employed when there are contraindications to percutaneous cholangiography (PTC) or ERCP, if therapeutic intervention is unlikely to be required, or as a first imaging test when there is a previous biliary-enteric or Billroth II anastomosis. MRCP has 95% sensitivity for detecting biliary obstruction, though it is inaccurate in assessing the grade of obstruction. Similarly, strictures cannot be well characterized due to a signal dropout. Its accuracy is equal to ERCP in determining the level of obstruction and whether it is due to a neoplastic process. Unlike PTC or ERCP, MRCP enables the biliary tract to be visualized above and below a complete obstruction. MRCP has an advantage over ERCP in being noninterventional and nonoperator dependent, and it does not require contrast injection, although unlike ERCP it is purely diagnostic. MRCP has already replaced direct diagnostic cholangiography in many clinical circumstances, but PTC and ERCP remain the tests of choice when a therapeutic intervention is necessary. MRCP has proved to be a useful tool for diagnosis of primary sclerosing cholangitis (PSC), with reported sensitivity of 83% and specificity of 98%,⁸ and it can also provide information about the periductal tissue, allowing for a single modality to provide both diagnosis of PSC and screening for cholangiocarcinoma. Because of its lack of complications compared to ERCP, MRCP is the diagnostic treatment of choice, particularly for older patients who may have relative contraindications to ERCP.

Endoscopic ultrasound

Endoscopic ultrasonography (EUS) combines endoscopy with real-time, high-resolution ultrasound. Unlike transabdominal ultrasonography (US), it provides excellent sonographic visualization of the extrahepatic biliary tree without interference of bowel gas. After conscious sedation, the echoendoscope is placed in the duodenum and the extrahepatic biliary tract is scanned from the duodenum upon instrument withdrawal.

EUS is superior to US and CT for diagnosing bile duct stones.⁴⁸ Prospective studies have supported the accuracy of

EUS compared to ERCP in the diagnosis of pancreatic and biliary conditions. In highly experienced hands, EUS has been found to be more sensitive than ERCP for choledocholithiasis.⁴⁹ The principal limitations of EUS are that it is an invasive procedure, its results are highly operator dependent, and procedure is not widely available in clinical practice. In addition, pathology identified at the time of EUS may require a subsequent therapeutic ERCP. Compared to high-resolution MRCP (using slice thickness <5 mm) in detecting bile duct stones, good-quality studies report that sensitivity of MRCP and EUS were 87% and 90%, respectively, and specificity was 95% and 99%, respectively (i.e., no significant difference).⁵⁰ Thus, MRCP should be the first-line investigation for common bile duct calculi because it is a noninvasive technique that does not require sedation nor admission to hospitals, and EUS should be performed when MRCP is negative in patients with moderate or high pretest probability. These would be patients with previous episodes of cholangitis and increased cholestatic tests.

Evidence comparing MRCP to EUS in the diagnosis of malignant strictures showed a lower sensitivity but a higher specificity for EUS being 80% and 90% and 80% and 65%, respectively.⁴⁴

The failure rate of EUS (2.3%) is lower than that of ERCP (8.3%).⁵¹ Morbidity rate of EUS is between 0 to 8% including complications like hypoxia resulting from sedation, transient abdominal pain, acute pancreatitis, and delayed bleeding; the mortality rate is zero.^{52–54}

Endoscopic retrograde cholangiopancreatography

Previously (before MRCP) this was the gold standard investigation for the visualization of the biliary tree as well as the pancreatic ducts. The technique involves the passage of an endoscope into the second part of the duodenum and cannulation of the ampulla; contrast material is then injected into both systems, and the patient is screened radiologically. In experienced hands, this procedure is successful in demonstrating the intra- and extrahepatic biliary tree in 95% of cases. In comparison with abdominal US, CT, and MRCP, ERCP is more invasive and requires conscious sedation.

It is highly accurate for the diagnosis of biliary obstruction, with a sensitivity of 89% to 98% and specificity of 89% to 100%. In addition to providing radiographic images, other diagnostic and therapeutic procedures can be carried out in the same session:

- Common bile duct stones can be removed after balloon dilatation (if small) or after a diathermy cut to the sphincter has been performed to facilitate their withdrawal. Sphincterotomy has a complication rate of 8% to 12%: acute pancreatitis in 5% of cases, severe hemorrhage in 2%, with an overall mortality of 0.5% to 1%.⁵⁵ These complications are reduced in experienced hands and with the initial use of biliary stents or nasobiliary stents, particularly in septic patients. Endoscopic balloon dilatation preserves biliary sphincter function and is safer in terms of bleeding.
- The biliary system can be drained by passing a tube (stent) through an obstruction or placement of a nasobiliary drain.
- Biopsy specimens and brushing for cytologic study can be obtained.

Percutaneous cholangiography

This is a procedure that complements ERCP. Contraindications are as for liver biopsy. Under a local anesthetic, a fine flexible needle is passed into the liver. Contrast is injected slowly until a biliary radicle is identified and then further contrast agent is injected to outline the whole of the biliary tree. In the presence of obstruction, bile can be aspirated and a guidewire can be passed to allow stenting.

Its sensitivity (98% to 100%) and specificity (89% to 100%) are comparable with those of ERCP. In difficult cases, the two techniques are sometimes combined, with PTC showing the biliary anatomy above the obstruction and ERCP showing the more distal anatomy. It is the procedure of choice if there is a high obstruction proximal to the common hepatic duct when interventional procedures are needed, such as balloon dilatation and stent placement to relieve obstruction of the biliary tree, and also when altered anatomy precludes ERCP. PTC may be technically difficult in the absence of dilatation of the intrahepatic bile ducts. The rates of morbidity (3%) and mortality (0.2%) are similar to those for ERCP and are due to major complications: biliary leakage, sepsis, perforation, and bleeding.

KEY POINTS

Biliary Tract Diseases

- Jaundice is clinically evident when the bilirubin concentration exceeds 50 mol/L.
- A careful history, physical examination, and review of the standard laboratory tests should allow a physician to make an accurate diagnosis in 85% of cases.
- In acute jaundice, liver ultrasound should be the first imaging modality, particularly in elderly people.
- If there is any evidence of biliary obstruction and a therapeutic intervention is planned, ERCP or PTC are the investigations of choice.
- MRCP should follow ultrasound if this has been technically difficult, obstruction has not been ruled out, or therapeutic intervention is not needed.
- Liver biopsy is needed to confirm the presence, cause, and severity of chronic liver disease.

Diseases of the small bowel can be divided into two categories for clinical purposes. Diffuse processes such as celiac disease result in the malabsorption syndrome, whereas discrete diseases like small bowel tumors produce focal manifestations. Some conditions like Crohn's disease and radiation enteritis can cause a combination of malabsorption and focal features. Malabsorption in elderly people is not due to aging alone, as the absorption of most nutrients is unaffected with a few exceptions. Lactose malabsorption is common in otherwise healthy elderly individuals^{1,2} and can coexist with other diffuse small bowel diseases. Calcium absorption declines with age because of a higher prevalence of vitamin D deficiency³ Lastly, atrophic gastritis is more common in elderly people and can adversely affect the absorption of vitamin B₁₂ and folic acid. Food-cobalamin malabsorption, the impaired release of the vitamin B₁₂ from food, is due to reduced or absent gastric acid secretion or to the use of acid-suppressing drugs. This is the most common cause of B₁₂ deficiency in elderly people,⁴ pernicious anemia and terminal ileal disease/resection being much rarer. Folic acid absorption in the proximal jejunum is also pH dependent and declines with achlorhydria. However, jejunal bacterial overgrowth, another consequence of achlorhydria, can compensate for reduced absorption of the vitamin because of bacterial folate synthesis⁵ Three conditions account for most cases of malabsorption in older individuals: bacterial overgrowth syndrome, celiac disease, and chronic pancreatitis (the latter is actually maldigestion resulting in malabsorption).

Steatorrhea, the typical symptom of fat malabsorption, is much less likely to occur in elderly patients who may even be constipated despite an increased stool volume. Carbohydrate malabsorption can cause watery diarrhea, abdominal distention, borborygmi, and flatulence. These symptoms are due to the action of bacteria on carbohydrate residues in the colon. The clinical presentation of malabsorption in elderly people is nonspecific. It consists of a variable combination of the following: fatigue, poor mobility, anorexia, nausea, diarrhea, anemia, weight loss, depression, and confusion.^{6,7} Peripheral edema may result from hypoproteinemia. Vague generalized body ache and muscle weakness can be early clinical indicators of osteomalacia. Vitamin K deficiency may cause bruising, petechiae, and bleeding manifestations. Abdominal discomfort and distention are common, but abdominal pain is relatively rare. Recurrent abdominal pain occurs with chronic pancreatitis, inflammation as in Crohn's disease, subacute obstruction as a result of strictures, or chronic mesenteric ischemia.

The diagnosis of malabsorption should therefore be considered in elderly patients with clinical and anthropometric evidence of undernutrition, even in the absence of gastrointestinal symptoms. A dietary assessment is important in determining whether the malnutrition can reasonably be attributed to inadequate nutrient intake. The details of previous surgical procedures should be ascertained: gastric surgery or intestinal bypass procedures can result in the bacterial overgrowth syndrome, and extensive small bowel resection

can cause malabsorption because of a critical reduction in the mucosal absorptive surface area.

INVESTIGATION OF SMALL BOWEL DISORDERS

Screening tests

Routine blood tests are often helpful in the diagnosis of small bowel disease. The full blood count and blood film may show anemia with macrocytosis, an iron deficient picture, or a dimorphic film. Macrocytosis, leukopenia, and thrombocytopenia suggest megaloblastic anemia. Ferritin, vitamin B₁₂, and red cell folate levels should be measured in patients with suspected malabsorption, even with a normal blood film, as typical changes may not be present in early deficiency. B₁₂ deficiency should be further investigated with serologic tests for pernicious anemia (gastric parietal cell and intrinsic factor antibodies), celiac disease (discussed later, a rare cause of isolated B₁₂ deficiency), and, if necessary, radiologic or endoscopic evaluation of the terminal ileum. A low B₁₂ with a normal or increased red cell folate raises the possibility of small bowel bacterial overgrowth. Howell–Jolly bodies in the blood film indicate splenic atrophy, which occurs in association with celiac disease. Osteomalacia results in a raised alkaline phosphatase with low calcium and phosphate levels and is confirmed by a low serum 25-hydroxycholecalciferol. Vitamin K deficiency prolongs the international normalized ratio (INR). Hypoalbuminemia is a common though nonspecific finding, as it also occurs with poor dietary intake, injury, sepsis, and malignancy. Malabsorption is unlikely if these screening tests are completely normal.

Tests of absorption

Tests of nutrient absorption such as fecal fat estimation and xylose absorption are no longer used in clinical practice: they are cumbersome to perform, unpopular with patients and professionals, and relatively insensitive, often giving equivocal results. Furthermore, these tests provide no information about the underlying disease process. Lactose absorption is the only nutrient absorption test that is widely used.⁸ In the standard lactose tolerance test, blood glucose levels are measured before, and 30 and 60 minutes after the ingestion of 50 g of lactose. A rise of less than 1.1 mmol/L indicates lactose malabsorption, and accompanying (transient) symptoms of abdominal bloating, discomfort, diarrhea, and wind are indicative of intolerance. Alternatively, a lactose hydrogen breath test can be used: after an oral dose of 25 to 50 g lactose, end-expiratory breath samples are collected every 30 minutes for 3 hours. Malabsorption of lactose results in fermentation of the sugar by colonic flora, producing a rise in breath hydrogen. This rise can also occur in patients with small bowel bacterial overgrowth, though usually much earlier than in patients with lactose malabsorption. Approximately 25% of patients will have a false negative test, and hence a trial of a lactose-free diet is reasonable if the diagnosis is suspected clinically.

Radiology and endoscopy

Double-contrast barium follow-through examination and enteroclysis (small bowel enema) have been used for many years to investigate the small bowel. Enteroclysis is probably more accurate but is more invasive. The role of abdominal ultrasound, computed tomography (CT) scanning, and magnetic resonance imaging (MRI) is described in the relevant sections.

Esophagogastroduodenoscopy (EGD) is the usual method for collecting fluid for culture and for obtaining biopsies from the distal duodenum. The detection of villous atrophy at endoscopy can be improved by viewing the duodenal mucosal surface at high magnification after spraying with indigo carmine.⁹ Wireless capsule endoscopy was introduced in 2000¹⁰ and can provide endoscopic images of the entire small bowel.¹¹ It consists of a capsule endoscopy system, which is swallowed and propelled by peristalsis, transmitting two images per second to a data recorder worn on a belt. Approximately 50,000 images are recorded over an 8-hour period, by which time the capsule will have reached the cecum in most patients. The images are then downloaded onto a computer workstation and are viewed as a video. Capsule endoscopy is currently used for the investigation of obscure gastrointestinal (GI) bleeding (discussed later), small bowel Crohn's disease, in suspected or refractory malabsorption syndromes (e.g., celiac disease), and in suspected small bowel tumors, including screening in familial polyposis syndromes.¹² The major drawbacks of capsule endoscopy are the inability to take biopsies, incomplete visualization of the mucosal surface, and capsule retention requiring surgical or endoscopic removal (1% to 7%).

Double-balloon enteroscopy (DBE), a technique that can traverse the whole of the small bowel using an enteroscope with an overtube, was first described in 2001. The enteroscope is inserted by either the oral or anal routes, and therapeutic procedures can be carried out.^{11,13} General anesthesia is often required for this complex and prolonged technique. The overall diagnostic yield is between 43% and 83% with a subsequent change in management for 57% to 84% of patients. Complications include postprocedural abdominal pain, pancreatitis, bleeding, and small bowel perforation. Push enteroscopy is currently the most widely available technique for endoscopic examination of the small bowel. The instrument can be inserted 30 to 160 cm beyond the ligament of Treitz and has a channel for biopsies and therapeutic procedures including thermocoagulation of bleeding lesions, polypectomy, and placement of feeding jejunostomy tubes. Lastly, intraoperative enteroscopy, in which the small bowel is "pleated" over an endoscope at laparotomy or laparoscopy, is the most accurate technique but has a significant complication rate.

SMALL BOWEL DISEASES

Celiac disease

In celiac disease, sensitivity to dietary gluten in cereals like wheat, barley, and rye leads to a characteristic small bowel mucosal lesion, hyperplastic villous atrophy. The disease affects the proximal small bowel, decreases in severity distally, and may spare the distal jejunum and ileum. The wider use of serologic screening tests has altered our

understanding of the epidemiology of the disease. It appears to be much more common than previously appreciated with current prevalence rates of approximately 1%.^{14,15} Only 30% to 40% of patients are symptomatic, the rest have clinically silent disease. This variable clinical picture is probably related to the extent of affected bowel. Currently 60% of newly diagnosed patients are adults¹⁶ with a peak incidence in the third decade and a second smaller peak in the fifth and sixth decades.¹⁷ In a recent multicenter Italian study, only 60 (4.4%) of 1353 patients with celiac disease were over 65 years at diagnosis.¹⁸ However, the seroprevalence of celiac disease in an English population of 7257 people aged 45 to 76 years was 1.2% with no significant difference between those under and over 65 years of age.¹⁹ In a Finnish population-based study of 2815 individuals, the prevalence of celiac disease in those aged 52 to 74 years was 2.13%, double that in younger adults.²⁰ The female to male ratio in adults is approximately 2:1, and this is no different in elderly patients.^{18,19}

Many elderly patients, like adults with celiac disease, are either asymptomatic or have trivial or nonspecific symptoms. However, in the Italian study referred to previously, 77% of patients over the age of 65 years presented with diarrhea and approximately 60% had weight loss and anemia.¹⁸ Despite these typical features, the diagnosis was only made after a mean interval of 17 years in this group. Celiac disease should be considered in patients with unexplained anemia, macrocytosis, or evidence of splenic atrophy on the blood film even in the absence of diarrhea or steatorrhea. Folate deficiency is the most common cause of anemia, but malabsorption of iron or vitamin B₁₂ can occur. Osteoporosis²¹ and osteomalacia are common in untreated celiac disease, particularly in elderly patients.

Celiac disease is associated with a number of autoimmune conditions, the most important being insulin-dependent diabetes mellitus, autoimmune thyroid disease, Sjögren's syndrome, autoimmune hepatitis, primary biliary cirrhosis, and Addison's disease.^{14,15,17,22} Dermatitis herpetiformis can be regarded as an extraintestinal manifestation of celiac disease as virtually all patients have an enteropathy with characteristic histologic changes. Neurologic disorders such as epilepsy, cerebellar syndrome, dementia, peripheral neuropathy, myopathy, and hyporeflexia have been reported in celiac disease.²³ IgA deficiency affects 2% to 3% of patients with celiac disease and can result in false-negative serologic tests. From 90% to 95% of celiac patients have the HLA class 2 molecule DQ2, and most of the remainder have DQ8. At least 1 in 10 first-degree relatives are affected.¹⁵

DIAGNOSIS

Serologic markers are now used routinely for screening patients and high-risk groups with associated disorders or a positive family history. IgA endomysial antibody (EMA) has a specificity of over 98% but antibody to IgA tissue transglutaminase (tTGA) is also very accurate and is a simpler and cheaper test.^{14,22,24} Patients with an absent tTGA or those in whom there is a strong clinical suspicion of celiac disease should have an IgA level to exclude deficiency—this is routinely carried out by some laboratories. If IgA deficiency is present, tests for IgG tTGA or EMA should be carried out. Patients with positive serology should undergo an EGD in order to take three to four distal duodenal biopsies.²⁵ The typical histologic features of celiac disease are villous

atrophy, crypt hyperplasia, intraepithelial lymphocytosis, and a lymphoplasmacytic infiltrate in the lamina propria. These changes, accompanied by a clinical response to a gluten-free diet, are adequate to establish the diagnosis.^{22,26} Antibody titers can decrease or disappear with treatment, but this is not a reliable marker of histologic remission.^{27,28} A repeat biopsy to confirm histologic remission is required only in asymptomatic patients or in those with an equivocal clinical response. Rebiopsy after a gluten challenge is rarely carried out now but may be required in cases where there is diagnostic difficulty, such as when the original biopsy was taken on a gluten-free diet. The absence of HLA DQ2 and DQ8 virtually excludes the diagnosis and is useful when the patient does not wish to undergo a gluten challenge. Lastly, 5% to 10% of patients have serology-negative disease, and thus histologic confirmation should be undertaken if the likelihood of celiac disease is high (e.g., in symptomatic patients with a positive family history).

MANAGEMENT

Most elderly patients respond to a well-balanced gluten-free diet and cope well with the change in lifelong eating habits. It is now generally accepted that patients can take a moderate amount of oats provided it is not contaminated with wheat gluten. Lactose intolerance can cause apparently resistant disease in some patients. However, milk and milk products are an important source of calcium and should be restricted only if they exacerbate symptoms—ideally after confirming the diagnosis with an objective test. Patients should receive supplements to correct nutrient deficiencies, as complete recovery of mucosal function can take months. Elderly patients with celiac disease should be given multivitamins and a calcium supplement initially. All patients with celiac disease should see a dietician, should be encouraged to join a patient support organization, and should have regular clinical follow-up.^{14,15} Bone mineral densitometry should be carried out at diagnosis in all elderly patients with celiac disease. Bone mass improves, but does not normalize, in adult and elderly patients on a gluten-free diet, and other therapeutic measures are often required.²¹ Approximately 5% of patients fail to respond to gluten withdrawal or relapse after an initial remission.^{14,29,30} Some patients with refractory disease respond to corticosteroids or immunosuppressive agents. Others (a proportion of whom have small intestinal ulcers and strictures: ulcerative enteritis) have a cryptic T-cell lymphoma of the intraepithelial lymphocytes³¹ with 5-year survival rates of less than 50%.¹⁴ Patients with ulcerative enteritis often require surgery for complications such as perforation or obstruction.

NEOPLASMS

The two-fold increase in mortality in the first year after diagnosis is largely due to the development of malignant complications.³² The overall risk of malignancy is less than previously reported³³ and is approximately 30% greater than that of the general population.³² T-cell lymphoma of the small intestine is the most common tumor,^{34–36} but there is an increased risk of developing squamous cell carcinomas of the esophagus, mouth, pharynx, adenocarcinoma of the small bowel, and colorectal carcinoma. The incidence of breast^{32,35} and lung cancer³² is decreased. Lymphoma may be the first manifestation of celiac disease, but the diagnosis

should also be considered in established patients whose condition is either resistant to, or relapses on, a strict gluten-free diet. Weight loss is the most common symptom, and patients also experience profound lethargy, muscle weakness, abdominal pain, and diarrhea. The prognosis is poor: less than a fifth of patients survive for 30 months.³⁷ A gluten-free diet has a protective effect against the development of malignancy in celiac disease.^{33,35,36}

Bacterial overgrowth syndrome

Intestinal bacterial counts normally increase abnormally and bacterial populations vary in different sections of the gastrointestinal tract: the jejunum is colonized by gram-positive aerobes and facultative anaerobes, ileal flora contain some strict anaerobes as well, and the colon is heavily populated by predominantly anaerobic bacteria.³⁸ Malabsorption can occur when the small bowel population increases and becomes more anaerobic. This is partly the result of direct injury to the intestinal mucosa, but uptake or binding of major nutrients and vitamin B₁₂ by the proliferating bacteria also play a part.³⁹ In addition, fat absorption is affected by deconjugation of bile salts by anaerobic bacteria, resulting in impaired micelle formation. Folic acid and vitamin K are synthesized by bacteria, and folate levels are often normal or raised when bacterial overgrowth is present. Two factors are largely responsible for regulating bacterial growth: gastric acid and intestinal motility.^{38,39} Gastric acid destroys microorganisms ingested with food and saliva. The interdigestive migrating motor complex, a cyclic fasting motility pattern, regularly propels luminal contents toward the colon, thus preventing stagnation and bacterial overgrowth.⁴⁰

PATHOGENESIS

The classic disorders associated with bacterial overgrowth are those in which disordered intestinal motility, abnormal reservoirs, or abnormal communications between the proximal and distal intestine result in proliferation of bacteria. Examples of the former are diabetic autonomic neuropathy, late radiation enteropathy, collagen diseases such as scleroderma, and the numerous causes of chronic intestinal pseudo-obstruction. Partial small bowel obstruction due to strictures or adhesions has a similar effect. Abnormal reservoirs that permit stagnation of luminal contents may arise *de novo*—for example, small bowel diverticula—or as a result of surgery (e.g., the afferent limb of a Billroth II gastrectomy). Abnormal communications between the proximal and distal intestine result in contamination of the former by denser, more anaerobic bacterial populations. Examples of this group include gastrocolic and jejunocecal fistulas, right hemicolectomy with resection of the ileocecal valve, and surgical bypass of obstructed or diseased intestinal segments. Small bowel bacterial overgrowth in elderly people also occurs under conditions that impair gastric acid secretion, such as atrophic gastritis,^{39,41} treatment with acid-reducing drugs,^{42–44} or after surgery for peptic ulcer disease. Gut immune defenses may be impaired in elderly people and thus contribute to their susceptibility to overgrowth.⁴⁵

CLINICAL PICTURE

Elderly patients who have bacterial overgrowth with malabsorption typically present with diarrhea, weight loss, and abdominal bloating associated with hypoalbuminemia and

low B₁₂ levels. Some anatomic abnormalities associated with bacterial overgrowth (e.g., small bowel diverticula) are more common with increasing age. Most patients who had surgery for peptic ulcer disease before the widespread use of proton pump inhibitors are now elderly. Bacterial overgrowth is thus more common in elderly people and is found in 52.5% to 70.8% of patients with symptoms of malabsorption.^{6,44,46} It also affects 14.5% to 25.6% of elderly people with no gastrointestinal symptoms.^{43,47–49} Some of these individuals are on acid-suppressing medication,⁴³ others have factors that are associated with slower small bowel transit: reduced intake of dietary fiber⁴³ and physical disability.⁴⁹ Subclinical malabsorption is probably present in a proportion who have low albumin and B₁₂ levels, and this may also adversely affect bone mineral density.⁵⁰

DIAGNOSIS

The literature on bacterial overgrowth is plagued by the absence of a reliable diagnostic test. Historically, culture of proximal small bowel aspirate (currently usually obtained during EGD) was the gold standard for establishing the diagnosis: proximal jejunal counts greater than 10⁵ colony-forming units (cfu)/mL were accepted as abnormal.³⁸ Although this is probably true for postsurgical patients with blind loops, jejunal bacterial counts in healthy individuals are much lower, in the range of 0 to 10³ cfu/mL, and a recent systematic review has found no evidence to support culture as a gold standard test.⁵¹ Furthermore, this technique only samples a limited region of the small bowel and may miss overgrowth in the more distal segments. Breath tests were developed as an alternative to the invasive procedure and cumbersome culture techniques were involved.^{51,52} However, these tests were largely validated against culture, which raises serious doubts about their reliability.

In the [¹⁴C] glycocholate breath test, 5 to 10 μCi of glycocholic acid, a conjugated bile acid radiolabeled with ¹⁴C is administered with a test meal. Bacterial deconjugation results in separation of [¹⁴C]glycine from cholic acid, and ¹⁴CO₂ produced from the former is measured in breath samples collected over the next 4 to 8 hours. Terminal ileal disease or resection also results in a positive test because the bile acid is not reabsorbed and is then metabolized by colonic flora. The test has largely been abandoned because of its poor sensitivity with a false negative rate of 30% to 40%.

Breath hydrogen measurement after ingestion of 50 to 80 g of glucose or 10 to 12 g of lactulose is an alternative technique that avoids the use of a radioisotope. Metabolism of either carbohydrate by the abnormal bacterial population produces hydrogen, which can be detected by breath testing. The timing of the hydrogen rise is crucial for the lactulose test, as this sugar is not absorbed in the small bowel and produces a second, higher "colonic" hydrogen peak. It is not possible to reliably distinguish the peak produced by small bowel bacterial overgrowth from that due to normal colonic flora without using an oral contrast medium as well. Glucose is thus a better substrate as it is absorbed completely in the proximal small bowel. Furthermore, a small study in healthy volunteers has shown that even a 10-g quantity of lactulose accelerates small bowel transit,⁵³ and hence the glucose-hydrogen breath test is probably more reliable. Approximately 15% of individuals are colonized by colonic flora, which produce methane, not hydrogen, and false negative

tests will occur unless breath methane and hydrogen are both measured.⁵² In the [¹⁴C]xylose breath test, elevated ¹⁴CO₂ levels appear in breath samples within 60 minutes of taking 10 μCi of [¹⁴C]xylose with 1 g of unlabeled xylose by mouth. Although the sensitivities and specificities of breath tests are variable, even when compared against culture, they are simple to perform and are probably useful if positive. Until a better test for bacterial overgrowth becomes available the most practical strategy would be to test, treat, and then retest, in addition to evaluating the clinical response.⁵¹ Patients with confirmed overgrowth should have a small bowel x-ray series to look for abnormal communications or reservoirs.

MANAGEMENT

The conditions underlying bacterial overgrowth (with the exception of strictures and some enteroenteric fistulas) are rarely amenable to surgical correction, and hence antibiotics are the mainstay of treatment.³⁹ Tetracycline was traditionally used to reduce bacterial flora, but about two thirds of patients do not benefit from this drug. Chloromycetin and clindamycin are rarely used now because of their toxicity. Co-amoxiclav and norfloxacin are effective in standard doses given for 7 to 10 days, as is metronidazole in combination with one of the cephalosporins.^{54,55} Rifamixin is also effective and systemic toxicity does not occur, as the drug is not absorbed.⁵⁶ In some patients, a single antibiotic course produces a satisfactory response lasting for months, but many patients need cyclic courses given at monthly intervals for 4 to 6 months. Octreotide, a long-acting analogue of somatostatin, has been tested in small numbers of patients with connective tissue diseases and chronic intestinal pseudo-obstruction. It improves motility and appears to be highly effective on its own⁵⁷ or in combination with erythromycin.⁵⁸

Prokinetic agents (including erythromycin) may play a role in the management of bacterial overgrowth, particularly in elderly patients with prolonged small bowel transit. Probiotics may also be helpful, but further work is required to define their role. Clinicians should avoid using acid-suppressing agents in elderly people without a clear indication: apart from their possible role in promoting clinically significant bacterial overgrowth, these drugs can cause food-cobalamin malabsorption and are implicated in an increased susceptibility to *Clostridium difficile* infection.

Crohn's disease

Crohn's disease is an idiopathic chronic relapsing disorder, characterized by transmural inflammation and ulceration, occurring in a segmental distribution. Intestinal ulceration ranges from aphthoid erosions to deep fissures, and the course is often complicated by the formation of strictures, abscesses, and fistulas. The disease has a predilection for the terminal ileum, but any region of the GI tract can be affected. The Vienna classification groups patients according to clinical phenotype including disease behavior and location.⁵⁹ The majority of patients (70%) initially have nonstricturing and nonpenetrating disease, approximately 17% have strictures, and 13% present with penetrating disease (i.e., fistulas or abscesses).⁶⁰ At diagnosis approximately 28% of patients have terminal ileal involvement only, 50% have ileocolic disease, and 25% colonic disease alone.⁶¹ Small bowel disease

is less common in older people.⁶² In a recent series from northern France, 34% of patients over the age of 60 years had small bowel involvement compared to 64% of younger patients.⁶³

Crohn's disease predominantly affects teenagers and young adults with a second smaller peak from the sixth to the eighth decades. Recent studies, however, have not described this bimodal pattern consistently.^{64,65} Nevertheless, a substantial minority of patients with Crohn's disease first present in later life, and the numbers of affected elderly people will also increase because of longer life expectancy. In the French study quoted earlier, 24% of patients were diagnosed with Crohn's disease at or above the age of 60 years.⁶³ In another population-based study from Belgium, 23 of 137 patients (17%) were over the age of 60 years at diagnosis with an annual incidence of 3.5 per 100,000 (4.8 per 100,000 in patients under 60 years).⁶⁶ Smoking, a family history of inflammatory bowel disease, and (in most studies) previous appendectomy are risk factors for Crohn's disease.⁶⁵

CLINICAL PICTURE AND INVESTIGATIONS

The clinical features of Crohn's disease, including the extraintestinal manifestations, are no different in elderly patients. Diarrhea is the main symptom, but right iliac fossa pain, fever, and an abdominal mass are typical features. Stricture formation can lead to subacute or acute bolus obstruction, and fistulas to a wide variety of manifestations. Ileocecal Crohn's disease can mimic acute appendicitis or an appendiceal abscess; the differential diagnosis in older patients includes cecal diverticulitis, colonic carcinoma, and small bowel ischemia. Gastrointestinal infections, smoking, and nonsteroidal anti-inflammatory drugs can all precipitate relapse. There is no single definitive test for Crohn's disease.⁶⁷ The diagnosis is established (and disease activity assessed) by clinical features, inflammatory markers, endoscopic, or radiologic imaging and histology. Standard activity indices, incorporating some of these features (Crohn's disease activity index [CDAI], Harvey-Bradshaw Index) are used in trials but can also be helpful in clinical practice (e.g., in assessing patients for therapy with antitumor necrosis factor [TNF] agents).⁶⁸ For example, a CDAI of <150 is used to define remission, and severe disease is characterized by a score of >450.^{68,69}

A discussion of investigative techniques used in small bowel Crohn's disease inevitably overlaps with the investigation of colonic disease. In practice, ileocolonoscopy will probably be the initial investigation of choice. Only a short segment of terminal ileum is examined at colonoscopy, and hence either a double-contrast barium follow-through or enteroclysis is traditionally used to define the extent and severity of small bowel disease. Advances in magnetic resonance imaging (MRI) (including MR enteroclysis) have resulted in improved small bowel visualization,^{61,70,71} including the ability to distinguish between inflammatory and fibrotic strictures. MRI has the advantage of not using ionizing radiation and is likely to replace barium studies. CT and ultrasound imaging have been used for many years in Crohn's disease to outline phlegmons (inflammatory masses) and abscess cavities and to drain the latter percutaneously. Technical advances have extended the range of both these modalities. Ultrasound is now also employed to image the bowel wall and detect strictures. Contrast-enhanced examinations with

multislice helical CT scanners have high sensitivity (71% to 83%) and specificity (90% to 98%) in the evaluation of small bowel inflammation.⁷¹ As stated previously, wireless capsule endoscopy can provide endoscopic images of the entire small bowel.^{11,61,71} In a meta-analysis of its use in non-stricturing small bowel Crohn's disease, the diagnostic yield was significantly better than other modalities for recurrent disease but not in a suspected initial presentation.⁷² Push enteroscopy is rarely used in Crohn's disease, as the terminal ileum is not visualized with this technique. Double balloon enteroscopy can be used to take biopsies and do therapeutic procedures such as dilation of strictures.^{1,13,61,71}

MANAGEMENT

Detailed guidelines (including a series of Cochrane reviews) usually discuss management under two headings: the induction of remission and the maintenance of remission.^{6,73–75} The medical management of elderly patients with Crohn's disease is essentially the same as that in younger patients.⁶⁴ However, particular caution is required when using corticosteroids, immunosuppressive agents, and biologic drugs in this age group.

Sulfasalazine is not effective in small bowel Crohn's disease without colonic involvement. Mesalamine preparations coated with a pH-sensitive resin or in ethylcellulose-coated granules start releasing the drug in the small bowel. However, recent meta-analyses have shown that mesalamine is little better than placebo for induction of remission,⁷⁶ and the drug is ineffective for maintenance of medically induced remission.⁷⁷ Mesalamine only has a role in reducing the relapse rate after surgical resection.⁷⁸ Budesonide (9 mg daily), a topically active steroid with extensive first-pass metabolism in the liver, is recommended for mild/moderate localized ileocecal disease. Budesonide has a better side-effect profile compared to other corticosteroids and does not result in osteoporosis. Prednisolone (40 to 60 mg/day up to 1 mg/kg body weight) is used for severe ileocecal disease and for extensive small bowel disease: over 80% of patients go into remission or have a partial response by 4 weeks. However, corticosteroids cause many side effects. At 1 year only 32% of patients will have had a prolonged response, 28% become steroid-dependent (i.e., require at least 10 mg/day of prednisolone or budesonide 3 mg/day to prevent recurrence), and 38% require surgery.⁷⁹ Steroids have no role in maintaining remission in Crohn's disease, although budesonide may delay relapse.

Immunosuppressive agents such as azathioprine (2 to 2.5 mg/kg), 6-mercaptopurine (1 to 1.5 mg/kg), and methotrexate (15 to 25 mg im/sc weekly with folic acid) are used as steroid-sparing agents. They are effective in maintaining remission and may need to be taken long term. They should be used cautiously in elderly patients given their potential for serious toxicity, although, in clinical trials, 6-mercaptopurine has been tolerated by patients in the seventh decade as well as their younger counterparts.⁸⁰ Antibiotics, including antimycobacterial agents, are not effective as primary therapy for small bowel Crohn's disease although the former will be required for septic complications associated with penetrating disease. Monoclonal antibodies against TNF alpha (infliximab, adalimumab, certolizumab) are used in refractory disease, in patients who are intolerant to conventional treatment, for maintenance of remission, for fistulating

disease, and for some extraintestinal manifestations.⁸¹ These drugs are expensive and significant adverse effects have been reported including reactivation of tuberculosis, serious infections, optic neuritis, infusion reactions, and a possible increased risk of developing lymphoma. They increase mortality, in patients with class 3 to 4 congestive cardiac failure and are therefore contraindicated in this group.

Malnutrition is common in small bowel Crohn's disease and is due to a variable combination of reduced nutrient intake, malabsorption, and increased energy requirements resulting from inflammation, sepsis, or surgery. In most patients, nutrient intake can be increased by using small, frequent, low-fiber meals and supplementary polymeric sip feeds. Some patients benefit from tube feeding, and a few need parenteral nutrition. Enteral nutrition, with either elemental or polymeric diets, can also be used as a primary treatment for Crohn's disease but is less effective than corticosteroid treatment⁸² and is also less acceptable to patients, despite the absence of side effects.

Patients with Crohn's disease are prone to osteopenia and osteoporosis. Bone loss occurs with corticosteroid use, as a direct result of the inflammatory process and also because of malabsorption of calcium and vitamin D in patients with extensive small bowel disease. Reduced bone mineral density is associated with low body mass index, male sex, long-standing disease, ileal resection, and active disease. Comprehensive guidelines for the prevention and management of osteoporosis in inflammatory bowel disease have been published.²¹

Surgery is required for obstruction as a result of strictures, for suppurative complications, and for disease that is refractory to medical treatment. Elderly patients usually tolerate surgery well. Although postoperative hospital stays are longer because of comorbidity, rates of mortality and of surgical complications are similar to those in younger patients.⁸³ Adenocarcinoma of the small bowel can complicate small bowel Crohn's disease. The risk of malignancy is higher in patients with disease confined to the small bowel than in ileocolic disease.⁸⁴ Patients with Crohn's disease also have a higher relative risk of developing colorectal cancer, lymphoma, and some extraintestinal malignancies.⁸⁴

Small bowel ischemia

Small bowel ischemia can be acute or chronic and of arterial or venous origin. Arterial ischemia predominantly affects middle-aged and elderly people. Mesenteric vein thrombosis accounts for 5% to 10% of patients with acute mesenteric ischemia. It affects a younger cohort of patients (mean age 48 to 60 years) and will therefore not be discussed further.

Acute arterial mesenteric ischemia^{85–87}

Acute arterial mesenteric ischemia is due to embolism, thrombus formation, or nonocclusive ischemia of the superior mesenteric artery (SMA) or its territory. Complete occlusion of the SMA, which supplies the jejunum, the ileum, and the right half of the colon, has catastrophic effects. Patients who survive frequently require long-term nutritional support and may need parenteral nutrition depending on the length of residual jejunum. Embolism accounts for 40% to 50% of cases and usually occurs in elderly people with predisposing causes such as atrial fibrillation, left-sided cardiac chamber enlargement, or myocardial infarction. Nonocclusive mesenteric

ischemia occurs in 20% to 30% of cases and is due to vasoconstriction of the mesenteric circulation following a low-output state or circulatory collapse, for example, severe congestive cardiac failure (CCF), hypotension, cardiac arrhythmias or following cardiac arrest. Thrombosis (20% to 30%) occurs in the setting of widespread vascular disease, and 20% to 50% of patients have a history of abdominal angina in the preceding weeks to months.

DIAGNOSIS

Patients present with severe abdominal pain, but physical examination is initially either normal or reveals only tenderness. This disparity between symptoms and physical signs in an elderly patient with cardiovascular disease or a hypercoagulable state should alert the clinician to the possibility of mesenteric ischemia. Signs of peritonitis, hypotension, vomiting, fever, dark or bright red rectal bleeding, increasing distention, leukocytosis, and metabolic acidosis are features of intestinal infarction. Up to 25% of patients have abdominal distention or gastrointestinal bleeding without pain, and about a third of elderly patients may present with an acute confusional state.⁸⁸ Leukocytosis and raised serum levels of lactate, amylase, alkaline phosphatase, and phosphate are not reliable markers. Fluid levels, dilated loops of bowel, and "thumbprinting" on plain abdominal films occur in up to a third of patients, but specific radiologic features of infarction such as gas in the intestinal wall or portal vessels are rare. CT scanning is more accurate in delineating these changes, can also demonstrate thrombus in the mesenteric vessels, and is useful in excluding other causes of abdominal pain.⁸⁹ Duplex ultrasonography has a limited role, but CT and MR angiography are promising approaches that have a high sensitivity and specificity for pathology in the SMA.^{90,91} Patients with abnormal films have a poor prognosis as even nonspecific changes usually signify intestinal necrosis. Mesenteric angiography is the gold standard for establishing the diagnosis and should ideally be performed before signs of infarction appear. It can, however, be difficult to differentiate between acute and long-standing vascular changes on an angiogram, particularly in patients with nonocclusive mesenteric ischemia.

MANAGEMENT

Management warrants aggressive measures in the appropriate patients, and initial resuscitation includes monitoring of central pressures, correction of hypovolemia, and inotropic support. Splanchnic vasoconstrictors, mainly norepinephrine (noradrenaline) and digitalis preparations, should be avoided. Broad-spectrum antibiotics are given empirically to treat the septicemia resulting from bacterial translocation across infarcted bowel. Early angiography is the cornerstone of management, even when the decision to operate has been made. The angiographic catheter is left in situ for two reasons: repeat angiography may be required, and the catheter can be used for intra-arterial infusion of the vasodilator papaverine. This relieves the associated mesenteric arterial spasm and improves perfusion perioperatively. Patients with established signs of infarction need emergency surgery with resection of infarcted bowel and embolectomy, thrombectomy, or arterial reconstruction. A second-look operation is often indicated 12 to 24 hours later to differentiate between viable and nonviable intestine. Full

anticoagulation with heparin is controversial but is generally started 48 hours after embolectomy, thrombectomy, and arterial reconstruction. There are many case reports and small case series of successful thrombolytic⁸⁷ and endovascular therapy including angioplasty, stenting, and mechanical thrombus fragmentation in patients with SMA embolism or thrombosis.^{92,93} These forms of therapy are generally only successful if carried out within 12 hours of presentation. The mortality rate of acute arterial mesenteric ischemia is 70% to 90% if the diagnosis is not made before irreversible infarction occurs. The overall mortality has improved since the late 1960s, probably because of earlier diagnosis and aggressive management with intensive care support. In one systematic review, mortality rates for arterial embolism, arterial thrombosis, and nonocclusive ischemia were 54.1%, 77.4%, and 72.7%, respectively.⁹⁴ Focal segmental ischemia causes localized infarction, often at multiple sites, and can be due to vasculitis, cholesterol, or atheromatous emboli and various nonvascular diseases. Management consists of surgical resection of the infarcted segment.

Chronic mesenteric ischemia

The syndrome of abdominal or intestinal angina is a rare condition that develops as a result of atherosclerosis of the splanchnic circulation.^{85–87} Mesenteric blood flow fails to meet the increased metabolic demand that occurs after meals, resulting in pain with or without malabsorption and disordered motility. The pain begins within 30 minutes of a meal and gradually increases to a plateau, which lasts for up to 3 hours. It is located in the upper abdomen, can radiate to the back, and is gnawing or cramping in character. It is sometimes relieved by lying prone or squatting. Constipation, diarrhea, steatorrhea, abdominal bloating, and flatulence may also occur. Patients may miss or restrict meals in order to avoid provoking symptoms (sitophobia), and hence lose weight.

DIAGNOSIS

Clinical assessment often reveals evidence of widespread vascular disease. An abdominal systolic bruit may be present but is not a specific finding. Individuals with advanced atherosclerotic disease can have severe stenosis or occlusion of two or even all three main mesenteric arterial trunks and remain asymptomatic. Diagnosis therefore depends on the history as well as on angiographic findings of proximal stenoses in at least two of the main mesenteric trunks, with a collateral circulation indicating chronic ischemia. Occlusion of two vessels is found in over 90%, and three-vessel occlusion in over 50% of patients with chronic mesenteric ischemia.⁸⁷ It is important to exclude atypical angina pectoris and other causes of recurrent abdominal pain such as biliary pain due to gallstones and peptic ulcer disease. Duplex ultrasonography, CT, and MR angiography are used to evaluate symptomatic patients before angiography.⁹⁵

MANAGEMENT

Surgical revascularization and percutaneous angioplasty with stenting are the two main therapeutic alternatives, both of which relieve symptoms in most patients. Surgery has higher revascularization rates and lower rates of restenosis or occlusion but also has a higher perioperative morbidity and mortality associated with longer hospital stays. Endovascular

therapy is not feasible in all patients but is particularly suitable for those with short segments of disease. The choice of therapy will therefore be made on an individual basis, as many patients will have widespread vascular disease and other comorbidities.^{95–97}

Small intestinal neoplasms

Primary small bowel tumors are relatively rare, accounting for only 1% to 2.4% of all gastrointestinal neoplasms.⁹⁸ Approximately two thirds of these tumors are malignant, and the small bowel is frequently involved by metastatic disease, particularly metastatic melanoma.

BENIGN TUMORS

Adenomas, leiomyomas, and lipomas are the most common benign tumors. Adenomas have a slight preponderance for the duodenum and ileum; lipomas are more frequent in the ileum. Leiomyomas are distributed more evenly in the small bowel but are more common in the jejunum. More than 50% of benign tumors are asymptomatic; the rest manifest with obstruction, intussusception, or occult bleeding. Adenomas and leiomyomas can undergo malignant transformation and should be removed by surgical resection or, in the case of adenomas, by endoscopic resection. Asymptomatic lipomas discovered incidentally can be left in situ, as malignant transformation is unknown.

MALIGNANT TUMORS

Data from the Surveillance, Epidemiology and End-Results (SEER) program estimated that 6110 American men and women would be diagnosed with small intestinal cancer in 2008, representing a progressive increase since the 1970s. The age-adjusted incidence for 2001–2005 was 2.2 per 100,000 for men and 1.6 per 100,000 for women with a median age of diagnosis of 67 years. The overall 5-year relative survival rate (RSS) for 1996–2004 was 57.8%; 31% of patients had localized disease at diagnosis with a 5-year RSS of 77%, 33% had regional spread (5-year RSS 62.2%), and 29% presented with metastases (5 year RSS 36%).⁹⁹ Adenocarcinomas (35% to 50% of tumors), carcinoid tumors (20% to 40%), lymphomas (14% to 18%), and sarcomas (10% to 13%) are the four major histologic types encountered.^{98,100}

PRESENTATION AND DIAGNOSIS

Abdominal pain, bleeding, intestinal obstruction, and weight loss are the major manifestations, a palpable abdominal mass being less frequent. Perforation occurs in about 10% of cases, periampullary tumors can present with obstructive jaundice, and diarrhea is more common in patients with lymphoma. With small bowel carcinoids, the carcinoid syndrome, due to the release of serotonin and other vasoactive compounds, causes flushing, telangiectasias, diarrhea, bronchospasm, and, less commonly, right heart failure, but it only occurs when hepatic metastases are present^{101,102}; 24-hour urinary 5-hydroxyindoleacetic acid and plasma chromogranin A are appropriate screening tests for carcinoid tumors.

The diagnosis of small bowel malignancy is often delayed because of the nonspecific history and the absence of clinical signs. Enteroclysis is more sensitive than barium follow-through in detecting tumors.¹⁰³ Modern multidetector-row CT scanning techniques have significantly improved the detection and staging of these relatively rare tumors.¹⁰⁴ CT

scans and barium studies may be normal in patients with small bowel carcinoids, but larger lesions are characterized by fixation, separation, thickening, and angulation with a starburst appearance because of the desmoplastic reaction produced by the tumor. Somatostatin receptor scintigraphy has a sensitivity of up to 90% for detection of the primary tumor and of 61% to 96% for metastases.¹⁰¹ Wireless capsule endoscopy, push enteroscopy, and DBE have transformed the investigation of small bowel tumors. The proportion of patients in whom the diagnosis is established only at laparotomy has correspondingly decreased.

Adenocarcinoma

The majority (52% to 55%) of adenocarcinomas arise in the duodenum, 18% to 25% in the jejunum, and 13% in the ileum.^{105,106} The mean age of presentation is 55 to 65 years. These tumors have a poor prognosis, largely because of late presentation and delayed diagnosis: the overall 5-year survival rate is 26% to 31% with a median survival time of 20 months.^{105,106} Surgical resection is curative in the appropriate patients without disseminated disease—usually a Whipple's pancreatoduodenectomy for lesions of the first and second parts of the duodenum and segmental resection for tumors at other sites. Chemotherapy and radiotherapy are not effective.

Carcinoid tumor

The small bowel is the most common site for carcinoid tumors, which are predominantly located in the ileum.^{107,108} Duodenal tumors are rare. The mean age of presentation is 64 years, and 40% to 70% of patients will have regional or distant (most commonly hepatic) metastases at diagnosis.^{101,108} However, carcinoid tumors grow slowly and are compatible with prolonged survival even with incurable disease. The overall 5-year survival rate is 61%, approximately double that of small bowel adenocarcinoma.¹⁰⁸ Surgical resection is the only curative treatment. When liver metastases are confined to one lobe, curative hepatic resection can also be carried out in patients with the appropriate functional reserve. The postoperative mortality of patients who undergo resection of the primary tumor or hepatic metastases is 6% with a 5-year survival of up to 87%.¹⁰¹ Resection of the primary tumor and regional lymph nodes is even appropriate in some patients with unresectable hepatic secondaries, as nodal metastases are associated with intense fibrosis and can compromise the vascular supply of the involved small bowel.¹⁰¹ The 5-year survival rate of patients with hepatic metastases is 18% to 32%.¹⁰² Treatment options for patients with unresectable disease also include the somatostatin analogues octreotide and lanreotide, interferon, hepatic artery embolization, and chemotherapy. The serotonin receptor antagonists, cyproheptadine, and ondansetron are used for symptomatic control of the carcinoid syndrome.

Sarcoma

Gastrointestinal stromal tumors (GISTs) are rare soft tissue sarcomas of mesenchymal origin arising from the gastrointestinal tract.^{109,110} These tumors were previously thought to originate from smooth muscle. However, only a minority exhibit the histologic characteristics of true smooth muscle tumors, and most GISTs express the tyrosine kinase growth factor receptor c-KIT, which is detectable by immunostaining

for the CD 117 cell surface receptor. They are therefore now usually clearly distinguishable from leiomyomas and leiomyosarcomas. All GISTs have malignant potential, but tumors smaller than 2 cm in diameter can be regarded as essentially benign. The annual incidence is approximately 10 to 15 per million, and 20% to 30% arise from the small bowel. Most GISTs are diagnosed between the ages of 50 and 70 years. The primary treatment is surgical resection. Conventional chemoradiotherapy is not effective but imatinib, a tyrosine kinase inhibitor, can result in a complete or partial long-term response in up to two thirds of patients with unresectable or metastatic disease.^{111,112} Leiomyosarcomas are slightly more common in the jejunum compared to the ileum and less than one fifth involve the duodenum. Surgical resection does not usually entail lymph node resection as these tumors rarely metastasize to the regional lymph nodes.⁹⁸

Lymphoma

Most B-cell lymphomas occur in the ileum, whereas the majority of T-cell lymphomas are jejunal.^{113,114} One-quarter of B-cell and 50% of T-cell tumors are multifocal with up to 10 lesions. Two thirds of primary small bowel lymphomas are of the B-cell type, the remainder being T-cell in origin.¹ Approximately 50% of T-cell lymphomas are associated with enteropathy, mainly celiac disease. Twenty percent of B-cell lymphomas are low-grade tumors of mucosa-associated lymphoid tissue (MALT lymphomas). Treatment is primarily by surgical resection, but the optimal treatment strategy with adjuvant chemoradiotherapy has not yet been established.^{114,115} T-cell tumors have a worse prognosis, with 5-year survival rates of 25% compared to 50% for high-grade and 75% for low-grade B-cell lymphomas, respectively.¹¹³ The overall 5-year survival in a population-based study of 328 primary small bowel tumors over a 25-year period was 54%.¹¹⁶

Obscure gastrointestinal bleeding

Obscure gastrointestinal bleeding is said to occur when bleeding from the gastrointestinal (GI) tract continues despite a normal EGD, colonoscopy, and barium follow-through or enteroclysis.^{11,117,118} It accounts for approximately 5% of cases of GI blood loss and can be classified into overt and occult subtypes, depending on whether or not bleeding is clinically evident. Some patients, initially

KEY POINTS

The Small Bowel

- Celiac disease, small bowel bacterial overgrowth, and chronic pancreatitis are the main causes of malabsorption in older patients.
- Celiac disease has a prevalence of 1%, and 60% to 70% of patients are asymptomatic.
- Small bowel bacterial overgrowth occurs in 52% to 70% of symptomatic and 14% to 25% of asymptomatic elderly individuals.
- Crohn's disease has a bimodal distribution with a second peak in the elderly population.
- The mortality rate in acute mesenteric ischemia is still very high at 54% to 77%.
- Small bowel tumors are rare and account for only 1% to 2.4% of all gastrointestinal neoplasms.
- Wireless capsule endoscopy and double-balloon enteroscopy have transformed the investigation of small bowel disease.

thought to have obscure bleeding, actually have pathology that is within the reach of conventional endoscopes but that has been overlooked. Cameron's ulcers (ulcers within a hiatus hernia), Dieulafoy lesions, collapsed esophageal or fundal varices, angioectasias, and gastric antral vascular ectasias can be missed at EGD. Even experienced colonoscopists fail to detect small neoplasms or angioectasias on occasion. Hence, a second-look EGD (and less commonly a colonoscopy) is recommended before assuming that the small bowel is the source of blood loss. Technologic advances that permit endoscopic evaluation of the whole of the small bowel have altered the management of these patients since the early 2000s. The use of radionuclide studies and mesenteric angiography has correspondingly declined. The classification of GI bleeding has also changed and the conventional terms *upper* and *lower GI bleeding* to denote a source above and below the ligament of Treitz have been replaced. Bleeding above the ampulla of Vater, which is within the reach of an EGD, is termed *upper GI bleeding*. *Mid-GI bleeding* defines a bleeding source in the small bowel from the ampulla of Vater to the terminal ileum and is currently best investigated by wireless capsule endoscopy and enteroscopy. *Lower GI* or *colonic bleeding* is assessed by colonoscopy.

Vascular ectasias are probably the most common reason for mid-GI obscure blood loss in elderly people. Nonsteroidal induced small intestinal ulcers, small bowel tumors, small bowel varices, Crohn's disease, and aortoenteric fistulas are the other causes encountered. Radionuclide scans and mesenteric angiography are being replaced by the new modalities. Patients with obscure bleeding should first undergo wireless capsule endoscopy that has a diagnostic yield of 40% to 80%. If negative, a repeat examination should be considered or, depending on availability, DBE should be carried out (diagnostic yield 75%). Intraoperative enteroscopy, the most accurate (diagnostic yield 70% to 93%) but also the most invasive technique, is usually reserved for critically ill patients with persistent bleeding or when other modalities have failed to reveal the bleeding source. A bleeding vascular lesion in the proximal jejunum may be amenable to therapy via a push enteroscope, but a more distal source (hitherto usually dealt with by surgery) is now accessible via the double balloon technique.

ANATOMY

The colon is a large, hollow organ that is derived embryologically from the primitive midguts and hindguts.¹ The appendix and transverse and sigmoid colons have mesenteries, whereas the ascending and descending colons do not. Like the stomach and small intestine, the colon has both circular and longitudinal smooth muscle layers, but uniquely, the longitudinal muscle of the colon is separated into three bundles known as taenia. The configuration of the taenia causes the colon to be divided into haustral folds, which presumably help to slow the passage of fecal material and thus facilitate absorption.

The superior mesenteric artery supplies the right colon to the midtransverse colon, whereas the inferior mesenteric artery supplies the left colon.² The anorectum derives its blood supply from branches of the internal iliac arteries.³ In the distal transverse to mid-descending colon, the superior and inferior mesenteric arteries are linked by a series of anastomoses known as the marginal artery of Drummond. This anatomic arrangement increases the vulnerability of this area to ischemic damage.

Innervation of the colon is via the autonomic nervous system and the enteric neurons.⁴ Parasympathetic innervation is by the vagus nerve in the right colon and by sacral parasympathetics from the second, third, and fourth sacral nerves. Sympathetic innervation is derived from the lowest cervical to the third lumbar nerves via the splanchnic nerves. However, colon function may persist even after vagal or splanchnic interruption because of the presence of a well-developed enteric nervous system, which can function in the absence of extrinsic innervation.

FUNCTIONS AND SYMPTOMS

The principal functions of the colon and rectum are to store fecal wastes for prolonged periods of time and to expel them in a socially appropriate manner. Storage is facilitated by adaptive compliance of the bowel and by muscular contractions of colonic smooth muscle, which retard the forward movement of stool, thereby promoting electrolyte and water absorption and reducing stool volume. Forward movement occurs principally by relatively infrequent peristaltic contractions, which move intraluminal contents over long distances. Continence is maintained by recognition of rectal filling and coordinated function of the anal sphincters and pelvic floor muscles to defer defecation until socially appropriate. Colonic motility and transit in healthy elderly people are similar to that in younger individuals,⁵ whereas aging is associated with diminished anal sphincter tone and strength and a less compliant rectum.^{6,7} The latter changes may lead to greater susceptibility to fecal incontinence in elderly people (see Chapter 103).

The major symptoms of colonic and rectal disorders are constipation, diarrhea, pain, and rectal bleeding. The conditions that produce these symptoms are not unique to the elderly population; those occurring with increased frequency in elderly people include diverticulosis, neoplasms,

ischemic colitis, vascular ectasias, fecal incontinence, constipation, and antibiotic-associated diarrhea and colitis. Inflammatory bowel diseases occur in all age groups, but onset of these diseases is less likely in the elderly population. In short, a challenge of evaluating older people with bowel symptoms is that these not uncommon complaints can arise from disorders that range from the minimally disruptive to the likely fatal, with a higher probability of worse illness as age increases. As with any other illness, disease in the colon can present in elderly people who are frail as delirium, falls, or immobility.

DIAGNOSTIC TESTING

Radiology

CONTRAST STUDIES

Contrast examination of the large intestine has traditionally been done by using barium sulfate in either a single- or a double-contrast technique in which a thickened barium suspension is used to coat the mucosa followed by insufflation to expand the viscus. Alternatively, water-soluble contrast agents can be used if perforation is suspected.

The single-contrast technique is preferred when studying patients with suspected obstruction, diverticulitis, or fistula, whereas the double-contrast technique is preferred for demonstrating fine mucosal lesions and neoplasms. Although there continues to be some controversy concerning the choice of barium contrast or colonoscopy when investigating colonic diseases, most clinicians favor colonoscopy for its greater sensitivity and opportunity for biopsy and therapy. Contrast studies may be indicated in cases where severe stricturing disease or adhesions make colonoscopy hazardous, where conditions such as diverticulitis are suspected, if the location and nature of a colonic obstruction requires assessment, and if functional and structural information is required. A barium enema should not be attempted when increases in colon pressure may worsen the patient's condition, for example, in patients with suspected toxic megacolon or those with peritoneal signs that suggest ischemic colitis.

When patients complain of constipation or a recent change in bowel habit, barium radiographs complement sigmoidoscopy in detecting organic causes and are also useful in diagnosing functional megacolon and megarectum. Complete filling of the colon with barium is neither necessary nor desirable in patients with megacolon. However, conventional barium studies provide limited information about colonic motor function in most patients with chronic constipation.⁸ Moreover, they are frequently inadequate in frail or hospitalized elderly patients.^{9,10}

IMAGING TECHNIQUES

Abdominal computed tomography

This procedure allows visualization of the thickness of the bowel wall, the solid viscera within the abdomen, the mesenteries, and soft tissues adjacent to the bowel. It offers a modest advance in the diagnosis of diverticulitis by

demonstrating inflammation of pericolic fat, abscesses that may contain collections of fluid and gas, and intramural sinus tracts. Fistulas to other organs can be identified when gas is found within the bladder or vagina. It also can identify extension of disease at a distance from the colon, including unsuspected intra-abdominal abscesses.

Computed tomography (CT) is also valuable when evaluating and managing complications of Crohn's disease, including abscesses, fistulas, and involvement of psoas muscles and ureters, and occasionally for percutaneous drainage of collections. Other complications, including sacral osteomyelitis, cholelithiasis, nephrolithiasis, and vascular necrosis of the femoral head associated with corticosteroid therapy, can also be diagnosed.

In appendicitis (and cecal diverticulitis, which is usually misdiagnosed as appendicitis), computed tomography may augment the clinical diagnosis by showing the periappendicular inflammatory process and differentiating phlegmon from abscess.¹¹ Occasionally, appendicoliths are identified, which are considered pathognomonic of appendicitis when associated with periappendicular inflammatory signs.

CT colonography is a new technique devised to detect colon polyps for screening purposes. Detection rates for colonic polyps of greater than 6 mm are similar to colonoscopy, but the test has low sensitivity for smaller polyps.¹² The use of 3-dimensional evaluation in addition to 2-dimensional evaluation may reduce perceptual errors.¹³ CT colonography is now recommended as an alternative for colon polyp screening in the United States.

Anal and rectal endosonography

Endoscopic anal and rectal ultrasonography accurately delineates the layers of the rectal wall, the internal and external anal sphincters, and the levator muscles.¹⁴ It can be used to evaluate pelvic floor structures in patients with fecal incontinence to detect occult sphincter injuries arising from childbirth or other conditions associated with potential injury to continence mechanisms.^{15,16}

Endoscopic ultrasonography is a rapid, minimally invasive technique used to image rectal polyps, focal malignancy within polyps, tumor masses penetrating into the bowel wall, and extramural lesions such as prostatic tumors and ovarian lesions. Perirectal fistulas and abscesses can also be evaluated (including determining whether there is destruction of pelvic muscles). It is considered the reference standard for the preoperative staging of rectal and anal cancers with relatively high accuracy in categorizing tumors and lymph nodes.¹⁷

Colonoscopy and flexible sigmoidoscopy

These procedures are usually performed in the prepared colon except when evaluating diarrheal illnesses. Colonoscopic examinations provide unparalleled evaluation of the mucosal surfaces and opportunities for biopsy and therapy. These include diagnosis and determining extent of inflammatory bowel disease, evaluation of patients with overt or occult gastrointestinal bleeding, evaluation of chronic watery diarrhea, endoscopic sampling and removal of polyps, decompression of sigmoid volvulus or functional megacolon, and ablation of vascular lesions. Colonoscopy is generally done under conscious sedation, whereas flexible sigmoidoscopy usually is not.¹⁸ In many elderly patients,

the physician must be aware of their increased sensitivity to sedatives and analgesic medications. As elderly people are susceptible to hypotension and respiratory depression, careful monitoring of the patient during the procedure is especially important. Even so, such procedures are generally safe in experienced hands and when done in units that monitor blood gases and cardiorespiratory functions. Major complications include bleeding and perforation, which should not occur more than 2 or 3 times in 1000 routine diagnostic procedures.

Histopathology

Mucosal biopsies are often indicated when evaluating undiagnosed diarrhea, in longstanding ulcerative colitis during surveillance for precancerous dysplasia, in obtaining tissue for viral culture, and in evaluating polypoid or ulcerated lesions. In inflammatory disorders of the colon and rectum, biopsies serve to establish the presence, extent, and distribution of colitis and to differentiate ulcerative from Crohn's colitis and these disorders from other inflammatory conditions such as infectious colitis. Biopsies should be obtained from endoscopically normal and abnormal areas, as characteristic changes may be patchy and therefore missed if too few biopsies are obtained. This is especially true in pseudomembranous, collagenous, and lymphocytic colitis in which the distal colon may be spared. As hypertonic phosphate enemas and purgative laxatives may induce mucosal changes that can be mistaken for mild colitis, they should be avoided when evaluating suspected inflammation of the colon.

Fecal occult blood testing

Fecal occult blood tests (FOBTs) identify hemoglobin or altered hemoglobin compounds in the stool. Food containing peroxidases, such as melon and uncooked broccoli, horseradish, cauliflower, and turnips, may produce false positive results, whereas reducing agents such as ascorbic acid may decrease sensitivity.¹⁹ Tests that extract the protoporphyrin from hemoglobin, such as Hemo Quant, are more specific and are quantitative but are also more time-consuming and expensive. Rehydration of Hemoccult slides increases sensitivity but decreases specificity and is not recommended. A weakly positive slide may become negative after 2 to 4 days of storage. Oral iron supplements do not interfere with any of these tests.

COLONIC DIVERTICULOSIS

Colonic diverticula are herniations of colonic mucosa through the smooth muscle layers. Diverticula occur in areas of anatomic weakness of the circular smooth muscle created by penetration of blood vessels to the submucosa. They are most commonly found in the sigmoid and descending colons and rarely, if ever, in the rectum.²⁰

This disorder has been recognized with increasing frequency in modern Western countries.²¹ Colonic diverticula are present in about one third of persons by age 50 and about two thirds by age 80. Dietary fiber insufficiency and the increased longevity of modern Western populations have been hypothesized to explain the increased prevalence of diverticulosis. Dietary factors may promote increased colonic motor activity and intraluminal pressures,

whereas aging may lead to structural weakness of the colonic muscle.²⁰ As diverticula are asymptomatic in most individuals, caution must be taken before attributing nonspecific gastrointestinal symptoms to them.²²

Painful diverticular disease

Painful diverticular disease is characterized by crampy discomfort in the left lower abdomen. Symptoms are often associated with constipation or diarrhea and with tenderness over the affected areas. These symptoms are similar to those of irritable bowel syndrome and partial bowel obstruction due to tumors or ischemia. Studies have shown that these patients have altered motor activity in the segments containing diverticula, which are associated with reporting of abdominal pain.²³ In contrast to diverticulitis, there is no fever, leukocytosis, or rebound tenderness.

Diverticulitis

Diverticulitis develops in approximately 10% to 25% of individuals with diverticulosis who are followed for 10 years or more; however, less than 20% of these patients require hospitalization. Inflammation begins at the apex of the diverticulum when the opening of a diverticulum becomes obstructed (e.g., with stool), leading to microperforation or macroperforation of a diverticulum.²⁴ The presence of a palpable mass, fever, leukocytosis, and/or rebound tenderness indicates an inflammatory process, which often remains localized in the adjacent pericolic tissues but may progress to a peridiverticular abscess.²⁵ Other complications include fibrosis and bowel obstruction, fistula formation to the bladder, vagina, or adjacent small intestine, and free perforation with peritonitis. The frequency of complications rises to about 60% with recurrent attacks of diverticulitis.

Making a clinical distinction between painful diverticular disease and diverticulitis carries a sizable rate of error.²⁴ In an elderly or debilitated patient, the absence of fever, leukocytosis, or rebound tenderness does not exclude diverticulitis.²⁵

Recently, a disorder characterized by localized inflammation associated with diverticulosis (SCAD syndrome) has been described in older symptomatic patients.²⁶ Symptoms appear after the age of 40 years and are most often characterized by rectal bleeding, diarrhea, and abdominal pain.

Other disorders such as carcinoma, inflammatory bowel disease, and ischemia may mimic symptomatic diverticular disease. Diagnostic studies include barium enema, CT, ultrasonography, and colonoscopy. In most cases of suspected diverticulitis, barium enema should be delayed for about a week to allow some resolution of the inflammatory process. A single-contrast study should be performed cautiously to minimize the risk of perforation. Radiographic findings suggesting diverticulitis include longitudinal fistulas connecting diverticula over segments of colon, fistula into adjacent organs, a fixed eccentric defect in the colon wall, contrast outside the lumen of the colon or diverticulum, and intraluminal defects representing abscesses.²⁰ CT and ultrasonic imaging of the abdomen provide superior definition of colonic wall thickness and extraluminal structures and are the procedures of choice at the time of initial evaluation. Colonoscopy is a less attractive option during an acute episode and is best employed to exclude tumors or other conditions if other diagnostic tests are inconclusive.

The treatment of painful diverticular disease is designed to reduce symptoms based on smooth muscle spasm, in contrast to the treatment of diverticulitis, which is designed to treat bacterial infection (Table 81-1). Patients with severe pain, nausea and vomiting, or complications should be hospitalized and given intravenous antibiotics until clinical improvement occurs.

Surgery is recommended for patients with diverticulitis who fail to respond to medical therapy within 72 hours, for immunocompromised patients, and those who have fistula to the bladder with pneumaturia and urinary infection or fistula to the vagina with discharge of stool into the vagina. Although some surgeons recommend elective sigmoid resection after two episodes of diverticulitis, others favor a more conservative approach.²⁷ A one-stage operation, in which the diseased segment of bowel is resected and continuity restored by a primary anastomosis, is preferred.²⁸ In cases of generalized peritonitis or emergent surgery for perforation with abscess or high-grade obstruction, a two-stage procedure requiring a diverting colostomy should be used.²⁹ Large abscesses can often be drained percutaneously by an interventional radiologist using CT or ultrasonography as a guide.^{30,31} Elective surgery can then be performed after 2 to 3 weeks of antibiotic therapy, often allowing for a single-stage resection.

Emergent surgery is required for generalized peritonitis or persistent high-grade bowel obstruction. Most patients with complicated diverticular disease require surgery, even if clinical recovery occurs, since there is a high risk of recurrent attacks.

Table 81-1. Medical Treatment of Diverticular Disease

Measure	Painful Diverticulosis	Diverticulitis
Diet	Increase fiber	Reduce fiber (or NPO)
Bulk laxatives	Sometimes effective	Not indicated
Analgesics	Avoid narcotics	Avoid morphine; meperidine is best
Antispasmodics	Propantheline bromide (15 mg tid); Dicyclomine hydrochloride (20 mg tid); Hyoscyamine sulfate (0.125 mg–0.250 mg q 4 h)	Not indicated
Antibiotics	Not indicated	Oral: Amoxicillin/clavulanate K ⁺ (875/125 mg bid) Ciprofloxacin (500 mg bid) and metronidazole 500 mg tid Parenteral 1. Gentamicin or tobramycin (5 mg/kg/day) plus clindamycin (1.2–2.4 g/day) or 2. Levofloxacin 500 mg/day and metronidazole (500 mg q 8 h) 3. Piperacillin-tazobactam (3.375–4.5 gm q 6 h)

Updated and modified from Wald²⁰ with permission.

Most patients with localized inflammation associated with diverticulosis respond with long-term resolution of the disease to 5-aminosalicylate therapy. On occasion, spontaneous remissions may occur or persistent chronically active disease may require resective surgery.²⁶

Bleeding

Bleeding associated with diverticula is typically brisk and painless and often arises from the proximal colon. Bleeding is thought to occur when a fecolith erodes into a vessel in the neck of the diverticulum or there is rupture of the penetrating arteriole in its course around the diverticular sac.²⁰

An important indication for emergent colonoscopy is to identify the source of bleeding in patients with diverticula, as other lesions not seen by contrast studies may be the actual source. If bleeding is brisk, a bleeding scan or selective mesenteric angiography can often locate the site of bleeding; superselective embolization of distal arterial branches has been demonstrated to be highly effective and relatively safe (<20% ischemia rates)³² (see Lower Gastrointestinal Bleeding).

APPENDICITIS

Elderly patients with appendicitis are at increased risk (about 60%) for perforation. They have a higher mortality and often do not exhibit a fever or elevated white blood cell count.³³

Classically, the onset of abdominal pain is abrupt, begins in the midabdomen, relocates to the right lower quadrant, and is often associated with nausea, vomiting, and fever. Physical examination characteristically reveals signs of local peritonitis in the right lower quadrant, and the white blood cell count is frequently elevated. The differential diagnosis includes pyelonephritis, Crohn's disease, gastroenteritis, pelvic inflammatory disease, ovarian cyst, and cecal diverticulitis. In elderly patients, appendicitis may occur in association with colon cancer in which low-grade obstruction results in distention of the appendix and mimics true appendicitis.

If the diagnosis is uncertain, ultrasonography has been shown to have positive and negative predictive values of about 90% for appendicitis and is also useful in identifying another cause of symptoms in patients with right lower quadrant pain.³⁴ One sonographic criterion for acute appendicitis is visualization of a noncompressible appendix with a diameter of greater than 6 mm.

INFECTIOUS DISEASES

Clostridium difficile

Clostridium difficile is responsible for approximately 3 million cases of diarrhea and colitis each year and is the most common cause of nosocomial diarrhea in the United States.³⁵

The vast majority of cases are associated with two protein exotoxins (A and B) produced by *C. difficile*. Toxin A is an enterotoxin that triggers diarrhea, epithelial necrosis, and a characteristic inflammatory process in animals, whereas toxin B is a cytotoxin in tissue culture but does not by itself cause toxicity in animals.³⁶ The disease spectrum ranges from mild diarrhea, with little or no inflammation, to severe colitis often associated with pseudomembranes,

which are adherent to necrotic colonic epithelium. Acquisition of *C. difficile* occurs most frequently in elderly persons in hospitals or nursing homes, potentially because of environmental contamination with *C. difficile* and spores carried on the hands of hospital or institutional personnel.³⁷ Acquisition is often asymptomatic but may have clinical consequences if elderly patients receive certain antibiotics or chemotherapeutic agents. Other possible risk factors include surgery, intensive care, nasogastric intubation, and length of hospital stay. A smaller number of patients have antibiotic-associated diarrhea but no evidence of *C. difficile* infection.

Although virtually all antibiotics have been implicated, the most common are cephalosporins, ampicillin or amoxicillin, and clindamycin.³⁸ Less commonly mentioned antibiotics include other penicillins, erythromycin, and fluoroquinolones.

Currently, the United States, Canada, and Europe are experiencing an outbreak of a new virulent strain of *C. difficile* designated as ribotype 027.³⁹ This strain has been shown to be resistant to the newer fluoroquinolones, as is the case of other existing strains of *C. difficile*.³⁵

The typical clinical picture of *C. difficile*-associated colitis includes nonbloody diarrhea, lower abdominal cramps, fever, and leukocytosis. Fever is usually low grade although, on occasion, it can be quite high. In severe cases, dehydration, hypotension, hypoproteinemia, toxic megacolon, or even colonic perforation may occur.

In severely ill patients, the diagnostic test of choice is flexible sigmoidoscopy or colonoscopy. As the distal colon is involved in the majority of cases, flexible sigmoidoscopy is usually satisfactory; however, changes may be confined to the right colon in up to one third of cases, making colonoscopy necessary if less extensive procedures do not confirm a suspected diagnosis. The yellowish-gray pseudomembranes are densely adherent to the underlying colonic mucosa, interspersed with mucosa that appears normal. Mucosal biopsies may exhibit characteristic findings of epithelial necrosis and micropseudomembranes ("volcano lesions") even when pseudomembranes are not grossly visible. Endoscopy particularly has a role in severely ill patients who present atypically and therefore require a rapid diagnosis.⁴⁰

Several tests identify *C. difficile* or its toxin. The enzyme immunoassay (EIA) for toxin A and/or B is the preferred test to detect toxin. On average, EIA tests range in sensitivity from 87% to 96% in confirmed cases of *C. difficile* diarrhea.⁴¹ Thus it should be emphasized that a negative EIA test does not exclude a diagnosis of *C. difficile* colitis.

The offending drug should be discontinued if possible. If symptoms persist, patients who are not seriously ill should receive oral metronidazole 500 mg tid for 7 to 10 days. Patients who are seriously ill and those with complicated or fulminant infections should receive oral vancomycin 125 mg PO qid for 7 to 10 days.⁴² If oral intake is not possible, metronidazole 500 mg IV q6h is given until oral administration can be accomplished. Metronidazole and vancomycin appear to be therapeutically comparable in nonseriously ill patients, but metronidazole costs less and there are current concerns about vancomycin-resistant enterococcus.⁴³ In general, fever resolves within 24 hours and diarrhea decreases within 4 to 5 days.

Relapses average about 20% to 25% following successful treatment with either agent,⁴⁴ often involving sporulation,

Table 81-2. Practice Guidelines for Prevention of *Clostridium difficile* Diarrhea

1. Limit the use of antimicrobial drugs.
2. Wash hands between contact with all patients.
3. Use enteric (stool) isolation precautions for patients with *C. difficile* diarrhea.
4. Wear gloves when contacting patients with *C. difficile* diarrhea/colitis or their environment.
5. Disinfect objects contaminated with *C. difficile* with sodium hypochlorite, alkaline glutaraldehyde, or ethylene oxide.
6. Educate the medical, nursing, and other appropriate staff members about the disease and its epidemiology.

From Fekety,⁴⁰ with permission.

which leads to relapse within 4 weeks after completion of successful treatment. These episodes invariably respond to another course of antibiotic therapy. About 5% to 10% of patients have multiple relapses. In such individuals, vancomycin in conventional doses should be followed by a 3-week course of cholestyramine 4 g tid and/or Lactinex 500 mg PO qid, or vancomycin 125 mg PO every other day. Others advocate a 6-week schedule consisting of a 2-week course of vancomycin given daily in the standard dose, a 2-week course in the same dose given every other day, followed by a 2-week course at the same dose given every third day. *Saccharomyces boulardii* is a nonpathogenic yeast which inhibits the binding of toxin A to rat ileum, with consequent prevention of enterotoxicity.⁴⁵

Guidelines for prevention of *C. difficile* diarrhea and colitis are based upon a few simple practices and attitudes and are shown in Table 81-2.⁴⁰

Shigella

These organisms consist of four groups: (1) *Shigella dysenteriae*, (2) *S. flexneri*, (3) *S. boydii*, and (4) *S. sonnei*, the last of which accounts for most clinical infections in Western countries. In contrast to other enteric pathogens, very few organisms are needed to produce infection, which is spread by fecal-oral transmission between humans and which continues to occur despite high standards of water purification and sewage disposal. At least 30 gene products are involved in *Shigella* invasion and its intercellular spread. Disease is caused by invasion of colonic epithelial cells, perhaps in part mediated by cytotoxins produced by *S. dysenteriae* and *S. flexneri*, but enterotoxins may also contribute to early symptoms of nondysenteric diarrhea.⁴⁶ Enterotoxins similar to Shigalike toxins secreted by enterohemorrhagic *Escherichia coli* are believed to mediate the hemolytic-uremic syndrome associated with severe colitis caused by *S. dysenteriae* type I.

SYMPTOMS

Colitis is heralded by the passage of bloody mucoid stools associated with urgency, tenesmus, abdominal cramping, fever, and malaise. The frequency of stools is highest during the first 24 hours of illness and gradually diminishes thereafter.

DIAGNOSIS

Stool examination reveals numerous polymorphonuclear cells, and leukocytosis is common. Stool culture grown on selective media is the definitive diagnostic study. Sigmoidoscopy is usually not necessary, but if done, will demonstrate

a friable hyperemic mucosa. Barium contrast studies are not indicated.

TREATMENT

If the illness is mild and self-limited, antibiotics can be withheld. As resistance to sulfonamides, ampicillin, tetracycline, and even trimethoprim-sulfamethoxazole is now common, treatment with a fluoroquinolone (e.g., ciprofloxacin 500 mg twice daily for 5 days) is indicated in frail or otherwise debilitated patients with acute disease to shorten the illness and the period of fecal excretion of the organism.⁴⁷ Antidiarrheal agents prolong the clinical illness and carrying of the organism and should not be administered.⁴⁸ The development of a chronic carrier state is rare and difficult to treat.

Pathogenic *Escherichia coli* that cause colitis

These organisms commonly cause disease in developed countries and are a major cause of diarrhea in tourists visiting underdeveloped countries. As older individuals increasingly engage in overseas travel, these organisms can be a major impediment to a successful trip.

Of the five major classes of pathogenic *E. coli*, only enteroinvasive (EIEC) and Shiga toxin-producing *E. coli* (STEC) primarily involve the colon. Both produce a clinical illness similar to that of shigellosis. Once thought to be a pathogen restricted to developing countries, STEC has been shown to produce diarrhea in the United States and is a relatively uncommon cause of traveler's diarrhea. It is more difficult to identify in stool cultures and is not a reportable illness. The clinical illness is generally milder than with shigellosis. A reasonable approach is to treat with a fluoroquinolone similar to treatment for shigellosis.³⁵

Preventive measures include eating cooked food only while it is still hot and avoiding local water, including fruits and vegetables washed with local water. In elderly tourists, the disease can be shortened by prompt use of a fluoroquinolone.⁴⁶

Shiga toxin-producing *E. coli* 0157:H7

This organism has been identified as a major pathogen in the United States and Canada, causing approximately 70,000 cases in the United States annually.³⁵ In addition to sporadic infections, epidemics have been traced to consumption of undercooked and raw ground beef, as healthy cattle serve as the primary reservoir for Shiga toxin-producing strains. Infections have also been associated with exposure to patients with bloody diarrhea, contaminated water supplies, and nonpreserved apple cider. Clinical manifestations include nonbloody diarrhea, hemorrhagic colitis, and hemolytic-uremic syndrome (HUS).⁴⁹ Unlike most bacterial enteric diseases, *E. coli* 0157:H7 is often characterized by low-grade fever or the absence of a fever.⁵⁰ The pathogenesis of colitis has been linked to Shigalike toxins (verocytotoxins 1 and 2), which bind to a glycolipid on the surface of colonocytes, but adherence factors may also play a role. Older age is both a risk factor for this infection and increases the risk of HUS and death. It is generally believed that antibiotics are not indicated for active infections and appear to predispose to hemolytic-uremic syndrome.⁴⁹

An important emerging group of related pathogens are the non-0157 toxin-producing *E. coli*, which can produce

an illness similar to 0157:H7 strains.⁵¹ Indeed, in Europe, a majority of STEC strains belong to the non-0157 serogroup.

Campylobacter species

Campylobacter jejuni and *C. coli* are among the most common bacterial causes of diarrhea and can be manifested by gastroenteritis, pseudoappendicitis, or colitis. These organisms are usually transmitted from animals to humans through contaminated food and water and sometimes by direct contact with pets. Constitutional symptoms usually precede diarrhea and abdominal cramps by up to 24 hours, and colitis may be characterized by fever and dysentery lasting for a week or more. Diagnosis is made by stool culture. Convalescent carriage up to a mean of 5 weeks is common after the onset of illness and is significantly reduced by antimicrobial treatment.

Although the infection is usually self-limited, antibiotics may be given if the illness is severe or in patients who are immunosuppressed.⁵² Treatment consists of erythromycin or fluoroquinolones; macrolides such as azithromycin and clarithromycin show excellent *in vitro* activity. Resistance rates to fluoroquinolones of up to 88% have been reported in Europe and Asia. In areas of high resistance, azithromycin 500 mg daily for 3 days is an effective alternative.

Entamoeba histolytica

This organism remains a primary cause of dysentery, which may be complicated by fulminant colitis, toxic megacolon, bleeding, stricture, and perforation. Severe disease is more common in elderly people and in patients who are immunosuppressed or debilitated.⁵³ The disease is typically acquired by ingesting cysts from contaminated water or fresh vegetables but can also be transmitted venereally through sexual practices that promote fecal-oral transmission. Studies on germ-free animals suggest that intestinal disease does not develop unless bacteria are present. This may partly account for the effectiveness of metronidazole, which is also active against anaerobic bacteria.

Three separate stool specimens should be examined if the diagnosis is suspected. A wet preparation should be performed within 30 minutes of passage to look for motile trophozoites, which may contain ingested red blood cells. A formalin-ethyl acetate concentration preparation should be examined for cysts. Barium, bismuth, kaolin compounds, magnesium hydroxide, castor oil, and hypertonic enemas all interfere with the ability to detect the parasite in stools.⁵³

Colonoscopy may reveal erythema, edema, friability of the mucosa, and scattered ulcers 5 to 15 mm in diameter, covered with a yellow exudate. These ulcers may occur anywhere in the colon but are most common in the cecum and ascending colon. Biopsies from the edge of these ulcers may reveal typical "hour-glass" ulcers containing trophozoites. Cathartics and enemas should not be used because they interfere with identification of the parasite.

As these techniques may miss identifying the parasite, serologic tests for antiamebic antibodies should also be obtained in suspected cases. The indirect hemagglutination assay (IHA) is positive in 75% to 90% of patients with amebic dysentery and in virtually all patients with amebic liver abscesses. The IHA remains positive for years after treatment of invasive amebiasis.⁵³

Treatment of acute amebic dysentery consists of metronidazole 750 mg three times daily for 5 to 10 days or, if not tolerated orally, 500 mg q 6 h by the intravenous route.⁵⁴ This should be followed by luminal acting oral drugs such as paromomycin 25 to 35 mg/kg in 3 doses daily for 7 days or iodoquinol 650 mg three times daily for 20 days to eliminate all cysts and prevent possible relapse.

Cytomegalovirus

Cytomegalovirus (CMV) is a member of the herpes virus family, which enters a lifelong latent phase after primary infection in immunocompetent persons. In patients who are immunocompromised with diminished T-cell function, reactivation may occur and may become persistent, with reappearance of IgM anti-CMV antibodies in the serum. Among the gastrointestinal syndromes associated with CMV are focal and diffuse colitis.

CMV colitis is associated with severe small-volume diarrhea, abdominal pain, and fever. Colonoscopy may reveal variable degrees of focal erythema, petechial hemorrhage, erosions, and in advanced cases, scattered ulcers. Mucosal biopsy may reveal characteristic intranuclear inclusions ("owl-eye" lesions) or cytoplasmic inclusions in vascular endothelial cells. In cases in which a biopsy is not diagnostic, polymerase chain reaction assay or *in situ* hybridization techniques may be helpful, together with serum IgM CMV-specific antibodies.

The treatment of choice is ganciclovir (5 mg/kg IV q 12 h for 21 days) to achieve remission.⁵⁵ For patients who relapse after discontinuation of the drug, chronic maintenance therapy (6 mg/kg five times per week) may be instituted. Valganciclovir is as effective as IV ganciclovir because of improved bioavailability over previous oral agents. As the drug has hematologic side effects such as neutropenia, regular blood counts should be obtained. Human immunodeficiency virus (HIV)-infected patients with CMV colitis should be placed on maintenance therapy indefinitely. Foscarnet is used in patients who do not respond to ganciclovir or who cannot tolerate its toxicity.

INFLAMMATORY BOWEL DISEASE

Both ulcerative colitis and Crohn's disease are more common in early adulthood but are found with increased frequency in older adults. In part, this is because increasing numbers of patients with inflammatory bowel disease (IBD) now live into old age. In addition, both ulcerative colitis and Crohn's disease exhibit a bimodal age of onset,^{56,57} the peak incidence occurring in the third decade and a minor later peak between the ages of 50 and 80 years; more than 10% of cases have their onset after the age of 60. This pattern persists even when other diseases that mimic inflammatory bowel disease, such as ischemic colitis and infectious causes, have been excluded. The reasons for this bimodal pattern are unknown.

ULCERATIVE COLITIS

Ulcerative colitis is a chronic inflammatory process of unknown cause that affects the mucosa and submucosa of the colon in a continuous distribution. Enhanced humoral immunity is more evident in ulcerative colitis than Crohn's disease and probably reflects disturbed immunoregulation

leading to unrestrained T-cell activation and cytokine release.⁵⁸

HISTOPATHOLOGY

Histologically, there are diffuse ulcerations and epithelial necrosis, depletion of mucin from goblet cells, and a polymorphonuclear and lymphocytic infiltration involving the superficial layers of the colon to the muscularis mucosa. The finding of crypt microabscesses is characteristic but not pathognomonic. The inflammatory process invariably involves the rectum and extends proximally for variable distances but does not involve the gastrointestinal tract proximal to the colon. Involvement of the rectum only is designated ulcerative proctitis, whereas disease extending no further than the splenic flexure is designated as left-sided disease.

SYMPTOMS AND SIGNS

Symptoms commonly are similar to those seen in younger persons.⁵⁹ The severity of ulcerative colitis may be classified as mild, moderate, and severe and is generally proportional to the extent of colonic inflammation (Table 81-3). Most patients exhibit diarrhea, with or without blood in the stools, although older patients with proctitis only occasionally have constipation or hematochezia. Systemic manifestations occur during more severe attacks and carry a poorer prognosis. Indeed, despite the occurrence of less extensive disease in older patients, they more often have a severe initial attack and have higher mortality and morbidity than do younger patients.⁶⁰

Toxic megacolon is a feared complication of ulcerative colitis, which occurs more frequently in elderly patients. Abdominal radiographs show colonic dilation, often to impressive proportions, and patients may exhibit mental confusion, high fever, abdominal distention, and overall deterioration.⁶¹

Extraintestinal manifestations may occur in ulcerative colitis, including arthralgias, erythema nodosum, pyoderma gangrenosum, uveitis, and migratory polyarthritis. These disorders occur less frequently than in Crohn's disease and are generally associated with increased disease activity.

DIAGNOSIS

The diagnosis is made by sigmoidoscopy and rectal mucosal biopsies since the disorder invariably involves the rectum. The extent of the disease is determined by colonoscopy or barium radiography, both of which should be avoided in patients who are severely ill because of the danger of

Table 81-3. Proposed Criteria for Assessment of Disease Activity in Ulcerative Colitis*

Factor	Severe	Mild
Bowel frequency	>6 daily	<4 daily
Blood in stool	++	+
Temperature	>37.5° C on 2 of 4 days	Normal
Pulse rate (beats/min)	>90	Normal
Hemoglobin (allow for transfusion)	<75%	Normal or near normal
Erythrocyte sedimentation rate (mm in 1 hr)	>30	<30

*Moderate disease is intermediate between severe and mild classifications. (Data from Truelove and Witts: *Br Med J* 1955;2:4941-8, with permission.)

inducing perforation or toxic megacolon. The characteristic findings are diffuse erythema, granularity, and friability of the mucosa without intervening areas of normal mucosa. Inflammatory pseudopolyps indicate more severe erosion of the mucosa and must be distinguished from true polyps.

Particularly in elderly people, it is important to exclude other diseases that may mimic ulcerative colitis, including Crohn's colitis (see later discussion), ischemic colitis, radiation proctocolitis, and diverticulitis. In acute presentations, infectious agents should be excluded with appropriate stool cultures, including *Salmonella*, *Campylobacter*, *Shigella*, amebiasis, *Yersinia*, and *E. coli* 0157:H7. Finally, *C. difficile*-associated diarrhea and pseudomembranous colitis should be considered in elderly persons, particularly those who have recently been treated with antibiotics, reside in institutions, or have recently been hospitalized.

TREATMENT

The treatment of ulcerative colitis is based on the extent and the severity of the disease (Table 81-4). Medical therapy consists of a number of effective drugs, which are administered intravenously, orally, or rectally. The major classes of drugs are corticosteroids, 5-aminosalicylate (5-ASA) products, immunomodulators, and anti-TNF- α agents.⁶² In elderly people, some drugs must be used more carefully than in younger patients. For example, corticosteroids have higher risk complications, such as hypertension, hypokalemia, and confusion, whereas sulfasalazine, 5-ASA products, and immunomodulators are generally tolerated well.⁶⁰

SEVERE DISEASE

Patients with severe or fulminant disease, including toxic megacolon, should be hospitalized for intravenous therapy. This treatment consists of hydrocortisone or

Table 81-4. Medical Treatment of Ulcerative Colitis

Indication	Drug	Dosage
Mild to moderate distal disease	Hydrocortisone enemas	hs
	5-ASA enemas	hs
	Sulfasalazine	2-4 g/day PO
Mild to moderate disease extensive disease	Mesalamine	2.4-4.8 g/day PO
	Sulfasalazine	2.4 g/day PO
	Mesalamine*	2.4-4.8 g/day PO
	Balsalazide*	6.75 g/day PO
Severe disease (recently receiving steroids)	Prednisone	40-60 mg/day PO
	Prednisolone	60-80 mg/day IV
Severe disease (not recently receiving steroids)	Hydrocortisone	300 mg/day IV
	Corticotropin (ACTH)	120 units d/IV
Maintenance of remission	Infliximab	5 mg/kg IV at 0.2 and 6 wk, then every 4-8 wk o.n. or q 3rd night
	5-ASA (mesalamine) enemas	
Distal disease	Sulfasalazine	2 g/day PO
Pancolonic	Mesalamine*	1.2-2.4/day PO
	Balsalazide*	3 g/day PO
	Azathioprine	2-2.5 mg/kgBW/day PO
	6-Mercaptopurine	1.5 mg/kgBW/day PO
	Infliximab	5 mg/kg/BW q 4-8 wk IV

Abbreviations: ASA, aminosalicylate; ACTH, adrenocorticotropic hormone.

*If patient is intolerant of sulfasalazine.

adrenocorticotrophic hormone (ACTH) infused in fluids containing sufficient amounts of potassium to prevent hypokalemia. One study suggests that ACTH is superior for treating patients who have not previously received corticosteroids, whereas hydrocortisone tends to be more effective in those who have.⁶³ If ACTH or hydrocortisone does not produce significant improvement within 2 to 3 days, IV cyclosporine may be attempted with close monitoring of renal function, an especially important consideration in an elderly patient.

Once improvement is noted, the patient should be converted to oral maintenance therapy (see later discussion). However, in some cases, surgery is preferred unless the patient is an extremely poor operative risk.

Infliximab is a chimeric monoclonal antibody of the IgG subclass directed against human TNF- α , an important proinflammatory cytokine that is elevated in ulcerative colitis and Crohn's disease. Several large multicenter studies have showed efficacy in patients with moderately to severely active ulcerative colitis who fail conventional therapy. The dose of infliximab is 5 mg/kg body weight IV at 0, 2, and 6 weeks followed by infusions every 8 weeks⁶⁴ and is now accepted as part of the standard treatment options in patients with ulcerative colitis.

MODERATELY SEVERE DISEASE

Oral corticosteroids are used to achieve remission or to sustain remission after intravenous therapy. Initial therapy should be 40 to 60 mg/day in divided doses, followed by conversion to a single morning dose. Corticosteroids should be viewed as acute phase drugs and should not be used as long-term maintenance therapy because of significant side effects related to both the dose and duration of therapy. Diabetes, congestive heart failure, osteoporosis, cataracts, and hypertension are common in elderly people and may be exacerbated by corticosteroids.⁶⁰ Corticosteroid reduction should be accomplished in stepwise fashion while monitoring clinical activity and appropriate laboratory studies.

5-ASAs may be started together with oral corticosteroids. Sulfasalazine is quite effective and inexpensive but is somewhat limited by side effects, which are often dose-dependent and occur in as many as 30% of patients. Side effects include nausea, anorexia, headache, and, less commonly, a generalized rash; in most cases, these conditions are due to the inactive sulfapyridine carrier rather than the 5-ASA moiety. If side effects occur, patients should be switched to the more expensive 5-ASA products such as mesalamine. Diarrhea is a potential side effect of all 5-ASA drugs.

If patients fail to respond to 5-ASA drugs and cannot be weaned from oral corticosteroids, a trial of azathioprine or 6-mercaptopurine should be considered as an alternative to surgery.⁶⁵ These drugs act slowly and have a response time ranging from 3 to 6 months. Complete blood counts should be monitored frequently when these agents are used.

An alternative approach is to use infliximab in an induction dose similar to those with severe disease. Before starting this therapy, a skin test for tuberculosis should be placed, as infliximab has been associated with reactivation of latent *Mycobacterium tuberculosis*.

MILD DISEASE

Patients with mild disease can be treated effectively with 5-ASA drugs, which can be administered orally, by enema in cases of left-sided disease, or by suppositories in patients with proctitis. Corticosteroid enemas are also effective in left-sided disease but in general are not more effective than 5-ASA products. As up to 60% of the rectal corticosteroid may be absorbed, they also are less suitable for maintenance therapy. Budesonide is a nonsystemic steroid with a significant first-pass hepatic metabolism, which does not affect the adrenal-pituitary-hypothalamic axis. It is available in both foam and enema for mild to moderate proctosigmoiditis or left-sided disease.⁶⁶

MAINTENANCE THERAPY

For patients in remission, long-term maintenance with a 5-ASA product reduces the frequency of relapses.⁶⁷ The usual maintenance dose of sulfasalazine is 1 g bid with little or no long-term adverse effects. For patients who are intolerant to sulfasalazine, mesalamine 1.2 mg/day is also effective. For those with ulcerative proctitis or left-sided colitis, 5-ASA suppositories and enemas, respectively, are very effective when given every night to every third night. Nonsteroidal anti-inflammatory drugs have been reported to activate quiescent inflammatory bowel disease and should be avoided if possible.⁶⁸

SURGERY

Indications for surgery include failure of medical therapy for acute fulminant disease, inability to wean patients from long-term corticosteroid therapy, development of precancerous colonic lesions identified during surveillance studies, and suboptimal response to medical therapy in chronic ulcerative colitis.

The surgical procedure most commonly performed for acute fulminant colitis in all age groups is subtotal colectomy and ileostomy. In the elderly patient, proctocolectomy and ileostomy also remains the most popular choice for chronic failure of medical treatment or because of the development of premalignant changes. Although procedures that avoid ileostomy, such as the ileoanal reservoir, are a viable choice for many younger patients, the increased morbidity of the treatment makes its use less attractive in elderly patients who also are at greater risk for fecal incontinence because of age-associated changes in anal sphincter function.

RISK OF COLON CANCER

The risk of developing colorectal cancer in elderly patients with ulcerative colitis is approximately nine times that of the general population of that age group.⁶⁹ The risk in all age groups increases about 8 years after the onset of the disease and is greatest in those with universal colitis. Carcinoma almost always develops many years after quiescent disease has been present and occurs at an earlier age than in the general population. For this reason, yearly colonoscopy has been recommended to detect mucosal dysplasia, which is considered a premalignant lesion in ulcerative colitis. Biopsies are obtained randomly throughout the colon and in areas that appear suspicious. Despite some shortcomings

in the interpretation of biopsies and in the outcome of surveillance programs, all patients with longstanding ulcerative colitis should receive periodic colonoscopy and biopsy to look for evidence of mucosal dysplasia. The presence of low-grade dysplasia in the absence of active inflammation is an indication for proctocolectomy.⁶⁹

CROHN'S DISEASE

Crohn's disease is a chronic inflammatory process of unknown cause that most often affects the terminal ileum and/or colon and is characterized by transmural inflammation of the bowel wall, often with linear ulcerations and granulomas.

HISTOPATHOLOGY

Histologically there is transmural inflammation affecting all layers of the bowel and often associated with submucosal fibrosis. Other features that serve to distinguish this disease from ulcerative colitis are linear ulcerations, fissures, fistulas, discrete mucosal ulcers, granulomas, skip areas, and frequent rectal sparing.⁷⁰ The disease can involve all areas of the gastrointestinal tract, from the mouth to the anus, but most frequently involves the ileum and colon. According to most published series, Crohn's disease confined to the colon (Crohn's colitis) occurs more frequently in elderly than in younger persons, and left-sided colitis appears to be prevalent in elderly women.⁶⁰

SYMPTOMS AND SIGNS

As with ulcerative colitis, the clinical picture in elderly patients is similar to that in younger individuals and includes rectal bleeding, diarrhea, fever, abdominal pain, and weight loss. In patients with colorectal involvement, perianal disease, including fistulas, may be an early manifestation. The prevalence of extraintestinal manifestations such as migratory arthritis, pyoderma gangrenosum, iritis, and erythema nodosum is similar to that in younger patients. Common laboratory abnormalities such as anemia, leukocytosis, hypoalbuminemia, and elevated sedimentation rate vary with the severity of the illness. Rarely, the disease may be manifested by peritonitis due to bowel perforation, but this occurs more commonly with ileal disease. In elderly patients, peritonitis may occur atypically with mild abdominal pain, often minimal abdominal findings, and mental confusion. Uncommonly, Crohn's colitis is characterized by massive lower gastrointestinal bleeding or bowel obstruction.

DIAGNOSIS

Prolonged delays in diagnosis probably occur more frequently in elderly patients. It has been speculated that there is a tendency for Crohn's colitis to appear in a more indolent fashion than does ileal or ileocolonic involvement.⁶⁰

As the disease may often not involve the rectum and the distribution in the colon is often not confluent, colonoscopy and barium radiography are the diagnostic tests of choice. Both procedures can identify the characteristic ulcerations, skip lesions, and areas of colonic narrowing. Barium studies are superior for identifying fistulas from the intestine to adjacent visceral organs, whereas colonoscopy provides superior examination of the mucosa and allows mucosal biopsies to be obtained. Biopsies should also be obtained from grossly normal-appearing mucosa to help distinguish Crohn's colitis from other diseases that may mimic it. This is particularly important

because of the increased frequency with which diverticula occur in elderly people and because of the tendency for ischemic colitis to occur in a discontinuous distribution.

Computed tomography provides superior definition of the wall of the colon and can identify extraintestinal abdominal pathology, such as abscesses in patients with fever or palpable masses. Computed tomography and ultrasonography can also identify renal lithiasis or ureteral obstruction, which often occur silently.

Perianal involvement is a well-recognized manifestation of Crohn's disease and may be characterized by rectal or anal strictures, fissures, fistulas, abscesses, prominent skin tags, and ulcers. Venereal disease (uncommon in elderly people) and carcinoma should be excluded, particularly as the latter may complicate long-standing Crohn's proctitis. Infectious agents should be excluded by appropriate studies.

Small bowel follow-through remains a frequently used radiologic examination to assess the extent of small bowel involvement and to detect fistulas and strictures.⁷⁰ Increasingly, capsule endoscopy is being used in patients without strictures because it appears to be more sensitive than radiology in the small bowel.⁷¹ Assessment of the small intestine should be done at least once in every patient, usually at the time of diagnosis, to stage the disease.⁷⁰

TREATMENT

As with ulcerative colitis, treatment of Crohn's disease is based on its extent and severity and its distribution. Medical therapy encompasses all the drugs used in treating ulcerative colitis⁶²; in addition, selected antibiotics and methotrexate are helpful in some patients (Table 81-5).

Table 81-5. Medical Treatment of Crohn's Disease

Indications	Drug	Dosage
Ileocolitis or colitis	Mesalamine	2.4–4.8 g/day PO
	Metronidazole	10–20 mg/kg/day PO
	Prednisone	40–60 mg/day PO
	Budesonide	9 mg/day PO
Perineal disease	6-Mercaptopurine or	50 mg/day up to 1.5 mg/kg/day
	Azathioprine or	50 mg/day up to 2.5 mg/kg/day PO
	Metronidazole or	1–2 g/day PO
	Ciprofloxacin	500 mg bid PO
Refractory disease	Infliximab	5 mg/kg/IV q 4–8 wk
	6-Mercaptopurine or	50 mg/day to 1.5 mg/kg/day PO
	Azathioprine or	50 mg/day up to 2.5 mg/kg/day PO
	Infliximab or	5 mg/kg/IV q at 0, 2, and 6 wk
	Adalimumab	40 mg SC q 2 wk after loading dose of 160 mg SC followed by 80 mg SC in 2 wk
Maintenance of remission	Certolizumab	400 mg SC at 0, 2 and 4 wk
	Methotrexate	25 mg SQ/wk
	Sulfasalazine or	2 g/day PO
	Mesalamine	800–1200 mg/day PO
	6-Mercaptopurine or	50 mg/day up to 1.5 or 2.5 mg/kg/day, respectively
	Azathioprine	
	Methotrexate	15 mg SQ/week
Infliximab	5 mg/kg BW q 4–8 wk IV	
Adalimumab	40 mg SC q 2 wk	
Certolizumab	400 mg SC q 4 wk	

ILEOCOLITIS AND COLITIS

Patients with mild to moderate disease often respond to 5-ASA products in doses similar to those used for ulcerative colitis. If the disease remains mild or only moderate in severity but responds inadequately to 5-ASA drugs, metronidazole 125 to 250 mg three times daily or ciprofloxacin 500 mg once or twice daily can be tried before using immunomodulating agents.⁷² Alternatively, budesonide 9 mg daily, a steroid with fewer side effects than prednisone, can be tried.

If the disease worsens despite conservative therapy or if the patient has moderate to severe symptoms, corticosteroids are begun in doses similar to those used in ulcerative colitis. After remission is induced, prednisone is tapered at a rate of 5 to 10 mg/wk until a dose of 20 mg/day is achieved. Subsequently, prednisone should be reduced by 5 mg/day every 3 weeks while monitoring clinical activity and laboratory studies.

Approximately 60% of patients who cannot be weaned from oral corticosteroids respond to azathioprine (up to 2.5 mg/kg per day) or 6-mercaptopurine (up to 1.5 mg/kg per day). Response may not occur for 6 to 9 months.⁷³ These drugs can be continued indefinitely, but at least one attempt should be made to discontinue them after 1 year of therapy to see if quiescence can be maintained. The folate antagonist methotrexate 25 mg IM once weekly appears to be effective in many patients who are resistant or intolerant to azathioprine or 6-mercaptopurine and has been used successfully to maintain remission.⁷⁴

Infliximab is now often used for the treatment of active Crohn's disease, which is resistant to immunomodulating agents^{75,76} and also for active fistulizing disease.⁷⁷ At all ages, a skin PPD and chest radiograph should be obtained before therapy because of reports of reactivation of latent tuberculosis. In the elderly, infliximab is contraindicated in patients with moderate to severe heart failure and should be used cautiously in patients with mild heart failure.⁷⁰ Infliximab-treated patients should not receive concomitant immunosuppression with azathioprine, 6-MP, methotrexate, or corticosteroids chronically, as side effects may be increased with no demonstrable benefits.

To avoid the problem of the development of antibodies to infliximab, fully humanized anti-TNF agent have been approved for treating Crohn's disease. Their advantage is that they are administered subcutaneously every 2 weeks, thus obviating the need for infusions and lessening the risk of reactions to infliximab.^{78,79}

PERIANAL DISEASE

Perianal fistulas and abscesses can be terribly debilitating and frustrating to treat. Although perianal disease often improves with standard therapy for bowel inflammation and control of diarrhea, some patients continue to have persistent symptoms. Short-term success has been reported with metronidazole in doses of 1.5 to 2 g/day, but side effects at these doses are not uncommon and relapses occur when the drug is discontinued or tapered. Ciprofloxacin 500 mg twice daily is a more expensive alternative, albeit one with fewer side effects, but again there is a high relapse rate when the drug is discontinued.

If an abscess develops, incision and drainage should be performed.

If perianal disease remains unresponsive to therapy, surgical diversion of the colon may be performed in an attempt to allow healing, but this too may be unsuccessful. Azathioprine or 6-mercaptopurine may be helpful in some patients with refractory disease.⁸⁰ Infliximab, a monoclonal antibody directed at human tumor necrosis factor, has been reported to be effective in severe Crohn's disease and those with resistant fistula.⁷⁷

SURGERY

Unlike ulcerative colitis, Crohn's disease cannot be cured by surgery. Therefore surgical procedures should be reserved for patients who do not respond to medical therapy.

Proctocolectomy with ileostomy is the best surgical option for patients with extensive Crohn's colitis. In elderly patients who are debilitated or malnourished, an initial subtotal colectomy with ileostomy is less debilitating and permits weight gain and improved physical well-being. If proctectomy is subsequently required, it can be done with a low complication rate but may not be necessary if rectal disease is mild or absent. More limited colonic resections may be appropriate if severe disease is localized or obstructive symptoms are caused by relatively circumscribed bowel involvement.

LYMPHOCYTIC AND COLLAGENOUS COLITIS (MICROSCOPIC COLITIS)

Lymphocytic and collagenous colitis are uncommon disorders characterized by chronic watery diarrhea and histologic evidence of chronic mucosal inflammation in the absence of endoscopic or radiologic abnormalities of the large bowel. They comprise two histologically distinct disorders, which have been grouped under the term "microscopic colitis" and which differ principally by the presence or absence of a thickened collagen band located in the colonic subepithelium.^{81,82} Both lymphocytic and collagenous colitis occur most commonly between ages 50 and 70 years, with a strong female predominance and a frequent association with arthritis, celiac disease, and autoimmune disorders.

In both lymphocytic and collagenous colitis, there is a modest increase in mononuclear cells within the lamina propria and between crypt epithelial cells, primarily consisting of CD8⁺T lymphocytes, plasma cells, and macrophages.⁸³ In collagenous colitis, there is a thickened subepithelial collagen layer, which may be continuous or patchy. Although inflammatory changes occur diffusely throughout the colon, the characteristic collagen band thickening is highly variable, occurring in the cecum and transverse colon in more than 80% of cases and less than 30% of the time in the rectum. Although involvement of the left colon appears to be less intense, multiple biopsies of the left colon above the rectosigmoid during flexible sigmoidoscopy is sufficient to make the diagnosis in about 90% of cases.

Patients with collagenous and lymphocytic colitis usually have chronic watery diarrhea, with an average of eight stools each day, often with nocturnal stools, ranging from 300 to

1700 g per 24 hours, occasional fecal incontinence, abdominal cramps, and decreased symptoms when fasting.⁸⁴ Nausea, weight loss, and fecal urgency have also been reported but are variable. Diarrhea is generally longstanding, ranging from months to years, with a fluctuating course of remissions and exacerbations. In one series of 172 patients, the median time from onset of symptoms to diagnosis was 11 months, whereas in another of 31 patients, it was 5.4 years. Physical examinations are usually unremarkable and blood in the stool is absent. Routine laboratory studies are also normal.

Examination of fresh stools showed fecal leukocytes in 55% of 116 patients with collagenous colitis. Mild steatorrhea, mild anemia, low serum vitamin B₁₂ levels, hypoalbuminemia, and mild steatorrhea have been reported in variable numbers of patients but are not characteristic. Autoimmune markers that have been identified in patients with collagenous colitis include antinuclear antibodies (up to 50%), pANCA in 14%, rheumatoid factor, and increased C₃ and C₄ complement components.

Colonoscopic examinations are usually normal. Infectious agents should be excluded by testing for stool ova and parasites, standard stool cultures, and *C. difficile* toxin assays. Many patients have been diagnosed to have irritable bowel syndrome, a disorder that can be excluded by abnormal colonic biopsies and the finding of increased stool volume, both of which are not characteristic of irritable bowel syndrome.

There have been very few controlled trials for either collagenous or lymphocytic colitis and therapy is largely empirical. NSAIDs and other colitis-inducing medications should be stopped.⁸² About one third of patients respond to antidiarrheal agents, such as loperamide or diphenoxylate with atropine and bulk agents such as psyllium or methylcellulose; however, they do not exhibit improvement in inflammation or collagen thickness. In an open-label trial of bismuth subsalicylate in 12 patients,⁸⁵ eight chewable tablets per day for 8 weeks resulted in resolution of diarrhea and reduction of stool weight within 2 weeks, and in nine patients, colitis resolved, including disappearance of collagen band thickening. Although the basis for its efficacy is unknown, bismuth subsalicylate possesses antidiarrheal, antibacterial, and anti-inflammatory properties.

The majority of other treatment trials for collagenous colitis and lymphocytic colitis have studied 5-ASA compounds and bile acid resins. Alone or in combination, these agents appear to improve diarrhea and inflammation in some but certainly not all treated patients. Although corticosteroids given in either the oral or enema route provide symptomatic improvement and decreased inflammation in more than 80% of cases, relapse usually occurs quickly after stopping the drug.⁸⁴ Moreover, long-term corticosteroids have undesirable effects, especially in older patients.

Budesonide is a topical steroid with both a high receptor-binding affinity and a high first-pass effect in the liver. It has similar efficacy to prednisone but fewer significant side effects. The recommended dose is 9 mg once daily with tapering by 3 mg daily for 2 to 4 weeks.^{86,87} Recurrences may occur and maintenance with 3 mg once daily may be necessary in some patients.

Azathioprine and methotrexate may be considered in steroid-refractory patients.⁸⁸ Some studies suggest that older patients are more likely to be controlled with antidiarrheal

agents or require no medication, in contrast to younger patients.⁸⁹

COLONIC ISCHEMIA

The blood supply to the colon is derived mainly from branches of the superior and inferior mesenteric arteries and is characterized by a rich collateral circulation, except for the potentially susceptible marginal artery of Drummond and the arc of Riolan located at the peripheral junction of the two mesenteric arteries.⁹⁰ Occlusion of a major artery results in immediate opening of collateral vessels to maintain an adequate blood supply to the bowel. Intestinal ischemia may occur as a result of generalized reduction of blood flow (nonocclusive ischemia), redistribution of blood flow (e.g., vessel obstruction with poor collateral circulation), or a combination of the two. Colonic ischemia is the most common vascular disorder of the intestines in the elderly population and one that is often misdiagnosed unless there is a high index of suspicion and an aggressive diagnostic approach is used in patients suspected of having this disorder.⁹¹

The clinical spectrum of colonic ischemia includes a vast array of presentations and may be associated with a number of potentiating factors. Ischemia may be classified as reversible and irreversible; the former may have submucosal or intramural hemorrhage or transient ischemic colitis, which completely resolves within weeks to months, depending on the severity of the process. Irreversible ischemia may be characterized by chronic ulcerations, strictures of varying lengths, colonic gangrene, or fulminant transmural colitis.⁹²

In most cases, the cause of colonic ischemia cannot be established with certainty and no vascular occlusions can be identified. A significant minority of patients are found to have a potentially obstructing process in the colon, such as a benign stricture, diverticulitis, or carcinoma. Other contributing factors include hypotension, dehydration, congestive heart failure, use of digitalis, polycythemia, volvulus, and cardiac arrhythmias.

Symptoms and signs

The most common manifestation is the sudden onset of mild to moderately severe left lower abdominal cramping pain; this is often accompanied by bloody diarrhea or hematochezia, which may not appear until 24 hours later. Frank hemorrhage is not characteristic of ischemia. Physical examination reveals tenderness at the site of the involved bowel; these sites encompass the distal transverse, splenic flexure, and/or descending colons in about two thirds of patients. Peritoneal signs may last for several hours, but persistence beyond that time suggests a transmural process. Fever, leukocytosis, absence of bowel sounds, and abdominal distention also suggest the possibility of bowel infarction.

Diagnosis

If the diagnosis is suspected on clinical grounds, colonoscopy with minimal insufflation with air is the preferred diagnostic test. When an ischemic segment is encountered, biopsies should be taken from the edge of the ulcerated area and of noninvolved tissue, and the procedure aborted. Barium studies may reveal "thumbprinting" in the affected areas of the colon, which represents submucosal or mucosal hemorrhages and edema during the early phase of the

process. This corresponds to the hemorrhagic nodules noted on colonoscopic examination. There is no meaningful role for mesenteric angiography in patients with colon ischemia, unless there is involvement of the right colon with suspected mesenteric ischemia of the small intestine.

Treatment

Patients should be managed with bowel rest, intravenous fluids, or plasma expanders, and in severe cases, systemic antibiotics such as gentamicin and clindamycin.⁹³ Corticosteroids are of no benefit and should not be administered. In mild disease, symptoms resolve within several days, and radiologic healing occurs within several weeks, although some patients may not heal for up to 6 months.

If the patient continues to have diarrhea, bleeding, or significant obstructive symptoms for more than several weeks, surgical resection is usually indicated. If colonic infarction is suspected, emergency laparotomy with resection of nonviable bowel is needed.⁹⁴ With colonic infarction and gangrene, the mortality rate in the elderly with multiple co-morbid conditions approaches 50% to 75% with surgery and is universally fatal with nonsurgical treatment.

Prognosis

Recurrent episodes of colonic ischemia occur in less than 10% of patients. Attempts should be made to correct or remove underlying conditions that predispose to this disorder. Peripheral vasculopathy and right colonic involvement are associated with more severe disease.

COLONIC PSEUDO-OBSTRUCTION

Acute colonic pseudo-obstruction, sometimes termed Ogilvie's syndrome, is characterized by nonobstructive, nontoxic dilation of the colon.⁹⁵ This condition may develop after surgical procedures, especially orthopedic ones, and also occurs in a setting of serious coexisting illness, including sepsis, pneumonia, acute pancreatitis, spinal cord injury, or administration of anticholinergic, narcotic, or psychotropic drugs. This disorder can compromise respiratory status and cause cecal perforation. The risk of cecal perforation is said to rise when the diameter of the cecum increases beyond 10 cm. A variant of this disorder is "megacigmoid syndrome," often described in psychotic patients but not exclusively seen within this group.

After obstruction has been excluded, treatment includes correction of electrolyte imbalances, discontinuation of offending drugs, treatment of underlying infection or inflammation, nasogastric suction, a rectal or colonic decompression tube with positioning of the patient on the right and left sides at intervals of several hours, or medical treatment with intravenous neostigmine.⁹⁶ Decompression with colonoscopy may be attempted if there is severe dilation and no response to medical therapy.⁹⁷ Surgical decompression under local anesthesia using a stab-wound cecostomy can be performed if other measures fail. Postdecompression x-ray films should be obtained for several days to document continued resolution.

Relapses are common after successful decompression of acute colonic pseudo-obstruction, being as high as 33%. The administration of 29.5 g PEG daily in two divided doses

after successful treatment resulted in no relapses versus a 33% relapse rate for patients receiving a placebo.⁹⁸

Chronic colonic pseudo-obstruction, with or without colonic dilation (megacolon), may be associated with amyloidosis, muscular dystrophy, myxedema, dementia, multiple sclerosis, Parkinson's disease, quadriplegia, schizophrenia, and idiopathic visceral neuropathy and myopathy. There may be esophageal, gastric, small intestinal, and genitourinary dysfunction. Although most patients have constipation, diarrhea occurs if there is small bowel bacterial overgrowth or overflow around a fecal impaction.

Subtotal colectomy may be necessary in some patients with refractory symptoms and if anorectal function is normal. If anorectal dysfunction is present, proctocolectomy with ileostomy is indicated. Sigmoid resection may be all that is necessary in patients with megacigmoid syndrome. Most patients can be treated conservatively.

VOLVULUS

Factors thought to contribute to colonic volvulus include increasing age, chronic constipation, fecal retention, poor peritoneal fixation during embryologic rotation of the hindgut, and, in some areas of the world, diets very high in fiber.⁹⁹ The clinical setting typical of a sigmoid volvulus is an elderly institutionalized individual with a history of chronic constipation or laxative abuse.⁹⁹

The sigmoid colon, with its copious mesentery, is most commonly involved, but cecal volvulus can occur when fixation to the posterior parietal wall is incomplete. Volvulus of the transverse colon is by far the least common. Patients have a sudden onset of severe abdominal pain, followed by rapid and marked abdominal distention. Compromise of blood flow occurs as a result of twisting of the mesentery and marked distention of the loop.

Abdominal x-rays reveal massive distention of a single loop of bowel; the obstructed loop frequently is shaped like a coffee bean, with the concavity marking the point of torsion. The concavity points to the left lower quadrant in patients with sigmoid volvulus, and to the right lower quadrant when cecal volvulus is present. Administering contrast through the rectum confirms the diagnosis by the appearance of the pointed twist of the contrast column.

Closely related to a cecal volvulus is a cecal bascule in which malfixation allows the cecum to fold anteriorly and in a cephalad direction, which can result in a flap-valve obstruction with cecal distention. Abdominal x-rays reveal distention of the cecum, but no "bird beak" is seen on a barium enema, as in volvulus. However, treatment is identical to that for conventional cecal volvulus.

Attempts to untwist a sigmoid volvulus may be made by gently inserting an endoscope as far as the twisted segment.¹⁰⁰ Successful detorsion must be followed by careful observation should the bowel continue to be ischemic. Nonoperative decompression is more successful with a sigmoid than with a cecal volvulus; indeed, attempts to treat a cecal volvulus by nonoperative means can be dangerous, and even if successful, recurrence rates are high. Opinion is divided as to whether the first episode of sigmoid volvulus should be treated with resection. Fixation without resection is not considered a useful option. Certainly, patients with more than one episode of sigmoid volvulus should have resection.

In elderly and frail patients with cecal volvulus, early surgical intervention to untwist the volvulus followed by cecal fixation (cecopexy) is frequently all that is necessary unless bowel necrosis is present. If the latter is present, resection with ileostomy is indicated. In healthy elderly patients, cecal resection with reanastomosis is the preferred option.

NEOPLASTIC LESIONS

Colonic polyps may be classified into: (1) neoplastic polyps, which include adenomatous polyps and carcinomas; (2) non-neoplastic polyps, which include hyperplastic, inflammatory, and hamartomatous types; and (3) submucosal tumors, such as lipomas, leiomyomas, hemangiomas, fibromas, lymphoid polyps, and carcinoids.¹⁰¹

Most (80%–90%) colonic polyps are either adenomatous or hyperplastic, and of these about 75% are adenomas. However, when only polyps less than 5 mm are considered, half are hyperplastic and most are found in the rectosigmoid colon. Current evidence has suggested that hyperplastic polyps are not of clinical importance.¹⁰² However, this view may be too simplistic. There are serrated polyps that appear to be hyperplastic but with important histologic differences, which do have malignant potential. In contrast, it is widely accepted that most carcinomas arise from adenomas.

Adenomatous polyps

These polyps arise from mucosal glandular epithelium and can be described based on the following characteristics:

1. Size: Approximately 25% of adenomas are larger than 1 cm, and more than 80% of large adenomas occur in the left colon and rectum.
2. Architecture: More than 80% of adenomas are tubular, 5% to 15% are villous, and the rest are tubulovillous. Those with a higher proportion of villous elements tend to be larger and carry a higher risk of malignant transformation.
3. Dysplasia: All adenomas are dysplastic, but high-grade dysplasia is strongly associated with malignancy.

In the United States, prevalence rates in men and women are similar. Except in familial syndromes, colonic adenomas are rare before the age of 40, increase steadily, and reach a peak after the age of 60. Population studies suggest that the environment strongly contributes to adenoma prevalence and probably to the frequency of colon cancer as well. For example, obesity may be a risk factor whereas nonsteroidal anti-inflammatory drugs (including aspirin) are associated with decreased risk.¹⁰³

It is logical to identify and remove all benign adenomas at an early stage to prevent progression to carcinoma. In one study, screening and polyp removal by rigid sigmoidoscopy during the previous 10 years resulted in a 70% reduction in the risk of fatal cancer of the rectum and distal colon compared with the outcome in nonscreened subjects.¹⁰⁴ In the National Polyp Study, colonoscopic polypectomy reduced the incidence of colorectal cancer by 76% to 90% during a follow-up of almost 6 years.¹⁰⁵ These findings form the basis for current screening recommendations.

There is epidemiologic evidence that aspirin and other, nonsteroidal anti-inflammatory drugs (NSAIDs) may reduce

the risk of colorectal cancer.¹⁰⁶ Several large studies, although not all, have found a significant reduction in death rates from colon cancer among both men and women who use NSAIDs on a regular basis. Such observations are supported by laboratory studies demonstrating that aspirin and other cyclooxygenase inhibitors demonstrate chemopreventive effects in animal models of colon carcinogenesis. There currently are insufficient data supporting the use of NSAIDs as colorectal cancer chemopreventive agents outside appropriately designed trials.

Management of polyps

Criteria for the adequacy of colonoscopic polypectomy are well established for pedunculated malignant polyps.^{107,108} In patients having favorable criteria, the risk of residual tumor is 0.3% for pedunculated lesions and 1.5% for sessile lesions, whereas the risk is 8.5% for those having unfavorable criteria. Surgery is therefore strongly considered in the latter situation, although recommendations should be individualized based on patient age and comorbid conditions.

The following recommendations for treatment after polypectomy are based on recent information.¹⁰⁹

1. Patients should undergo complete colonoscopy at the time of polypectomy and removal of all synchronous polyps.
2. In 3 years the first follow-up colonoscopy should be performed to check for missed synchronous and/or metachronous adenomas. If the results are negative, subsequent surveillance intervals may be increased to 5 years.
3. Selected patients with multiple adenomas or those with large sessile polyps (>3 cm) or those with suboptimal initial clearing examinations require colonoscopy at 1 year or sooner and again 3 years later if the colon is clear.

Screening strategies

It is generally accepted that colorectal cancer largely can be prevented by the detection and removal of adenomatous polyps. Screening tests may be divided into those that primarily detect cancer early, and those that can detect cancer early and also detect adenomatous polyps that can be removed.¹¹⁰ Although a yearly FOBT for all patients 50 years and older has been suggested, controversy exists regarding the cost and benefits of such a policy. The sensitivity of Hemoccult II tests for detecting asymptomatic colorectal cancer ranges from 45% to 80% in mass-screened populations and is less than 25% for detecting polyps 1 cm or larger in diameter.^{111,112} Thus a FOBT is a relatively effective way to screen for asymptomatic cancers but is ineffective in detecting even sizable premalignant polyps. Moreover, at least 50% of screened individuals over the age of 40 are false-positive or have an upper gastrointestinal source of bleeding. However, the specificity of an unrehydrated FOBT is about 98% to 99%.

A recent systematic review of colorectal cancer screening using the fecal occult blood test indicated that screening had a 16% to 25% reduction in the relative risk of CRC mortality for studies that used biennial screening.¹¹³

A recently published consensus document expressed the strong opinion that colon cancer prevention should be

the goal of screening and indicated a preference for tests designed to detect both early cancer and adenomatous polyps if resources are available and patients are willing to undergo an invasive procedure.¹¹⁰ Testing options under this scenario include flexible sigmoidoscopy or double contrast barium enema every 5 years, full colonoscopy every 10 years, and computed tomographic colonography every 5 years for asymptomatic adults aged 50 years or older. The finding of adenomatous polyps on flexible sigmoidoscopy should be followed by colonoscopy to remove all polyps followed by a repeat colonoscopy in 3 to 5 years depending upon number of polyps and histology. Although somewhat controversial, many believe that finding polyps on imaging studies should be confirmed by colonoscopy with removal of any polyps. Others believe that polyps less than 1 cm may be watched with repeat studies every 2 years.¹²

Colorectal cancer

Colorectal cancer is the third most commonly diagnosed cancer and the second most common cause of cancer death in the United States and the United Kingdom.¹¹³ Epidemiologic evidence strongly suggests that colon cancer is an acquired genetic disease produced by chronic exposure to environmental carcinogens. Thus deaths from colon cancer increase slowly by middle age and rise steeply thereafter. Moreover, immigrants from areas of low incidence acquire, within a single generation, the increased risks of the indigenous population in areas of higher incidence.¹¹⁴ Except for the increased risk for colorectal cancer among individuals with ulcerative colitis and those with a family history of colorectal cancer, no high-risk exposures have consistently been identified in the United States. However, epidemiologic evidence implicates both decreased dietary fiber and increased consumption of animal protein and fat. That colorectal cancer is caused by cumulative alterations in the cellular genome, and not by a single genetic alteration, may explain the long latency period between initial exposure to carcinogen(s) and the appearance of cancer.¹¹⁵

In about 80% of cases, somatic mutations in the APC gene on chromosome 5 are the earliest recognized genetic alterations in sporadic colonic carcinogenesis and are found in the smallest adenomas. These mutations permit unregulated proliferation at the base of the colonic crypt. A multistep genetic model for sporadic colorectal tumorigenesis involves sequential mutations in cellular oncogenes and tumor suppressor genes.^{115,116} Two cellular proteins associated with the APC gene have been identified and appear to be involved in cell adhesion, which may provide an important clue to the mechanism of tumor initiation.

In about 15% of sporadic cases, a colon cancer "susceptibility gene" on the short arm of chromosome 2 has been identified in patients with families with hereditary nonpolyposis colon cancer (HNPCC) and in sporadic colon cancers as well. Widespread mutations in short, repeated DNA sequences due to defective or mutant DNA mismatch repair enzymes have been identified on chromosome 2p. At least six such repair genes have now been identified in the pathogenesis of colon cancer.¹¹⁷ These tumors appear to have a genetic pathogenesis different from that of the hereditary polyposis syndromes that result in different clinical features and less aggressive behavior.

Colonic cancers can be classified by gross appearance, histology (well to poorly differentiated, mucinous, signet-ring type) or by DNA content.¹¹⁴ In general, poorly differentiated carcinomas have a somewhat worse prognosis than well-differentiated tumors. More helpful is staging, for example, by the Astler and Collier modified Dukes (Dukes-Turnbull) classifications: A, tumor limited to the muscularis mucosa; B1, tumor extends into the muscularis propria or, B2, penetrates through serosa with no lymph node involvement; C1, four or fewer regional lymph node metastases or, C2, greater than four nodes involved; and D, distant metastases. Actuarial 5-year survival rates diminish from 85% to 95% for Dukes A lesions to less than 5% for Dukes D lesions. As expected, prognosis is much poorer when there is vascular or neural invasion.

In an attempt to provide a uniform classification, the American Joint Committee on Cancer introduced the tumor-node metastases (TNM) classification for CRC.¹¹⁸ This system classifies the extent of the primary tumor (T), the status of regional lymph nodes (N), and the presence or absence of distant metastases (M). Cases are assigned to one of five stages (O through IV); it has in most cases replaced the Dukes classification in therapeutic trials.

The primary treatment for colorectal cancer is surgical resection. Preoperative studies include a complete evaluation of the colon, preferably by colonoscopy and a chest x-ray. Routine measurement of carcinoembryonic antigen (CEA) is often done. Although serial measurements of CEA have been advocated to detect early recurrences after surgery, cancer cures attributable to CEA monitoring appear to be infrequent¹¹⁹ and it must be questioned whether such a practice is justified in view of the substantial cost or the emotional stress that CEA testing may cause patients. Abdominal imaging studies are most useful for detecting advanced disease (i.e., hepatic metastases) but are less useful in finding localized extracolonic spread. Moreover, such information can be obtained directly at the time of surgery, and the presence of metastases does not influence the need for surgery or the type of surgery that is performed. In contrast, rectal endosonography is superior to computed tomography and magnetic resonance imaging in staging rectal cancers.¹⁷

There is no benefit from adjunctive radiation therapy for colon cancer outside the rectum. However, adjuvant chemotherapy with fluorouracil (and levamisole)¹²⁰ or fluorouracil and leucovorin has been associated with a significant reduction in tumor recurrence and enhanced survival in patients with stage III colon cancer.¹²¹ These data support the use of postoperative adjuvant chemotherapy in stage III colon cancers. In contrast, the benefit of adjuvant fluorouracil-based therapy in stage II colon cancer is less clear.¹²² Adjuvant combined radiotherapy and chemotherapy improve postsurgical survival in patients with rectal carcinoma, albeit with increased and often severe toxicity.¹²³ Some patients with unresectable rectal cancer may become surgical candidates following radiation therapy.

LOWER GASTROINTESTINAL BLEEDING

The two most frequent causes of acute lower gastrointestinal bleeding in elderly patients, defined as originating below the ligament of Treitz, are diverticulosis and vascular ectasias (angiodysplasia).¹²⁴ These two entities account for two

Table 81-6. Clinical Presentation of Common Causes of Lower Gastrointestinal Bleeding

Symptom	Young Adult	Middle Age	Elderly
Abdominal pain	IBD	IBD	Ischemia, IBD
Painless bleeding	Meckel's diverticulum, polyp	Diverticulosis, polyp, cancer	Angiodysplasia, diverticulosis, polyp, cancer
Diarrhea	IBD, infection	IBD, infection	Ischemia, infection, IBD
Constipation	Hemorrhoids, fissure, rectal ulcer	Hemorrhoids, fissure	Cancer, hemorrhoids, fissure

Abbreviation: IBD, inflammatory bowel disease.

thirds of hemodynamically significant lower gastrointestinal bleeding (Table 81-6). The most common causes of chronic lower gastrointestinal bleeding are hemorrhoids, angiodysplasia, and colonic neoplasms. Known causes of acute lower gastrointestinal bleeding other than angiodysplasia and diverticulosis make up perhaps 25% of all bleeding episodes. These include neoplasm, radiation enterocolitis, ischemic, ulcerative, and Crohn's colitis; solitary rectal ulcer syndrome; and internal hemorrhoids. Less frequently reported causes of bleeding include small intestinal and Meckel's diverticula, vasculitis, and Dieulafoy lesions of the small intestine and colon.

Angiodysplasia

Angiodysplasia are small clusters of dilated and tortuous veins, which appear in the mucosa of the colon and in the small intestine.¹²⁵ They are thought to result from age-associated degeneration of colonic submucosal veins, are often multiple, and are an important cause of lower gastrointestinal bleeding in the elderly population; two thirds of patients with angiodysplasia are over 70 years of age. The principal theory concerning their development is that repeated episodes of low-grade partial obstruction of submucosal veins occur during muscular contraction or from increased intraluminal pressure, resulting in dilation and tortuosity of the vein.¹²⁶ This process may extend to the mucosal veins, which are drained by the submucosal vein. Finally the precapillary sphincter becomes incompetent, and a small arteriovenous communication with an ectatic tuft of vessels develops. The tendency of vascular ectasias to occur in the right colon is best explained by the greater tension on the bowel wall, as expressed by Laplace's law relating tension to the diameter of the bowel lumen. A review of the literature casts doubt on a causal association between vascular ectasias and aortic stenosis.¹²⁷ Nevertheless, it has been reported that recurrent bleeding from these lesions decreases after replacement of a stenotic aortic valve.¹²⁸

Vascular ectasias remain asymptomatic in most individuals. The usual manifestation is that of painless subacute or recurrent bleeding, which stops spontaneously in most cases. Bleeding may consist of bright red blood, maroon stools or (rarely) melena, or may be occult.¹²⁴ About 10% to 15% of patients have episodes of brisk blood loss, and up to half exhibit iron deficiency anemia.

Diagnosis may be made by colonoscopy or angiography; of the two, colonoscopy is preferred, since it can exclude

other causes of bleeding and can be used for therapeutic interventions.^{129,130} Because lesions are small, often multiple, and difficult to see, thorough cleansing of the colon is necessary to provide adequate visualization of the mucosa. Colonoscopy is usually performed after bleeding has stopped and within 48 hours to permit identification of other bleeding sources.

Mesenteric angiography is the diagnostic procedure of choice when acute bleeding is brisk. The finding of tortuous, densely opacified clusters of small veins that empty slowly represents the advanced ectatic process. Early filling of the vein, indicative of the presence of an arteriovenous communication, is found in most patients who are studied for bleeding. Extravasation of contrast into the bowel lumen is seen when there is active bleeding at a rate of at least 0.5 mL/min; because bleeding is often intermittent, a bleeding site is identified by angiography in only a minority of patients.

Bleeding can be controlled acutely by intra-arterial administration of vasopressin in doses ranging from 0.2 to 0.6 units/min. This often permits stabilization of the patient and appears to be more effective when bleeding is from the right colon. When bleeding cannot be controlled, surgery is required. Colonoscopic therapeutic modalities generally involve thermal ablation techniques, but rebleeding remains a significant problem.¹³¹ A right hemicolectomy is performed if bleeding from the right colon has been identified by angiography or colonoscopy and if other sources of bleeding have not been identified. The extent of resection should not be influenced by the presence of left colonic diverticulosis. Recurrent bleeding, probably due to undetected ectasias, occurs in up to 20% of patients who may require either more extensive colonic resection or exploratory laparotomy.

Treatment should be conservative whenever possible and consists of blood or iron replacement as appropriate. For recurrent bleeding, transcolonoscopic electrocoagulation or laser coagulation may be attempted; difficulties include identifying the ectatic lesion(s) and excluding other causes of blood loss if bleeding has stopped. Perforation of the right colon with coagulation therapy is a hazard.¹³²

The development of capsule endoscopy may reduce the need for diagnostic laparotomy in patients with recurrent bleeding from obscure sites.¹³³

Vasculitis

Inflammation and necrosis of blood vessels may lead to ischemia and ulceration, resulting in pain and/or bleeding. Polyarteritis nodosa, Churg-Strauss syndrome, Henoch-Schönlein purpura, systemic lupus erythematosus, rheumatoid vasculitis, Behçet's disease, and essential mixed cryoglobulinemia have all been reported to produce gastrointestinal bleeding and are best diagnosed with endoscopic procedures in the appropriate clinical setting.

Dieulafoy lesions

These lesions have been reported to cause bleeding, in several cases massive, in the small intestine and colon.¹³⁴ They are characterized by a small mucosal defect with minimal inflammation and a congenitally large, tortuous, thick-walled arteriole at the base which ruptures into the bowel lumen. The histology of these vessels is normal, and their abnormality is their size relative to their superficial location. Bleeding can be localized with angiography, although

occasionally colonoscopy can identify the lesion if bleeding has stopped and the colon is well prepared. Surgical resection, embolization therapy, or thermal coagulation therapy are the treatments of choice.

Evaluation and management of lower gastrointestinal bleeding

The first goal of management is to rapidly assess the severity of bleeding and cardiovascular status of the patient and to resuscitate those with major blood loss (Figure 81-1). Vital signs reflecting orthostatic changes and other signs of hypovolemia should be checked immediately and at frequent intervals thereafter. If signs of shock or hypovolemia are present, one or two large-bore intravenous catheters should be placed to facilitate fluid resuscitation. Initial blood work, including hemogram, platelet count, coagulation profiles, routine blood chemistries, and type and cross-match should be obtained immediately. Only after these critical tasks are completed should a more detailed history and physical examination be performed to help determine the

site of bleeding and potential causes. Another important step is to distinguish acute bleeding from active bleeding superimposed on chronic blood loss. This is best done with the hematocrit and mean corpuscular volume; if the latter is low, chronic bleeding should be suspected.

The third step is to consider the location of the gastrointestinal bleed based on characteristics of the bleeding and a BUN/creatinine ratio.¹³⁵ Although hematochezia, defined as the passage of red blood through the rectum, suggests a lower gastrointestinal source, up to 20% of patients with upper gastrointestinal bleeding may have hematochezia because of the rapid passage of large amounts of blood through the small and large intestines.¹³⁶

Such patients always show evidence of severe hemodynamic compromise, and most have a BUN/creatinine ratio greater than 25 on initial evaluation.¹³⁵ On the other hand, melena is often characteristic of upper gastrointestinal bleeding but can also be seen in patients with bleeding from the small intestine or right colon when colonic transit is slow. Fresh unclotted blood dripping into the toilet after

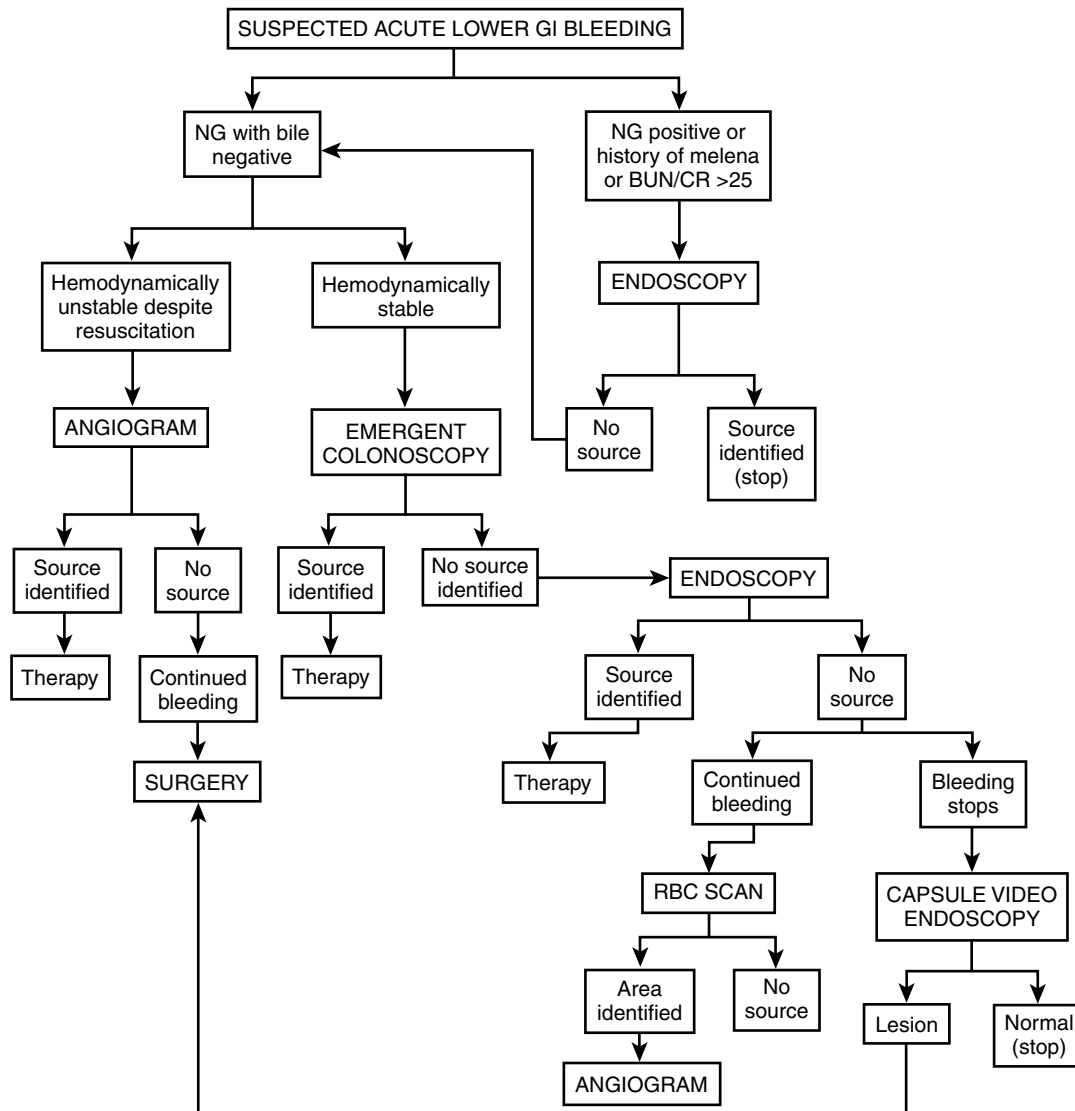

Figure 81-1. Suspected acute lower gastrointestinal bleeding.

defecation suggests a very distal anorectal source, whereas blood streaking the stool suggests origin in the left colon.

Exclusion of an upper gastrointestinal site begins with passage of a nasogastric tube and examination of gastric contents for red blood, coffee ground materials, and bile. The presence of bile and an absence of blood or coffee ground materials significantly diminishes but does not exclude bleeding proximal to the duodenojejunal junction; thus, an upper endoscopy should be performed in a setting compatible with an upper gastrointestinal source. There is no role for occult blood testing of a nasogastric aspirate in the absence of coffee grounds or bloody material. Finally, hemorrhoidal and low rectal bleeding should be excluded by sigmoidoscopy in patients thought to have lower gastrointestinal hemorrhage.

When evaluating stable patients with acute lower gastrointestinal hemorrhage, colonoscopy preceded by oral bowel preparation is preferred in identifying and potentially treating a colonic bleeding source. If an emergency colonoscopy is to be considered, the nasogastric tube should be left in place to permit rapid administration of a polyethylene glycol electrolyte solution to cleanse the colon.

If bleeding is active and bowel preparation cannot be done, scintigraphy with ^{129}Tc -labeled red blood cells can be used in an attempt to locate a bleeding site. This technique detects active bleeding at rates of approximately 0.1 mL/min, and the patient can be serially scanned for up to 36 hours if bleeding is intermittent. Site localization may be impaired if delayed films are taken too infrequently and, of course, the patient must be actively bleeding at the time of the study. Although there were initial enthusiastic reports of an approximately 90% rate of detection of active bleeding, subsequent studies have yielded conflicting results.^{137,138} These latter reports have raised serious concerns regarding a rigid policy of routinely performing nuclear scintigraphy before mesenteric angiography, particularly in high-risk patients for whom rapid diagnosis is preferred. It may be more accurate if upper gastrointestinal bleeding has been excluded.¹³⁸ If bleeding is active and severe and/or scintigraphy is not diagnostic, selective mesenteric angiography can be used to detect extravasated contrast into the bowel when bleeding rates are 0.5 to 1.0 mL/min, or to demonstrate vascular lesions, neovascularity, or tumors in the absence of extravasation.¹³⁹ Sensitivity declines when bleeding is recurrent or chronic. Attempts have been made to increase diagnostic sensitivity and accuracy by using systemic heparinization, intra-arterial vasodilators, or thrombolytic agents during angiography if the initial study is negative.¹⁴⁰ More extensive experience is needed to determine whether the increased yield justifies the increased risk of bleeding complications.

Angiography also offers the potential for local therapy, provided selective catheterization can be achieved. These modalities include infusion of vasopressin to control acute arterial bleeding in colonic diverticular disease or angiodysplasia, and selective embolization of an identified bleeding site with a gelatin sponge, vascular coils, or polyvinyl alcohol

particles.¹⁴¹ Complications include electrolyte disturbances, cardiovascular complications, and bowel ischemia with vasopressin infusion and bowel infarction following embolization. The latter should be attempted only at centers that have the expertise to perform superselective catheterization. Some investigators report that urgent colonoscopy is superior to selective mesenteric angiography in identifying the source of severe lower gastrointestinal bleeding. If bleeding is massive, emergent surgery with or without intraoperative endoscopy may be the best option. There is little or no place in modern surgical practice for blind colonic resection.

If no source of bleeding is detected by colonoscopy and no further bleeding occurs, a small bowel enteroscopy or capsule endoscopy should be performed. Enteroscopes can often be advanced to 60 to 100 cm past the ligament of Treitz if the procedure is done by experienced personnel.¹⁴² The diagnostic yield has varied from 30% to 60%, with arteriovascular malformations accounting for most of the causes of bleeding. Video capsules allow visualization of most or all of the small intestine.

Barium radiographic procedures have no role in the evaluation of patients with acute lower gastrointestinal bleeding. They are unable to demonstrate active bleeding and interfere with attempts to perform colonoscopy or mesenteric angiography. Even if a lesion is detected, there is no proof that it is the source of the bleeding.

KEY POINTS

The Large Bowel

- Principal functions of the colon are to store fecal wastes and to expel them in an appropriate manner. Colonic dysfunction may result in constipation, diarrhea, or fecal incontinence.
- Making a clinical distinction between painful diverticular disease and diverticulitis carries a sizable rate of error in elderly people. Computed tomography and ultrasonography often help in this process, which is important as treatment approaches.
- Both ulcerative colitis and Crohn's disease are found with increased frequency in elderly people. There are more and better drugs to treat these patients, both acutely and to maintain remissions.
- Colonic ischemia is often underdiagnosed in elderly people, is characterized by the sudden onset of abdominal pain and bleeding, and often is benign and reversible. Colonoscopy is the diagnostic procedure of choice.
- Colon cancers are a frequent but often preventable cause of death in both men and women. The aggressive use of colonoscopy to detect premalignant polyps is the gold standard for prevention and should begin at age 50 in persons of normal risk.
- Lower gastrointestinal bleeding in elderly people is most often associated with angiodysplasias and diverticulosis. Colonoscopy is the preferred diagnostic test, whereas scintigraphy and angiography are helpful if no source of bleeding is seen or if bleeding is so brisk as to exclude colonoscopy.

NUTRITION IN AGING

The nutrition goals in caring for older adults are to maintain or even improve their overall health and quality of life as well as to prevent or treat age- and nutrition-related problems by improving the nutritional status of individuals and population groups. Whether defined as “the condition of a population’s or individual’s health as affected by the intake and utilization of nutrients and non-nutrients”¹ or as the degree of balance between nutrient intake and nutrient requirements, nutritional status is extremely important to overall health and to maintaining optimal nutritional status. Optimal nutritional status also has been shown to influence the aging process, various physiologic systems and functions, body composition, and the onset and management of various chronic conditions. The process of aging also affects nutritional status. Specifically, aging directly contributes to the changes in nutritional needs, although requirements for specific nutrients can decrease, increase, or remain the same.² With aging, changes in economic and social status arise that contribute to decreased access to food, poor food choices, nutrient deficiencies, and poor nutritional status, which in turn lead to increased risk of illness, poor health, and limited mobility and independence, as illustrated in Figure 82-1.³

Like overall health, nutrition is influenced by social determinants such as income, educational level, social support, gender, culture, and other factors outlined in the population health framework.^{4,5} Such factors partly account for the wide and stubbornly resistant disparities in nutritional and health status that exists in populations. For example, research in the area of food costing shows that seniors living alone are not able to afford nutritious diets.⁶ The consumption of vitamin and mineral supplement is higher among those older adults with higher levels of education.⁷ Furthermore, seniors who live alone and lack social support tend to have poorer nutritional status compared to elderly individuals with social support.

NUTRITION SCREENING AND ASSESSMENT

Many physiologic factors impact the nutritional status and well-being of older adults. An inadequate or excess intake of nutrients is the result of ingestion and utilization of nutrients from a variety of dietary sources, as well as other various elements (e.g., age-related changes, medication intake, socioeconomic factors, and functional and cognitive capacity). These factors facilitate the depletion or storage of tissue stores, change in plasma nutrient levels, enzymatic activity, and other physiologic functions, which affect anthropometric indicators (e.g., weight, body composition). As a result, anthropometric measures, as well as biochemical, clinical, and dietary factors, are critical and must be considered in the assessment of an individual’s nutritional status.

Anthropometric measures are used to assess nutritional status through the examination of body proportions and composition, as well as the fluctuations in these indicators over

time, and include body weight, weight history, height or other estimates of stature, body mass index (BMI), skin-fold thickness, and circumference measurements.^{8,9} Self-reported measures are often inaccurate, and trained technicians should adopt standardized measurement protocols to reduce measurement error.^{10,11} Body weight is a key indicator in nutritional status, and one’s weight history serves as an indicator of nutritional risk. Periods of excessive or significant weight loss include 2% body weight in a week, 5% in a month, 7.5% in 3 months, or 10% in 6 months. In addition to weight changes, height changes, which are largely due to the shortening of the spine, are reliable indicators of an at-risk individual. If an individual is unable to stand or stand straight, estimates of stature can be estimated via arm span, demispan, or knee height. Arm span measurements can determine the maximal height in adulthood rather than one’s actual height, whereas age-, gender-, and race-specific equations are used to estimate stature from knee height measures¹² with supine knee height valued as more reliable than seated knee height. Once height and weight measures are obtained, body mass index (BMI) can be calculated. Body weight (kg) is divided by height squared (m), which evaluates weight independent of height but does not directly measure body fat. For older adults, a BMI of less than 24 is associated with poor nutritional health, a BMI between 24 and 29 is believed to be a healthy weight, and a BMI of over 29 is seen as overweight and may lead to health problems.¹³ Skinfold thickness measurements are used to determine body fatness. However, with aging, skin changes in thickness, elasticity, and compressibility, and skinfold thickness is not a reliable measurement for older adults as a result. Body fat stores can be assessed through circumference measurements (e.g., waist, waist-to-hip ratio, and upper arm circumference), much like measures that are used to estimate skeletal muscle mass (somatic protein stores). Body fat measurement can be used as a quick screening tool to pinpoint high-risk individuals who may be susceptible to under- or overnutrition and are useful alone or combined with height and weight measurements.

Another useful measure for individuals at risk for nutritional problems is *biochemical data*, which can be used to find subclinical deficiencies (e.g., through blood or urine specimens). Through such tests, biochemical indicators of visceral protein status, which include serum albumin, thyroxine binding prealbumin, serum transferrin, and retinol binding protein as well as total lymphocyte counts, can be substantiated. Although serum albumin is a commonly used screening tool, it is not always a reliable measure in older adults. Values can be elevated because of dehydration, or values can decline because of age-related degeneration of muscle mass. Other biochemical measures such as total cholesterol, high-density lipoprotein, low-density lipoprotein, and triglycerides are used to assess lipid status and are also used to measure micronutrient status (e.g., iron status). Biochemical measures of iron status can include hemoglobin, hematocrit, mean cell volume, mean cell hemoglobin concentration, and total iron binding capacity. A combination of these measures is used for a proper clinical diagnosis

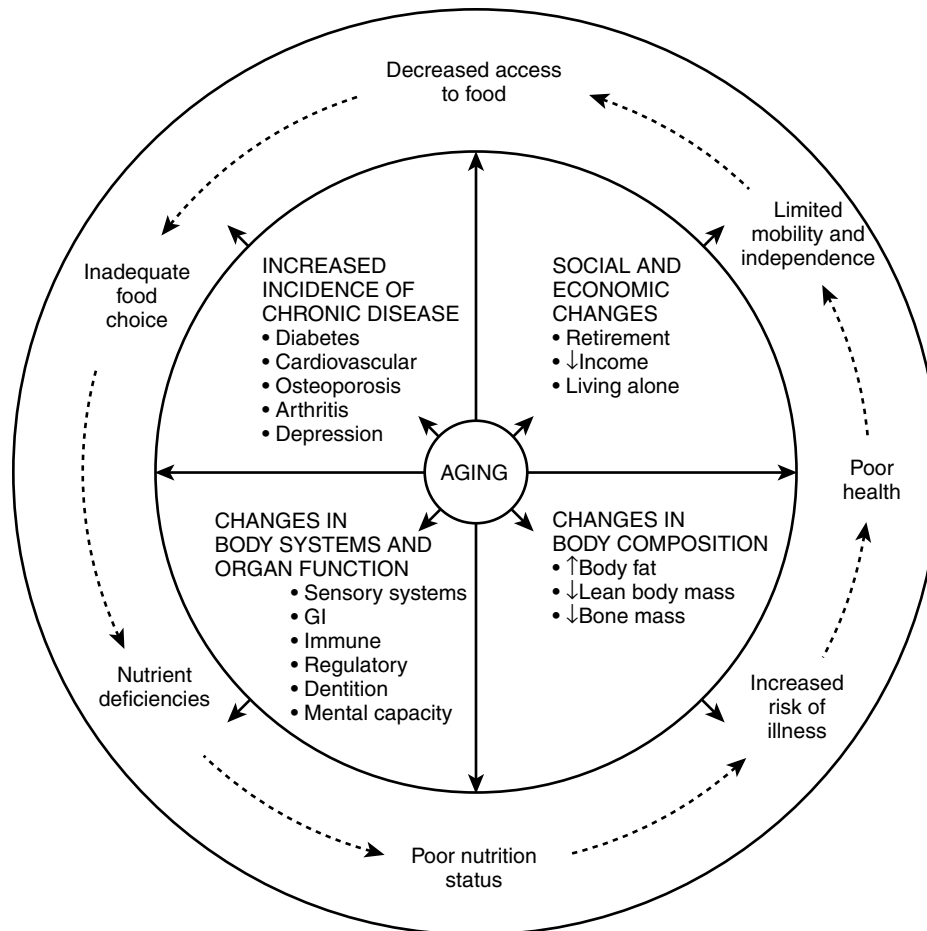

Figure 82-1. Changes in economic and social status contribute to decreased access to food, poor food choices, nutrient deficiencies, and poor nutritional status, which lead to increased risk of illness, poor health, and limited mobility and independence.

and can be compared to normative age and gender group values.

Clinical indicators are also used to assess nutritional status, and the components of clinical assessment can include medical history and physical signs and symptoms associated with nutritional deficiencies, functional status, and cognitive status. Some clinical signs and symptoms are nonspecific and attributed to the aging process rather than to a particular nutritional deficiency. Functional status can be assessed in several different ways, usually with a focus on the person's abilities to perform basic activities of daily living (ADL), which include basic self-care such as bathing, feeding, and toileting and instrumental activities of daily living (IADL), which includes activities such as cooking, shopping, and managing one's own affairs. These can serve as clinical indicators useful in the assessment of nutritional status. The inability to execute such tasks may indicate a higher risk of poor nutrition, although some clinical signs may be nonspecific and attributed to aging rather than to a specific deficiency. Clinical assessment can include physical signs and symptoms affiliated, not only with nutritional deficits, but also functional and cognitive status. Both functional and cognitive status can be assessed in multiple ways.

Dietary assessment is an integral component in the measurement of nutritional status and can be categorized as retrospective or prospective. A retrospective assessment

involves the recall of all foods and fluids consumed in a particular time frame (often 24 hours). Retrospective assessment can be unreliable if the individual has problems with cognition status. In this case, a prospective assessment may be favored, as this involves keeping a written record of all foods and fluids consumed in a given period of time (e.g., 3 days including 2 weekdays and a weekend day or 7 days). Although this aids those with cognitive challenges, it does pose a problem for those individuals who suffer from a particular functional disability such as arthritis of the hand or poor vision. A 3-day food record with intakes of 2 weekdays and one weekend day recorded is considered to be one of the better dietary assessment methods as it does not depend on memory and can provide detailed intake data, although no single best method exists.

Given that a comprehensive assessment of nutritional status is complex and time-consuming, rapid screening is beneficial to identify those who might be at risk for poor nutrition and individuals who might need in-depth assessment. Several screening tools exist. The DETERMINE checklist determine your nutritional health checklist developed as part of the Nutrition Screening Initiative provides public awareness about basic nutrition information and can help identify individuals at risk for poor nutrition in community settings. The checklist is widely used in the United States¹⁴ and is executed in two stages or levels. Level I can

include the following assessments: body weight, eating habits, living environment, and functional status—particularly ADLs and IADLs—and is usually filled out by the individual's primary caregiver.¹⁵ The level II screen can include anthropometric measurements, laboratory data, polypharmacy, and cognitive status assessments. Based on the assessment, specific nutritional care plan or support is provided. In Canada, a screening tool titled Seniors in the Community: A Risk Evaluation Tool for Eating and Nutrition Version II (SCREEN II) has been developed for assessing nutritional risk among community-dwelling seniors.¹⁶ The Mini Nutritional Assessment (MNA) is also widely used for initial screening and assessment for individuals in the community as well as in the long-term care settings.^{17,18}

In addition to these commonly used screening tools, several others exist. These include the Payette Nutrition Screening Scale, the Nutritional Risk Index (NRI), the Nutritional Risk Score (NRS), the Nutritional Risk Assessment Scale (NuRAS), the Prognostic Nutritional Index (PNI), the Sadness-Cholesterol-Albumin-Loss of weight-Eating-Shopping (SCALES) measurement, and the Subjective Global Assessment (SGA). Screening tools are beneficial for identifying individuals at risk or as an educational tool as they can provide simple, rapid, and reliable assessments.¹⁹ Even so, screening tools may have limited value in apparently healthy elderly people.²⁰ It is therefore important to select and use appropriate screening tools based on the target group (e.g., home care, long-term care), ease of use, and psychometric properties (validity/reliability).

Although researchers and clinicians have traditionally relied on the nutritional assessment and screening based on anthropometric, biochemical, clinical, and dietary considerations as well as the presence of various risk factors that could predispose one to have less than optimal nutritional intake, we need to consider what the appropriate indicators of nutritional health are in the context of the aging population. Is it the nutrient intake of macro- and micronutrients or body mass index (an indicator of weight status based on the proportion of weight for height) as we have traditionally measured, or should we pay attention to the variety, moderation, and balance in food group consumption, or should we include indicators of food security such as availability, access, and affordability of nutritious diet? How do we measure availability and access to traditional diet and the quality and safety of traditional foods or cultural foods for the minority populations? There is a considerable need for identifying appropriate indicators of nutritional health among the aging population.

NUTRITIONAL REQUIREMENTS

Determination of a person's nutritional requirements is critical to ensure optimal nutrient intake. Reduction in energy requirements is one notable difference between individuals over 65 years of age and their younger counterparts.²¹ For example, energy needs for individuals 51 to 75 years of age typically decrease by approximately 200 kcal/day. After age 75, energy needs decrease on average by an estimated 500 kcal/day for men, whereas women's energy needs decrease an estimated 400 kcal/day.^{22,23} The decrease in energy needs is largely attributed to the age-related reduction in resting metabolic rate and activity-related energy expenditure.^{24–26} Historically, decreases in energy expenditure have been

Table 82-1. Formulas for Estimating the Energy Requirements of Older Persons (kcal/day)

Harris-Benedict Equations

Males: $BEE = 66.4730 + 13.7516 (Wt) + 5.003 (Ht) - 6.7550 (A)$

Females: $BEE = 655.0955 + 9.5634 (Wt) + 1.8496 (Ht) - 4.6756 (A)$

World Health Organization Equations

Males: $BEE = 8.8 (Wt) + 1128 (Ht) - 1071$

Females: $BEE = 9.2 (Wt) + 637 (Ht) - 302$

Weight-Based Method

20–25 (Wt)

Wt = weight (kg); Ht = height (cm); A = age (yr).

attributed to less physical activity, reduced mean muscle mass, and lower metabolic rate with advancing age. Yet other problems, including chewing difficulties, living alone, and low income, contribute to a decline of intake in the elderly. The third National Health and Nutrition Examination Survey (NHANES III, 1976–1980) reported that women and men aged 60 to 69 years and 70 to 79 years consumed an average of 550 kcal/day and 745 cal/day less than women and men aged 30 to 39 years, respectively.²⁷

Different methods exist for estimating the energy requirements of older individuals, and knowledge of patient-specific information is required such as height, weight, and age. One simple method, only requiring a patient's weight, estimates energy expenditure in the range of 20 to 25 total kcal/kg/day. Thus, the energy requirements of an elderly 70-kg individual could be met with the provision of 1400 to 1750 total kcal/day. These estimates appear to be appropriate because indirect measurements of energy expenditure in critically ill older adults were found to be 22 to 25 kcal/kg/day.²⁸ If weight gain is the desired objective, an increase in calories up to 30 kcal/kg/day may be warranted.

Although widely used to predict energy expenditures, the Harris-Benedict equations (Table 82-1),²⁹ which are based on the measurement of oxygen consumption and carbon dioxide production using direct calorimeter, are likely not accurate for older adults. They were developed in 1919, and although subjects ranged in age from 15 to 74 years, only 9 of the 239 healthy male and female subjects studied were greater than 60 years of age. In consequence, some authorities favor more recent equations established by the World Health Organization (see Table 82-1). Recommendations from the National Research Council include multiplying the calculated energy expenditure by coefficients accounting for various levels of physical activity.³⁰ An activity coefficient 1 to 1.12 times the energy expenditure is used for older adults who are sedentary or fairly inactive. Activity coefficients of 1.27 to 1.45 should be used to account for energy expended by the elderly with highly active lifestyles.

In contrast to declining energy requirements, protein requirements actually increase with advanced age because of the loss of skeletal muscle mass. Because of changes in metabolism, changes in body composition, and protein utilization efficiency, the age-related increase in protein needs is necessary for the repletion of body protein. In addition, infections, surgery, trauma, and pressure ulcers may also increase protein needs as a person ages. Sarcopenia is used to describe the age-associated loss in skeletal muscle and its functional consequences.³¹ The etiology of sarcopenia is currently unknown. However, loss of muscle mass has been

linked to neurogenic processes, dietary protein deficiencies, and sedentary lifestyles. There is no consensus on the recommended daily protein intake to enhance muscle protein anabolism and minimize the loss of muscle mass with age. Studies show that the average adult needs 0.8 gm of protein/kg of body weight in order to maintain protein equilibrium, whereas older adults require as much as 1.0 to 1.2 gm of protein/kg of body weight.^{32–35} This level of protein intake is generally recognized as safe and appropriate for maintaining nitrogen equilibrium in free-living, healthy elderly persons. Increasing protein intake to dosages of 1.2 to 1.5 g/kg/day may be required in older individuals with pressure ulcers who are undernourished or those with burns or gastrointestinal diseases that exhibit extraordinary nitrogen losses.³⁶ Elderly patients generally tolerate moderately high protein intakes without deterioration in renal function. However, subjects with existing renal disease should avoid high-protein diets as they may hasten a greater decline in renal function.³⁷

Another key factor in maintaining healthy nutritional status is an appropriate intake of dietary fat. Fats contain twice as many calories per gram as carbohydrates or proteins, and given the fact that higher intakes of dietary fat are associated with an increased risk of developing diabetes, heart disease, and other chronic ailments, lower-fat choices, such as skim milk rather than whole milk, are recommended. However, for older adults who are unable to consume enough of their daily energy requirement, the risks associated with a higher fat intake may be overlooked in favor of meeting the necessary daily energy requirement.

To maintain a healthy nutritional diet and nutritional status, one must maintain an opportune intake of vitamins and minerals as one ages. Because energy needs decrease while vitamin and mineral needs increase, the challenge of creating an optimal intake for the elderly is vital. According to the dietary reference intakes (DRI), calcium, vitamin D, and vitamin B₆ needs increase with age. For example, 1200 mg/day of calcium is essential to protect against bone loss. Similarly, the DRI indicates that vitamin D needs increase from 5 µg to 10 µg for individuals aged 51 to 60, and 5 µg to 15 µg for those over age 70. Hypovitaminosis D is currently a significant problem among elderly individuals. An age-related decline in vitamin D intake is correlated with lower dietary intakes, less sun exposure, less efficient skin synthesis of vitamin D, and impaired kidney function, which in turn impairs the conversion of vitamin D from its inactive to active form. Also, insufficient levels of folate and vitamins B₆ and B₁₂ are known to contribute higher than normal levels of serum homocysteine, a known risk factor in the development of coronary artery disease, stroke, and depression, as well as a decrease in cognitive function. Individuals over age 50 need to consume more vitamin B₁₂ or rely on supplements to avoid the malabsorption of food-bound B₁₂, because as many as 30% of older adults are deficient in vitamin B₁₂ daily.

Water is often overlooked as an essential nutrient, and inadequate hydration poses an additional risk for increased morbidity and mortality in the elderly. Age-related decline in intracellular water and fluid reserves, paired with changes in renal function (causing an inability to concentrate urine), can result in difficulty maintaining appropriate fluid levels in older adults. Not only do these physiologic factors impair fluid levels, but altered thirst perception resulting in reduced fluid intake also becomes an obstacle. Furthermore,

external factors provide the elderly with more impediments to balanced fluid intakes. Residents of long-term care facilities (LTCF) are especially at risk for dehydration because of their limited access to oral fluids or underlying conditions (vomiting, diarrhea, colostomy/ileostomy) that increase fluid losses. Institutional issues including inadequate staffing and a subsequent need for better supervision places the frail elderly at greater risk.³⁸ Untreated dehydration in hospitalized elderly can result in mortality exceeding 50%.³⁹ As a result, LTCF staff members use specific triggers to detect inadequate hydration (Table 82-2). As such, older adults should make a conscious effort to increase fluid intake and not just rely on thirst perceptions. A water intake of 1 mL per calorie ingested or 30 mL/kg per day is generally recommended to meet dietary water requirements and achieve adequate fluid intake in older adults.⁴⁰

In accordance with Canada's Food Guide to Healthy Eating, dietary guidelines have been created to help avoid energy and vitamin deficiencies in the older population, by encouraging the elderly to meet their needs from healthy dietary sources. The DRI encourages older adults to acquire 45% to 65% of their daily energy intake from complex carbohydrates in order to obtain enough dietary fiber (25 to 30 gm/day). Dietary recommendations from the 2005 Dietary guidelines for Americans include the consumption of nutrient-dense beverages from the food groups that limit saturated and trans fats, cholesterol, added sugar, salt, and alcohol; a diet rich in fiber found in natural sources such as fruit, vegetables, and whole grains; and limiting sodium intake to 1500 mg per day. Other recommendations such as the consumption of calcium and vitamin D through foods or supplements and the maintenance of a healthy body weight through a balanced diet and exercise also play a key role in helping older adults meet their daily nutritional needs.

COMMON NUTRITIONAL PROBLEMS AND DEFICIENCIES

Imbalance between nutrient intake and nutrient requirements or less than optimal nutritional status can result from less than optimal dietary intake, age-related changes, disease conditions and their treatment, or other contextual factors such as cultural and religious beliefs, practices, and socioeconomic conditions. This imbalance can result in nutrition-related problems and deficiencies among older adults. The most common nutritional deficiencies include malnutrition, which encompasses both under- and overnutrition, micronutrient deficiencies, and dehydration. Malnutrition is common in elderly adults and can be divided into protein energy

malnutrition and micronutrient deficiency. Whether the imbalance is a result of poor dietary intake, age-related changes, disease conditions/treatments, or other factors such as cultural or religious beliefs, practices, or socioeconomic issues, malnutrition varies in its prevalence. Protein energy undernutrition varies from 1% to 15% in the community to 25% to 85% in long-term care facilities.⁴¹ It is important to recognize that undernutrition is not simply a result of poor dietary intake but is the combination of many factors that interrupt the balance between intake and need. The presence of cognitive decline or dementia, depression, chronic disease, or functional deficits are also factors in undernutrition, which are common in individuals suffering from sarcopenia (loss in skeletal muscle and its functional consequences as one ages) and geriatric failure to thrive (GFTT), a syndrome where individuals suffer involuntary weight loss and cannot maintain functional capacity or social and cognitive skills with no visible cause. Although the exact prevalence is unknown, the incidences increase with age and are more common in men and those living in LTCF. In both cases, nutritional interventions and the use of an interdisciplinary team approach have been successful through an increase of energy and protein intake through both dietary sources and oral supplements.⁴² Other interventions such as exercise programs have also been beneficial to prevent sarcopenia.

Micronutrient deficiencies among older adults occur when calcium, vitamin D, iron, vitamin B₁₂, and other minerals or vitamins are lacking. Such deficiencies are common and can be easily remedied through the use of supplements. Vitamin D deficiency is widespread among all age groups but is especially prevalent among the elderly.⁴³ Adequate vitamin D nutrition is important for maintaining healthy bone status and reducing the risk of fractures and osteoporosis. The Institute of Medicine (IOM) recommendations for vitamin D daily intake are 400 IU for adults 51 to 70 years old and 600 IU for adults > 71 years old.⁴⁴ Calcium also plays an important role in maintaining bone health in the elderly. The IOM-recommended calcium intake for adults 51 years and older is 1200 mg/day, with the maximal dose of elemental calcium not to exceed 500 mg at any one time.⁴⁴ Calcium carbonate is the most cost-effective form of calcium, well absorbed, and tolerated by most individuals when consumed with a meal. Of note, calcium citrate is the preferred form to be used in elderly with intestinal absorption problems, such as achlorhydria or inflammatory bowel disease.⁴⁵ Noteworthy changes in B vitamin status occur with advancing age. Observational studies suggest that low plasma concentrations of B vitamins folate, cyanocobalamin (B₁₂), and pyridoxine (B₆) in elders may be linked to greater bone loss.⁴⁶ Concern for toxicity of fat-soluble vitamins, such as vitamin A, exist in older adults because of increased liver stores and declining renal function associated with increasing age. Osteoporosis and hip fracture are associated with vitamin A intakes that are only twice the current recommended daily intake of 1000 µg retinol equivalents (RE)/day in males and 800 µg RE/day in females.⁴⁷ Thus, caregivers of elders who take vitamin supplements should understand the risks and effects that chronic high intakes of vitamin A may have on bone loss.

The prevalence of obesity has steadily increased since the late 1980s. Obesity is generally defined as an unhealthy excess of body fat characterized as a body mass index

(BMI \geq 30 kg/m²). In 1991, approximately 15% of individuals aged 60 to 69 years old and 11% of those over 70 years old were obese.⁴⁸ The prevalence of obesity in these same age groups increased to approximately 23% and 16%, respectively, 9 years later.⁴⁹ Higher risks of mortality and other serious medical complications, including hypertension, arthritis, obstructive sleep apnea, urinary incontinence, and cancer, are associated with older men and women who have a BMI over 30 kg/m². The current treatment guidelines for weight management in older persons are lifestyle intervention involving diet, behavior modification with physical activity, and pharmacotherapy.⁵⁰ A reduction in calorie intake by 500 to 750 kcal/d with an intake of 1 g protein/kg/d of high-quality protein is recommended. Regular physical activity in the form of stretching and aerobic and resistance activity is important to increase flexibility and endurance while preventing frailty. Experience with weight-loss medications is limited, however, orlistat appears to be the safest for older individuals. Bariatric surgery is reserved for selected individuals who fail diet and medication therapy and continue to suffer from disabling obesity. The perceived benefits of the procedure in terms of quality of life must be weighed against the postoperative morbidity and risk of potential complications.

NUTRITIONAL STRATEGIES

Several strategies can be used to increase dietary intake of the frail elderly person. High nutrient-dense feeds can be incorporated into the diet if the individual tolerates traditional solid foods. Peanut butter spread on whole-wheat bread, enriched cereal, or powdered instant breakfast products can be substituted at breakfast to increase caloric intake. High-protein and high-calorie snacks, in the form of crackers and cheese, milkshakes, or sandwiches, can be given throughout the day to supplement oral intake.³⁶ Dietary adjustments and special utensils are often beneficial when physical or neurologic disorders contribute to poor oral consumption. Institutionalized residents often require assistance from staff for eating and drinking.⁵¹ Use of semicircular tables is a simple method to assist understaffed caregivers in feeding several residents at a time in an LCTF. Modified spoons have been used to decrease spillage by elders afflicted with hand tremors. Changes in food texture, such as pureed vegetables or puddings, can avoid intake problems in subjects with poor dentition. Patients with swallowing dysfunction should be taught appropriate eating positions and safe swallowing techniques to minimize dysphagia.

Enteral nutrition (EN) delivered through a feeding tube can be initiated when older subjects are unable to maintain adequate nutrient and fluid intake by oral ingestion. Small-bore gastric or duodenal tubes may be placed through the nose to provide short-term (i.e., a few weeks) enteral access to treat elderly patients admitted for rehabilitation after hip or knee surgery, patients with pressure ulcers, or those with temporary swallowing disorders. Chronic disorders such as head/neck cancer, stroke, head injuries, or neuromuscular disorders impairing the ability to swallow would necessitate placement of a long-term (months to years) enteral access device. Long-term enteral access is achieved with gastric tubes that are inserted directly into the stomach by a surgeon in an operating room or by a gastroenterologist at the

bedside. Percutaneous endoscopic gastrostomy (PEG) tubes placed with an endoscope are becoming more common than open surgical gastrostomy tubes because the expense and risks associated with an invasive surgical procedure can be avoided. If gastroparesis or an anatomic defect is present that prevents normal gastric emptying, a feeding tube placed in the jejunum is most appropriate to reduce the risk of aspirating EN into the lungs.

Complications of EN include pulmonary aspiration, diarrhea, and mechanical obstruction of the feeding tube. Aspiration of EN remains one of the most dangerous complications of EN administration. Mortality rates from aspiration of gastric contents range from 40% to 90%.⁵² Recommendations for reducing the risk of aspiration in older individuals receiving gastric feedings include elevating the head of the bed over 30° and frequent exams for abdominal distention. EN is often identified as a cause of diarrhea, despite numerous other factors such as medications, hyperosmolar EN formulations, hypoalbuminemia, and infection. Sorbitol is used as a vehicle for many liquid formulations of pharmacologic agents and has been associated with diarrhea. Antibiotics or prokinetic agents like metoclopramide are examples of concurrent therapies more likely to cause diarrhea than the EN formulation. *Clostridium difficile* is a well-known cause of diarrhea in patients receiving EN and should be ruled out before antidiarrheal agents are initiated.

Elderly patients who require nutrition support but do not have functional or accessible gastrointestinal tracts are candidates for parenteral nutrition (PN). This may include patients with severe inflammatory bowel disease (e.g., Crohn's disease or ulcerative colitis), malabsorption (e.g., celiac sprue), bowel obstruction, a history of extensive bowel surgery (e.g., short bowel syndrome), and severe acute pancreatitis when enteral nutrition has failed. The primary goal of PN should be to prevent undernutrition from inadequate energy and nutrient intake or to treat undernutrition and its complications. Guidelines published by the American Society for Parenteral and Enteral Nutrition exist for appropriate use of PN.⁵³ Table 82-3 lists some monitoring guidelines for fluid,

electrolyte, and micronutrient abnormalities that should be performed in geriatric patients during PN administration.

NUTRITION PROGRAMS AND SERVICES

Many services are available to support the nutritional and health needs of the elderly. Examples include meal-delivery programs, community meals, grocery-delivery services, food banks and food stamps, and nutrition screening and education initiatives. In-home programs such as the Elderly Nutrition Program (ENP) in the United States, mandated through the Older Americans Act, provides in-home and community-based nutrition services to individuals over 60 years of age and targets those at highest economic and social need.⁵⁴ ENP offers meal-delivery services and congregate meals, as well as nutrition screening and assessment. Although a program such as ENP is not available in Canada, for-profit and not-for-profit organizations provide a similar array of services.

Many *meal-delivery services* in Canada, such as the Meals on Wheels program, offer meals for elderly Canadians for a nominal fee, and many church groups, for-profit, and not-for-profit organizations offer similar programs for those who have difficulty preparing meals for themselves, thereby placing them in a high-risk category. These meal-delivery services provide one hot meal, usually lunch, to people's homes at least 5 days a week. Frozen meals are also available to the elderly on request. The delivered meal is required to meet one third of the daily nutritional requirement. However, for the frail, largely homebound elderly, one meal is insufficient to meet nutritional needs and avoid nutritional deficiencies. This type of meal-delivery service has shown benefit to seniors who have difficulty preparing meals for themselves and are at risk for poor nutrition. A recent study examining the impact of home-delivered breakfast and lunch showed significant improvement in nutritional intake and quality of life among frail, homebound older adults.⁵⁵

Congregate and community meals offered by churches and other community-based organizations not only assist the

Table 82-3. Complications of Parenteral Nutrition and Management Techniques

Complication	Management
Mechanical	
Pneumothorax	Possible chest tube placement; minimize number of catheter insertions; placement by experienced personnel
Air embolism	Placement by experienced personnel
Catheter occlusion	Anticoagulation locally with urokinase or streptokinase; routine line flushing
Venous thrombosis	Anticoagulation; catheter removal
Metabolic	
Hyperglycemia	Slowly initiate PN; check blood glucose frequently before advancing nutrition; administer insulin if needed
Hypoglycemia	Decrease amount of insulin administered; avoid abrupt discontinuation of PN by tapering rate of infusion; administer 10% dextrose if PN is abruptly discontinued
Hypertriglyceridemia	Decrease lipid volume administered; increase length of infusion time; avoid lipid administration >60% of total calories; assess risk factors for hypertriglyceridemia
Electrolyte disturbance	Monitor fluid intake and output and serum chemistries; replace electrolytes as necessary
Essential fatty acid deficiency	Provide 8% to 10% of total calories as lipid
Prerenal azotemia	Increase fluid intake; decrease protein administered; increase nonprotein calories; analyze nitrogen balance
Gastrointestinal	
Cholestasis	Avoid over-feeding; use gastrointestinal tract as soon as clinically able
Gastrointestinal atrophy	Use gastrointestinal tract as soon as clinically able
Infectious	
Catheter-related sepsis	Remove catheter and place at alternate site; adequately care for catheter site; possible treatment with intravenous antibiotics

elderly by providing them with balanced meals, but they also function as social events that many seniors would otherwise not experience. The community meals can be served as breakfast, lunch, or dinner, and their frequency ranges from once a week to once a month. Economic need can be offset through the use of *food stamps* or *food banks* on a short-term basis. The selection of foods offered in food banks primarily includes dry goods and nonperishable food items. Some food banks in Canada have facilities for refrigeration and offer selected perishable foods. For accessing these services, a rent receipt, identification, and proof of income may be required. *Community kitchens* allow small groups of individuals to pool resources and cook meals together that are later taken home, thus saving money and creating social time for elderly individuals. If mobility is an issue, *grocery-delivery services* are available for a fee and can be accessed via telephone or the Internet. Lastly, *nutrition screening* and *education programs* are offered through government agencies such as the ENP who utilize the DETERMINE checklist to aid seniors with nutritional risk assessments. Other lectures and community nutrition education programs are also offered to elderly individuals.

ETHICAL CONSIDERATIONS

A common but controversial issue is the withdrawal of nutrition when death is imminent (i.e., within 6 months). Although families may decide to discontinue life-sustaining medical treatment such as mechanical ventilation or dialysis, nutrition and hydration are often considered a basic human right. Most health care professionals agree that the wishes of the individual constitute the most important factor to consider in the development of a nutritional care plan.⁵⁶ Thus, most health care teams consider it ethical and acceptable for a competent individual to refuse or halt administration of artificial nutrition, although cultural differences are notable.^{57,58} If an individual is considered incompetent, caregivers should provide family members the support needed to facilitate a thoughtful decision with the individual's quality

of life taken into consideration. Communication among all parties involved (health care personnel, patients, family, friends, guardian) is paramount in making informed decisions concerning the delivery of artificial nutrition and end-of-life issues. Providing hydration solely without EN or PN is an appropriate alternative, as patients do not suffer from signs of dehydration. Additional information concerning the ethics of forgoing life-sustaining treatments may be found at www.partnershipforcaring.org/homepage/index.html.

KEY POINTS

Nutrition in Aging

- Nutrition affects aging and aging affects nutrition; each amplifies the impact of the other on health status.
- Nutrition assessment combines anthropomorphic, biochemical and clinical/dietary evaluation. Several screening tools exist, but appear to have their greatest impact when screening targeted populations, such as people receiving home care.
- Average energy requirements decrease with age; typically men >75 years require 500 fewer kcal/day, and women 400 fewer kcal/day. Protein requirements, however, increase due to the loss of skeletal muscle mass. The minimum requirement for muscle anabolism has not been established, but absent renal impairment, most older adults can tolerate moderately high protein intakes.
- Individuals over age 50 need to consume more vitamin B₁₂ or rely on supplements to avoid the malabsorption of food-bound B₁₂, since as many as 30% of older adults are deficient in vitamin B₁₂ daily.
- Water is often overlooked as an essential nutrient.
- Protein energy undernutrition varies from 1% to 15% in the community to 25% to 85% in long-term care facilities.
- Vitamin D deficiency is widespread among all age groups, but is especially high in older adults.

INTRODUCTION

Obesity is defined as an unhealthy excess of body fat, which enhances the risk of morbidity and untimely mortality. Obesity is a growing epidemic in developed countries and is also becoming increasingly problematic in our aging population. Obesity in older adults is accompanied by an untoward burden of chronic disease, metabolic complications, and a worsening in quality of life. More important, obesity in older adults exacerbates the age-related decline in physical function, which leads to frailty and disability. The current treatment designed for weight loss in older persons includes lifestyle intervention (diet, exercise, and behavior modifications), pharmacotherapy, and surgery. Existing evidence indicates that weight-loss therapy in obese older adults prevents or delays functional decline and medical complications, as well as improves quality of life. However, weight-loss therapy in the older adult population is controversial because it can potentially lead to adverse effects on a person's muscle and bone mass. This chapter describes the clinical importance of obesity in older adults and provides medical professionals with evidence-based treatment guidelines for obesity in the elderly.

MEASUREMENT

Body mass index (BMI) and waist circumference are widely used and accepted as simple methods to classify overweight and obesity. BMI is calculated as weight (kg)/height squared (m^2). However, the measurement of height is often unreliable and impractical in older adults in nursing homes. In this situation, it seems that using alternative measurements such as arm span may be more reliable.¹ Central obesity, as measured by waist circumference, is the excessive accumulation of fat in the abdomen. It is an independent predictor of comorbidities like diabetes, hypertension, and cardiovascular disease.² Table 83-1 incorporates both BMI and waist circumference in the classification of overweight and obesity and estimates relative disease risk.³

OBESITY PREVALENCE

The prevalence of obese older adults is rising sharply. According to National Health and Nutrition Examination Survey (NHANES) data from the period 1991-2000, the prevalence of obesity has increased dramatically for those in the age range of 60 to 69 and 70 to 79 years,^{2,3} by 56% and 36%, respectively.⁴ Only the very old, such as individuals older than 85 years of age, remain relatively constant in body fat percentage. The prevalence of obesity in older adults is likely to continue to increase and challenge our health care systems.⁵ Moreover, obesity poses an increasing dilemma for long-term care facilities and raises concerns about nursing home preparedness and access.⁶ The global growth rate for age-related obesity in developed countries is predicted to be 15% to 20%, and the same trends are now being observed

even in developing countries as they gain more economic affluence.⁷

THE RELATIONSHIP BETWEEN BODY COMPOSITION AND AGING

Aging is associated with significant changes in body composition. After the age of 30 years, individuals tend to show a progressive decrease in fat-free mass (FFM), such as muscle and bone, and an increase in fat mass. Moreover, in women after the age of 60 years, data from some studies suggest an accelerated loss of FFM.^{8,9} FFM attains its peak during the third decade of life, whereas fat mass reaches its peak during the seventh decade followed by a subsequent decline thereafter.⁹ In addition, aging is associated with the redistribution of body fat. The intra-abdominal fat (central adiposity) increases with aging, whereas the subcutaneous fat and total body fat decrease with aging.¹⁰

The hormonal changes with aging may explain some of the age-related shifts in proportion of fat and FFM. These age-related changes include a reduced production of the anabolic hormones, growth hormone, insulin-like growth factor-1 (IGF-1), testosterone, and dehydroepiandrosterone (DHEA), without a concomitant decline in the catabolic hormone, cortisol.^{11,12}

CAUSES OF OBESITY IN THE ELDERLY

Obesity results when total energy intake exceeds the energy output. Energy intake neither changes nor declines with advancing age. Hence, the decrease in total energy output (EO) is an important contributor in the gradual accumulation of body fat with aging. Aging is associated with a decrease in all major components of EO. These components are basal metabolic rate (which explains 70% of EO), thermal effect of food (10%), and physical activity (20%). The resting metabolic rate decreases with age largely because of an age-related decline in FFM.¹³ The thermic effect of food also declines with aging. The decline in physical activity with aging contributes ~50% of the reduction in EO that occurs with aging.¹⁴

ADVERSE EFFECTS OF OBESITY

Obesity is associated with several complications that are commonly known to increase mortality and morbidity¹⁵ (Table 83-2). In addition, obesity has a detrimental effect on physical function and quality of life in the elderly. These adverse effects of obesity are discussed in this chapter.

Mortality

Obesity is associated with increased cardiovascular and overall mortality in both younger and older adults.¹⁶ Even though obesity is associated with a higher relative risk of death for younger adults than for older ones, an elevated BMI increases absolute mortality and health risks linearly up to 75 years of age.¹⁷ The relationship of obesity in individuals 75 years or

Table 83-1. Classification of Overweight and Obesity by BMI, Waist Circumference, and Associated Disease Risk¹⁸

	BMI (kg/m ²)	Obesity Class	DISEASE RISK* (RELATIVE TO NORMAL WEIGHT AND WAIST CIRCUMFERENCE)	
			Men <40 in; Women <35 in	Men >40 in; Women >35 in
Underweight	<18.5		—	—
Normal [†]	18.5–24.9		—	—
Overweight	25.0–29.9	I	Increased	High
Obesity	30.0–34.9	II	High	Very high
	35.0–39.9		Very high	Very high
Extreme obesity	>40	III	Extremely high	Extremely high

*Disease risk for type 2 diabetes, hypertension, and CVD.

[†]Increased waist circumference can also be a marker for increased risk even in persons of normal weight.

Table 83-2. Adverse Effects of Obesity in the Elderly

Disorders Directly Caused by Obesity	Disorders Aggravated by Obesity
Metabolic syndrome	Osteoarthritis
Hypertension	Urinary incontinence
Dyslipidemia	All cardiopulmonary abnormalities
Coronary artery disease	Postoperative complications
Diabetes mellitus	Cataracts
Neoplasia	
Obstructive sleep apnea	

older with total mortality is equivocal. In very old persons, the prevalence of obesity could actually be lower. One explanation for this demographic shift is selective mortality. The underlying diseases can themselves increase the risk of early mortality in obese adults, thus causing an underestimation of the relation between obesity and mortality in older adults. Although those who are vulnerable to the adverse effects of obesity die at a younger age, the remaining surviving group of obese older adults are called the “resistant” survivors.

Comorbid disease

Obesity and increased abdominal fat are associated with increased morbidity (see Table 83-1), mortality, and poor quality of life.¹⁵ The prevalence of medical conditions commonly associated with obesity—such as hypertension, diabetes, dyslipidemia, and cardiovascular disease—increases with age.¹⁸ Therefore, obesity and weight gain during middle age may contribute to medical complications and the increasing health care expenditures that occur during old age.¹⁹

The age-related glucose intolerance increases with abdominal obesity and lack of physical activity. Older people who are physically active and do not have increased abdominal girth are much less likely to develop insulin resistance and type 2 diabetes mellitus.²⁰ In addition, obese older adults have higher prevalence of dyslipidemia (high triglyceride and low high-density lipoprotein [HDL])²¹ and hypertension.²² In a 15-year longitudinal study, increased BMI in older men was associated with an increase in new cases of coronary heart disease and cardiovascular disease mortality.²³

Functional impairment and quality of life

Advancing age causes physical dysfunction because of both a progressive decline in muscle mass and strength and an increase in joint immobility and arthritis.²⁴ These functional limitations adversely affect the activities of daily living (ADL) and quality of life. Obesity exacerbates this age-related decline in physical function. In addition, medical

comorbidities like diabetes, heart disease, and pulmonary disorders frequently coexist with obesity and contribute to functional decline. Moreover, older adults who are obese (BMI greater than 30) have a greater rate of nursing home admissions than those who are nonobese (BMI between 18.5 and 24.9).²⁵ Both cross-sectional studies^{26,27} and longitudinal studies²⁸ have consistently demonstrated a strong link between a decline in physical function of older persons and an increase in BMI.

Obesity is also associated with frailty syndrome in older adults. In one study, 96% of community-living obese (BMI greater than 30) older subjects (65 to 80 years old) were frail, as determined by physical performance test scores, peak oxygen consumption, and self-reported ability to perform ADL.²⁹ In another study, which was conducted in older women (70 to 79 years old), obesity was linked with a marked increased risk of frailty, determined by weakness, slowness, weight loss, low physical activity, and exhaustion.³⁰

Despite having higher absolute muscle mass, obese older adults are particularly susceptible to the adverse effects of obesity because not only do they have smaller muscle mass relative to their body weight (relative sarcopenia)³¹ but they also have age-related decline in muscle mass leading to sarcopenic obesity.³² With higher fat mass and lower muscle mass, physical activity becomes progressively more difficult. Hence, sarcopenic obesity acts synergistically with aging to augment disability. This leads to functional dependence, inactivity, and poor quality of life.

BENEFICIAL EFFECTS OF OBESITY

It should be noted that a potential benefit of obesity with aging is the protection from osteoporosis-related fractures. Higher body weight is associated with greater bone mineral density.³³ This is explained by the bone-stimulating effects of carrying extra body weight as well as hormonal changes (e.g., increased adipose tissue conversion of androstenedione to estrone). Heavier individuals have been found to have higher bone densities even in their non-weight-bearing bones. Furthermore, in the event of a fall, the extra cushioning provided by body fat can serve as protection against fractures, particularly of the hip.

MECHANISMS BY WHICH OBESITY INCREASES MORTALITY AND MORBIDITY

Adipose tissue is recognized as a source of inflammatory mediators by producing cytokines such as tumor necrosis factor-alpha (TNF-alpha) and interleukin-6.³⁴ It appears

that the relationship between obesity, insulin resistance, and atherosclerosis may depend partially on the increased production and the release of these inflammatory mediators from adipose tissue. It is postulated that the visceral fat (intra-abdominal fat) is most responsible for producing these deleterious cytokines, which in turn leads to diabetes, coronary artery disease, and malignant disease more commonly seen in older adults. Similarly, cytokines and inflammatory mediators produced by adipose tissue may play an important role in the pathophysiology of sarcopenic obesity.³⁵ A better understanding of the mechanisms that lead from gain in fat mass to muscle loss or vice versa seems to be crucial. Thus, more research is needed to better characterize this new area.

EFFECTS OF INTENTIONAL WEIGHT LOSS IN OLDER ADULTS

Body composition

Because weight loss results in a decrease in both fat mass (75%) and FFM (25%),³⁶ it is possible that weight loss in obese older persons could worsen the age-related loss of muscle mass. Nevertheless, adding regular exercise to a weight loss program can attenuate the loss of FFM. This effect was observed in a randomized controlled trial conducted on obese older subjects. There was no significant difference in the loss of FFM after regular exercise was added to a diet-induced weight loss program compared to a control group that did not lose weight.³¹

Medical complications

It is well known that weight loss improves or normalizes metabolic abnormalities associated with obesity in young and middle-aged persons.³⁷ Clinical trials conducted in obese older adults have shown similar results. It was observed that a decrease in multiple coronary artery disease risk factors (including the prevalence of the metabolic syndrome) and insulin resistance, as well as an increase in insulin secretion, resulted from weight-loss therapy in obese older adults.^{38,39}

Physical function and quality of life

Data from studies conducted in overweight and obese older persons with or without joint disease have shown that the combination of moderate diet-induced weight loss and exercise therapy improves both subjective and objective measures of physical function and health-related quality of life.^{31,40,41} Weight loss in combination with exercise training has also been shown to have beneficial effects on muscle strength and muscle quality (muscle strength/cross-sectional area).^{31,42}

Most of the weight loss studies that analyzed physical function as an outcome have included an exercise component. Therefore, data on the effect of weight loss alone on physical function are limited. Nevertheless, one study demonstrated that diet-induced weight loss programs can indeed improve both endurance capacity and exercise tolerance in obese older adults despite the loss of FFM.⁴³ These findings indicate that obesity is a remediable cause of frailty.

Mortality

In epidemiologic studies, it has been observed that older adults who lost weight, or who experienced weight recycling, had an increased relative mortality risk compared to those

who were weight-stable.^{23,44} However, it was not described whether the observed weight changes were intentional or unintentional. Self-reported weight change was used, and in addition, unintentional weight loss is a frequent complication of underlying serious illnesses, which can confound the explanation of weight-loss effects on mortality. Furthermore, there have not been any randomized controlled trials of weight loss that examined mortality as an outcome.

Bone mineral density

Weight loss can have adverse effects on bone mass. Prospective interventional studies conducted in young and middle-aged adults report that weight loss causes bone loss that may be proportional to the amount of weight loss.^{45–47} A clinical trial conducted in young and middle-aged persons showed that diet-induced weight loss, but not exercise-induced weight loss, is associated with reductions in bone mineral density (BMD) at weight-bearing sites. This suggests that exercise is an important component of a weight loss program designed to offset the adverse effects of diet-induced weight loss on bone.⁴⁸ Regular exercise can potentially attenuate weight loss–induced bone loss. Therefore, including exercise as part of a weight-loss program is particularly important in older persons to reduce bone loss. However, one study showed that moderate weight loss, even when combined with a multicomponent exercise, decreases hip BMD in obese older adults.⁴⁹ It is unclear whether the beneficial effects of weight loss and exercise on physical function lower the overall risk of falls and fractures, despite the decline in hip BMD. Additionally, it is unknown whether the bone loss associated with intentional weight loss increases the risk of osteoporotic fractures in obese persons.

TREATMENT

Weight loss in obese persons, regardless of age, can improve obesity-related medical complications, physical function, and quality of life.¹⁵ In older adults, improving physical function and quality of life may be the most important goals of therapy. The current therapeutic options available for weight management in older persons are (1) lifestyle intervention involving diet and exercise therapy, (2) pharmacotherapy, and (3) surgery.

Lifestyle intervention

Lifestyle intervention is just as effective in older subjects as in younger subjects.³¹ The combination of an energy-deficit diet, increased physical activity, and behavior therapy results in moderate weight loss and is associated with a lower risk of treatment-induced complications. Weight-loss therapy that reduces muscle and bone losses is recommended for older adults who are obese and who have functional limitations or metabolic complications.

DIET THERAPY

A successful diet-induced weight-loss program should help patients set realistic, yet clinically meaningful weight loss goal of an 8% to 10% reduction in initial body weight by 6 months. Following a calorie-reduced (calorie deficit ~500 to 1000 kcal/d) but balanced diet that provides for as little as 1 or 2 pounds of weight loss a week is recommended for a safe

Summary of Management Algorithm

Initial Evaluation

- A comprehensive medical history, physical examination, relevant laboratory tests, and medication review should be performed to evaluate the patient's current health status and comorbidity risks.
- Further information such as the patient's willingness to lose weight, prior attempts at weight loss, and current lifestyle should be gathered before starting weight loss therapy.
- Health professionals should facilitate in setting personal goals for the patient and welcome family members and care providers to participate in the management.
- Health professionals should personalize the weight loss plan after taking into considerations the special needs of this population.
- Advocate a combination of energy-deficit diet, exercise, and behavior modification.

Weight Loss Therapy

- Recommend a moderate energy intake (calorie deficit ~750 kcal/day) containing 1.0 g/kg high-quality protein/day, multivitamin, and mineral supplements (1500 mg Ca and 1000 IU vitamin D/day).
- Recommend referral to a registered dietitian trained in behavior therapy for nutritional education, counseling, and behavior modification techniques.
- Advocate a combination of energy-deficit diet, exercise, and behavior modification.
- Bariatric surgery may be an alternative for patients who have failed multiple weight loss attempts.
- Weight maintenance efforts should be implemented once weight loss goals have been achieved.

Exercise Therapy

- Evaluate the need for stress test before starting an exercise regimen.
- Recommend an exercise regimen that is gradual, personalized, and monitored.
- Recommend a multicomponent exercise program including stretching, aerobic activity, and strength exercises.

and effective weight-loss program.¹⁵ Because of the increased risk of medical complications, a very-low-calorie diet (<800 kcal/d) should be avoided. The diet should contain 1.0 g/kg high-quality protein/d,⁵⁰ a multivitamin, and mineral supplements to ensure that all daily recommended requirements are met. This includes 1500 mg Ca/d and 1000 IU vitamin D/d to prevent bone loss. It is important that health professionals help older adults set personal goals, closely monitor their progress, and use encouragement strategies to improve adherence to the weight-loss program. The diet therapy should be consistent with the National Cholesterol Education Program Expert Panel (Adult Treatment Panel III)'s Therapeutic Lifestyle Changes Diet (Table 83-3).⁵¹

Referral to a registered dietitian with experience in weight management is often necessary to ensure that appropriate nutritional counseling is provided. Patients should be educated on food composition, portion control, food preparation, and preferences. Counseling from an exercise specialist or a behavioral therapist who has weight-management experience can also facilitate behavior modification. A specific behavioral therapy strategy includes self-monitoring, goal setting, social support, and stimulus control.⁵² These techniques can be utilized to improve compliance.

Table 83-3. Nutrient Composition of the Therapeutic Lifestyle Changes Diet⁵¹

Nutrient	Recommended Intake
Saturated fat*	<7% of total calories
Polyunsaturated fat	Up to 10% of total calories
Monounsaturated fat	Up to 20% of total calories
Total fat	25% to 35% of total calories
Carbohydrates [†]	50% to 60% of total calories
Fiber	20 to 30 g per day
Protein	Approximately 15% of total calories
Cholesterol	<200 mg per day
Total calories [‡]	Balance energy intake and expenditure to maintain desirable body weight

*Avoid trans fatty acids as well because they increase low-density lipoprotein (LDL) and lower high-density lipoprotein (HDL) cholesterol levels.

[†]Carbohydrates should be derived from foods rich in complex carbohydrates, including whole grains, fruits, and vegetables.

[‡]Daily energy expenditure should include at least moderate physical activity.

It is important to realize that changes in the diet and activity habits of older adults may present special challenges because older adults have an increased burden of comorbid conditions, depression, hearing and visual difficulties, and cognitive dysfunction. This increase in chronic disabilities with aging reduces physical activity and functional capacity. Older adults are more likely to have unique psychosocial situations such as dependency on others, cognitive impairment, institutionalization, widowhood, loneliness, isolation, and depression. These situations should be addressed because such factors pose a challenge to weight loss. Because dependency in older age is common, lifestyle-change programs must include participation by family members and caregivers. A successful weight loss and maintenance program should be based on sound scientific rationale. The program must not only be safe and nutritionally adequate, but it must also be practical and applicable to the patient's ethnic and cultural background.

EXERCISE THERAPY

The introduction of an exercise component early in the treatment course can improve physical function and ameliorate frailty in older adults.³¹ In addition, exercise is a key component in maintaining weight loss. The exercise program should be started gradually and must be customized individually with consideration of diseases and disability. It should be started at a low to moderate intensity, duration, and frequency to prevent injuries and promote adherence. Subsequently, the exercise program should gradually intensify over time with longer duration and with more frequency, if feasible. The goals of regular exercise in obese older persons are to increase flexibility, endurance, and strength. Therefore, a multicomponent exercise program that includes stretching, aerobic activity, and strength exercises is the most appropriate. Very old and frail persons should not be excluded from these activities.

PHARMACOTHERAPY

Clinical trials that studied the role of pharmacotherapy in obesity treatment have enrolled very few older individuals. Therefore, limited data are available to determine the efficacy and safety of pharmacotherapy for obesity treatment in older adults.

The use of pharmacologic agents to treat obesity can further burden older patients. Most obese older patients are on a host of other medications for concomitant illnesses, which would increase the likelihood of noncompliance or errors with obesity pharmacotherapy. In addition, the potential side effects could have serious implications in older adults. Moreover, health insurance and Medicare often do not cover weight-loss drugs. This can cause an additional financial burden in older patients because they tend to live on a fixed income. All medications should be carefully reviewed because some medications can cause weight gain (e.g., antipsychotics, anticonvulsants, steroids, and antidepressants). Furthermore, weight loss–induced clinical improvements may require changes in medications in order to prevent iatrogenic complications.

BARIATRIC SURGERY

The available evidence concerning the effectiveness and safety of bariatric surgery in older adults is insufficient because only a handful of studies include older adults. Consequently, bariatric surgery should be considered in select older adults—those who have disabling obesity that can be ameliorated with weight loss and have failed multiple weight loss attempts in the past. The specific bariatric surgical procedure that is performed depends on the skill and experience of the surgeon. A multidisciplinary team should carefully evaluate the potential surgical candidates to make certain that the risk of postoperative morbidity and mortality is acceptable and that the perceived benefits of the procedure outweigh the risk of potential complications. A preoperative evaluation should include an assessment for depression, which is common in older adults and could influence outcome. Postoperative care should include monitoring

for nutrition-related abnormalities, particularly osteoporosis and deficiencies in iron and vitamin B₁₂.

CONCLUSION

There has been a dramatic increase in the prevalence of obesity in older adults. Obesity exacerbates the age-related decline in physical dysfunction and the increase in metabolic abnormalities, which leads to frailty, disability, and poor quality of life. It is particularly important to consider weight-loss therapy in order to improve physical function in obese older persons and prevent or improve medical complications associated with obesity. Therapeutic approaches must consider the potential undesirable effects of weight loss on muscle and bone masses.

KEY POINTS

Obesity

- The increase in prevalence of obesity in older adults is a major public health issue.
- Obesity causes frailty in older adults by exacerbating the age-related decline in physical function.
- Lifestyle intervention such as weight loss, behavior modification, and exercise therapy should be considered in older adults to improve physical function, quality of life, and medical complications associated with obesity.
- The treatment must consider the potential adverse effects of weight loss on bone and muscle mass.

INTRODUCTION

Older adults are particularly vulnerable to renal diseases as changes in the aging kidney diminish the capacity to respond to various physiologic and pathologic stresses. The diagnosis of renal disease in older people remains challenging, and the causes are seldom as straightforward as in younger people. The etiology is often multifactorial, and other concomitant nonrenal conditions such as diabetes and vascular disease commonly complicate the clinical picture.

DIAGNOSTIC PROBLEMS IN OLDER ADULTS

Atypical presentation of disease

As with any illness, the presentation of renal disease is often different in older adults compared to younger people. They may present with nonspecific symptoms that could be associated with a decline in their cognition or function or decreased mobility and falls, or they may be completely asymptomatic. Clinical examination findings can be hard to interpret. Typical signs of renal disease in younger people such as decreased skin turgor and postural hypotension are common in older adults without necessarily signifying hypovolemia and dehydration. Leg edema is also common, particularly in those with reduced mobility without necessarily indicating volume overload.

Measuring renal function

Although serum creatinine is most commonly used to detect renal dysfunction, it is an insensitive measure in older people because levels depend on age, sex, muscle mass, and diet. Renal disease is often undetected in older adults as their muscle mass is relatively lower and their serum creatinine levels may fall within the normal range even when renal function is severely diminished.¹ Nevertheless, in the context of acute renal failure, changes in serum creatinine remain the best marker of kidney function. In chronic kidney disease however, the glomerular filtration rate (GFR) is the preferred indicator and can be estimated by creatinine clearance, through a timed urine collection or formulae such as the Cockcroft-Gault² or Modification of Diet in Renal Disease³ (MDRD). The four-variable MDRD formula (Table 84-1) is the current method of choice in older people^{4,5} and is recommended by current guidelines.⁶ Cystatin C, a cysteine protease inhibitor freely filtered by the kidney, is an alternative serum marker of kidney function that is unaffected by age, sex, and muscle mass and approximates direct measurements of GFR more precisely. It is more sensitive in detecting early kidney dysfunction in older people and has been shown to be a strong prognostic indicator of death and cardiovascular disease,⁷ but it has yet to come into routine clinical use.

Collecting urine specimens

Obtaining a clean urine sample for analysis can be challenging, particularly in bed-bound female patients or incontinent patients, but not impossible with good nursing care. An early morning urine sample is preferable to exclude postural

proteinuria. Occasionally, catheterization may be necessary, but it should only be performed as a last resort as the procedure itself can cause infections.

Interpretation of urine examinations

In older people, urinalysis often shows increased leukocytes and epithelial cells, which are not necessarily pathologic. Mixed growth of organisms on culture is frequently a result of contamination, although mixed infections may occur in those with indwelling urinary catheters. Urinalysis may also reveal red cell casts, hematuria, or proteinuria as a result of intrinsic renal disease and should prompt further investigations and specialist input.

INFECTIONS OF THE URINARY TRACT

Up to 25% of women and 10% of men aged over 65 years have asymptomatic bacteriuria, which is defined as $\geq 100,000$ colony-forming units per mL urine on two or more consecutive tests in the absence of any clinical symptoms. This figure rises to $>50\%$ in women and $>35\%$ in men aged over 80 years.⁸ The prevalence is higher in people in institutionalized care, people with urinary catheters, and people with diabetes. Routine screening and treatment is not recommended, as unnecessary antibiotics result in more adverse effects and antimicrobial resistance without any clear benefits in mortality and morbidity.⁹ The only exceptions are those who are symptomatic or those about to undergo invasive urologic procedures such as transurethral resection of prostate or cystoscopy.

Urinary tract infections (UTI) occur when bacteria which colonize the superficial epithelium of the urinary tract breach this mucosal barrier. Once this barrier is breached, bacteria are able to invade bladder epithelial cells¹⁰—hence, the recommendation for treating asymptomatic bacteriuria in patients undergoing invasive urologic procedures. Recurrent UTI may occur because of susceptibility of the mucosal barrier, for example, in trauma secondary to urinary catheters, stones, or neoplasia or in people with problems clearing bacteria from bladder epithelial cells because of impaired immune response.

The diagnosis of UTI is based on clinical evaluation of symptoms and signs indicating breach of the mucosal barrier. The usual features of dysuria, urinary frequency, and urgency may be absent in older patients. Other typical symptoms and signs that significantly increase the likelihood that a UTI is present are hematuria, back pain, and costovertebral angle tenderness, whereas a history of vaginal discharge, vaginal irritation, or presence of vaginal discharge on examination significantly reduces the probability.¹¹ UTI is also associated with urinary incontinence in women¹² and should be excluded in people presenting with this symptom. Distinguishing asymptomatic bacteriuria from a clinically significant UTI may be difficult, particularly in those with cognitive impairment. A systematic review of the use of dipstick tests to diagnose or rule in UTI indicates that a positive result for either the leukocyte esterase or nitrite test showed the highest sensitivity and the lowest negative

Table 84-1. Estimation of GFR Using the Four-Variable MDRD Equation

$$\text{GFR}(\text{mL}/\text{min}/1.73 \text{ m}^2) = 186 \times \left\{ \left[\frac{\text{serum creatinine } (\mu\text{mol/L})}{88.4} \right]^{-1.54} \right. \\ \times \text{age (years)}^{-0.203} \\ \times 0.742 \text{ if female, and} \\ \left. \times 1.21 \text{ if African American} \right\}$$

likelihood ratio.¹³ However, a study in younger women aged 16 to 50 years found that a 3-day course of trimethoprim reduced dysuria equally in those with and without positive nitrite tests on urinary dipstick even though the dipstick test reliably predicted who did and who did not have a UTI.¹⁴ It is unclear whether this is generalizable to older adults, but it raises the question of balancing symptomatic relief against potential promotion of antibiotic resistance. The problem of promoting antibiotic resistance also occurs with regard to management of recurrent UTI. In women aged 21 to 72 years, both cranberry juice and cranberry tablets reduced the risk of UTI by around 20%,¹⁵ and this may be a useful first-line approach, though benefit in older age groups is less certain. There is a paucity of evidence to support long-term antibiotic prophylaxis in older adults, and attention to risk factors such as local hygiene, diabetic control, and catheter use is more important.

Although mild uncomplicated lower UTI can be managed safely in the community, bacteremic urinary sepsis carries a significant mortality rate of 25% to 60%.¹⁶ The most common causative organisms are *Escherichia coli*, *Klebsiella*, *Pseudomonas*, and *Proteus*. Several guidelines have been published with treatment recommendations.^{17–18} Uncomplicated lower UTI in women should be treated empirically with three days of trimethoprim or trimethoprim-sulfamethoxazole (cotrimoxazole). Longer courses of antibiotics have not been found to be better than short courses in older women.¹⁹ A 3-day course of ciprofloxacin is equally effective,²⁰ but this antibiotic should not be used as a first-line approach in older people, especially in hospitals, because of its association with increased risk of the hypervirulent ribotype 027 *Clostridium difficile*-associated diarrhea.²¹

The evidence for treating UTI in men is less robust. Most infections are associated with prostatitis or instrumentation of the urinary tract, and a 2-week course of quinolone therapy may be needed, though this has to be balanced against *C. difficile* risk as noted previously. Catheter-associated UTI is a major problem in older people, causing symptoms in 30% of patients, bacteremia in 4%, and a three-fold increase in the risk of death in the hospital.²² Symptomatic infections require broad-spectrum antibiotics based on local susceptibility patterns, then adjusted to culture results. A catheter change should be considered in those with long-term indwelling catheters before commencing antibiotics. There is some evidence to support the use of antimicrobial urinary catheters to prevent catheter-associated UTI in hospitalized patients,²³ which thus may be a useful adjunct to the general measures of avoiding catheter use when possible and careful catheter care.

Pyelonephritis refers to infection of the upper urinary tract. This mostly occurs through ascending infection from

the urethra and urinary bladder. Prostatic hypertrophy in men causes urinary obstruction, increasing susceptibility to infection. Immunocompromised and chronically ill patients, as well as those with renal calculi or any abnormality of the renal tract, are at a higher risk of complicated pyelonephritis. Clinical presentation ranges from mild illness to septic shock, often associated with fever, flank pain, and costo-vertebral tenderness as well as lower-urinary tract symptoms. Older people may be completely asymptomatic and only diagnosed with chronic pyelonephritis when they are found to have renal failure. Prompt antibiotic treatment is important in acute pyelonephritis because of the high risk of bacteremia as well as complications such as intrarenal and perinephric abscess. Most cases require hospital admission and parenteral antibiotics, although outpatient oral treatment is effective in selected uncomplicated cases.²⁴

ACUTE RENAL FAILURE

Acute renal failure (ARF) refers to the sudden reduction in the capacity of the kidney to excrete nitrogenous waste products and maintain adequate fluid and electrolyte homeostasis. Despite the lack of a universal definition of ARF,²⁵ commonly accepted criteria are a substantial rise in serum creatinine from baseline or beyond a set limit, with or without a reduction in urine output. The RIFLE classification scheme²⁶ (Table 84-2) attempts to further stratify ARF into severity categories with clinical outcomes, and it has been validated in several studies.²⁷

ARF is more common in older people with an incidence of 949 to 1129 per million population (pmp) in those aged over 80 years.²⁸ It is also more common in hospital inpatients, particularly within the intensive care unit. The causes of ARF have traditionally been divided into three categories: prerenal, intrinsic, and postrenal. There is substantial overlap between these categories, particularly the first two, and causes are often multifactorial in older adults.

Prerenal ARF

This is an appropriate physiologic response to renal hypoperfusion, which may occur as a result of true hypovolemia from dehydration, blood loss, vomiting or diarrhea, or functional hypovolemia in sepsis, cardiac failure, or decompensated liver cirrhosis. Drugs such as nonsteroidal anti-inflammatory drugs (NSAIDs), angiotensin-converting enzyme (ACE) inhibitors, or angiotensin II receptor blockers (ARBs) interfere with autoregulation of renal blood flow and can cause ARF in preexisting renal disease or hypoperfused kidneys. ACE inhibitors and ARBs can also cause hemodynamically mediated ARF in patients with renal artery stenosis in a solitary kidney or bilateral renal artery stenosis.²⁹ The integrity and function of the kidney is usually preserved after these insults, and prerenal ARF is reversible if perfusion and oxygenation is normalized by correcting the underlying cause promptly.

Intrinsic renal failure

Intrinsic ARF involves structural injury to renal cells, most commonly acute tubular injury. Unfortunately, many causes of acute tubular injury are iatrogenic in nature, through diagnostic procedures, therapeutic interventions, or nephrotoxic medications. The most common drugs causing hospital-acquired renal failure are aminoglycoside antibiotics.³⁰ They

Table 84-2. RIFLE Classification of ARF²⁹

	GFR Criteria	Urine Output Criteria
Risk of renal dysfunction	Serum creatinine increased 1.5 times or GFR decrease >25%	<0.5 mL/kg/hour for 6 hours
Injury to the kidney	Serum creatinine increased 2 times or GFR decrease >50%	<0.5 mL/kg/hour for 12 hours
Failure of kidney function	Serum creatinine increased three times or GFR decrease 75% or serum creatinine >350 $\mu\text{mol/L}$ (with an acute increase of > 44 $\mu\text{mol/L}$)	<0.3 mL/kg/hour for 24 hours or anuria for 12 hours
Loss of kidney function	Persistent ARF, complete loss of kidney function > 4 weeks	
End-stage renal disease	End-stage renal disease > 3 months	

Reproduced with permission of BioMed Central. Bellomo R, Ronco C, Kellum JA, Mehta RL, Palevsky P, and the ADQI workgroup. Acute renal failure—definition, outcome measures, animal models, fluid therapy and information technology needs: the Second International Consensus Conference of the Acute Dialysis Quality Initiative (ADQI) group. *Critical Care* 2004;8:R204–R212.

are directly toxic to renal tubules; therefore, serum levels should be closely monitored.

Drugs can also cause acute tubulointerstitial nephritis, a pertinent problem considering the prevalence of polypharmacy among older people. A thorough drug history of current and recent medications is therefore crucial, including any over-the-counter preparations. Common culprits include NSAIDs, diuretics, allopurinol, proton-pump inhibitors, and antimicrobials such as penicillin, ciprofloxacin, and acyclovir. A rash, fever, and arthralgia may also suggest acute interstitial nephritis. Stopping the offending drug should improve renal function, but corticosteroids are often used to help recovery by diminishing the inflammatory process.

Radiocontrast nephropathy is a growing problem accounting for 11% of ARF cases in hospitals.³⁰ The rise in serum creatinine generally occurs 2 to 5 days after exposure to contrast medium. The risk is four-fold higher in patients with preexisting renal disease and diabetes, whereas contrast osmolality and volume are also directly correlated to nephrotoxicity.³¹ Regional hypoperfusion causing hypoxia and direct tubular toxicity are mechanisms thought to be involved but the underlying pathophysiologic process is still poorly understood. There is some evidence supporting the use of periprocedural hydration as prophylaxis, but the optimal type, route, volume, and timing require further studies to determine this. Other prophylactic measures using antioxidants such as *N*-acetylcysteine or ascorbic acid may be beneficial, but current evidence is still inconclusive. Contrast media should therefore be avoided if at all possible, but if used, it should involve the lowest volume of iso-osmolar contrast, and other potentially nephrotoxic medications should be temporarily stopped.

Cholesterol embolism can occur following vascular procedures such as cardiac surgery, angiography, angioplasty, and stenting. It can also occur following thrombolysis and anticoagulation. Showers of small cholesterol crystals break off from atherosclerotic plaques and occlude arterioles or larger vessels. It can affect almost any organ in the body including the kidney, and it can be difficult to recognize. Malignant hypertension, mesenteric, and cutaneous ischemia as well as encephalopathy may be more prominent than the associated ARF. Symptoms and signs usually manifest weeks to months after the procedure. One study found the incidence of cholesterol embolism to be 4%,³² but true incidence is difficult to determine because of the lack of large epidemiologic studies.

Acute tubular necrosis may also be caused by endogenous renal insults. In rhabdomyolysis, skeletal muscle breaks down, releasing its contents and causing myoglobinuria,

accounting for 7% to 10% of cases of ARF.³³ This is caused by muscle injury resulting from direct trauma, metabolic disorders, prolonged exercise or seizures as well as medications such as statins and neuroleptics. Up to a third of rhabdomyolysis patients will develop ARF,³³ and this is important to exclude in older people sustaining a stroke or a fall with a prolonged lie.

Multiple myeloma is another condition mostly affecting older adults, of whom approximately 50% will develop renal failure.^{34,35} This is mediated through the direct toxic effects of light chains to renal tubules or intratubular obstruction by their casts. The associated hypercalcemia and hyperuricemia may also give rise to intratubular crystals. Renal failure is reversible in approximately half of these cases, and this is associated with better long-term survival.³⁴

Acute tubular necrosis can also be caused by renal ischemia, making prerenal ARF and ischemic acute tubular necrosis part of the same continuum. The most common cause is sepsis, particularly with multiple organ failure. Postoperative acute tubular necrosis may also occur, again often with prerenal causes.

Glomerulonephritis refers to immune-mediated conditions causing inflammation in the kidney, usually classified according to their histologic appearances. Previously thought to be rare in older people, it is now recognized to be a frequent finding as increasing numbers of renal biopsies are performed in this patient group. Rapidly progressive or crescentic glomerulonephritis is more common in older than younger patients.³⁶ The clinical features depend on the underlying causes, which include antibodies to the glomerular basement membrane, connective tissue diseases, infections, and systemic vasculitides (Table 84-3). Prompt diagnosis and treatment is essential to prevent irreversible loss of renal function. The presence of blood, protein, or red cell casts on urinalysis are useful clues. A full history and examination will often narrow down the differential diagnosis.

Postrenal ARF

An obstructive cause must be ruled out in all patients with ARF as prompt relief of the obstruction should result in improvement and recovery of their renal function. The longer this is delayed, the higher the risk of irreversible damage. Prostatic disease is a common cause and a history of hesitancy, poor stream, dribbling, and nocturia is usually present. Other causes include renal calculi, urethral strictures, retroperitoneal fibrosis, renal papillary necrosis, and pelvic malignancies. Examination may reveal a palpable bladder and a large residual volume following catheterization, unless

Table 84-3. Common Causes of Crescentic Glomerulonephritis and Associated Clinical Features

Causes	Clinical Features
Antiglomerular basement membrane (GBM) antibody	Goodpasture's syndrome—hemoptysis and pulmonary hemorrhage
Immune complex-mediated disease	Anti-GBM disease—renal involvement only
	Connective tissue diseases
	<ul style="list-style-type: none"> • Systemic lupus erythematosus—fever, malaise, myalgia, Raynaud's phenomenon, hypertension, edema, frothy urine • Essential mixed cryoglobulinemia—peripheral neuropathy, arthralgia, skin purpura • Henoch-Schönlein purpura—skin purpura, arthritis, abdominal pain, gastrointestinal hemorrhage
	Infection-associated causes
	<ul style="list-style-type: none"> • Poststreptococcal infection—edema, hypertension, hematuria • Endocarditis—fever, sweats, weight loss
	Glomerular disease
	<ul style="list-style-type: none"> • IgA nephropathy—frank hematuria, hypertension • Membranoproliferative nephropathy—hypertension, edema • Wegener's granulomatosis—nasal and upper airway symptoms, pulmonary nodules and infiltrates, c-ANCA positive • Microscopic polyangiitis—general malaise, weight loss, cutaneous lesions, p-ANCA positive • Churg-Strauss syndrome—late-onset asthma, eosinophilia, gastrointestinal upset, peripheral neuropathy, p-ANCA positive
Antineutrophil cytoplasmic antibodies (ANCA)-associated systemic vasculitis	
Others	<ul style="list-style-type: none"> • Malignancies: solid organ carcinomas and lymphoma • Drugs: penicillamine, hydralazine

the obstruction is more proximal. Ultrasound scan of the renal tract should show hydronephrosis. However, the sensitivity of renal ultrasonography is only 80% to 85%,³⁷ and serial ultrasound scans or other radiologic imaging methods such as computed tomography or pyelography may be indicated.

Immediate Management

The principal aim is to treat any life-threatening features promptly and stop the decline in renal function before it becomes irreversible. Hypotension, shock, and respiratory failure will be obvious clinically and sepsis should be treated immediately with appropriate antibiotics and fluid resuscitation, preferably in a high-dependency or intensive care unit. Other life-threatening features associated with ARF are hyperkalemia, pulmonary edema, and severe metabolic acidosis.

Hyperkalemia is dangerous because it precipitates fatal cardiac arrhythmias. ECG changes include absent or flattened P waves, broadening of the QRS complex, tall-tented T waves, and eventually ventricular fibrillation or asystole. If any of these Electrocardiogram (ECG) changes is present or if the serum potassium is >6.5 mmol/l, treatment should be started immediately. The myocardium should be stabilized with intravenous calcium, followed by an infusion of insulin and dextrose to increase cellular potassium uptake. Salbutamol has a similar effect to insulin. These measures simply redistribute potassium within the body, and the excess potassium still needs to be excreted, either through restoration of renal function with increased renal potassium excretion or renal replacement therapy (RRT) if the patient remains oliguric or anuric.

Pulmonary edema resulting from volume overload in oliguric or anuric patients is difficult to treat. Respiratory support with oxygen is mandatory, and ventilation may be considered depending on the clinical situation. Opiates and a nitrate infusion may reduce cardiac workload. Large doses of diuretics may be needed to induce diuresis. However, if unsuccessful, then fluid can be removed by RRT.

Severe metabolic acidosis can be treated with intravenous sodium bicarbonate, but there is little evidence that this is beneficial. The acidosis will improve as renal function recovers, but severe acidosis in patients who remain oliguric or anuric will require RRT.

Subsequent Management

The cause of ARF needs to be determined so treatment is targeted appropriately. Thorough history-taking and examination should enable the clinician to establish a differential diagnosis. Several blood tests and radiologic investigations may be helpful (Table 84-4). A renal biopsy may be necessary for accurate histopathologic diagnosis, and although there is a risk of bleeding, it is reasonably safe in older people.³⁸

Crucial to the management of ARF is accurate assessment of the patient's volume status and hydration. The majority of patients will be volume deplete and require intravenous fluids. However, bearing in mind the high prevalence of cardiac disease among older people, in particular diastolic dysfunction, this needs to be done cautiously to avoid acute pulmonary edema caused by overzealous fluid resuscitation. Assessment of fluid balance can be difficult in older adults, so a central venous pressure monitor may be useful but is not without its risks.

A urinary catheter should be inserted early, not just because it may relieve obstruction, but to allow accurate measurement of urine output. Relief of upper urinary tract obstruction will require either percutaneous nephrostomy or retrograde cystoscopy with urethral catheterization. Post-obstructive diuresis may be up to 20 liters a day,²⁹ requiring careful management to prevent prerenal ARF resulting from the subsequent volume depletion. Hyperkalemic renal tubular acidosis may also occur but generally resolves spontaneously.

All nephrotoxic medications should be stopped as soon as renal failure is identified. Some drugs are removed by dialysis, and this should be considered when elimination is slowed down because of the associated ARF—for example, in toxicity resulting from lithium, salicylates, barbiturates, and inorganic acids. Special considerations and dose adjustments

Table 84-4. Useful Investigations in ARF

Investigation	Comments
Urea and electrolytes	Identifies renal failure, hyperkalemia, and acidosis
Full blood count	Identifies anemia, infection
Clotting	Coagulopathy may occur
Group and save or cross-match	If acute bleeding suspected
Calcium, phosphate	Hypercalcemia may occur in multiple myeloma
Creatinine kinase, myoglobin	If rhabdomyolysis suspected
Blood cultures, as well as cultures of sputum, urine, wound sites	To identify causative organism in septicemia
Immunoglobulins, protein electrophoresis	If multiple myeloma suspected
Autoantibodies	If glomerulonephritis suspected
<ul style="list-style-type: none"> • Antinuclear (ANA) • ANCA • Anti-GBM • Antiextractable nuclear antigen (ENA) 	
Complement	
Cryoglobulins	
Rheumatoid factor	
Antistreptolysin O (ASO) titer, throat swab	If poststreptococcal glomerulonephritis possible
Hepatitis and HIV serology	If urgent hemodialysis considered
Other serology	If immunosuppressive treatment considered
<ul style="list-style-type: none"> • Cytomegalovirus (CMV) • Epstein-Barr virus (EBV) • Varicella-zoster virus (VZV) 	
Urinalysis	Identifies blood, protein, red cell casts
Spot urine protein:creatinine ratio	To quantify proteinuria
Midstream urine	Microscopy, culture, and sensitivities in infection Bence-Jones protein in multiple myeloma
Renal ultrasound scan or other radiologic imaging	Identifies urinary obstruction, size of kidneys, renal calculi, other structural abnormalities of renal tract
Electrocardiogram	Changes may occur with hyperkalemia
Renal biopsy	May be required for histopathologic diagnosis

are also necessary when prescribing drugs such as antibiotics and analgesia, as their pharmacokinetics may be altered in renal failure.

Once the cause of ARF is identified, definitive treatment should be commenced as soon as possible. Hypovolemia caused by bleeding may need endoscopic or surgical intervention. Uremia itself induces platelet dysfunction and coagulopathies requiring correction with vitamin K and blood products. Glomerulonephritis as suggested by the history, urinalysis, and autoimmune serology requires early involvement of nephrologists. Immunosuppression with corticosteroids or other agents, and occasionally plasma exchange, are necessary treatment measures once the diagnosis is clear.

RENAL REPLACEMENT THERAPY

Life-threatening conditions such as severe metabolic acidosis, pulmonary edema, and hyperkalemia refractory to medical therapy may require urgent RRT in the form of peritoneal

dialysis, hemodialysis, or continuous RRT. Other indications for initiation of RRT include poisoning with a dialyzable toxin and severe uremia with its complications of pericarditis, encephalopathy, and neuropathy.

Peritoneal dialysis uses the peritoneum as the semipermeable membrane for dialyzing. Solutes pass from blood into the dialysate along their concentration gradient, and water by an osmotic gradient created by adding glucose or a polymer to the dialysate. This method is less efficient at solute and fluid removal compared to hemodialysis and is rarely used in the acute setting in developed countries. It is still useful where hemodialysis resources are limited and when anticoagulation or vascular access is not possible.

Hemodialysis involves passing blood into a dialyzer, where it interfaces with dialysate across a semipermeable membrane. Molecules diffuse across this membrane and large volumes of fluid can be removed by ultrafiltration. Good vascular access and anticoagulation with heparin is required. Intermittent hemodialysis is more suitable in severe hyperkalemia, has a lower risk of bleeding, and costs less, but adequacy and hemodynamic control are more difficult. Continuous RRT—for example, continuous venovenous hemofiltration (CVVH) or continuous venovenous hemodiafiltration (CVVHD)—is preferred for patients with cerebral edema and multiple organ failure as it offers better hemodynamic stability and biochemical and fluid volume control. Slowly extended daily dialysis (SLEDD) combines the advantages of both intermittent hemodialysis and continuous RRT by removing fluid more slowly with greater hemodynamic and metabolic control and may be preferable in the elderly. No particular modality has been proven to have better outcomes.²⁸

Age alone should not preclude a patient from receiving RRT. However, each patient should be assessed individually, taking into account his or her premorbid functional level and other nonrenal comorbidities, as well as the patient's wishes and that of his or her family. Even so, at the moment we lack an evidence base that would suggest when, if ever, a patient might be too frail to withstand hemodialysis.

Outcome

Mortality in ARF has been estimated at 40% to 70%.³⁹ Prognosis is worse with increasing age and comorbidity and those with hospital-acquired ARF.⁴⁰ Fifteen percent to 30% of ARF survivors remain dependent on long-term RRT,⁴¹ and many more never fully recover renal function and continue to have chronic kidney disease with its associated risks and complications. Prevention of ARF is therefore vital, with good clinical care and judicious use of potentially nephrotoxic drugs and procedures. Once present, ARF needs to be identified and treated promptly to maximize chances of full renal recovery.

CHRONIC KIDNEY DISEASE

Chronic kidney disease (CKD) is defined as at least 3 months of either decreased GFR of <60 mL/min/1.73m² or kidney damage, which may be indicated by persistent microalbuminuria, proteinuria, or hematuria; radiologically demonstrable structural abnormalities; or biopsy-proven chronic glomerulonephritis. The stage of CKD is determined by the level of kidney function, regardless of the underlying cause of renal failure (Table 84-5).^{6,42}

Table 84-5. Classification of CKD

Stage	GFR (mL/min/1.73m ²)	Description
1	>90	Normal kidney function, but with evidence of kidney damage
2	60–89	Mildly reduced kidney function with evidence of kidney damage
3	30–59	Moderately reduced kidney function
4	15–29	Severely reduced kidney function
5	<15 or on dialysis	Established renal failure

CKD mainly affects older people. The prevalence in the United States is estimated to be 13%, with 37% of those aged over 70 years having CKD stage 3 and above.⁴³ An English study found the prevalence of significant CKD to be 5554 pmp, with almost 90% of those not referred to nephrologists being aged over 70 years.⁴⁴

Causes of CKD

The most common cause of CKD is diabetes mellitus, accounting for 22% of people commencing RRT in the United Kingdom.⁴⁵ In older adults, renovascular disease and hypertension are also important causes, but in the majority of cases the primary renal diagnosis remains unconfirmed. Other causes more common in older patients include obstructive uropathy, myeloma, and systemic vasculitis. Glomerulonephritis, pyelonephritis, and polycystic kidney disease predominantly affect younger patients.

Clinical manifestations and complications

CKD is often asymptomatic, even in advanced stages. A large proportion of CKD is found incidentally on blood tests done for other reasons. Clinical features include poor appetite, nausea and vomiting, tiredness, breathlessness, peripheral edema, itch, cramps, and restless legs.

CKD is associated with increased mortality and morbidity, particularly from cardiovascular disease. The cardiovascular risk increases exponentially as CKD progresses, so the risk is increased 2-fold to 4-fold in stage 3 and 10-fold to 50-fold in stage 5.⁴⁶ Hypertension is common in CKD because of sodium retention and activation of the renin-angiotensin system. Most CKD patients also have other traditional cardiovascular risk factors such as age, diabetes, dyslipidemia, and smoking. Renal dysfunction itself causes oxidative stress, vascular calcification, increased circulating cytokines as a result of chronic inflammation, and elevated asymmetrical dimethylarginine (ADMA) levels that inhibit nitric oxide synthesis contributing to endothelial dysfunction and accelerated atherosclerosis. All of these mechanisms lead to a higher prevalence of myocardial infarction and ischemic heart disease, cardiac failure, stroke, and peripheral vascular disease.

Other complications of CKD involve the bones, anemia, acidosis, and malnutrition. Renal bone disease and anemia start at stage 3. The production of active 1,25-dihydroxyvitamin D is impaired, and secondary hyperparathyroidism occurs because of hypocalcemia and hyperphosphatemia. This is particularly significant in older people because of the high

incidence of osteoporosis. Anemia is due to erythropoietin deficiency, decreased erythrocyte life span, and blood loss. If left untreated, it may contribute to cardiac failure, cognitive impairment, and poor quality of life. Metabolic acidosis and malnutrition occur mainly at stages 4 and 5. Acidosis accelerates bone loss, muscle wasting, and hypoalbuminemia, as well as decline in renal function. Anorexia, dietary restrictions, increased catabolism, and chronic inflammation all contribute to malnutrition in CKD, causing muscle weakness, poor exercise tolerance, and increased susceptibility to infection.

Management

The rate of deterioration in renal function can be assessed by reviewing previous biochemistry results. Serum creatinine should always be rechecked so that any rapid decline can be identified and treated promptly. Any potentially reversible causes of renal failure should be considered, such as medications and infections. Urinalysis is important to check for hematuria and proteinuria. A urologic malignancy should always be excluded in macroscopic hematuria with a normal GFR. Proteinuria requires confirmation by laboratory testing, but 24-hour protein quantification is cumbersome and unnecessary. This can be estimated by multiplying the urine protein:creatinine ratio (P/Cr) measured from a spot urine sample by a factor of 10. P/Cr ≥ 45 mg/mmol is considered positive for proteinuria.

Clinical guidelines have been published outlining the management of CKD and indications for referral to nephrologists.^{6,47} Most patients up to stage 3 can be managed safely in the community, but disease progression should be monitored with regular kidney function tests. The rate of GFR decline can be estimated by graphing 1/creatinine over time and can be as high as 7 to 8 mL/min/year.⁴⁸ Changes in the gradient of the curve indicating a faster rate of decline should prompt investigations for potentially reversible causes. CKD progression is accelerated with proteinuria and uncontrolled hypertension.

The mainstay of treatment in CKD is optimal management of cardiovascular risk factors. Not only does this reduce mortality and morbidity, it also slows the progression of early CKD to established renal failure (ERF). Smoking, weight loss, exercise, alcohol, and sodium consumption are important issues to address. Aspirin and lipid lowering agents should be considered in all patients, and diabetics should aim for target glycated hemoglobin (HbA1c) of 6.6% to 7.5%. Hypertension should be carefully controlled, aiming for a target blood pressure of 130/80, and 125/75 if P/Cr > 100 mg/mmol. All patients with proteinuria and diabetics with microalbuminuria should be on ACE inhibitors or ARBs. Serum creatinine and potassium should be rechecked 2 weeks after commencing or increasing the dose of these drugs, withdrawal should be considered if creatinine increases by $> 20\%$ or GFR falls by $> 15\%$, and investigations for renal artery stenosis may be warranted.

All CKD patients should have their hemoglobin (Hb), potassium, calcium, and phosphate monitored at least annually. Treatment with erythropoiesis-stimulating agents and intravenous iron should be considered in anemic patients with Hb < 11 g/dL, aiming to maintain a stable Hb between 10.5 and 12.5 g/dL, depending on their functional needs.⁴⁹ If the parathyroid hormone concentration is raised and serum

25-hydroxyvitamin D is low, treatment with ergocalciferol or cholecalciferol with calcium supplement should be commenced. Phosphate binders are also useful in hyperphosphatemia, aiming for a phosphate level ≤ 1.8 mmol/L. Renal ultrasonography or other radiologic imaging may be indicated, especially in patients with lower urinary tract symptoms, intractable hypertension, and unexpected deterioration in GFR.

As CKD progresses to stages 4 and 5, patients should have blood tests mentioned earlier checked every 3 months. They should also receive dietetic input regarding appropriate sodium, fluid, potassium, and phosphate restrictions. Supplementary sodium bicarbonate can be used to correct acidosis, aiming to maintain plasma bicarbonate ≥ 20 mmol/L. All patients with stages 4 or 5 of CKD should discuss their condition with a nephrologist, unless there are other mitigating factors—for example, terminal illness. This is to ensure that patients are adequately informed about their treatment options as they approach ERF. Most patients need a minimum of 1 year to prepare themselves and their caregivers for RRT,⁵⁰ but late referral is significantly more frequent in older patients, contributing to excess mortality.⁵¹

ESTABLISHED RENAL FAILURE

The number of older patients on RRT continues to grow, and the median age of patients starting dialysis in the United Kingdom is 65 years.⁴⁵ Guidelines recommend starting RRT when GFR falls below 15 mL/min/1.73m² with symptomatic uremia, difficult fluid balance, or blood pressure control and progressive malnutrition. RRT should be started when GFR falls below 6 mL/min/1.73m², even when the patient is asymptomatic.⁵²

The most common form of RRT in older adults is hemodialysis. Subcutaneous arteriovenous fistula is the preferred vascular access and should be formed at least 6 months before commencing dialysis. In the short to intermediate term, synthetic grafts, central venous catheters, and semipermanent tunneled central catheters may also be used. Most patients undergo three hemodialysis sessions per week, each lasting 3 to 5 hours, usually in hospital units. Access to home hemodialysis is limited but may be considered for appropriate patients and is associated with good outcomes.⁵³

Peritoneal dialysis allows greater independence as it can be carried out in the patient's own home and tailored to the patient's daily routine. However, it is contraindicated in patients with a history of major abdominal surgery or peritoneal adhesions, unrepaired inguinal hernias, or compromised respiratory function, which unfortunately excludes many older people. Common problems include infection and fluid overload resulting from inadequate ultrafiltration, and conversion to hemodialysis may be necessary.

Transplantation can restore renal function completely and is clearly preferable to dialysis. Scarce donor organs, however, means that many older patients are not considered for transplantation because of their comorbidity and shorter life expectancy. Only 14% of renal transplant recipients in the United Kingdom are aged over 60,⁵⁴ despite no age limit to transplantation. Renal transplantation has been shown to be worthwhile in older patients with good graft survival rates, provided they are carefully selected and their immunosuppression tailored sensibly.^{55,56} Main complications are graft

rejection, infection, and malignancy, but cardiovascular disease remains the leading cause of death.

RRT may not always be in the best interest of all older patients. In heavily dependent patients with more comorbidity, survival on RRT is not significantly longer than those treated palliatively.⁵⁷ Many older patients on RRT spend a considerable proportion of their time in the hospital with a higher risk of developing multiple complications.⁵⁸ Conservative management aims to relieve the symptoms of ERF and maximize health for the remainder of patients' lives. This includes treating anemia with erythropoiesis-stimulating agents and controlling nausea and pruritus with appropriate drugs. Many renal units now have conservative care specialist nurses to facilitate this treatment option for patients. End-of-life care is equally important, not just in patients who choose not to dialyze but also for those who choose to withdraw from dialysis. Close collaboration with palliative services and primary care is essential.

Outcome

Mortality increases exponentially with declining GFR, by 17% for stage 3 and nearly 600% for stage 5.⁵⁹ Most patients are more likely to die of cardiovascular disease before reaching ERF. In a 5-year observational study in the United States, 3% of patients with CKD stages 2 through 4 eventually required RRT, whereas 24% died.⁶⁰ Our efforts should therefore concentrate on early identification and good management of cardiovascular risk factors, which will also delay progression to ERF.

CONCLUSION

The number of people with renal disease will continue to increase as our population ages and the diabetes epidemic grows. Early recognition of risk factors is essential as the disease is often asymptomatic in older people. Age per se should not be a contraindication to good treatment, and appropriate patients should be referred to nephrologists promptly. Bearing in mind the great heterogeneity of older people, each patient should be considered individually. Patients need to be adequately informed about the likely course and prognosis of their disease to guide them in making choices about treatment options.

KEY POINTS

Diseases of the Aging Kidney

- Renal disease is frequently underdiagnosed and undertreated in older people because they present with nonspecific or no symptoms and their serum creatinine may be normal.
- Asymptomatic bacteriuria does not require treatment.
- Iatrogenic renal failure is a growing problem because of nephrotoxic drugs and radiocontrast agents.
- Good management of cardiovascular risk factors is important in chronic kidney disease to reduce mortality and morbidity and delay progression to established renal failure.
- Appropriate referral to nephrologists improves outcomes.

Disorders of Water, Electrolyte, and Mineral Ion Metabolism

M. Shawkat Razzaque

INTRODUCTION

Water is the main component of living cells and tissues. Water balance is important for the proper physiologic function of various organ systems. An imbalance of water homeostasis, in the form of either dehydration or overhydration, can lead to severe health problems. Even mild alteration of the water balance can significantly affect the homeostasis of electrolyte and mineral ions, including sodium, potassium, calcium, and phosphorus; in addition, the body requires adequate amounts of magnesium, chloride, copper, fluoride, iodine, iron, selenium, and zinc. To maintain adequate functionality of the organ systems, the body needs to continuously recycle and replace water, electrolyte, and mineral ions. A unique coordination among the neural, endocrine, gastrointestinal, and renal systems maintains the necessary balance of water, electrolytes, and mineral ions in the body. As people age, this system becomes more prone to disruptions that can have clinical consequences.

WATER BALANCE

The mechanisms underlying the regulation of water balance are not yet clearly understood; however, increased knowledge of the effects of water channels in the kidney, namely aquaporins, as well as the functions of antidiuretic hormone (ADH) has provided molecular insights. ADH, also known as vasopressin, is a peptide hormone secreted by the hypothalamus. ADH secretion is influenced by several factors, including increased plasma osmolarity that activates receptors in the hypothalamus to release ADH. In normal physiologic conditions, water intake and water output are tightly regulated. If water output exceeds intake, a thirst sensation is stimulated to facilitate fluid intake. Higher serum osmolality, hypotension, and hypovolemia can stimulate thirst. In mild water disturbances, the kidneys conserve water according to the needs of the body. In conditions of severe volume depletion or hypertonicity, secretion of ADH is stimulated to reabsorb more water in the kidneys, resulting in the excretion of concentrated urine. In contrast, in conditions of hypotonicity, ADH is suppressed, and diluted urine is excreted. Similarly, when the blood pressure falls, stretch receptors in the aorta and carotid arteries are activated to stimulate ADH secretion so that the body can retain enough fluid to restore blood pressure. In addition, stretch receptors in the atria of the heart are activated when a larger than normal volume of blood returns to the heart from the veins; this activation of atrial stretch receptors inhibits ADH secretion, resulting in excretion of excessive fluid.

Maintaining water, electrolyte, and mineral ion balance becomes difficult in elderly individuals, as older people tend to retain less water than younger individuals. A healthy 30- to 40-year-old person usually has a total-body water content of 55% to 60%; however, by the age of 75 to 80 years, the total-body water content declines to 50%, which is even more marked in elderly women.¹ In aged

individuals, the urine-concentrating ability of the kidneys is reduced, and this may lead to more water loss through the urine.² Impairment of water homeostasis in elderly individuals is also associated with decreased renal mass,³ reduced cortical blood flow,⁴ and a decreased glomerular filtration rate,⁵ as well as altered responsiveness to sodium balance.⁴ Moreover, elderly individuals with urinary incontinence tend to drink less to avoid frequent micturition. Diarrhea, vomiting, or gastrointestinal bleeding can also contribute to water dys-equilibrium in elderly individuals. Common neurologic disorders, including dementia, anorexia, or depression, can affect water intake and water balance in older individuals. Similarly, poorly controlled diabetes, strokes, draining wounds, fever, rapid breathing, infection, or burns can destabilize not only water balance but also electrolyte balance in the elderly.

ELECTROLYTE BALANCE

The serum concentration of sodium usually reflects the status of water homeostasis in the body. The elderly show impairments in thirst sensation, renal function, and factors that regulate salt and water balance, and they are thus more vulnerable to age-associated diseases and iatrogenic events involving water and electrolyte disturbances. A comprehensive review of all the aspects of the regulation of electrolytes is beyond the scope of this chapter. Rather, emphasis will be given to the conditions that are associated with abnormal regulation of sodium and potassium, the two most extensively studied electrolytes.

Sodium is one of the major cations in the extracellular fluid, and it mostly determines serum osmolality. Systemic electrolyte disturbances, either in the form of hyponatremia or hypernatremia, are common in older adults and most evident in hospitalized patients or individuals living in long-term care facilities. Cross-sectional studies have found that hyponatremia may be present in as many as 15% to 18% of the individuals living in chronic care facilities.⁴ In contrast, about 30% of nursing home residents who required acute hospitalization have hypernatremia.⁶ Impaired water metabolism can be attributed to electrolyte imbalance in the form of hyponatremia or hypernatremia. For instance, elderly individuals have a reduced ability to excrete a water load,⁷ which may contribute to hyponatremia and be aggravated by receiving intravenous fluids.⁴ When hyponatremia is accompanied by central nervous system manifestations (hyponatremic encephalopathy), the morbidity is quite high. Hyponatremia can cause confusion, drowsiness, muscle weakness, and seizures, and a rapid fall in the sodium level can intensify these symptoms.

Dysequilibrium of salt and water input and output can lead to hypernatremia. In a hypernatremic microenvironment, cells become dehydrated, as increased extracellular sodium extracts water out of the cells. Dehydrated cells start to shrink, and to protect cells from such shrinkage, the resting potentials of electrically active membranes are

altered. Within an hour of hypernatremia, intracellular organic solutes are formed and they try to restore cell volume to minimize structural damage. It is important to note that the effects of cellular dehydration are marked in the components of the central nervous system, where stretching of shrunken neurons and alteration of membrane potentials from electrolyte flux may result in loss of cellular functions. In extreme cellular shrinkage, subsequent stretching may lead to rupture of the bridging or overlying veins in the brain, resulting in intracranial hemorrhage. The available evidence supports the fact that a hyperosmolar microenvironment resulting from water loss can induce neuronal cell shrinkage and brain injury, while uncontrolled water replacement can lead to the development of cerebral edema.

The prevalence of high plasma tonicity is significantly higher in adults older than 50 years of age, an indicator of cell dehydration.⁸ Among adults aged 70 years or older, the prevalence of plasma hypertonicity can be as high as 30%.⁸ Hypertonicity is positively associated with older age, Hispanic and African-American race, impaired glucose tolerance, diabetes, and hemoconcentration. In a community-based longitudinal observational study with more than 500 adults aged 70 years or older, plasma hypertonicity (≥ 300 mOsm/L) was suggested to be associated with early frailty.⁹ Taken together, plasma hypertonicity is an important determining factor for ill health in elderly individuals.

Potassium likewise needs to be adequately balanced to help maintain normal function of the organ systems. Hypokalemia is often caused by the use of a diuretic and may also result from prolonged diarrhea or vomiting. It is important to note that in prolonged hypokalemia, the body tends to produce less insulin, which may lead to increased blood sugar levels. Moreover, hypokalemia is also associated with

fatigue, confusion, muscle weakness, and cramps. In patients consuming digoxin to treat heart failure, even a moderately low level of potassium can cause abnormal heart rhythms. Hyperkalemia, however, poses much more health risks than hypokalemia. The most common cause of hyperkalemia is kidney failure or the use of drugs that impair potassium excretion by the kidneys (Table 85-1). These drugs include the diuretics spironolactone, triamterene, and amiloride, and angiotensin-converting enzyme (ACE) inhibitors, or angiotensin receptor blockers. Moreover, the use of nonsteroidal anti-inflammatory drugs (NSAIDs), cyclosporine or tacrolimus, trimethoprim or sulfamethoxazole, heparin, ketoconazole, and metyrapone can also lead to the development of hyperkalemia. One of the severe complications of hyperkalemia is severe cardiac arrhythmias.

As will be apparent, maintenance of an adequate electrolyte and mineral ion balance is essential for normal functionality of the vital organ systems, and this balance is often disrupted because of water imbalance in elderly individuals.

MINERAL ION BALANCE

Here we emphasize calcium and phosphate homeostasis and the disorders associated with their dysregulation. Maintaining normal calcium and phosphate balance is crucial for various essential biologic activities that include, but are not limited to, energy metabolism, signaling activities, and normal skeletal growth, development, and function. Abnormal mineral ion metabolism can affect the functionality of almost all the tissues or organ systems. In spite of the wide biologic importance and clinical significance of maintaining normal calcium and phosphate homeostasis, it is not yet clearly elucidated how homeostasis of these mineral ions is regulated.

A healthy adult usually contains ~25,000 mmol (~1 kg) of calcium. More than 99% of this is in the bone and less than 1% (~20 mmol) is in the extracellular fluid. In healthy individuals, the extracellular calcium concentration is remarkably stable, and a balance exists between the extracellular calcium concentration and the body calcium content. The extracellular calcium concentration depends on the balance between the amount of calcium entering the extracellular fluid (mainly from bone) and the amount of calcium leaving the extracellular fluid (in urine). Any functional impairment can lead to an abnormal extracellular calcium concentration. For instance, septicemia and sepsis can lead to the development of hypocalcemia. Reduced activities of parathyroid hormone or vitamin D deficiency are also associated with hypocalcemia. In addition, pancreatitis and a low dietary intake of calcium can facilitate development of hypocalcemia. Generalized weakness, numbness of the extremities, confusion, and seizures are a few commonly encountered complications of hypocalcemia. In contrast, hypercalcemia is found in skeletal diseases that are associated with abnormal release of calcium from the bone into the circulation. Skeletal metastasis of tumor cells and hyperparathyroidism can cause hypercalcemia. Mild hypercalcemia may not produce visible symptoms; however, more severe forms may cause dehydration, loss of appetite, nausea, vomiting, confusion, and even coma. Severe hypercalcemia needs immediate medical attention.

The total phosphorus content in the adult human body is about 12 g/kg, and most of it is present in mineralized

tissue. The serum phosphate level is held relatively stable by the regulated excretion of phosphate through the kidney. This control is primarily mediated by the action of parathyroid hormone and fibroblast growth factor 23 (FGF-23). Identification of FGF-23 as a “phosphatonin” has significantly enhanced our understanding of phosphate homeostasis.¹⁰ FGF-23 is a 30 kDa-secreted protein that is mainly produced in the bone by osteocytes.¹¹ It is presumed that bone-derived FGF-23 exerts its influence in the proximal tubules to induce urinary phosphate excretion to maintain phosphate homeostasis, but it is not yet clear how it interacts with or influences molecules that are also involved in regulating mineral ion homeostasis, including the transient receptor potential cation channel, subfamily V, member 5 (TRPV5), sodium–phosphate cotransporter 2a (NaPi2a), Calbindin_{28k}, the Na⁺/Ca²⁺ exchanger, and plasma membrane ATPase in the kidney.

Altered regulation of FGF-23 has direct relevance to human diseases, as gain-of-function mutations of FGF-23 have been shown to be associated with autosomal dominant hypophosphatemic rickets (ADHR).¹² These mutations are believed to prevent the proteolytic cleavage of the FGF-23 protein, with the net effect being phosphate wasting and skeletal defects, perhaps because of the enhanced biologic activities of FGF-23. Similarly, the increased serum level of FGF-23 in patients with oncogenic osteomalacia (OOM) is the causative factor for tumor-induced phosphate wasting.¹³ Likewise, X-linked hypophosphatemia (XLH) is caused by inactivating mutations of the gene encoding the phosphate-regulating gene with homologies to endopeptidases on the X chromosome, resulting in increased FGF-23 serum levels that lead to phosphate wasting and osteomalacia.¹⁴ Moreover, the presence of inactivating mutations in the dentin matrix protein 1 (*DMP1*) gene has been described in patients affected with autosomal recessive hypophosphatemia (ARHP),¹⁵ a rare genetic disorder with similar clinical features to those seen in patients with OOM, XLH, and ADHR. The clinical similarities of these diseases are thought to be due to increased activity of circulating FGF-23 protein. In contrast, patients with familial tumoral calcinosis (FTC) are characterized by the presence of ectopic calcifications and elevated serum levels of phosphate resulting from loss-of-function mutations in the FGF-23 gene.¹⁶ A list of the diseases caused by abnormal regulation of FGF-23 can be found in Table 85-2.
