recently and may serve simply as a gross depiction of the cognitive profile.

### Dementia with Lewy Bodies

According to consensus criteria for probable dementia with Lewy bodies (DLB), cognition must be carefully assessed. A progressive cognitive decline, usually over the course of a number of years, must be observed to a degree that it disables the patient. In addition, the patient must show some combination of fluctuations in attention, recurrent visual hallucinations, or spontaneous parkinsonism. Many patients may also present with other psychotic symptoms, neuroleptic sensitivity, and a history of falls and syncopal attacks. Based on these criteria, the differential diagnosis between DLB and PD is obviously difficult. At this time, the differential diagnosis is based purely on the timing of the onset of the cognitive symptoms. A patient with PD who develops cognitive symptoms after 1 year of motor symptoms is classified as "Parkinson disease with dementia." Earlier cognitive symptoms indicate DLB.

The differential diagnosis between DLB and AD can also be difficult. The presence of visual hallucinations in patients with MMSE scores greater than 20 is highly suggestive of DLB. Neuropsychological studies have identified typical cognitive profiles that may aid in diagnosis. In DLB, patients have more difficulty than patients with AD in copying complex designs, assembling pieces of an object, or completing other tasks requiring visuospatial skills. In contrast, AD subjects generally show significantly more impairment on delayed recall tasks than patients with DLB. Patients with DLB have attentional skills that are generally equivalent to those of patients with AD; however, patients with DLB exhibit significant attentional fluctuations. As a result, evaluating attention over time is more helpful than the overall severity of attention problems in the differential diagnosis. The clinical overlap of the two diseases may be related, in part, to the pathological overlap of the diseases. Neuropathological studies indicate that the majority of DLB cases have Alzheimer pathology (especially plaques) and that Lewy bodies are common in patients with AD. Finally, these cognitive profiles are most evident early in the course of the diseases. As the diseases progress, all cognitive functions become impaired and neuropsychological testing is less helpful for diagnosis.

### Progressive Supranuclear Palsy

Progressive supranuclear palsy (PSP) is less common than PD. Although Lewy bodies are found in only the minority of PSP cases, PSP is frequently misdiagnosed as PD. A core feature of the disorder is vertical supranuclear gaze palsy, although this symptom may not present early in the course of the disease. Patients also present with postural instability, and falls are often seen shortly after onset. Cognition is characterized by mental slowing and executive dysfunction. Memory impairments are observed, but they are not as severe as in AD. Language functions resemble those seen in PD. Visual spatial deficits and increased apathy are also observed.

### Alcohol-Related Dementia

Recent epidemiological analyses suggest that mild to moderate alcohol use reduces the risk for developing certain dementias, including AD and VaD. Chronic and profound alcohol use, however, can

have a negative effect on cognition and may exacerbate the cognitive symptoms of other dementias and brain injuries. Poor nutrition (thiamine deficiency in particular) resulting from alcohol abuse is a primary contributor to the onset of cognitive problems. In addition, liver disease itself can interfere with thiamine regulation in the brain and may be a factor in the multiple cognitive and motor impairments associated with long-term alcohol use. Chronic alcoholics are often impaired on neurocognitive tests even following a period of abstinence, and many continue to show cognitive deficits indefinitely.

### Persistent Alcohol Dementia

Alcohol dementia involves impairment in more than one area of cognitive function that persists after the patient stops drinking for a period of time. Visuospatial problem solving deficits and executive problems, including apathy, decreased judgment, and reduced interest in self-care, are prominent in these patients. Memory problems, in particular anterograde amnesia, are also common, but are generally not more impaired than other cognitive domains, and recognition is often intact. Typical neuropsychological sequelae include impairments on tasks requiring visual scanning, visuospatial organization, perceptual-motor speed, sustained attention, abstraction, and mental flexibility, while language functions are generally preserved. Perseveration and confabulation are common indicators of impaired executive function in the responses of patients with chronic alcohol use. It is also noteworthy that chronic alcohol use may potentiate the onset of AD, and produce a clinical picture of conjoint cognitive deficits.

### Wernicke–Korsakoff Syndrome

The most severe neurological outcome of heavy and prolonged alcohol use, and the result of critical malnutrition, is Wernicke–Korsakoff syndrome. In contrast to patients with persistent alcohol dementia, patients with Wernicke–Korsakoff exhibit an acute symptom onset, often beginning with a grave confusional state, nystagmus, and significant ataxia. During this phase, symptoms progressively and rapidly worsen if treatment (immediate thiamine replacement) is not applied. This phase is almost always followed by a chronic and progressive stage that is associated primarily with impaired frontal and cerebellar functions. Unlike persistent alcohol dementia, patients with Korsakoff have significant impairments in memory relative to other cognitive effects, and memory impairment includes both retrograde and anterograde amnesia for episodic events, frequently with prominent confabulation. In contrast to AD, semantic memory is relatively spared in the Korsakoff patient. Patients show a characteristic gradient of remote memory impairment, with better recall for remote events and progressively reduced recall of recent events. As with persistent alcohol dementia, executive dysfunction and visuospatial impairments are also significant symptoms of the syndrome. Cerebellar atrophy and peripheral nerve damage lead to impaired gait, decreased or abnormal reflexes, and other movement abnormalities in these patients.

### Prion Diseases

The prion diseases are a group of rare fatal spongiform encephalopathies that result from mutations and polymorphisms in the

prion protein gene (PrP), causing rapid neurodegeneration. These diseases, of which Creutzfeldt–Jakob is the most well known, produce a profound and quickly progressive dementia, and may be sporadic, familial, or infectious. Sporadic cases are the most common, and are generally diagnosed in people in their 60's, with a typical age range between 40 and 80. Early cognitive signs of the prion diseases are usually vague and nonspecific, such as poor memory, concentration, and problem solving. Initially, there are also often psychiatric symptoms, including apathy, emotional lability, impaired sleep, and appetite loss. Early frank neurological symptoms are not common, but as the disease progresses, hyperreflexia, impaired coordination, changes in saccadic eye movements, and incontinence may occur. Given the early vague symptoms and dearth of neurological symptoms, patients are not likely to present for evaluation until they are in the more moderate to advanced stages, which can occur in a matter of months. Diagnosis typically involves measuring electroencephalographic changes, hyperintensities on magnetic resonance imaging, and abnormal 14-3-3 protein deposits in the cerebrospinal fluid. The most common differential diagnoses include depression, AD, and LBD.

### Normal Pressure Hydrocephalus

Normal pressure hydrocephalus is a potentially reversible progressive dementia that makes up approximately 6% of the dementia cases. Abnormalities in the production, absorption, or flow of CSF result in ventricular dilatation. Patients may present with a triad of clinical symptoms that include gait or balance disturbance, urinary incontinence, and cognitive deficits. Unlike most other dementias, cognitive symptoms often present later in the course. This can make early clinical diagnosis difficult since gait abnormalities and incontinence have a variety of etiologies in geriatric populations. Radiographic evidence and intraventricular pressure measurement aid in the diagnosis. When cognitive deficits are present, they are most frequently observed in executive functioning. Although many subjects may have subjective memory complaints, memory deficits are not a prominent early symptom, and some memory declines are attributable to attention problems, which are more common.

When treated, a ventriculoperitoneal shunt is usually used to divert CSF for better absorption. However, surgery in geriatric populations always involves added risks, and the benefits of shunt surgery remain unclear. A wide variety of success rates have been reported, with better outcomes often reported after shorter follow-up periods. Patients with the full triad of symptoms appear to respond best to shunt surgery. Gait problems show the most frequent improvement, while cognitive function improves in the fewest patients. Recently, findings from a 5-year follow-up of normal pressure hydrocephalus patients with and without shunt surgery showed that at the 6-month assessment, 83% of the shunt cases improved in gait and 46% improved in memory. Of surviving shunt cases 5 years after surgery, 39% remained improved in gait, and fewer than 10% continued to show improvements on cognitive tests. Results suggested that outcomes may be improved in younger patients.

### Human Immunodeficiency Virus

Although there is often the perception that geriatric patients are not at risk for HIV infection, the CDC reported that 10% of all HIV cases in the United States are in patients 50 years of age or older,

and these numbers are expected to grow. The earliest cognitive areas affected are usually speed of information processing, attention, and motor speed. A subgroup of patients progresses to HIV-associated dementia, which is usually characterized by impairments in executive functioning, psychomotor speed, and memory.

## Neurosyphilis

Neurosyphilis is an advanced syphilitic infection that may present with hallucinations, delusions, mood disturbance, personality change, strokes, ataxia, or cognitive decline. Deficits are observed in short-term memory and mental status with progressive cognitive decline in all areas of functioning. Although neurosyphilis is often classified as a reversible dementia, there is only limited evidence to support cognitive benefits with treatment. The onset of dementia in neurosyphilis often occurs several decades after contraction of the disease. Although screening procedures remain controversial, neurosyphilis should be considered in a differential diagnosis of dementia of unclear etiology in geriatric patients.

## CONCLUSIONS

We have greatly furthered our understanding that age-related medical conditions not considered classically neurological in nature can nevertheless impact the central nervous system and thereby affect cognition. This knowledge has led to the realization that many of the changes in cognition previously thought to be unavoidable concomitants of normal aging are in fact preventable and in some cases even reversible. The deleterious consequences of not treating such disorders has become evident, given that many common diseases such as type 2 diabetes and hypertension appear to be risk factors for dementia. In turn, early identification of dementia or the prodromal condition mild cognitive impairment will become critical as therapeutic options for delaying disease progression proliferate. Careful characterization of cognitive status through neuropsychological assessment can provide the clinician with essential information to determine whether the patient is experiencing symptoms that warrant concern or further treatment. As the field of geriatrics approaches the goal of controlling or even preventing endemic late-life chronic diseases, it will become increasingly clear that the cognitive changes that occur with healthy aging are fewer than we thought, that they

are more subtle in nature, and that they should not affect our ability to have rich, active lives into our eighties and beyond.

# Psychoactive Drug Therapy

*Bruce G. Pollock ■ Todd P. Semla ■ Christina E. Forsyth*

## INTRODUCTION

In this chapter, we focus on the use of psychotherapeutic medications in the elderly, including the antidepressant, psychostimulant, antipsychotic, mood stabilizer, and anxiolytic medications that are used to treat the psychiatric disorders of late life, including major depression, anxiety, and the psychosis and behavioral disturbances that frequently accompany Alzheimer's disease (AD) and related disorders.

Mood and behavioral disturbances are of particular concern in the elderly. Late-life depression, including major depressive disorder and dysthymia, affects 5% to 12% of older adults. These rates are consistent with those in younger adults; however, the elderly face a disease profile that is more chronic and treatment resistant with an element of cognitive impairment. Frequently, depression in elderly, community dwelling individuals remains unidentified and untreated. Depression occurring past age 60 is likely distinct from that which occurs in younger age groups. It has been associated with significant vascular disease as evidenced in the imaging literature, and with low testosterone levels in older dysthymic men. This idiosyncratic disease profile may account for treatment resistance. For example, structural abnormalities in frontal white matter have been linked to a poorer remittance of depressive symptomatology.

Late-life depression leads to further deterioration in quality of life, as well as increasing risk for dementia and suicide. Depressed elders suffer greater rates of disability, mortality, and nursing home placement. Furthermore, when depression co-occurs with other medical or psychiatric illness, it negatively alters the disease process. For example, cardiac mortality is increased in depressed patients with unstable angina, postmyocardial infarction, or congestive heart failure, and comorbid anxiety impairs interpersonal function and leads to greater severity of physical symptoms. Consequently, the effects of depression result in greater strain on an already overburdened health care system.

Anxiety disorders are also highly prevalent in older adults, between 2% and 19% in community dwelling elders, with the most common forms being generalized anxiety disorder (GAD) and phobias. Anxious symptomatology not meeting criteria for a clinical diagnosis is experienced by a further 20% of elderly individuals. Late-life anxiety can co-occur with physical illness, depression, or side effects of medication use. Risk factors for anxiety in elders include cognitive and physical impairments, economic difficulties, and social segregation.

Older anxious individuals experience greater physical disability and cognitive impairment, as well as reduced ability to carry out activities of daily life. Quality of life is diminished and risk of mortality and coronary artery disease (particularly in men) is greater when anxiety is present in later life. Anxious elders are prone to excessive use of medical services, with anxiety disorders comprising 38% of mental health claims as compared to 21% for affective disorders.

Behavioral instability, including agitation, aggression, and psychosis, also appears frequently in late-life, especially when associated with dementia. Approximately 2% to 5% of elderly individuals 60 years of age or older suffer from dementing illnesses, while 15% to 40% of those older than 85 develop dementia. At some point in the course of dementia, most nursing home and community dwelling patients experience behavioral dysfunction and/or psychosis. For example, studies indicate that 10% to 70% of dementia patients experience psychotic symptoms. In a 4-year study, primary psychosis in patients with AD was reported to occur in 51% of patients. Across samples of AD patients, delusional symptoms, frequently related to theft or suspicion, can present in as many as 50% of patients. Hallucinations, typically related to phantom boarder syndrome (the belief that another person is in one's home), can involve either visual or auditory stimuli, and have been reported in 5% to 15% of dementia patients.

Alterations of personality can develop early in the course of illness. Such changes include depression, apathy, irritability, emotional withdrawal, and disinhibition (e.g., wandering, aggression, repetitive

calling out or screaming). More severe reactions associated with frustration can include angry or violent outbursts. Such psychopathology can be particularly troublesome for caregivers. Patients may become stubborn, combative, or neglectful of activities essential to daily life. As such, many caregivers are compelled to institutionalize their loved ones. Both in long-term care residents and community dwelling elderly, patients experiencing behavioral or psychological symptoms of dementia (BPSD) are at increased risk for mortality. Incidence of increased extrapyramidal symptoms (EPS) and greater cognitive decline has also been associated with BPSD. The use of psychotropic medications to treat these conditions is second only to the use of cardiovascular medications among older patients, including the frail and chronically ill elderly. Nearly one in five community dwelling elders and 47% of nursing home residents were found to be taking regular psychotropic medications. However, the basic pharmacokinetic and clinical evidence base underlying this use is limited. In fact, most psychiatric medications have been tested only in younger and healthier patients, prior to their release.

There are indications that this limited knowledge base can compromise care in elders. In an acute geriatric medical unit, a recent study found that the prevalence of adverse drug reactions (ADRs) was 16% on admission for those patients taking appropriate medications and that 66% of admissions were preceded by at least one inappropriate medication. In the long-term care setting, psychoactive medications (antipsychotics, antidepressants, and sedative/hypnotics) and anticoagulants were the most common medications associated with ADRs, and neuropsychiatric events were the most common manifestations of preventable ADRs. There is also evidence that commonly used antidepressants may have limited efficacy and more adverse effects in the oldest old and frail elderly, and that the atypical antipsychotic agents often used for the treatment of the psychotic and aggressive symptoms in dementia may lead to cerebrovascular events and increased mortality in nursing home residents.

As with other medications, the treatment of older patients with psychotropics is also complicated by age-associated pharmacokinetic and pharmacodynamic changes, which are exacerbated by illness and their concomitant potential for drug–drug interactions and poor adherence. An additional complication for psychotropics is the lack of diagnostic precision and pathophysiologic understanding of what is being treated. Psychotropic treatment is based on treating symptoms that have a heterogeneous etiology. The strategy for drug discovery in psychiatry has relied upon the serendipitous observation of symptomatic benefit of a known drug, study of the mechanisms of that compound, and efforts to develop similar compounds with improved efficacy and tolerability. The limitations of this approach are evident in the treatment of “psychoses” in dementia, as if it were the same disorder as schizophrenia in younger patients. Similarly, depression appearing later in life may be associated with ischemic injury or associated with the development of AD. For currently available psychotropics, there have been few studies of their “real world” comparative effectiveness. One example is the recently published Clinical Antipsychotic Trials of Intervention Effectiveness–Alzheimer’s Disease (CATIE-AD), which found an unfavorable risk to benefit ratio for use of atypical antipsychotic medications in patients with AD. It is also difficult to demonstrate efficacy when there is variability in drug exposure. The recent use of population pharmacokinetic methodologies in elderly psychiatric patients treated with antidepressants or antipsychotics is beginning to demonstrate

the extensive interindividual differences in drug clearance for these medications.

## ANTIDEPRESSANTS

### Selective Serotonin Reuptake Inhibitors

The selective serotonin reuptake inhibitors (SSRIs) are considered first-line pharmacotherapy for late-life depression. These drugs act on the serotonergic system by blocking the reuptake of this neurotransmitter. In comparison with other antidepressants, the SSRIs generally have a more favorable side effect profile and are well tolerated. They are also markedly safer than tricyclic antidepressants in overdose. Over 30 randomized, placebo-controlled, clinical trials with more than 5000 older patients with SSRIs have been conducted. These studies have included patients with a variety of psychiatric and medical illnesses including mild cognitive impairment, dementia, minor depression, schizophrenia, cardiovascular and cerebrovascular disease, or other medical conditions. SSRIs have received substantial attention in the treatment of anxiety in younger adults, however, only a single placebo-controlled trial and two open label studies have suggested efficacy in anxious elderly patients. Limited evidence supports the efficacy of SSRIs in treating dementia related behavioral disturbances, such as agitation, disinhibition, delusions, and hallucinations.

Although there is similar efficacy between each of the SSRIs, citalopram, escitalopram, and sertraline have better pharmacokinetic profiles, are less of a risk for drug–drug interactions, and appear not to interfere with cognition. As such, these drugs are preferable to fluvoxamine, fluoxetine, or paroxetine. In the elderly, starting dosages are administered in one daily dose, and are half the amount administered in younger populations (Table 63-1). Dosages can be doubled after a week of use. Fluvoxamine is the only SSRI that should be given according to a twice-daily dosing regimen.

#### Fluoxetine

The first SSRI to become available on the market in 1988 was fluoxetine. This drug ushered in a new era of treatment, providing an alternative to the tricyclic antidepressants. In geriatric patients, fluoxetine has demonstrated superiority as compared to placebo, and is as efficacious as amitriptyline, doxepin, escitalopram, paroxetine, sertraline, and trimipramine. Dosage recommendations for the elderly indicate starting at 10 mg/day, which can be increased every 14 days by 10 mg to a maximum of 40 mg/day. This SSRI and its active metabolite norfluoxetine have mean half-lives of 4.6 and 9.3 days, respectively, rendering it an unfavorable choice for older adults. Fluoxetine and norfluoxetine inhibit the enzyme CYP2D6, and to a lesser extent CYP1A2 and CYP3A4. Thus, it is crucial to consider interactions with other medications metabolized by these enzymes to avoid drug accumulation and toxicity (Table 63-2).

#### Sertraline

Sertraline was the second SSRI introduced, and is more specific in its effects on the inhibition of serotonin (5-hydroxytryptamine,

TABLE 63-1

## Antidepressant Oral Dosages and Side Effects

CLASS/ MEDICATION	INITIAL DOSE (mg)	MAX DOSE (mg)	RISK FOR DRUG INTERACTION	SIDE EFFECTS
<i>Selective serotonin reuptake inhibitors</i>				
Citalopram	10–20 qam	40 qd	Low	EPS, hyponatremia, GI distress, sexual dysfunction, slight weight gain
Escitalopram	10 qd	20 qd	Low	GI distress, sexual dysfunction, slight weight gain
Fluoxetine	10 qd	40 qd	High	Insomnia, slight anticholinergic effects, GI distress, sexual dysfunction, slight weight gain
Paroxetine	10 qd	40 qd	Moderate	GI distress, sexual dysfunction, moderate weight gain, minimal sedation, withdrawal symptoms
Paroxetine CR	12.5 qd	50 qd		
Sertraline	25–50 qd	200 qd	Low	Sexual dysfunction, slight weight gain
<i>Serotonin norepinephrine reuptake inhibitors</i>				
Duloxetine	20 qd or bid	60 qd or 30 bid	Low	GI distress, dry mouth, urinary hesitancy
Venlafaxine IR	25–50 bid	75–225 total bid	High	GI distress, minimal sedation, headaches, sexual dysfunction, serotonin syndrome, SIADH, hyponatremia, withdrawal symptoms, adrenergic effects, dose-dependent hypotension, ECG changes, arrhythmia, acute ischemia, EPS
Venlafaxine XR	75 qam	75–225 qd		
<i>Other second-generation antidepressants</i>				
Bupropion IR	37.5–50 bid	75–150 bid	Moderate	Slight GI distress, slight sexual dysfunction; CYP2B6 inhibitors: risk for seizure, gait disturbance, falls, psychosis
Bupropion SR	100 qd	150 bid		
Bupropion XR	150 qd	300 qd		
Mirtazapine	15 qhs	45 qd	Low	Mild anticholinergic events, hypotension, high sedation, slight sexual dysfunction, serotonin syndrome, increased appetite
<i>Preferred tricyclic antidepressants</i>				
Desipramine	10–25 qhs	50–150 qd	High	Therapeutic serum level $\geq 115$ ng/mL; mild anticholinergic events, hypotension, slight GI distress, sedation, sexual dysfunction, slight weight gain
Nortriptyline	10–25 qhs	75–150 qd	High	Therapeutic window 50–150 ng/mL; anticholinergic events, hypotension, sedation, sexual dysfunction, slight weight gain

qd, once daily; bid, twice daily; qhs, once before bedtime; CR, controlled release; IR, immediate release; XR, extended release; SR, sustained release; EPS, extrapyramidal symptoms; GI, gastrointestinal (e.g., nausea, vomiting, diarrhea, constipation); SIADH, syndrome of inappropriate secretion of antidiuretic hormone; ECG, electrocardiogram. Adrenergic effects: dry mouth, constipation, increased ocular pressure, cardiovascular difficulties, agitation.

5HT) reuptake than fluoxetine. Its effects on the reuptake of norepinephrine and dopamine are modest. Sertraline is more effective than placebo, and is comparable to amitriptyline, fluoxetine, fluvoxamine, imipramine, nortriptyline, and venlafaxine in treating late-life depression. It is tolerated more favorably than imipramine and venlafaxine and demonstrates greater cognitive improvement than nortriptyline or fluoxetine. Dosing in elderly patients is typically initiated at 25 mg or 50 mg, with increases occurring after 7 days to a daily maximum of 200 mg. This SSRI does require titration, with one study of frail nursing home patients noting an average maintenance dose of 77 mg/day. Although sertraline is a mild inhibitor of CYP2D6, its minimal effects translate to lower risk for drug interactions.

### Paroxetine

Evidence supports that paroxetine is as effective in depressed geriatric patients as amitriptyline, bupropion, clomipramine, doxepin, fluoxetine, imipramine, and nortriptyline. Again, this SSRI demonstrates superiority to placebo; however, in a study of very old long-term care patients with minor depression, paroxetine resulted in greater cognitive impairment as compared to placebo. Mirtazapine has displayed marginal efficacy over paroxetine in one double-blind, randomized

trial. Paroxetine elicits fewer side effects compared to the tricyclic nortriptyline. A starting dose of 10 mg/day is recommended for geriatric patients. After 1 week, dosing can increase by 10 mg to a maximum of 40 mg/day. Dose titration from 20 mg to 30 mg results in median half-life changes (30 hours and 38 hours, respectively), as well as changes in steady state concentrations (46 ng/mL and 80 mg). Paroxetine can be given by controlled release tablets at an initial dose of 12.5 mg/day and titrated each week up to a maximum of 50 mg/day. This drug is another potent inhibitor of CYP2D6, and thus the metabolic activity of concomitant medications must be examined prior to administration of paroxetine.

### Citalopram and Escitalopram

The majority of published trials examining citalopram in depressed older individuals include those with concomitant dementia or cognitive impairment. Escitalopram is the S-enantiomer of racemic citalopram. Only one randomized, controlled trial has evaluated escitalopram in late-life depression. Citalopram has demonstrated greater efficacy over placebo in depressed elderly without dementia, and similar efficacy as amitriptyline, and venlafaxine. While citalopram has been associated with lower remission rates than nortriptyline, it is much better tolerated. In the single study comparing escitalopram,

fluoxetine, and placebo, both active drugs were well tolerated. However, neither was more efficacious in reducing depressive symptoms beyond placebo. Geriatric dosage recommendations for citalopram indicate a starting dose of 10 mg or 20 mg, which can be increased after 7 days to a maximum of 40 mg/day. For patients taking other medications, citalopram is an excellent choice as it is neither significantly affected by, nor does it affect, the CYP450 system. However, in older patients, the half-life of citalopram is increased, while availability and clearance are decreased. Those patients with mild to moderate renal function experience a 17% reduction in citalopram clearance.

### Side Effects and Safety

Side effects are a particular concern in the elderly, especially in the oldest old, frail, or medically ill. SSRIs have received significant attention in the treatment of patients with ischemic heart disease, congestive heart failure, and immediately postmyocardial infarction. Evidence shows no increased cardiac risk, with no effects of SSRIs on blood pressure, cardiac conduction or arrhythmias. Patients with bradycardia or those taking  $\beta$ -blockers may, however, experience a further reduction in heart rate. Though the SSRIs are well tolerated in the geriatric population, caution should be exercised. Following initial treatment some patients may experience gastrointestinal (GI) difficulties (e.g., nausea), and there is slight potential for GI

or postsurgical bleeding. This may be a result of decreased platelet activation affecting platelet aggregation to prolong bleeding time. GI bleeding is also a concern when using SSRIs in conjunction with nonsteroidal anti-inflammatory medications (NSAIDs) or low-dose aspirin. Concomitant use, or use within 3 to 4 weeks of cessation, of monoamine oxidase inhibitors (MAOIs) can lead to the potentially fatal serotonin syndrome. Hyponatremia, especially in those patients with borderline sodium levels, is a possible consequence of SSRI use and should be assessed especially early in treatment or if there is a change in cognitive status.

While Parkinson's patients are able to tolerate SSRIs, EPS may be caused by SSRI use in some elderly patients. Antidepressant use is associated with risk for falls and hip fractures, and prolonged use of SSRIs may affect bone metabolism leading to risk of fragility fractures. Risk for suicide in the first month of SSRI treatment has been demonstrated in the elderly; however, there is a significant decrease in suicidal ideation in patients taking SSRIs versus placebo. This suggests that there may be a particular subgroup more susceptible to an unusual SSRI response.

### Other Antidepressants

For those elderly patients who are unresponsive to, or are unable to tolerate the use of, SSRIs, medications such as bupropion, duloxetine, mirtazapine, or venlafaxine may be used as second-line therapy.

In younger patients, these medications exhibit favorable side-effect profiles; however, the controlled data are limited thus caution must be exerted when administering these agents to the elderly.

### Bupropion

Nonresponders to SSRIs, or those elderly depressed patients who cannot tolerate SSRIs, may be given bupropion on its own or in augmentation to another medication. For example, bupropion is favored in those patients experiencing nausea, diarrhea, severe fatigue, or sexual dysfunction with SSRI use. This antidepressant is well tolerated in medically ill patients, including those with heart disease, those that smoke, and patients with neuropathic pain. Bupropion has demonstrated similar efficacy as imipramine and paroxetine in depressed elders. Starting dose recommendations for older patients are 37.5 mg of immediate release tablets twice daily, or 100 mg daily of the sustained release tablets. Increases consistent with initial dosages can be made every 3 to 4 days up to a maximum of 450 mg/day. However, evidence supports that the elderly may respond at doses up to 150 mg/day in divided administration. Bupropion should be avoided in patients with, or at risk for, seizure disorders or psychotic symptoms. Although seizures are not frequent in those patients taking sustained-release bupropion, case reports have demonstrated the onset of psychosis with bupropion possibly owing to its action on the dopaminergic system. This mechanism of action may also account for the association between bupropion use and gait disturbance and falls. In older adults, the half-life of bupropion is increased and it inhibits CYP2D6 moderately. It is metabolized by CYP2B6, thus medications inhibiting this isozyme (e.g., fluoxetine, paroxetine) may increase bupropion's adverse effects.

### Duloxetine

Efficacy and tolerability of duloxetine in young adults are supported by several randomized, controlled trials in patients with major depression, pain associated with diabetic neuropathy, and stress urinary incontinence. In the elderly, duloxetine has been efficacious in the treatment of depression and associated pain symptoms as compared to placebo. Duloxetine inhibits both serotonin and norepinephrine reuptake, and aging does not seem to affect its pharmacokinetic profile. Initial doses are typically 20 mg/day in either single or divided doses. Increases can be made to a maximum of 60 mg/day in either one to two doses per day. Duloxetine has a moderate ability to inhibit CYP2D6 and CYP3A4. Although it is reported to have minimal effects on heart rate and blood pressure in healthy young adults, duloxetine's action on norepinephrine may have greater implications for older patients with heart disease. In the absence of further evidence of the safety of this newer antidepressant in the treatment of the elderly, duloxetine should be used cautiously.

### Mirtazapine

By blocking  $\alpha_2$  autoreceptors, mirtazapine enhances noradrenergic and specific serotonergic transmission. Patients who do not tolerate SSRIs because of sexual dysfunction, tremor, or severe nausea may respond well to mirtazapine. This drug has also shown success in the treatment of depressed oncology patients receiving chemotherapy. Mirtazapine has demonstrated similar efficacy in the treatment of late-life depression to low-dose amitriptyline and marginal superi-

ority to paroxetine, yet no placebo-controlled trials have been published. As a result, mirtazapine is regarded as a third-line treatment following intolerance of, or nonresponse to, SSRIs or venlafaxine. Its concurrent use with other SSRIs raises concerns owing to the risk for serotonin syndrome in older adults. Furthermore, cognitive impairment in the elderly taking mirtazapine is another concern, possibly because of antihistaminergic and sedative effects. Two trials including healthy subjects taking this drug have reported driving impairments, and in demented elderly patients delirium has resulted. Drug–drug interactions are of minimal concern when taking mirtazapine, as it has little effect on the CYP450 system.

### Venlafaxine

Venlafaxine is another serotonin–norepinephrine reuptake inhibitor. Geriatric trials of this antidepressant have included patients with atypical depression, dysthymia, and poststroke depression. Studies also show the utility of venlafaxine in the treatment of late-life GAD or chronic pain. However, higher doses of venlafaxine (i.e., 225 mg/day or greater) are required in the treatment of pain to activate its antinociceptive effects via its action on adrenergic mechanisms. Meta-analyses data indicate that venlafaxine may be as efficacious as SSRIs in the treatment of depression in younger adults and have benefits to remission rates above that of the SSRIs. Such benefits may be further enhanced in woman 50 years of age or older. Published randomized, controlled trials of venlafaxine including depressed geriatric patients demonstrate that it is as efficacious as citalopram, clomipramine, dothiepin, nortriptyline, and sertraline, and is superior to trazodone. These studies found venlafaxine to be less well tolerated than sertraline, but as tolerable as citalopram and dothiepin, with superior tolerability over clomipramine, nortriptyline, and trazodone.

Venlafaxine's effects on the serotonergic system occur at lower doses. However, its effects on norepinephrine neurotransmission result from higher doses. In younger individuals, dosages as high as 225 mg or more per day may be required, though these doses may elicit adverse reactions in a geriatric population. Patients may experience a similar side-effect profile as with SSRI use, including GI distress, headaches, sexual dysfunction, serotonin syndrome, the syndrome of inappropriate antidiuretic hormone secretion, and hyponatremia. Symptoms associated with the discontinuation of venlafaxine may also occur, regardless of drug preparation type. In addition, side effects associated with the adrenergic system can occur, such as dry mouth, constipation, increased ocular pressure, cardiovascular difficulties, and agitation. Hypertension results in a dose-dependent fashion, with hypotension, electrocardiographic changes, arrhythmia, and acute ischemia also possible when taking venlafaxine. Experts discourage the use of venlafaxine in patients with heart disease, and recommend close cardiac monitoring for patients on higher dosages. While venlafaxine has minimal effect on the CYP450 system, it is metabolized by CYP2D6. Thus, poor 2D6 metabolizers or patients taking other drugs inhibiting this isozyme may have higher concentrations of venlafaxine. Venlafaxine should only be considered after nonresponse to SSRIs has been established.

### Tricyclic Antidepressants and Monoamine Oxidase Inhibitors

Once widely prescribed for the treatment of depression, tricyclic antidepressants (TCAs) have largely been supplanted by SSRIs as

the treatment of choice. TCAs have been studied in numerous randomized, placebo-controlled, and comparator trials. Though these studies demonstrate the efficacy of TCAs in treating late-life depression, most do not account for optimal dosing strategies using plasma level monitoring. MAOIs have also shown antidepressant effects similar to TCAs. Both of these drug classes require significant efforts to prevent associated adverse events, many of which can be severe and toxic. As such, TCAs and MAOIs are considered third- and fourth-line treatments of geriatric depression.

Common side effects of the TCAs include sedation, orthostatic hypotension (leading to dizziness, falls, and fractures), and anticholinergic effects such as dry mouth, blurred vision, constipation, confusion, and delirium. Nortriptyline, a secondary amine TCA, is better tolerated in the elderly and has a lower tendency to result in orthostasis, falls, and anticholinergic effects. This TCA has an established therapeutic window, the optimal serum plasma level resulting in efficacy (50–150 ng/mL) or toxicity ( $\geq 300$  ng/mL), which allows for more accurate and effective dosing. Two open trials of nortriptyline have found this medication to be effective in treating depression in the elderly. Three randomized, comparator trials found that nortriptyline was as efficacious as paroxetine and sertraline in alleviating geriatric depression; however, paroxetine was better tolerated than the TCA, and sertraline was associated with better cognitive improvement. Starting doses are usually 10 mg to 25 mg before bedtime. Plasma levels are taken within 5 to 7 days, and linear dosage adjustments can be made up to target plasma levels of 50 to 150 ng/mL. Though nortriptyline is preferred to the tertiary TCAs (i.e., amitriptyline, clomipramine, doxepin, imipramine), it is still associated with anticholinergic effects. Cardiovascular events are also a significant concern with tricyclics as even slight overdoses can result in lethal heart block or arrhythmia. Patients with ischemic heart disease should not be given TCAs as risk for sudden cardiovascular death is increased.

MAOI use in elderly populations is infrequent. While these medications are associated with fewer cardiac and anticholinergic side effects, serious hypo- and hypertension or serotonergic crisis may result from the concurrent intake of other medications or foods containing tyramine. Thus, it is crucial for patients taking MAOIs to adhere to strict dietary restrictions, inform all health care providers of MAOI use, and have their blood pressure monitored. Any signs of headache, stiff neck, nausea, or vomiting require an evaluation of blood pressure; if blood pressure is elevated, immediate medical attention is required. Though very rarely used in the elderly owing to adverse events and dietary restrictions, phenelzine is the preferred MAOI as it has received the most study in geriatric patients and has been shown to treat late-life depression. Recently, a transdermal patch form of selegiline has also been approved by the Food and Drug Administration (FDA) to treat major depression. However, there is very limited geriatric experience with this medication and dietary restrictions are still recommended for higher dosages.

## PSYCHOSTIMULANTS

### Methylphenidate

Methylphenidate is a controlled substance used for the treatment of attention deficit disorder and for the management of the som-

nolence symptoms of narcolepsy. Some data indicate that depressed elderly with concomitant medical complications may have symptomatic benefit with acceptable tolerability. In particular, it may improve symptoms of apathy and anergia that often occur with depression or dementia. Using methylphenidate with an SSRI could potentiate its antidepressant effects; however, more systematic data are still required. Side effects associated with methylphenidate may be of particular concern in a geriatric population, such as anxiety, psychosis, anorexia, and hypertension. Drug interactions with warfarin are also concerning, as methylphenidate may decrease the metabolism of anticoagulants.

## ANTIPSYCHOTICS

Atypical antipsychotic medications are first-line drugs in the treatment of psychotic symptoms associated with many late-life etiologies, but particularly in dementia. Studies examining medication use in long-term care facilities suggest that as many as 30% to 50% of elderly residents are prescribed an antipsychotic. Available evidence suggests that these agents may be efficacious in geriatric populations to alleviate schizophrenia, delirium, and the BPSDs. However, issues of the safety and tolerability of antipsychotics in elders remain a concern.

### Conventional Antipsychotics

The first antipsychotics were introduced in the 1950s. Generally, all of the typical antipsychotics share similar rates of efficacy. However, side-effect profiles can vary. This class of medications has been shown to treat BPSDs; although placebo response rates were also high. Yet early studies have found EPS (e.g., dystonia, parkinsonism, akathisia, tardive dyskinesia) to be a significant adverse reaction associated with the conventional antipsychotics, even when administered at moderate doses. In a study comparing low and moderate doses of haloperidol to placebo, moderate doses of the antipsychotic were more effective in treating psychosis and psychomotor agitation, but again were associated with greater instances of EPS. In a comparison of perphenazine to citalopram and placebo, the antipsychotic was comparable in efficacy to citalopram and superior to placebo; however, the SSRI had a more favorable side-effect profile. Similar results were demonstrated in a comparison of citalopram and risperidone, where both medications successfully reduced symptoms of agitation and psychosis in hospitalized patients with dementia, yet citalopram was associated with significantly fewer adverse events. Nonetheless, further studies are required before the utility of antidepressant treatments in alleviating BPSDs in nondepressed patients can be recommended. Currently, the use of atypical antipsychotics is preferred to that of the typical antipsychotics in treating BPSDs.

### Atypical Antipsychotics

In comparator trials of atypical and typical antipsychotics, olanzapine and risperidone have demonstrated comparable or greater efficacy and tolerability over promazine or haloperidol in elderly patients with BPSDs, schizophrenia, or delirium. Notable was the lower incidence of milder EPS with use of the atypical agents. Older patients have also been found to be at much greater risk of tardive dyskinesia

TABLE 63-3

## Atypical Antipsychotic Dosages, Half-Life and Side Effects

MEDICATION	DOSE (mg/day)	CLEARANCE (HALF-LIFE)	SIDE EFFECTS
Aripiprazole	Start 10–15 qd; max 30	75–96 hrs	Sedation (limited geriatric data)
Clozapine	25–150 qd	Mean 12 hrs	Excessive sedation, seizure, anticholinergic effects, agranulocytosis, orthostatic hypotension, sustained tachycardia, weight gain, high risk of diabetes mellitus and dyslipidemia
Olanzapine	2.5–10 qd	Mean 30 hrs	Sedation, dose-dependent anticholinergic effects, gait disturbance, orthostatic hypotension, high risk of weight gain, hyperglycemia, diabetes mellitus, risk of cerebrovascular events, dose-dependent EPS, EEG abnormality
Quetiapine	25–800 qd or total bid	3–6 hrs	Sedation, orthostatic hypotension, moderate risk of weight gain, diabetes mellitus, and dyslipidemia
Risperidone	0.25–1 qd or total bid	Mean 20 hrs	Orthostatic hypotension, dose-dependent EPS, tardive dyskinesia, hyperprolactinemia, risk of cerebrovascular events, weight gain, moderate risk of diabetes mellitus and dyslipidemia, moderate EEG abnormality, mild sedation, rare cognitive effects
Ziprasidone	20 total bid	7 hrs	Prolongation of QTc interval (limited geriatric data)

qd, once daily; bid, twice daily; EPS, extrapyramidal symptoms; EEG, electroencephalography; QTc, QT (cardiac output) corrected for heart rate. Anticholinergic effects: dry mouth, blurred vision, constipation, confusion.

when treated with conventional antipsychotics. Cognitive difficulty in dementia is typically treated using cholinesterase inhibitors, such as donepezil, rivastigmine, or galantamine; these medications are safe to use concurrently with atypical antipsychotics. In selecting a particular medication from this class, it is prudent to consider both the clinical profile of the patient as well as the side effects common to that medication (Table 63-3).

### Clozapine

The first atypical antipsychotic approved for use by the FDA was clozapine. It is a partial agonist of the 5HT<sub>1A</sub> receptor, has a high affinity for the dopaminergic type 4 (D<sub>4</sub>) receptor, and is a strong antagonist at adrenergic, cholinergic, muscarinic, and histaminergic receptor sites. Clozapine is indicated for the treatment of schizophrenia in younger adults, and is highly efficacious with relatively no risk for the development of tardive dyskinesia. Two case series provide evidence that moderate dosages of clozapine may provide symptomatic relief for elderly patients with primary psychotic diagnoses, and a randomized, comparator trial of clozapine and chlorpromazine supports these results. Lower dosages of clozapine (e.g., 12.5–50 mg/day) are suggested as safe and efficacious in the treatment of drug-induced psychosis in Parkinson's patients. There are no double-blind, placebo-controlled trials evaluating the efficacy or tolerability of clozapine in the treatment of BPSDs.

Data from retrospective reviews and case studies have found this atypical agent to be moderately effective, but not without significant side effects. Clozapine levels increase in a dose- and age-dependent fashion and levels may be attenuated in women. Adverse events are numerous with this drug, and range from minor to severe and potentially fatal. Common side effects include excessive sedation, and seizure; anticholinergic effects include dry mouth, constipation, and cognitive impairment. Agranulocytosis is a potentially serious and life-threatening adverse event that occurs in 0.38% of patients. Intensive hematological monitoring is required, especially in an elderly population. Orthostatic hypotension is another side effect that increases the risk for falls and fractures in older patients. Thus,

the side-effect profile of clozapine limits its utility in the treatment of late-life etiologies. Its use in demented elderly patients should be restricted to instances where other antipsychotics fail to produce relief.

### Risperidone

Risperidone is a strong antagonist of 5HT<sub>2</sub>, D<sub>2</sub>, adrenergic  $\alpha_1$  and  $\alpha_2$  receptors, a mild histaminergic H<sub>1</sub> antagonist, and has little effect at cholinergic receptor sites. Geriatric evidence including various conditions is the most extensive with risperidone. Several randomized, placebo-controlled trials; randomized, comparator trials (with haloperidol, promazine and olanzapine, or olanzapine); and uncontrolled or case studies have indicated that BPSDs are treated safely and effectively with risperidone. Risperidone has shown further success in the safe and efficacious treatment of schizophrenia in older adults as compared to olanzapine and in a randomized, open-label study, where patients were switched from a typical antipsychotic to either risperidone or olanzapine. Uncontrolled data including elderly schizophrenic patients and those with other psychotic disorders demonstrate similar results, as does an evaluation of a long-acting injectable preparation of risperidone in older schizophrenics.

Delirium in late-life has been shown to respond to risperidone, and risperidone is well tolerated, as indicated by a randomized, comparison trial with haloperidol and additional supportive uncontrolled reports. Yet conflicting case studies suggest the occurrence of risperidone-induced delirium. Risperidone's safety and efficacy, even at low doses, have not been clearly established in patients with drug-induced psychosis in Parkinson's disease or Lewy bodies dementia; some of these data suggest an aggravation of parkinsonism. The use of risperidone in these etiologies should be approached prudently and with careful monitoring. Furthermore, while evidence supports the use of risperidone in young bipolar patients, there is a paucity of data regarding risperidone for older bipolar patients. In this case, mood stabilizers are the preferred line of treatment. When severe mania or mania with psychosis co-occurs, a mood stabilizer is typically combined with risperidone, olanzapine, or quetiapine.

Risperidone, and its active metabolite 9-hydroxyrisperidone (paliperidone), appear to increase in concentration at certain dosages in an age-dependent manner. As such, in older demented patients dosages should range between 0.5 and 2 mg/day; initial doses can start at 0.5 mg and titration should be slow. In elderly patients without dementia, dosages should be initiated at 0.25 to 0.5 mg/day, increasing by 0.5 mg increments every 7 days to a maximum below 4 mg/day. Since the half-life of risperidone ranges from 20 to 22 hours, once daily dosing is acceptable. A common initial side effect is orthostatic hypotension, and EPS can occur in a dose-dependent manner. Tardive dyskinesia has been reported in patients with dementia taking an average dose of risperidone at 0.96 mg daily (SD 0.56 mg); however, the persistence of these symptoms one year later was quite low. Risperidone is the atypical antipsychotic most associated with hyperprolactinemia, but leads to moderate abnormalities in electroencephalography (EEG), and its limited affinity for muscarinic receptors results in rare effects on cognition. Mild sedation has also been reported. Weight gain, diabetes, or dyslipidemia are more likely to occur with use of risperidone than with aripiprazole or ziprasidone; however, these side effects appear more frequently when taking the atypical agents clozapine or olanzapine than risperidone.

Paliperidone is the most recently approved atypical antipsychotic for the treatment of schizophrenia in North America. Its action, efficacy, and safety are expected to be similar to that of risperidone, as it is risperidone's active metabolite. Furthermore, as a metabolite, hepatic impairment or metabolism by CYP2D6 should not impact paliperidone's clearance; however, renal function could affect clearance rates. The extended release formulation of paliperidone can be given once daily, which may be beneficial to patients with compliance difficulties. Geriatric evidence is limited to three small trials, but do not include patients with dementia, thus caution must be exercised when attempting treatment in this group.

### Olanzapine

The use of olanzapine in geriatric patients has also received extensive examination. This atypical agent inhibits various receptor sites, with a high affinity for 5HT<sub>2A/2C</sub>, and milder effects at D<sub>4/3/2/1</sub>, H<sub>1</sub>, muscarinic acetylcholine, and  $\alpha_1$  receptors. Randomized, placebo-controlled trials and randomized, comparator trials (with haloperidol, promazine and risperidone, and risperidone) have demonstrated that olanzapine can safely and effectively treat BPSDs. As well, elderly schizophrenic patients have seen effective and tolerable benefits from olanzapine treatment in two randomized, comparator trials each, with haloperidol and risperidone. A large randomized, controlled trial found olanzapine and haloperidol to be similarly efficacious in the treatment of late-life delirium. Yet evidence from other controlled trials suggests cognitive worsening in demented patients receiving olanzapine, and case reports indicate the occurrence of olanzapine-induced delirium. Olanzapine's efficacy and tolerability are again uncertain in treating drug-induced psychosis in Parkinson. This agent did not reduce symptoms of psychosis beyond placebo, but did result in a worsening of parkinsonism and activities of daily living. Another randomized study found no difference between the efficacy of olanzapine and clozapine, and more toxicity with the former atypical antipsychotic. Furthermore, while a few open trials or case series have been positive, many have demonstrated that olanzapine can exacerbate motor symptoms in patients with Parkinson's or Lewy body dementia. Geriatric data regarding the utility and

safety of treating bipolar disorder with olanzapine have not been established; although this agent is effective and tolerable in younger bipolar adults and those with other mood disorders. Thus, caution must be exercised when using olanzapine in conditions other than late-life schizophrenia or to treat BPSDs.

Dosing in patients with schizophrenia, mood disorders, or BPSD can be initiated at 2.5 mg/day with clinically indicated titration up to 5 to 10 mg daily. Response should be evaluated for at least a week before doses are increased. The daily dosing schedule is made possible by olanzapine's mean half-life of 30 hours, and it is well absorbed with no effect of food intake. A 2004 consensus conference, examining available data including younger patients with psychotic or mood disorders taking olanzapine and clozapine, found that these agents demonstrated the highest diabetes risk, most risk for weight gain, and dyslipidemia as compared to other atypical antipsychotics. However, metabolic risks may be different for elderly patients, particularly in the presence of dementia. Sedation and gait disturbance are the most common complaints associated with olanzapine; however, dose-dependent EPS do occur, as well as orthostatic hypotension, typically above geriatric doses of 5 to 10 mg daily. EEG abnormalities have been reported with use of this agent. Other reported effects include constipation (institutionalized dementia patients), dose-dependent decreased efficacy (patients with BPSD), differential cognitive effect versus risperidone (elderly schizophrenics and dementia patients), cognitive decline (AD patients), and delirium. These adverse reactions may be associated with olanzapine's antagonism of the muscarinic receptor. Higher concentrations of olanzapine can be associated with greater risk for side effects and are of concern in elderly patients, women, nonsmokers, and those taking medications that inhibit CYP1A2 (e.g., fluvoxamine or ciprofloxacin). Olanzapine should not be considered a first-line therapy in geriatrics where cognitive impairment, constipation, diabetes, diabetic neuropathy, dyslipidemia, obesity, xerophthalmia, or xerostomia are of concern.

### Quetiapine

This atypical antipsychotic works to inhibit 5HT<sub>1A/2</sub>, D<sub>2/1</sub>, H<sub>1</sub>,  $\alpha_1$  and  $\alpha_2$  receptors. As with olanzapine, quetiapine has a higher affinity for the serotonergic receptors than the dopaminergic sites. Furthermore, quetiapine has no effect on cholinergic, muscarinic, or benzodiazepine receptors. Quetiapine has been found to be efficacious in the symptomatic treatment of BPSDs, elderly patients with primary psychotic disorders, dementia, and delirium. Although, in four trials including patients with dementia or parkinsonism, quetiapine failed to significantly alleviate agitated or psychotic behaviors above placebo, with one trial demonstrating greater cognitive decline in patients treated with quetiapine. Evidence from published studies examining quetiapine in drug-induced psychosis and Parkinson's disease generally supports the efficacy and tolerability of this medication. However, one double-blind trial does report a high drop-out rate in patients taking quetiapine. Nonetheless, the positive data in patients at high risk for EPS indicate quetiapine is a first-line option for elderly Parkinson's or Lewy body dementia patients, and those with tardive dyskinesia.

Initiation of quetiapine can cause somnolence, and though most patients adjust to this relatively fast, quetiapine should be started at doses as low as 25 mg before bedtime. Maximum dosages can range between 25 and 800 mg daily. Generally, elderly patients are

maintained around 100 mg/day, as the lower clearance rates in older adults can result in higher concentrations of this agent. Its short half-life of 3 to 6 hours may necessitate a twice-daily dosing regimen. Complaints of sedation and dizziness can be combated with a slower dose titration, and the risk for EPS is relatively low. Quetiapine and risperidone have similar risk for causing weight gain, diabetes, or dyslipidemia, but the risk for these side effects is greater with use of clozapine or olanzapine.

### Aripiprazole and Ziprasidone

Aripiprazole and ziprasidone were approved by the FDA in 2002 and 2001, respectively. Aripiprazole acts as a partial D<sub>2</sub> agonist, though at increased concentrations, typical in elders, more complete dopaminergic inhibition results; while ziprasidone has a high affinity for dopaminergic, serotonergic, and alpha-adrenergic receptors, and little affinity for muscarinic and histamine receptors. These atypical antipsychotics have limited impact on glucose, lipids, and weight, and their lack of effect on the muscarinic receptor means limited propensity to impair cognition. As such, aripiprazole and ziprasidone show potential for the treatment of psychosis in the elderly. However, geriatric data are limited with these medications. A single randomized, placebo-controlled trial of aripiprazole to treat BPSDs has shown minimal efficacy in reducing psychosis on secondary outcome measures; and the average dose of 10 mg/day was well tolerated. The long half-life of this agent in younger adults (75–96 h) could also be a concern in the elderly. Similarly, evidence for the oral preparation of ziprasidone in older patients is limited to a published case series and a pharmacokinetic examination. Use of intramuscular ziprasidone has been reported in two studies, with no aversive cardiovascular or EEG effects observed. Concern regarding the potential of ziprasidone to prolong the QTc interval may limit its use in elderly patients with cardiovascular disease. Both of these atypical antipsychotics should be used as second-line treatments in the absence of further geriatric data in a variety of conditions.

### Side Effects and Safety

Elderly patients are more susceptible to the side effects associated with antipsychotics, such as sedation, cardiac effects which include tachycardia and orthostatic hypotension, anticholinergic effects including dry mouth, blurred vision, constipation and urinary retention, neuroleptic malignant syndrome with hyperpyrexia, autonomic instability, pigmentary retinopathy, weight gain, allergic reactions, and seizures. Orthostatic hypotension, which can lead to falls and fractures in elders, is a likely consequence with low-potency typical antipsychotics such as chlorpromazine and thioridazine, and atypical agents like clozapine, risperidone, olanzapine, and quetiapine. Anticholinergic effects are most common with low-potency conventional antipsychotics and clozapine. Tardive dyskinesia and EPS are also of particular concern in the elderly; the low-potency atypical agents are less prone to causing EPS when compared to similar doses of high-potency typical antipsychotics (e.g., haloperidol). While, approximately half of patients aged 60 to 80 taking typical agents experience EPS or tardive dyskinesia. Elderly patients require doses of antipsychotics that are lower than those used in younger adults to try to limit the emergence of side effects.

According to published reports and an FDA issued warning, the rate of death in elderly patients with BPSD treated with atypical

antipsychotics is close to double that seen in patients randomized to treatment with placebo (i.e., 2.6% mortality with placebo vs. 4.5% with atypicals over 12 weeks), though the absolute risk of mortality is low. Risk of sudden cardiac death in patients taking antipsychotics is also increased, with thioridazine users at particular risk. Some studies have challenged whether the atypical agents lead to reduced incidence of falls or EPS as compared to typical antipsychotics, especially when higher drug dosages are involved. Typical antipsychotics may demonstrate decreased risk for cerebrovascular events, venous thromboembolism, or pancreatitis; yet several meta-analytic and pharmacoepidemiologic studies have suggested these drugs have similar or increased risk to atypicals for diabetes mellitus, cerebrovascular events, stroke, or death. In light of the lack of consensus with regard to the safety of antipsychotics and paucity of data concerning alternate drug classes, clinicians must consider individualized risk–benefit analysis when providing care for patients. For treatment of agitation/psychosis in dementia, it was estimated from a meta-analysis of placebo-controlled studies with atypical antipsychotics that the number needed to treat is approximately 7 to 12 and the number needed to harm is between 44 and 118. In treating a particular disorder, it is also important to consider the strength of the data available for that condition for each drug, as well as the associated side-effect profiles of those drugs.

## MOOD STABILIZERS

Randomized, controlled trials of mood stabilizers including geriatric patients are severely lacking. This class of medications is considered to be high-risk because of their potential for toxicity, serious adverse events, and interactions with other drugs. However, lithium continues to be prescribed for the treatment of bipolar disorder in elders. Whether lithium should be utilized as a first-line mood stabilizer or to treat mania in elderly patients remains to be determined. Anticonvulsants have also been prescribed to combat the agitation often associated with dementia.

### Lithium

Lithium carbonate has been demonstrated as an effective acute and preventative treatment of mania in older patients. However, the use of lithium in elders necessitates special care. Renal function declines with age and as such so does the clearance of lithium by the kidneys. This increases the older adult's sensitivity to side effects and increases risk for toxicity. Also contributing to the toxicity of lithium in the elderly are common medical conditions such as renal dysfunction, hyponatremia, dehydration, and heart failure. Renal clearance is further complicated by use of thiazide diuretics, angiotension-converting enzyme inhibitors, and NSAIDs. Thus, lower serum levels of lithium should be maintained in elderly patients. Serum levels should be measured 12 hours after dosing (150–600 mg once daily) with safe and efficacious measurements being 0.4 to 0.8 mmol/L (mEq/L).

Common side effects of lithium use include nausea, fine tremor in the hands, and urinary frequency. Neurological side effects indicating toxicity can include coarse tremor, slurred speech, ataxia, confusion, and drowsiness. Toxicity can develop at levels between 1.5 and 2 mmol/L in adults, and in the elderly can manifest with levels as low as 1.0 mmol/L; the lower range of the former serum level

**TABLE 63-4****Drug-Interactions with Lithium**

CLASS/MEDICATION	TOXICITY RISK
Acetylcholinesterase inhibitors	ACEI/ARBs: lithium toxicity Toxicity via sodium depletion
Carbamazepine	Neurotoxicity (ataxia, tremors, nausea, vomiting, diarrhea, tinnitus)
Calcium channel-blockers (e.g., diltiazem, verapamil)	Neurotoxicity
Haloperidol	Neurotoxicity; encephalopathy (results in irreversible brain damage)
Diuretics	Decrease in renal clearance leading to toxicity
MAOIs	Fatal malignant hyperpyrexia
Methyldopa	Neurotoxicity
Metronidazole	Lithium toxicity (rare) NSAIDs: Lithium toxicity
Phenothiazines	Neurotoxicity
Phenytoin	Lithium toxicity
SSRIs	Neurotoxicity (particularly fluoxetine and fluvoxamine)
Sibutramine	Serotonin syndrome
Tricyclic antidepressants	Neurotoxicity

ACEI, Angiotensin converting enzyme inhibitor; ARB, Angiotensin receptor blocker; MAOI, Monamine oxidase inhibitor; NSAIDs, Nonsteroidal antiinflammatory agent.

has been associated with delirium, and levels below the latter have resulted in cognitive impairment in older adults. Lithium toxicity necessitates immediate medical attention as it can result in death or persistent neurological dysfunction. Regular monitoring of electrolytes and electrocardiogram results should be completed, in addition to measurements of lithium levels in the elderly. Lithium-induced renal impairment should be monitored via checks of serum creatinine and urine osmolality, and lithium-induced hypothyroidism should be monitored via thyroid-stimulating hormone concentrations every 6 months. Drug interactions affecting renal clearance must also be considered to avoid toxicity (Table 63-4).

### Anticonvulsants

Bipolar disorder can be treated using anticonvulsants as opposed to lithium. Bipolar patients with dysphoria or rapid cycling may actually respond better to anticonvulsants than lithium. Secondary mania, defined as mania occurring in the presence of dementia or other neurological illness, may similarly respond well to anticonvulsants.

### Valproate

Valproate's anticonvulsant activity is thought to be mediated by increasing concentrations of gamma-aminobutyric acid (GABA) in the central nervous system. Case studies have shown tolerability of valproate by elderly bipolar patients and geriatrics with dementia related agitation. However, four placebo-controlled trials challenge this evidence by demonstrating that valproate did not relieve agitation symptomatology in dementia beyond placebo. Valproate is prepared

in several mutually exclusive formulations: valproic acid, divalproex sodium, and an extended-release preparation. Divalproex sodium is most commonly recommended, with doses initiating at 250 mg twice daily. Titrations can be made up to a maximum of 500 to 2000 mg/day in two or three divided doses. Efficacious and tolerable serum levels are between 200 and 700 mmol/L (35–100 mg/mL). Common dose-dependent side effects include sedation, nausea, weight gain, hand tremor, reversible elevations in liver enzymes and blood ammonia levels, and thrombocytopenia, which is a particular concern manifesting at lower drug levels in elderly patients. Liver failure or pancreatitis may also occur in rare instances. Metabolism of valproate initially occurs via mitochondrial  $\beta$ -oxidation, with minor metabolism occurring via the CYP450 system. Administering valproate in conjunction with carbamazepine, lamotrigine, diazepam, phenobarbital, or primidone increases these drug's concentrations. Concomitant use of valproate with carbamazepine, lamotrigine, topiramate, or phenytoin decreases valproate levels. Valproate works synergistically with fluoxetine and erythromycin, causing its effects to be amplified.

### Carbamazepine

This drug inhibits the repetitive activation of sodium channels and works well to reduce seizures. In young patients, carbamazepine has been found to treat mania both acutely and as a preventative measure. In patients with dementia, this medication has also demonstrated efficacy in reducing agitated and aggressive symptomatology versus placebo. In elderly patients, serum levels of carbamazepine beyond 38 mmol/L (9 mg/L) are associated with higher risk for side effects, including nausea, dizziness, confusion, ataxia, neutropenia, hepatotoxicity, leucopenia, agranulocytosis, and drug interactions. Carbamazepine clearance is reduced with age. It is primarily metabolized by CYP3A4, and those medications that inhibit this isoenzyme (e.g., macrolide antibiotics, antifungals, some antidepressants) can lead to toxic concentrations of carbamazepine. Conversely, those medications that induce CYP3A4 (e.g., phenobarbital, phenytoin, and carbamazepine) will lower concentrations of drugs metabolized by this isoenzyme.

### Gabapentin and Pregabalin

Gabapentin has a mild side-effect profile and works to reduce symptoms of anxiety and neuropathic pain. Trials have not established the efficacy of this medication in treating patients with bipolar disorder or dementia, though it is used clinically in these populations. It is eliminated exclusively via renal excretion. Renal impairment can result in ataxia, involuntary movements, disorganized thinking, excitation, and excessive sedation. In elderly patients, initial dosages are recommended at 100 mg twice daily. Pregabalin is the potent successor to gabapentin. No geriatric evidence is available using this drug, though its pharmacokinetic profile is favorable and it may have use in the treatment of neuropathic pain in older adults.

### Lamotrigine

The FDA has granted approval for the use of lamotrigine in the preventative treatment of the depressive, manic, or mixed episodes of bipolar disorder. In elderly bipolar patients, lamotrigine has demonstrated superior efficacy versus placebo. Dosing in the elderly begins

at 25 mg daily for 2 weeks. For the following 2 weeks, 50 mg is administered daily. The next titration is maintained at 100 mg/day for 7 days. Dosages can then be increased up to 200 mg daily. However, in patients also taking valproate, lamotrigine's titration schedule is reduced and target dosages are halved since valproate increases lamotrigine levels. Though lamotrigine does not appear to increase weight, common side effects in the elderly include excessive drowsiness, headaches, and rashes. Any sign of rash or hypersensitivity related to lamotrigine use should result in its discontinuation and immediate evaluation of the patient. While rare, severe rashes such as Stevens–Johnson syndrome or toxic epidermal necrolysis have occurred in 0.3% of adults. Reducing the dose titration of lamotrigine can lessen the risk for rashes.

## ANXIOLYTICS

### Benzodiazepines and Nonbenzodiazepine Hypnotics

Anxiety and insomnia in the elderly are frequently treated using benzodiazepines. However, the pharmacokinetic properties of these drugs must be taken into consideration as the rate of metabolism in the elderly is significantly slowed. Thus, the half-lives of benzodiazepines are far longer resulting in the accumulation of medication and an increased likelihood of adverse events. As such, intermediate acting benzodiazepines (e.g., lorazepam) are preferred when treating anxiety in older adults; although SSRIs and venlafaxine are increasingly prescribed. A meta-analysis examining the published studies of sedative-hypnotics in the elderly suggests that the significant adverse effects associated with benzodiazepines far outweigh the relatively minimal, short-term benefits. Side effects can include incidence of excessive daytime sedation, risk of falls and hip fractures, and impairments of cognition and psychomotor performance, even when doses are low. Chronic use of benzodiazepines in high doses followed by abrupt discontinuation can lead to symptoms of withdrawal, including anxiety, insomnia, tremor, tachycardia, delirium, psychosis, or seizure. Elderly patients experiencing heavy snoring (suggestive of sleep apnea), dementia, or concurrent use of other sedatives or alcohol should not be administered a benzodiazepine. Lorazepam and oxazepam do not affect the CYP450 isozymes and are not associated with drug interactions. Oxazepam exhibits variability in absorption making lorazepam the favored sedative. Lorazepam is administered in low dosages of 0.5 mg/day and should not exceed 2 mg daily.

### Buspirone

The anxiolytic buspirone does not lead to sedation, is not addictive, and is tolerated well by anxious elders. It is a partial agonist of the 5HT<sub>1A</sub> receptors with no affinity for the benzodiazepine/GABA receptors, and may be particularly useful in treating GAD in geriatric patients that are susceptible to falls, confusion, or chronic lung disease. A disadvantage of buspirone is that its onset of anxiolytic action may not be evident for 1 to 3 weeks following initial dosing. This drug may also lead to dizziness, headache, and nervousness. Initial dosages of buspirone are at 5 mg three times per day. Increases by 5 mg can be made weekly to a maximum daily dose of 60 mg/day. The pharmacokinetic profile of buspirone is similar in young and

old adults, as well as between genders. However, concurrent use of verapamil, diltiazem, erythromycin, or itraconazole will elevate concentrations of buspirone, and concomitant administration of SSRIs can lead to serotonin syndrome.

## SUMMARY

As with other classes of drugs, the use of psychoactive agents in older patients is complicated by comorbid medical illness and concomitant use of multiple medications. Consequently, geriatric patients experience more adverse events with psychoactive medications, which tend to be more serious than those in younger groups. Health care practitioners must consider individual patient risk to benefit (efficacy) regarding the use of psychoactive agents in geriatrics. Additionally, health specialists must take into account specific side effect profiles associated with potential medications and determine safety of use with other agents a patient may be taking. The detrimental effects of depression, anxiety, or psychosis in late-life on activities of daily living, cognition, institutionalization, and mortality cannot be ignored. These disorders further complicate concurrent physical ailments in patients and increase burden to the health care system. Although efficacy data are limited, clinical anecdotal and study data indicate that many elders are able to maintain an improved quality of life with the use of psychoactive agents. While psychotropic use in the elderly can be challenging, drug therapy can be an important tool in combating many debilitating behavioral and psychiatric illnesses.

# Cerebrovascular Disease

*Eric Edward Smith ■ Ferdinand Buonanno ■ Aneesh Bhim Singh ■ J. Philip Kistler*

Although cerebral vascular disease is the third leading cause of death in the United States after heart disease and cancer, it remains the single most important cause of disability. One of several pathologic processes that either lead to occlusion or rupture of an extra- or intracranial artery or vein produces the clinical manifestation of cerebral vascular disease in terms of primary ischemic stroke, transient ischemic attacks (TIAs), and/or primary hemorrhagic stroke. With either TIA or primary ischemic or hemorrhagic stroke, the prelude to acute, chronic, or preventive therapy is precise diagnosis. The diagnostic formulation must not only establish that the clinical entity is an ischemic stroke or TIA, or a hemorrhagic stroke, but also must localize and characterize the precise arterial or venous pathologic process causing the stroke, as well as elucidate the nature of the spared collateral circulation (Figures 64-1 and 64-2). This chapter focuses on identifying this pathological process as the pivot on which hinge rational medical and/or surgical treatments or preventive strategies. For both primary ischemic and/or primary hemorrhagic stroke, as for TIAs, the precise pathophysiological process divides logically into specific stroke or TIA subtypes.

## ISCHEMIC STROKE OR TIA SUBTYPE

### Pathophysiology and Clinical Presentation

It is important to recognize that ischemic stroke and/or TIAs share the same pathophysiological causation in terms of the underlying arterial pathology. The terms “stroke” and “TIA” are no more a diagnosis that dictates a specific therapeutic strategy than are the terms “fever” and “abdominal pain.” Just as the primary care physician would treat the pneumococcal pneumonia giving rise to the fever, or the pancreatitis giving rise to abdominal pain, so should the underlying arterial pathophysiology of the ischemic stroke or TIA be the focus of a treatment strategy. The term “cerebral vascular accident”

should be discarded and the terms “TIA” and “ischemic stroke” should be complemented by terms defining their pathophysiological subtype. Primary ischemic stroke and TIA conveniently divide into four subtypes: (1) large artery atherothrombotic (15%); (2) embolic (57%—cardiac, ascending aorta, or unknown source); (3) small vessel lacunar (25%); and (4) other (3%), such as arterial dissection, venous sinus occlusion, and arteritis. The percentages of the various ischemic stroke or TIA subtypes or pathophysiological cause identified in the National Institutes of Health (NIH) Stroke Databank vary with different ethnic population groups. African-Americans are at relatively higher risk of lacunar stroke and atherothrombotic stroke, particularly that portion of atherothrombotic stroke caused by intracranial arterial atherosclerosis.

When transient or sustained focal neurological symptoms or signs develop in a patient, the history, physical examination, and neurologic examination suggest that it is a stroke, and may even suggest the pathophysiological subtype. This presumed pathophysiological TIA or stroke subtype diagnosis requires immediate noninvasive assessment of the extra- and intracranial arterial system, focusing on the arteries supplying the suspected symptomatic arterial territory. This includes the large arteries from the aortic arch to the locus of ischemia or infarct. The “parent” artery pathology, or lack thereof, then confirms the subtype, namely, large artery atherothrombotic, embolic, small vessel disease, or other. Often an embolus has fragmented and migrated, leaving the parent vessel patent, or it may have entered a branch of the parent vessel not shown in the scheme outlined in Figure 64-2. In that case, embolism is suggested only by the specific territory of the infarction. When a small infarction occurs in the territory of a single penetrating vessel deep in the brain (as might arise from the basilar artery, the middle cerebral artery stem, or the arteries of the circle of Willis), a small vessel lacunar stroke is diagnosed. To confirm the clinically suspected presumed pathophysiological diagnosis, computed tomography (CT) scanning alone in the acute or subacute phase is inadequate. CT has nearly perfect sensitivity for acute intracerebral hemorrhage (approaching 100%)

**FIGURE 64-1.** (A) Arrangement of the major arteries of the right side carrying blood from the heart to the brain. Also shown are vessels of collateral circulation that may modify the effects of cerebral ischemia (a, b, and c). Not shown is the circle of Willis, which also provides a source for collateral circulation. *a.* The anastomotic channels between the distal branches of the anterior and middle cerebral artery, termed borderzone or watershed anastomotic channels. Note that they also occur between the posterior and middle cerebral arteries and the anterior and posterior cerebral arteries. *b.* Anastomotic channels occurring through the orbit between branches of the external carotid artery and ophthalmic branch of the internal carotid artery. *c.* Wholly extracranial anastomotic channels between the muscular branches of the ascending cervical arteries and muscular branches of the occipital artery that anastomose with the distal vertebral artery. Note that the occipital artery arises from the external carotid artery, thereby allowing reconstitution of flow in the vertebral from the carotid circulation. (Part A courtesy of C. M. Fisher, MD.)

and good sensitivity for acute subarachnoid hemorrhage (approximately 90%). Sensitivity for ischemic infarction in the acute setting is, however, much lower. Ischemic infarction may not be demonstrable by noncontrast CT for 12 to 14 hours after symptom onset; additionally, infarction involving only the cortical surface supratentorially, or infarction in the posterior fossa, can often be obscured by bone artifact. Therefore, contrast CT angiography, magnetic resonance imaging (MRI) with MR angiography, and/or carotid duplex Doppler and transcranial Doppler, should be obtained to outline the parent vessels (Figure 64-2), before specific treatment based on the pathologic process can be devised. Only with precise knowl-

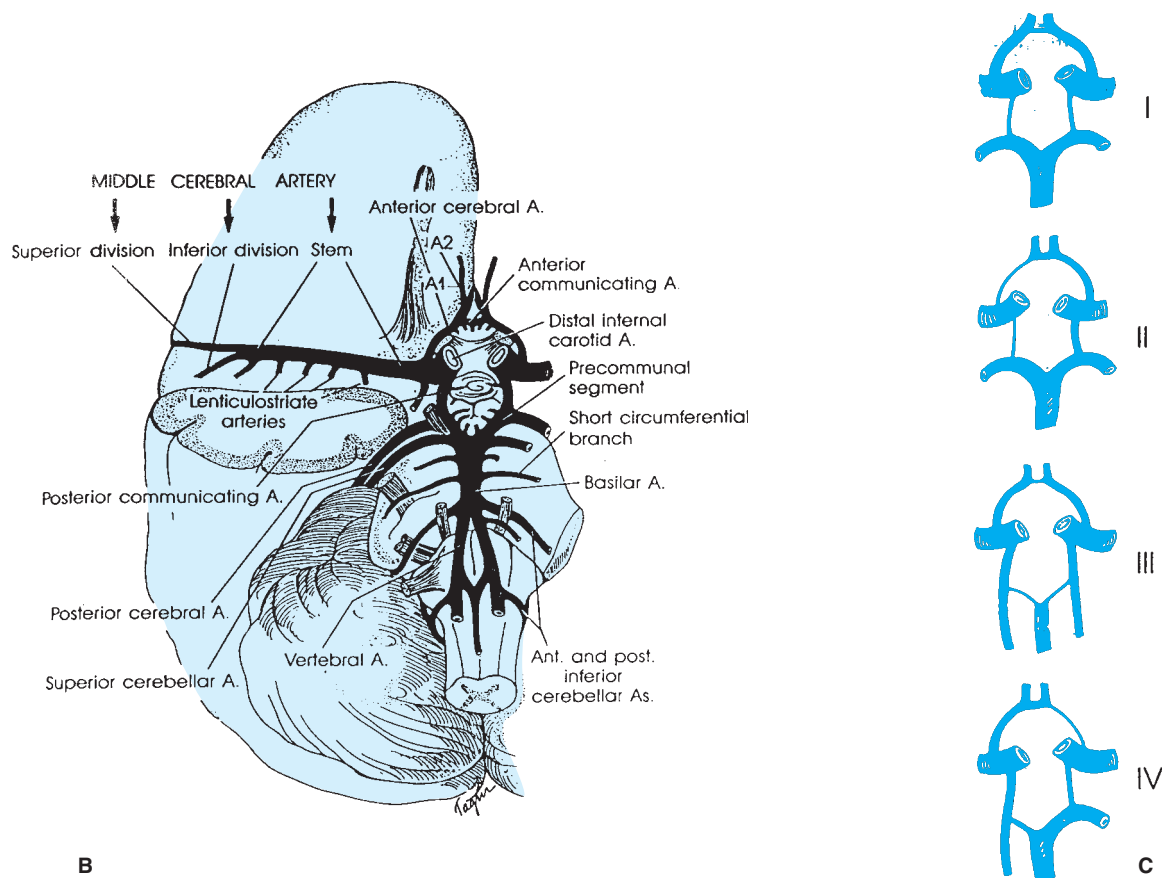

edge of the parent vessel pathology, or its absence, can therapy be properly addressed—whether it be thrombolytic, anticoagulant, or antiplatelet, interventional intra-arterial, or surgical. The following sections outline each of the four ischemic stroke and TIA subtypes, and intracerebral and subarachnoid hemorrhage, in terms of their pathophysiological process and clinical presentation. A discussion of a focused diagnostic approach to confirm that clinically presumed diagnosis follows. Based on the particular TIA or stroke subtype and its causative pathological process, acute, subacute, and preventive management strategies can then be addressed.

### Large Vessel, Atherothrombotic Stroke/TIA Subtype

Atherothrombotic cerebral vascular disease accounts for only 15% of all ischemic infarcts in the NIH Stroke Databank. The atheromatous process occurs in strategically focal locations with predilection for four extra- and intracranial arterial locations (Figure 64-2): (1) the internal carotid artery origin, (2) or its siphon portion, (3) the middle cerebral stem, and (4) the vertebrobasilar junction. Although the origin of the common carotid artery and the vertebral arteries also are sites of atheromatous disease, they are less-often implicated in stroke or TIA. At each of the sites of predilection, two mechanisms are responsible for causing the stroke or TIA: (1) atherothrombotic plaque with clot formation that either occludes the vessel and gives rise to an embolic fragment that occludes a more distal vessel, that is, artery-to-artery embolus, or thrombus that propagates into a distal vessel; or (2) the atherothrombotic process might occlude or narrow the vessel to such a degree that distal flow is diminished and not compensated via the circle of Willis, that is, low-flow stroke or TIA. Generally, both artery-to-artery embolism and low-flow stroke occur when the vessel is narrowed by the atheromatous process to a degree that decreases pressure across the arterial segment, that is, producing a 70% or greater diameter stenosis, or frank occlusion. A TIA is said to occur if symptoms clear within an arbitrarily set time of 24 hours. In artery-to-artery embolic events, symptoms may last for shorter periods of time, and in low-flow transient ischemic events they may last only minutes to as long as an hour or more. Often, artery-to-artery or low-flow transient ischemic events may be associated with an MRI-proven area of infarction, notwithstanding resolution of the symptoms. When symptomatic stroke ensues in this setting, it is because the artery-to-artery embolic fragment lodges in an intracranial vessel with inadequate distal collateral supply, or because the clot propagates and occludes the vessel. A dramatic example of the latter occurs with internal carotid artery origin occlusion and propagation of the clot distally into the middle cerebral stem (Figures 64-1 and 64-2).

Low-flow stroke or TIA occurs less often from a cervical lesion because the circle of Willis provides distal collateral circulation. However, low-flow stroke or TIA occurs more often with atheromatous disease in the distal vertebral or in the basilar arteries. Similarly, the frequency of low-flow stroke or TIA increases when the atheromatous process is in the middle cerebral stem and compromises the ability of the circle of Willis to provide sufficient collateral flow. In 70% of the population, the circle of Willis is incompetent, with one or more of the connecting arteries atretic or functionally inadequate (Figure 64-2); in this circumstance, low-flow TIA or stroke may arise from atherothrombosis at the internal carotid artery origin or in its petrous or siphon portions.

Because of the advent of thrombolytic therapy, acute stroke diagnosis and management strategies differ significantly from those for

**FIGURE 64-1.** (Continued) (B) Diagram of the brainstem, cerebellum, inferior right frontal lobe, and temporal lobe transected. Principal branches of the vertebral basilar arterial system are pictured. Small branches of the vertebral and basilar artery that penetrate the medulla and pons are not pictured. The stem of the middle cerebral artery with its small, deep-penetrating lenticulostriate arteries and the circle of Willis with its small, deep-penetrating branches, are shown. (C). Roman numerals I, II, III, and IV represent some of the possible variations of the circle of Willis caused by atresia of one or more of its arterial components.

subacute stroke or TIA. Acute treatment strategies for all subtypes of ischemic stroke are discussed at the end of this section. In subacute stroke or TIA, the evaluation and management are best directed in relation to the specific pathophysiological subtype, as outlined in the sections that follow.

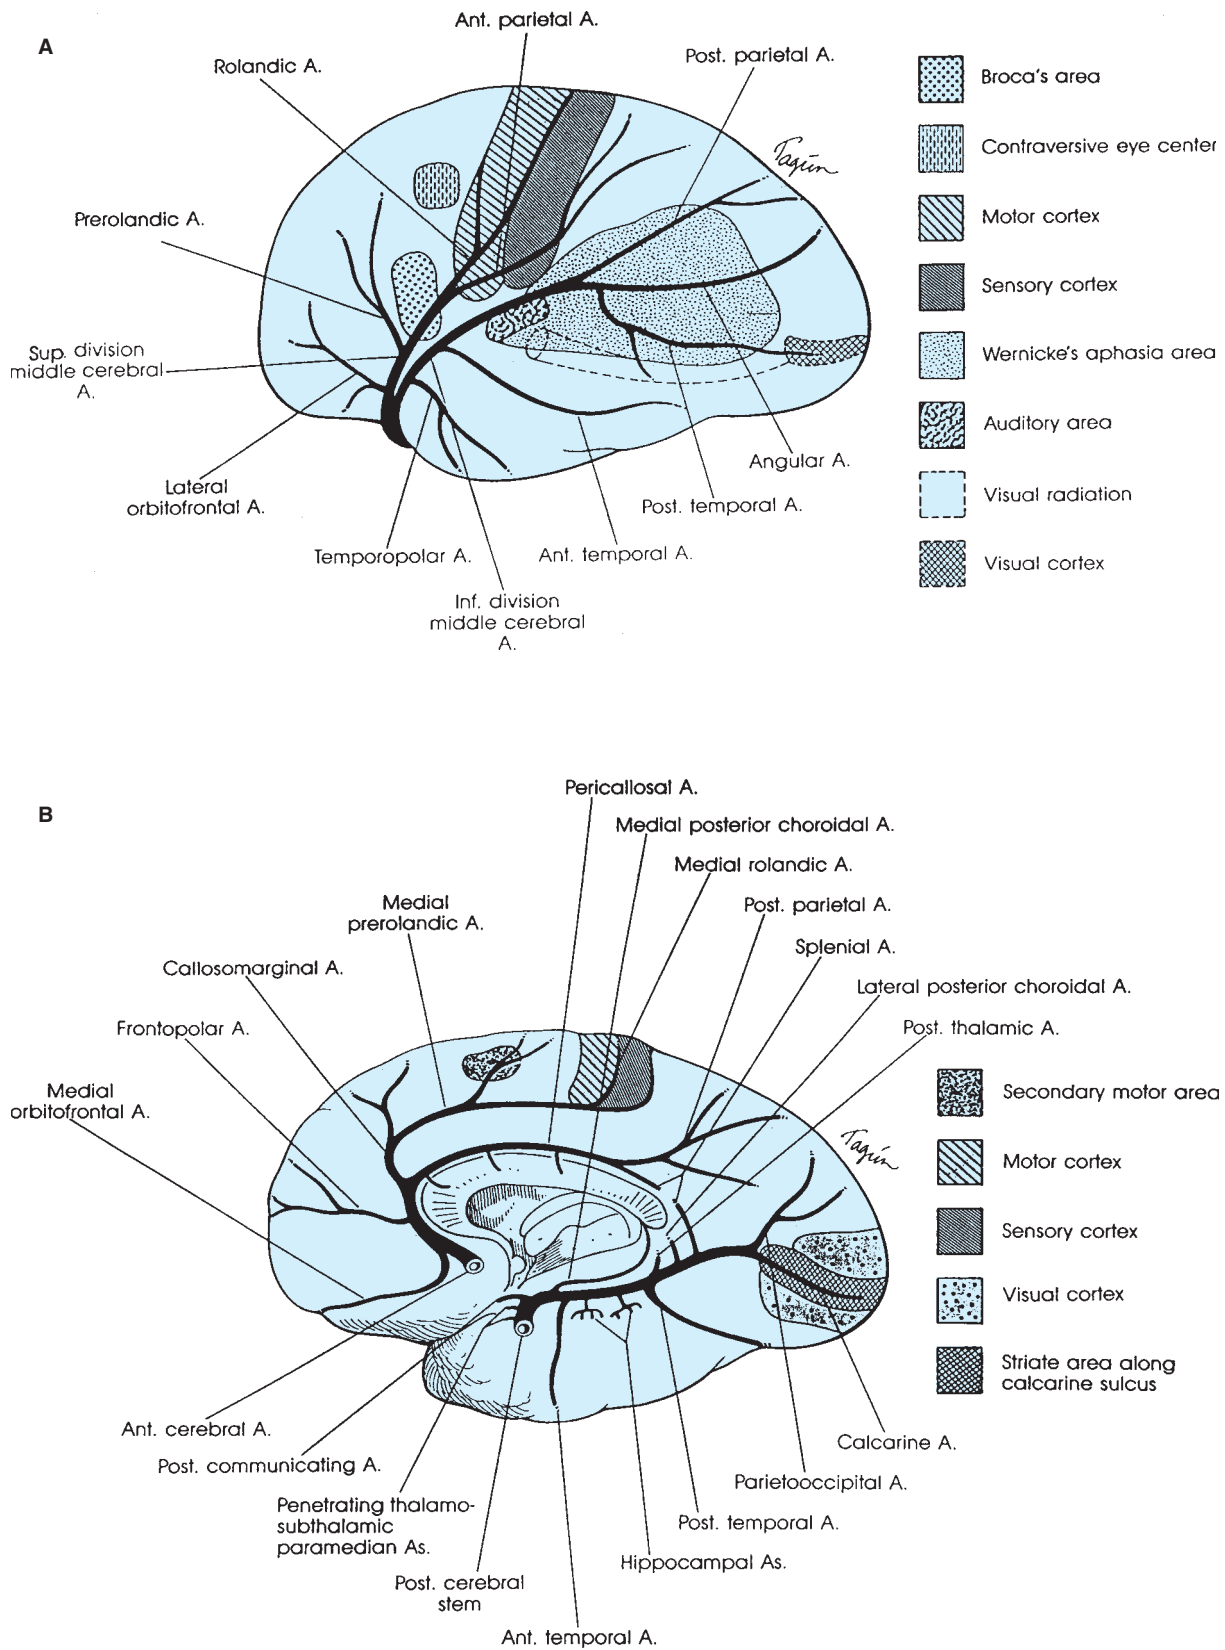

**Atherothrombotic Disease of the Anterior Cerebral Circulation (Origin of the Internal Carotid Artery, Its Major Branches, and the Common Carotid Artery).** In this arterial territory, atheroma occurs most often at the bifurcation of the common carotid artery, and usually begins on the posterior wall of the internal carotid artery origin.

- **Internal carotid artery:** Most often, atheroma at the origin of the internal carotid artery becomes symptomatic after it has narrowed the lumen by 70%, leaving a residual lumen diameter of 1.5 mm—the point where the pressure begins to drop across the stenosis, allowing both embolic or low-flow ischemic TIA and stroke to occur. Embolism from thrombus forming in an ulcerated crater may occur at 50% to 70% stenosis, but it is much less common, and very rarely occurs with lesser degrees of stenosis. Artery-to-artery embolism can also occur if the atheromatous process occludes the internal carotid artery origin forming a thrombus at the site. At times, the occluding thrombus may also propagate without embolization, reaching the ophthalmic artery

origin and producing monocular blindness, or extending even more distally to the middle cerebral artery origin and producing a devastating, total, middle cerebral territory stroke.

The symptoms of the artery-to-artery embolism are variable, depending on the distal branch in which the embolism lodges, and the degree of distal collateral flow. The middle cerebral artery territory is the most often affected. The exact clinical manifestations depend on the precise location of the ischemia, whether in the territory of the ophthalmic artery, the middle cerebral artery, or the anterior choroidal artery. Transient monocular blurring or blindness, often with a shade lowering or telescopic effect, points to ischemia in the *ophthalmic artery* territory. Symptoms associated with ischemia in the other territories are discussed, in their respective sections, below.

Low-flow symptoms caused by internal carotid artery origin stenosis are less common than artery-to-artery embolism, and occur only if two conditions exist: (1) the lesion has to be hemodynamically significant, that is, severe enough to provoke a drop in pressure across the lesion, which is a situation supervening at a residual lumen diameter <1.5 mm and (2) collateral flow distally through the circle of Willis or external carotid artery ophthalmic routes is inadequate, leading to a low-pressure state either in the middle cerebral artery or in one or both of the anterior cerebral arteries. If there is internal carotid artery occlusion and little distal collateral flow then a complete middle

**FIGURE 64-2.** (A) Diagram of a cerebral hemisphere, lateral aspect, showing the branches and distribution of the middle cerebral artery and the principal regions of cerebral localization. Note the bifurcation of the middle cerebral artery into a superior and inferior division. (B) Diagram of a cerebral hemisphere, medial aspect, showing the branches and distribution of the anterior cerebral artery and the principal regions of cerebral localization. (Courtesy of C. M. Fisher, MD.)

cerebral syndrome may result. The posterior cerebral artery (PCA) territory may also be vulnerable to low flow when this artery arises directly from the internal carotid artery, that is, a “fetal PCA.” If the circle of Willis is complete, then occlusion of the internal carotid artery can be asymptomatic if it does not have an associated embolic or propagated thrombotic component.

Atheromatous disease in the internal carotid artery siphon occurs less often, but shares the same type of physiologic mechanisms for TIA and stroke as seen with atheromatous disease of the internal carotid artery origin. By contrast, middle cerebral stem atheromatous lesions mainly cause low-flow TIA or stroke. Emboli to the middle cerebral artery branches from that source occur less frequently and tend to be small. Common carotid origin stenosis rarely causes symptoms, but when they occur, they are most commonly caused by embolism to a distal intracranial artery.

- **Middle cerebral artery:** Middle cerebral artery territory symptoms may conveniently be divided into those involving the stem territory (M1 segment; see Figure 64-2) and those symptoms resulting from ischemia in the superior or inferior territory division or one of their cortical surface branches (Figures 64-1 and 64-2). When the stem of the middle cerebral artery is occluded by thrombosis of an ulcerated atheromatous plaque or artery-to-artery embolism, a complete middle cerebral artery syndrome may occur. It produces a complete hemiplegia equally involving the face, arm, hand, leg, and foot because of the ischemia in the small penetrating (lenticulostriate) arteries that arise from the middle cerebral stem supplying the basal ganglia and internal capsule. Eye deviation toward the ischemic hemisphere occurs when either hemisphere is affected. In addition, ischemia in the upper and lower division cortical surface branches of the middle cerebral artery gives rise to global or partial aphasia (dominant hemisphere) or to neglect and apractognosia (nondominant hemisphere). Which cortical surface structures are involved depends on the level of occlusion and degree of cortical surface collateral flow (Figure 64-1). Smaller emboli cause single superior or inferior branch of the middle cerebral artery syndromes, or partial branch syndromes. In the superior division, these might result in unilateral hand, hand and arm, or hand, arm, and shoulder weakness, unilateral face weakness, or expressive aphasia. Inferior division branch embolic syndromes include difficulty with reading, writing, auditory comprehension of language, or fluent aphasic speech with no limb weakness. Paraphasic errors abound in both inferior and superior division syndromes. Neglect of the left visual hemifield occurs most noticeably in nondominant syndromes, but may also occur on the right with dominant syndromes.

Low-flow syndromes occur when the internal carotid artery occlusion is not supported by adequate collateralization distally. They include recurrent transient brief episodes of hip and shoulder weakness, arm and leg weakness, speech trouble, and face or tongue numbness or weakness, many of which are similar, that is, stereotyped. Cortical surface infarcts secondary to low flow tend to occur in the distal field of the middle cerebral artery branches, before they anastomose with the anterior or posterior cerebral artery cortical surface branches, or in the distal field of the lenticulostriate penetrating arteries, affecting the deep white matter of the corona radiata.

- **Anterior cerebral artery:** Anterior cerebral arteries divide into two segments: part of the circle of Willis (A1 or stem) and the post-

communal (A2) segment distal to the anterior communicating artery (Figure 64-1). The A1 segment gives rise to several deep penetrating arteries that supply the anterior limb of the internal capsule, the anterior perforate substance, medullar anterior hypothalamus, and posterior part of the head of the caudate nucleus. Infarction in these territories is more often caused by an embolus than by local atheromatous disease. If the A2 segments of both right and left anterior cerebral arteries arise from a single anterior cerebral artery A1 segment, a normal anatomic variant, then symptoms occur in both hemispheres and include bilateral leg weakness. The most common symptoms of A2 segment occlusion are foot and leg weakness, and incontinence; occasionally—when both A2 segments are affected—abulia, gait apraxia, and forced grasping may also occur.

- **Anterior choroidal artery:** This artery arises from the internal carotid artery and supplies the posterior limb of the internal capsule and its posterolateral white matter, through which pass some of the geniculocalcarine fibers. The complete clinical syndrome consists of contralateral hemiparesis, hemianesthesia, and hemianopia. However, because this territory is also supplied by penetrating vessels of the middle cerebral artery stem and the posterior communicating and posterior choroidal arteries, syndromes with minimal deficits occur and patients frequently have an excellent recovery.
- **Common carotid artery:** All of the neurologic symptoms of internal carotid artery stenosis or occlusion can occur with common carotid artery thrombosis or an atherothrombotic lesion occurring at its origin. But the occurrence of transient ischemia or ischemia stroke arising from disease in the common carotid artery is far less than that of the internal carotid artery. Bilateral common carotid occlusions can cause faintness on arising, recurrent loss of consciousness, bilateral dim vision, headache, atrophy of the iris, pericapillary arteriovenous malformations, rubeosis iridis, optic atrophy, and claudication of the jaw muscles. They are associated with an incomplete aortic arch syndrome and have been associated with various combinations of carotid, subclavian, and innominate stenosis or occlusion.

**Atherothrombotic Disease of the Posterior Cerebral Circulation: Vertebrobasilar and Posterior Cerebral Arteries and Their Branches.** As seen in the anterior circulation, atherosclerosis has a predilection for certain parts of the posterior circulation—most frequently, the distal vertebral artery and the lower- to mid-basilar artery (Figure 64-1).

- **Vertebral and posteroinferior cerebellar artery:** An occlusion of the distal vertebral or its major branch, the posteroinferior cerebellar artery (PICA), may be caused by either atherothrombosis or by embolism from a proximal artery or the heart. An occlusion of either artery produces infarction in the lateral medulla. Atherothrombotic vertebral artery stroke is often heralded by TIA or minor stroke before the larger, completed stroke. The symptoms and signs vary, but the most frequent include vertigo, nausea and vomiting, hoarseness, dysphagia, ipsilateral facial numbness associated with impaired sensation of pain and heat over the ipsilateral face and contralateral arm and leg, ipsilateral Horner syndrome, and ipsilateral limb ataxia. The PICA also supplies the posteroinferior cerebellum that may become infarcted if collateral circulation from the superior cerebellar artery is inadequate.

The infarct resulting from vertebral occlusion does not differ anatomically from that produced by PICA occlusion, except for a greater involvement of the restiform body in the latter. Nevertheless, involvement of the cerebellum does not appreciably alter the clinical picture, except in cases where cerebellar edema formation increases the pressure in the posterior fossa enough to result in progressive obtundation and death. Although cerebellar edema can be treated with osmotic agents such as mannitol, surgical decompression may be necessary.

- *Basilar artery*: TIA usually heralds atherothrombotic basilar artery occlusion and the consequent accompanying devastating brainstem infarction. The symptoms of a TIA in the territory of the distal vertebral and the basilar artery are more varied than in the carotid-middle cerebral territory because of the many different neuronal structures involved. Moreover, brainstem TIAs may be caused by disease of either of the small penetrating branches of the basilar or vertebral artery or of the basilar or vertebral arteries themselves. The penetrating branch disease may be atherothrombotic, involving the proximal origins of these small branch vessels, or lipohyalinotic, involving the small vessels deeper in the brainstem (see “Lacunar stroke/TIA subtype” later in this chapter). In general, small vessel disease is less threatening than disease of the basilar trunk. Therefore, when brainstem TIA or acute stroke occurs, it is extremely important to determine whether the problem lies in the basilar artery or in one of its smaller branches. Disease of a basilar branch produces unilateral infarction, whereas disease of the basilar artery itself usually causes bilateral infarction. Transient dizziness associated with diplopia, dysarthria, and numbness around the mouth strongly indicate the presence of basilar insufficiency. Other important symptoms occurring less often include a general profound feeling of weakness of the entire body, staggering, and/or a feeling of propulsion. Bilateral signs such as gaze paresis or internuclear ophthalmoplegia associated with ipsilateral sensory loss or weakness signify ischemic infarction in both sides of the pons, and therefore exclude single penetrating branch disease as the culprit.

Many branch syndromes have been described; others await clinical correlation. Syndromes of unilateral brainstem infarction typically involve some combination of ipsilateral signs of the head and face, from involvement of cranial nerve nuclei or their fascicles, and contralateral signs in the limbs, from involvement of ipsilateral crossed long tracts, such as the corticospinal tract or spinothalamic tract. In both instances, that is, symptomatic disease of the basilar artery proper or its branches, the neurologic deficit may fluctuate, and usually is of low-flow type; artery-to-artery embolic TIA occur, but much less often, usually from embolism to the small basilar branches from a proximal or distal vertebral atheromatous lesion. In the case of an artery-to-artery embolic TIA or minor stroke, the events are single and the symptoms are less likely to fluctuate.

- *Major basilar branches—anteroinferior cerebellar artery, superior cerebellar artery, posterior cerebral artery*: These major artery branches of the basilar artery produce their own distinct pathophysiologic syndromes. They are most often caused by artery-to-artery embolism from an atherothrombotic source within the proximal basilar artery or the proximal or distal vertebral artery. Less often, an aortic or cardiogenic source is found. Rarely, pri-

mary atherothrombotic occlusion at their origins is the cause of the stroke or TIA.

- *Superior cerebellar artery*: Occlusion of the superior cerebellar artery results in one or more of the following symptoms: ipsilateral cerebellar ataxia (caused by ischemia of the middle and/or upper cerebellar peduncle, or dentate nucleus); nausea and vomiting; dysarthria and contralateral loss of pain and temperature sensation over the extremities, body, and face (caused by ischemia of the spinal and trigeminal thalamic tract); and ataxic tremor of the ipsilateral upper extremity. Horner syndrome, partial deafness, and palatal myoclonus may occur rarely. Partial syndromes occur frequently.
- *Anteroinferior cerebellar artery*: Occlusion of the anteroinferior cerebellar artery produces variable degrees of infarction because the size of this artery varies inversely with that of the PICA. The territory it supplies usually includes the lateral midpons, middle cerebellar peduncle, cerebellum, and the labyrinth and cochlea. The principal symptoms may include ipsilateral deafness, facial weakness, vertigo (whirling dizziness), nausea, vomiting, nystagmus, tinnitus, deafness, cerebellar ataxia, Horner syndrome, and paresis of conjugate lateral gaze. The opposite side of the body loses pain and temperature sensation. An occlusion close to the origin of the artery may cause cortical spinal tract signs.
- *Paramedian and short circumferential branches of the basilar artery*: Occlusion of one of the 5 to 7 short circumferential branches of the basilar artery affects the lateral two-thirds of the pons and/or middle or superior cerebellar peduncle, whereas occlusion of one of the 7 to 10 paramedian branches of the basilar artery affects a wedge-shaped area on either side of the medial pons. Many brainstem syndromes with cranial nerve abnormalities and crossed hemiplegia have been given eponyms; others await description.
- *Posterior cerebral artery*: Arising from the bifurcation of the top of the basilar artery, each posterior cerebral artery divides into two segments, each with its distinct clinical pathophysiologic syndrome: (1) the proximal precommunal segment, beginning at the top of the basilar artery and going to the posterior communicating artery takeoff, gives penetrating branches to the subthalamus, thalamus, and midbrain, (2) the postcommunal segment, beginning at the posterior communicating artery takeoff, supplies the medial inferior temporal lobe and the medial occipital lobe distally. Twenty percent of the time, one or both of the right or left posterior cerebral artery precommunal (P1) segments are atretic. In that case, the postcommunal (P2) segment is then supplied by the internal carotid artery via the posterior communicating artery. The majority of ischemic syndromes, TIA, or stroke, result from embolism (artery-to-artery, cardioaortic, or unknown source) to the pre- and postcommunal segments and/or one of their branches. Primary atherothrombotic disease of the posterior cerebral artery is much less common.
  - *Precommunal posterior cerebral artery syndromes* include midbrain, subthalamic, and thalamic signs that vary depending on whether the embolus occludes the top of the basilar area, the right or left posterior cerebral artery precommunal segment, that is, the stem, or the penetrating artery branches of the precommunal segment. Coma and

quadriplegia, resulting from infarction of the reticular activating system and bilateral corticospinal tracts within the midbrain, are the consequence of a devastating top of the basilar occlusion. But, otherwise, branch syndromes abound, usually with third nerve and contralateral motor or sensory findings. There is a normal anatomic variant in which a single large medial mesencephalic artery, the artery of Percheron, penetrates upward to supply both sides of the subthalamus as well as part of the midbrain. Occlusion of this artery results in bilateral ptosis, paralysis of upgaze, and decreased consciousness, caused by involvement of the periaqueductal gray and the mesencephalic reticular formation. When only a single penetrating precommunal artery territory is involved, small vessel lacunar disease results (see “Lacunar or Small Vessel Disease” later in this chapter).

- *Postcommunal posterior cerebral artery syndromes* include cortical branches to the medial inferior temporal lobe, giving rise to memory loss and delirium, and branches to the medial occipital lobe, giving rise to homonymous visual field defects. Distal field border zone ischemia of the posterior cerebral and middle cerebral arteries give rise to visual impairment syndromes that include inability to recognize faces or pictures or to put items in a picture together to form an object (Balint syndrome).

### Lacunar Stroke/TIA Subtype (Small Vessel Disease)

As defined by C. Miller Fisher through fastidious brainstem serial section, lacunar infarct results from an occlusion of a small single penetrating artery arising from the circle of Willis, the middle cerebral stem, the basilar artery, or either distal vertebral arteries. These penetrating arteries vary in size from 100 to 400 microns in diameter, rendering the infarct size finite from 0.5 to 1.5 cm in diameter, and usually no more than 3 cm in the longest dimension. The cause is lipohyalinotic narrowing or occlusion in the mid- or distal part of the artery or atherothrombotic lesion at its origin; embolism is rarely the cause. Lacunar strokes account for 25% of all strokes in the NIH Stroke Databank. These strokes cause recognizable clinical syndromes that evolve over hours to days, and may be preceded by transient symptoms (lacunar TIAs). The location of the ischemia determines the nature and severity of the symptoms. Recovery occurs often within days, but in some with especially strategically placed infarcts, significant disability is persistent.

The most common lacunar syndromes are the following:

- *Pure motor hemiparesis* from an infarct in the posterior limb of the internal capsule or basis pontis. The face, arm, leg, foot, and toes are equally paretic or plegic, but with no sensory deficit. The weakness may be intermittent (TIA), progress in a stepwise manner, or appear abruptly. The progression may result in a complete hemiplegia. Improvement almost to normal occurs in many cases.
- *Pure sensory stroke* from an infarct in the ventrolateral thalamus. This type of infarct produces face, arm, and leg sensory involvement with numbness, tingling, and loss of pain and temperature. The patient generally recovers but often is left with a sensory sensation that is abnormal. On rare occasions, an intolerable pain syndrome with dysesthesia occurs in the involved extremities some months afterwards (Dejerine–Roussy syndrome).

- *Ataxic hemiparesis* from an infarct in the basis pontis caused by an infarct in the basis pontis or corona radiata near the genu of the internal capsule.
- *Dysarthria–clumsy hand syndrome* caused by lacunar infarction of the genu of the internal capsule or, less frequently, the corona radiata or the paramedian rostral pons, with resulting mild contralateral arm ataxia or arm weakness, and dysarthric speech.

When multiple, lacunar infarctions may produce bilateral pyramidal and corticobulbar motor system signs, dysarthria, and a slowed abulic mental state with emotional lability, that is, pseudobulbar palsy. Such presentations have, however, become rare in today's era of effective antihypertensive therapy.

Careful attention to antihypertensive, diabetic, and dyslipidemic therapies offer the best form of prevention. In all lacunar stroke or TIA, it is essential to ascertain that the large arteries at the base of the brain giving rise to the penetrating small arteries, that is, the basilar artery, the middle cerebral artery stem, or the posterior cerebral artery stem, are not, in themselves, harboring a thrombus threatening their occlusion and causing the lacunar syndrome (see “Evaluation and Therapeutic Strategies” below).

### Embolic Stroke/TIA Subtype

In this pathophysiologic stroke/TIA subtype the embolic fragment occluding the intracranial vessel, leading to the ischemia or infarction is derived from the aortic arch, the heart, or an unknown source (cryptogenic stroke), rather than from a local arterial source in the extra- or intracranial arteries, such as atherothrombosis or dissection.

Embolic strokes are diagnosed when a sudden or stuttering neurologic deficit appears in the territory of a large intracranial artery at the base of the brain or in one of its major branches, and the extra- or intracranial arterial supply to the ischemic zone does not have a detectable significant stenotic or thrombotic occlusive lesion as detected by ultrasonography, MRI, or CT angiographic imaging. In some cases, the embolic fragment may be seen, on imaging, to occlude the vessel or a distal branch. In other cases, the suspected embolic material is not visualized because it has already been dissolved by the endogenous fibrinolytic system, but not before significant ischemia has occurred. When the above definition of embolic stroke is used, it accounts for fully 60% of all strokes in the NIH Stroke Databank.

It is most convenient, for determining appropriate preventive therapy, to divide these types of emboli into treatment categories. First, those commonly accepted cardiac source emboli where anticoagulant therapy is standard of practice. Second, commonly accepted cardiac source emboli where anticoagulant therapy is contraindicated, as in bacterial endocarditis or atrial myxoma. Third, those possible cardioaortic sources that can only be diagnosed by transthoracic echocardiogram or transesophageal echocardiogram, in which debate exists as to the best therapy, be it anticoagulant, antiplatelet, or cardiointerventional. Fourth, those truly cryptogenic strokes in which a possible or definite cardiac and aortic source is excluded (Table 64-1). Within all of the source categories above, the level of activity of the hemostatic system may be a significant determinant in the incidence of local thrombus formation and embolism. Therefore, in addition to careful evaluation of the heart, evaluation of the hemostatic system, as well as exclusion of a primary arterial source of

**TABLE 64-1****Embolic Stroke Classification**

Cardiac source is definite: anticoagulant therapy generally considered standard of practice.
Left ventricular thrombi
Left atrial thrombi
Rheumatic valvular disease
Mechanical prosthetic valves
Atrial fibrillation
Nonbacterial thrombotic endocarditis
Cardiac source is definite: anticoagulation considered hazardous.
Bacterial endocarditis
Atrial myxoma
Cardiac source is possible: synonyms in the literature include “unknown source,” “cryptogenic stroke”—these diagnoses are made by transthoracic or transesophageal echocardiogram. The efficacy of antiplatelet versus anticoagulant therapy is uncertain.
Mitral annular calcification
Left ventricular dysfunction and dilated cardiomyopathy
Postmyocardial infarction with or without left ventricular aneurysm or thrombi
Left atrial spontaneous echo contrast
Patent foramen ovale
Atrioseptal aneurysm
Valvular strands
Ascending aortic atheromatous disease: mobile plaque 4 mm or greater.
Truly unknown-source embolic stroke.

embolism, is essential in order to plan appropriate pathophysiology-based treatment.

The clinical presentation of embolism in the anterior and posterior cerebral circulation is similar to that of artery-to-artery embolism, and was discussed in the preceding section. The nature and severity of the symptoms depend entirely on the location of the embolic fragment occluding the artery and the spared collateral circulation to its cerebral territory. The artery occluded, in turn, depends on the size of the embolic fragment and the extracranial artery it enters. In the case of an embolic fragment ending in the vertebral artery, it may migrate, stop, and then migrate again, leaving a trail of infarcted tissue from the cerebellum and lower brainstem to the upper brainstem, thalamus, and temporal and occipital lobes. Embolic fragments that enter the middle cerebral stem often disperse to branches of the superior and inferior division of the middle cerebral artery, giving rise to a patchy infarct in the deep or basal lenticulostriate arterial territory, and in the cortical surface branch territories.

In every case of embolic stroke, embolism from an infected heart valve should be considered because of the devastating consequences if not detected. Subacute bacterial endocarditis may have a very subtle presentation. A normal erythrocyte sedimentation rate at the time of the initial evaluation is a quick means of excluding it.

**Patent Foramen Ovale and Embolic Stroke.** Patent foramen ovale (PFO) is the consequence of failure of complete closure of the atrial septum primum and septum secundum immediately following birth, thereby leaving a communication between the right atrium and left atrium. PFO has been associated with stroke in epidemiologic studies, which show its prevalence is doubled in younger persons with otherwise cryptogenic embolic stroke. Stroke may be more common in those with PFO because the atrial communication pro-

vides a channel by which a venous embolism can pass from the right side to the left side of the heart with the potential for subsequent cerebral embolism (so-called “paradoxical embolism”). Alternately, the PFO may itself be the source of thrombus formation with subsequent embolism. The PFO may be identified by transthoracic echocardiography with injection of agitated saline; transesophageal echocardiography offers increased sensitivity. Transcranial Doppler ultrasound can also be used to detect the presence of right-to-left shunting by documenting the passage of agitated microbubbles into the cerebral circulation following a peripheral venous injection; it has equal or greater sensitivity than transthoracic echocardiography and can be used to guide the cardiac evaluation.

There is considerable controversy regarding the significance and therapeutic implications of PFO in stroke, both because of a lack of clinical trials and because PFO is common even in persons without stroke (15–20% of asymptomatic normal individuals have a PFO). Preventive therapy with aspirin or warfarin has been used, as well as invasive strategies to physically occlude the PFO, mostly using endovascular devices rather than cardiac surgery. One study identified the coexistence of an atrial septal aneurysm as an additional risk factor for recurrent stroke; however, it is unclear whether this should affect the therapeutic strategy. If a PFO is identified, the patient should be screened for the presence of deep venous thrombosis, which would itself be an indication for a period of anticoagulation. The significance of identifying PFO in elderly patients with “traditional” risk factors is unclear. A subgroup analysis of the Warfarin versus Aspirin Recurrent Stroke Study (WARSS), enrolling mostly patients older than 60 years with vascular risk factors, found that, among the subgroup with PFO, there was no difference in recurrent stroke among those on warfarin compared to those on aspirin.

### Other Causes of Cerebral Infarction

Although other causes of cerebral infarction account for only 3% of all stroke in the NIH Stroke Databank, they are extremely important because their precise pathophysiologic diagnosis can lead to effective treatment.

*Dissection of the cervical cerebral arteries* is, by far, the most common cause of stroke in this category subtype. Generally, dissection begins at the point where the internal carotid artery enters the petrous bone, approximately 1 cm distal to the origin of the internal carotid artery, or in the vertebral artery as it transverses the foramen transversarium. The dissections divide the media and adventitia, or the media and intima, and clot forms in the division. Thrombus may form in the arterial lumen if it is compromised or occluded. Trauma, either severe or trivial, may be cause of the dissection, but Valsalva maneuvers with coughing and vomiting, weight-lifting, contact sports, or chiropractic manipulations are other recognized associations. Spontaneous dissections, without clear antecedent, are not uncommon. Dissections occur at all ages, but are a frequent cause of stroke in school-aged children or young adults. The clinical hallmark of carotid dissection is a Horner syndrome, which occurs in 50% of instances. Headache, cervical pain, or pain behind the eye occurs frequently. Carotid artery-to-artery embolism or low-flow infarction syndromes occur, just as they do for atherothrombotic disease of the internal carotid artery. Similar pathophysiologic circumstances exist for vertebral artery dissections; with them, cervical spine pain and occipital headache are the suggestive symptoms. The most common site of infarction in vertebral dissection is the lateral medulla, with

or without concomitant involvement of a PICA territory. Dizziness, ataxia of gait, nausea and vomiting with a unilateral Horner syndrome, and ipsilateral face numbness with contralateral body numbness are the hallmark symptoms. Occasionally, diplopia and a hoarse voice are evident. Artery-to-artery emboli arising from a thrombus at the site of dissection in the vertebral artery may migrate to distal branches of the basilar artery, producing brainstem, cerebellar, or thalamic infarction. Although not proven by randomized clinical trial, our experience suggests that immediate anticoagulation with intravenous heparin, followed by 4 to 6 months of anticoagulant therapy with warfarin, using a target international normalized ratio (INR) of 2.0 to 3.0, is helpful in preventing recurrent or worsening stroke.

*Fibromuscular dysplasia* typically occurs in the extracranial carotid artery. On angiography, it looks like a ruffled sock. It is rarely symptomatic unless it becomes hemodynamically significant; then, both embolic or low-flow TIA or stroke can occur. Generally, antiplatelet therapy is used for prevention, but no clinical trial evidence exists in its support. Anticoagulant therapy and interventional arterial therapy are other possible options after symptoms have occurred.

*Infectious arteritis* caused by bacterial or syphilitic infection is no longer a common cause of cerebral thrombosis. Arteritis may rarely follow herpes zoster, particularly if the ophthalmic division is involved. Cerebral arteritis may rarely accompany certain systemic vasculitides, including polyarteritis nodosa or Wegener granulomatosis. Necrotizing granulomatous arteritis, or primary angiitis of the central nervous system, involves the distal small branches (less than 2 mm diameter) of the main intracranial arteries and produces small ischemic infarcts in the brain, optic nerve, and spinal cord. There is no systemic involvement. This rare disease is often relentlessly progressive. There may be cerebrospinal fluid pleocytosis. In some cases, glucocorticoid therapy (prednisone, 40–60 mg/day) has been helpful, as has immunosuppressive therapy (e.g., cyclophosphamide). Idiopathic giant cell arteritis involving the great vessels arising from the aortic arch (Takayasu syndrome) may, on occasion, cause carotid or vertebral thrombosis; nevertheless, it is an infrequent cause of the aortic arch syndrome in the western hemisphere.

*Temporal arteritis* is a relatively common affliction of elderly persons, in which the external carotid system—particularly the temporal arteries—is the site of a subacute granulomatous infiltration with an exudate of lymphocytes, monocytes, neutrophilic leukocytes, and giant cells. Usually, the most severely affected parts of the artery become thrombosed. Headache or facial pain is the chief complaint. The inflammatory nature of the illness is indicated by one or more of the following: fever, slight leukocytosis, increased erythrocyte sedimentation rate, and anemia. Systemic manifestations include anorexia, loss of weight, malaise, and polymyalgia rheumatica. Occlusion of the branches of the ophthalmic artery results in blindness of one or both eyes. Occasionally, an ophthalmoplegia caused by involvement of extrinsic ocular muscles occurs. In some cases, an arteritis of the aorta and its major branches, including the carotids, subclavian, coronary, and femoral arteries, has been found at postmortem examination. Significant inflammatory involvement of the intracranial arteries is rare, but strokes occur occasionally on the basis of occlusion of the internal carotid, middle cerebral, or vertebral arteries. The diagnosis depends on the finding of a tender thrombosed or thickened cranial artery and demonstration of the lesion in a biopsy specimen. The hallmark symptom is transient blindness. When that occurs in patients older than age 50 years, a

sedimentation rate with a fibrinogen level and complete blood count should be done urgently. Corticosteroids may bring striking relief and prevent blindness. Prednisone is most often used, beginning with large daily doses of 80 to 100 mg/day and then tapering over 2 to 4 weeks using the sedimentation rate as a guide.

*Moyamoya disease* is a poorly understood occlusive disorder involving large intracranial arteries, especially the distal internal carotid artery, and the stem of the middle cerebral artery, as well as the anterior cerebral artery. The lenticulostriate arteries develop a rich collateral network around the middle cerebral occlusive lesion giving the impression of a puff of smoke (“moyamoya” in Japanese) on cerebral angiography. Other collaterals include transdural anastomoses between the cortical surface branches of the middle cerebral artery and the scalp arteries. The disease mainly occurs in the Oriental population, but should be suspected when TIAs or stroke occur in children or young adults. Its etiology is unknown; although it has been associated with sickle cell disease, cranial radiation, neurofibromatosis type I, and Down’s syndrome, many cases are idiopathic. There have been few pathologic studies; they suggest that hyalinotic fibrous type material is associated with the arterial narrowing and microaneurysm formation. The best treatment is not known. Although no formal study has been performed to determine the optimal treatment of patients with symptoms of ischemia or infarction, aspirin or other antiplatelet agents have often been used. Anticoagulation is not recommended in all symptomatic cases, but rather on a case-by-case basis. The use of antiplatelet and anticoagulant drugs must be balanced against the risk of hemorrhage (both intraparenchymal and subarachnoid) from rupture of the small, fragile anastomotic channels, or from rupture of the microaneurysms occurring in the perforating arteries from the circle of Willis. In the case of hemorrhage, of course, hematoma evacuation and ventricular drainage may be indicated. A variety of surgical revascularization procedures has been proposed to improve collateral flow and prevent brain infarction and hemorrhage: cervical sympathectomy, omentum transplantation, superficial temporal artery–middle cerebral artery bypass, or encephaloduroarteriosynangiosis.

*Reversible cerebral vasoconstriction syndrome* has been noted in patients with severe “thunderclap” headache, often recurrent, and fluctuating neurologic symptoms and signs. Brain imaging can be normal or show cerebral infarction, hemorrhage, or transient brain edema. The etiology is unknown. Eclampsia, the postpartum period, head injury, migraine, and sympathomimetic and serotonergic drugs have all been associated with this entity. Conventional contrast angiography is the only definitive means of establishing the diagnosis although newer imaging techniques such as CT angiography and MR angiography are proving useful. Cerebrospinal fluid is normal in most cases. The disease is self-limited and, with adequate supportive care, partial or complete recovery occurs in the majority of cases. The headaches and arterial vasoconstriction usually resolve within a few weeks. There is no proven therapy to prevent neurological deterioration. Vasodilators such as nimodipine, a calcium channel blocking agent, or intravenous nitroglycerin might be considered. Maintenance of normal systemic arterial pressure and adequate hydration seems important on empirical grounds.

*Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy* (CADASIL) is a rare primary arteriopathy affecting small penetrating vessels to the basal ganglia, thalamus, and cerebral white matter. The disease is caused by a variety of mutations in the *Notch3* gene. The typical clinical symptom complex includes

late-onset migraine with aura, recurrent stroke and/or TIAs, neuropsychiatric problems such as depression, bipolar disease, or subcortical dementia with pseudobulbar features occurring in persons between 40 and 50 years of age. Cerebrospinal fluid examination and cerebral angiography are normal. There is no specific treatment to date. The diagnosis can be made by genetic testing with sequencing of the *Notch3* gene. Cerebral, leptomeningeal, or skin biopsy with demonstration, by electron microscopy, of typical osmophilic granular deposits in or around the vascular smooth muscle cells of the tunica media and basal lamina matrix is also diagnostic.

*Binswanger subcortical leukoencephalopathy*, now rare, is a syndrome seen with advanced small-vessel hypertensive disease. Diffuse vascular lesions are seen in the subcortical layers of the cerebral hemispheres and there is widespread white matter demyelination. Usually affecting individuals around 50 years of age, it is characterized by fluctuations in mood and consciousness, perhaps even seizures; a dementia may be an early and prominent symptom preceded or accompanied by symptoms and signs of one or more small vessel infarctions. Confusional states, memory difficulties, and abulia are prominent, and sometimes accompanied by focal cortical–subcortical deficits such as aphasia, apraxia, or neglect. Focal neurological deficits, or uni- or bilateral limb signs may lead to a pseudobulbar state; gait difficulties are prominent. There is often evidence of vascular compromise in other body districts.

Binswanger disease must be differentiated from disorders with prominent subcortical white matter involvement on CT or MRI; these include hypertensive encephalopathy, cerebral amyloid (conophilic) angiopathy, CADASIL, normal pressure hydrocephalus, and Alzheimer's disease.

Hematological diseases such as acute and chronic leukemia, essential and secondary thrombocytosis, thrombocytopenia, and sickle cell disease, can be complicated by ischemic or hemorrhagic stroke. Hypercoagulable states such as the deficiency of protein C, protein S, or antithrombin III, are extremely rare causes of stroke, but are often included in the evaluation of stroke in the young.

Finally, stroke can ensue during the course of a severe attack of migraine, especially migraine with aura ("migraine-induced stroke"). It is often difficult to distinguish whether the patient developed a migraine-induced stroke, a stroke-induced headache, or had the coincidental occurrence of stroke and migraine. Since migraine-induced stroke is a diagnosis of exclusion, a thorough evaluation is required to exclude other potential causes, both common and uncommon, before making this diagnosis.

## Evaluation

The initial history and physical is the hallmark of the evaluation to obtain a presumed pathophysiological stroke or TIA subtype diagnosis. The initial electrocardiogram and blood work should include a sedimentation rate as a screen for subacute bacterial endocarditis. In addition, the standard complete blood count, platelet count, prothrombin time, partial thromboplastin time, and general chemistry examination is essential. None of those laboratory assessments should interfere with the urgent timing of neuroimaging and ultrasound studies. Special clotting studies are not essential urgently, but are often useful when a hypercoagulable state is suspected or when there is embolism of uncertain origin. Such studies could include assessment of protein C, protein S, and antithrombin 3, antiphospholipid antibodies, factor V Leiden mutation, and prothrombin 20210 A gene mutation. The screen of thyroid function with a

thyroid-stimulating hormone has helped us in identifying clinically inapparent hyperthyroidism, a condition that may be associated with atrial fibrillation or hyperlipidemia. In the initial blood evaluation, cardiac enzymes are also essential to rule out an associated myocardial infarction.

The pathophysiological stroke subtype, inferred from the history and physical examination, should then be urgently confirmed by imaging evaluation of the brain and the suspected arterial lesion. Noncontrast head CT is, for most centers, the initial component of the imaging evaluation that allows rapid exclusion of hemorrhage, but does not usually define the area of infarction and, of course, does not demonstrate the arterial pathology. The next urgent step, therefore, is imaging of the cerebral large arterial system with CT angiography (CTA), MR angiography (MRA), or transcranial Doppler ultrasound.

CTA is an extremely rapid, accurate way of identifying the pathology in the parent vessel from the origin of the aortic arch to the ischemic zone distal to the great vessels at the base of the brain (vessels shown in [Figure 64-1B](#)). This technique can be combined with *CT-perfusion* imaging, in which a contrast bolus is tracked, by serial scanning, as it passes through the tissue and the results deconvoluted into a map of perfusion times. Although CTA provides excellent definition of the arterial system, it is not good at defining acute infarction. In particular, CT scanning is insensitive to recent infarcts of less than 12 hours duration and small cortical surface embolic infarct and infarcts in the posterior fossa, because of beam-hardening artifact from the closely approximated bones of the skull.

*MRI and MRA* are the best ways of identifying infarcts accurately in terms of their extent and location, but do not offer as good resolution of the arterial system as conventional transfemoral angiography or CT angiography. Susceptibility sequences identify subacute hemorrhagic infarcts and small areas of chronic hemorrhage that might be associated with small vessel diseases such as amyloid angiopathy or hypertensive vasculopathy. MRA, especially when enhanced with gadolinium, can outline the parent vessel pathology from the arch all the way through to the branches of the major vessels at the base of the brain. Gadolinium should be avoided, however, in patients with renal dysfunction because of rare reports of subsequent nephrogenic fibrosing dermopathy. *MR perfusion weighted imaging* can, in an analogous way to CT-perfusion imaging, identify areas of perfusion delay that indicate tissue at risk of progression to infarction. The disadvantage of MRI imaging is the time it takes for the scan to be obtained. In addition, because of the small head diameter of the imaging system, there is a significant claustrophobic effect in approximately 10% of patients. These disadvantages decrease its efficacy in hyperacute stroke state, where the most urgent issue is elucidating the nature of the arterial pathology of the parent vessel leading to the ischemic infarct and the exclusion of hemorrhages, tasks that CT and CT angiography perform admirably.

*Neurosonology* tests include *carotid duplex Doppler* and *transcranial Doppler* assessment of the extra- and intracranial arterial system. *Carotid duplex Doppler* allows assessment of flow at the bifurcation of the common carotid artery, including flow in the proximal internal carotid artery; in addition, flow in the middle portion of the vertebral artery can be assessed to identify more proximal or distal obstructive lesions. *Transcranial Doppler* allows assessment of flow of the intracranial carotid artery and flow in the ophthalmic artery through the transorbital approach. The transtemporal approach permits assessment of flow in the middle, anterior, and posterior cerebral artery stems. The occipital foramen magnum approach easily and reliably

allows determination of flow in the distal vertebral arteries and in the basilar artery. These ultrasound studies allow for immediate evaluation of the stroke or TIA presumed subtype and are important in the identification all four ischemic stroke subtypes. They can identify the presence and severity of an obstructive lesion in the parent vessel as well as identify the presence of collateral flow to the ischemic zone. Their disadvantage is that, on some occasions, the parent vessel of interest escapes examination. Nevertheless, in atherothrombotic stroke, often the severity and location of the atherothrombotic parent vessel lesion and the nature of the spared collateral flow can be identified. In addition, in an embolic stroke, migration and lysis of an embolism in a parent vessel can be noted by detecting normal flow in that vessel. In lacunar small-vessel stroke, the diagnosis can be supported by the identification of normal flow in the parent vessel to the penetrating artery that is suspected of being occluded. In dissection of the carotid or vertebral artery extracranially, obstruction of flow proximally in the vessel can be identified if the dissection is severe enough to affect flow distally. In cases of temporal arteritis, the pathology can be suspected by duplex ultrasound of the temporal artery. These neurosonology tests allow for ease in following these arterial lesions in terms of their progression or resolution. These tests have the advantage of being simple, can be used by the physician similar to the cardiologist's stethoscope examination, and are highly portable. We use these tests to identify acutely the suspected arterial lesion, but always confirm with neuroimaging studies. We then use neurosonology tests to follow the progression of the arterial pathology subacutely and chronically. The quantification of carotid artery atheromatous disease and its progression is an especially important use of carotid duplex Doppler combined with transcranial Doppler.

### Cardiac Evaluation

Cardiac evaluation, in addition to an electrocardiogram, cardiac enzymes, and sedimentation rate acutely obtained, should include, on a subacute basis, cardiac ultrasonography and cardiac rhythm monitoring when an embolism is considered in the differential diagnosis. A cardiac evaluation, including echocardiography, should therefore also be considered in patients with lacunar stroke based on evidence that, uncommonly, small vessel lacunar strokes are caused by emboli. Echocardiography generally starts with transthoracic echocardiogram but, in cases where the diagnosis is not obvious, transesophageal echocardiogram is considered, especially when the obvious diagnostic source is important in deciding a precise preventive treatment. Contrast echocardiography or contrast transcranial Doppler ultrasonography can easily identify patients who have a PFO. Cardiac rhythm monitoring on a portable basis is very helpful if atrial fibrillation or other cardiogenic arrhythmias are to be considered. Only then can precise therapeutic preventive strategies be planned.

### Therapeutic Strategies for Ischemic Stroke

With the acute onset of neurological deficits suggesting ischemia, the essential therapeutic goal is to prevent worsening and to try to facilitate or reestablish blood flow to the ischemic zone. The therapeutic strategy should always be guided by pathophysiology, whether presumed (history and physical) or confirmed (history, physical, and positive neuroimaging or neurosonology confirmatory diagnostic study). The diagnosis should include not only one of the four ischemic stroke or TIA subtypes noted earlier, but also the presence or absence of pathology in the parent vessel supplying the ischemic

zone and the extent of the spared collateral flow to it. The time of onset to treatment determines the therapeutic options. Three phases exist: (1) the hyperacute (1–3 hours) to acute (3–12 hours) phase, (2) the subacute phase, and (3) the preventive phase.

After the pathophysiological diagnosis has been determined and the patient has been evaluated for therapies designed to facilitate or reestablish cerebral perfusion and prevent subsequent strokes, further management efforts are directed at preventing common complications, such as deep venous thrombosis and aspiration pneumonia, and assisting with neurological recovery through rehabilitation.

### Hyperacute/Acute

In this hyperacute/acute phase, the goal is to open the occluded parent artery. For patients in whom treatment can be initiated within 3 hours of symptom onset, intravenous recombinant human tissue plasminogen activator (Activase), at a dose of 0.9 mg/kg with 10% given as an immediate bolus and the remainder infused over 1 hour, has been shown to reduce stroke-related disability. In the pivotal NINDS rt-PA trial, patients treated with recombinant tissue plasminogen activator (rt-PA) had a 12% greater absolute chance of a good outcome, defined as minimal or no stroke-related disability. This benefit was present despite a 6% risk of intracranial hemorrhage in the rt-PA group, of which more than half were fatal. There is incomplete evidence regarding which stroke pathophysiological subtypes respond best to rt-PA; posthoc analysis of the trial did not show statistical evidence that the treatment effect varied by presumed stroke subtype, although the power to detect differences was modest.

Because of the risks of hemorrhage, the decision to give rt-PA should be based on an individual assessment of the benefits and risks for the specific individual, with careful attention to the treatment inclusion and exclusion criteria. Patients with well-established CT evidence of infarction should not be treated. Those with early CT signs of infarction, such as loss of differentiation of the cortical ribbon from the underlying white matter in greater than one-third of the middle cerebral artery territory, have a worse prognosis from stroke and may not warrant treatment in all cases. Patients expected to have an excellent outcome may not warrant treatment because of the overall excellent prognosis. The decision not to give rt-PA should be made carefully, however, because data suggest that some patients with mild or improving stroke may have stroke recurrence or extension. The ability to predict which patients will have subsequent worsening is, unfortunately, limited. There has been concern about treatment of the elderly because age may be a risk factor for rt-PA related hemorrhage; however, the trial data show that this increased risk does not outweigh the potential benefit in elderly persons. Age is not an exclusion criterion to rt-PA use at our institution; the oldest subject we have treated was 99 years of age. Intravenous rt-PA is best administered by experienced stroke teams with expert neuroradiologic consultation available 24 hours a day. The Joint Commission on Accreditation of Hospital Organizations (JCAHO) now offers an accreditation program to certify hospitals as “primary stroke centers”, which includes documentation of competency in administering rt-PA.

Intra-arterial approaches to therapy have been employed, in selected centers, in patient with moderate to severe neurological deficits within 6 to 8 hours of stroke onset. Patients with a basilar thrombus up to 12 hours after stroke onset are also sometimes treated because in the posterior circulation, particularly the brainstem and cerebellum,

a rich collateralization can delay the progression to infarction for longer periods of time. Intra-arterial therapy is sometimes used after intravenous rt-PA in cases where there was no immediate response to the intravenous rt-PA because of persistent arterial occlusion. Intra-arterial treatment options include direct administration of thrombolytics, wire manipulation, angioplasty or stenting, or clot retrieval. Most of these approaches have not been proven effective in a randomized trial. Observational studies suggest, however, that they may be able to achieve recanalization of arterial occlusions of the proximal branches of the circle of Willis. Intra-arterial infusion of prourokinase was shown to produce better outcomes than placebo in the Prolyse in Acute Cerebral Thromboembolism II (PROACT-II) study, but the evidence was not sufficient to prompt the United States Food and Drug Administration (FDA) to grant approval for the drug. More recently, the FDA has approved the Concentrics device for retrieval of intracranial thromboemboli within 8 hours of symptom onset. The efficacy of this device in reducing stroke-related disability has, however, never been tested in a controlled trial, therefore its role in therapy remains controversial.

Intravenous and low-molecular-weight heparins, as well as heparin-like anticoagulants, have been tested in a number of clinical trials with conflicting results. Reflecting this, current guidelines acknowledge that the benefit of using heparin for acute stroke, in any clinical setting, is uncertain. On the other hand, it is possible that heparin could prevent clot propagation in the parent vessel (although clot lysis is unlikely), or prevent early recurrent stroke especially from a high-risk arterial source. Intravenous heparin has been used in five common clinical settings. First, in large-vessel atherothrombotic disease to prevent clot propagation from the atherothrombotic locus, or to prevent further embolization from the atherothrombotic site. Second, in embolic stroke from a cardiac or aortic source where the embolus remains in the stem of the middle cerebral artery, the internal carotid artery or the basilar artery, that is, one of the parent vessels, and the deficit is submaximal, that is, the deficit could worsen if the embolus propagates as a thrombus. Third, in lacunar stroke, it is occasionally given when the motor weakness is relentlessly progressive. Its efficacy has not been very high in this setting in our hands. Fourth, it is likely of benefit in patients who have carotid or vertebral artery dissections, or sinovenous thrombosis; only in the latter setting has the efficacy of heparin been proven in a randomized trial. Many centers, including ours, use heparin in the acute setting of arterial dissection in order to prevent clot propagation and artery-to-artery embolus. Fifth, in patients with a high-risk cardioembolic source or arterial source of embolism, it may reduce the risk of early recurrent stroke. Heparin is associated with an increased risk of hemorrhagic transformation of ischemic stroke, and this risk is greater when the infarct volume is large. The risk of hemorrhage is, however, much lower than with rt-PA. In our practice, heparin is not given if the stroke is large (greater than one-third of the middle cerebral artery territory or the complete posterior cerebral artery territory), particularly if the stroke involves the deep penetrating branches to the basal ganglia. In patients who have received thrombolytics, heparin should not be given within 24 hours of treatment.

### Subacute

Surgical therapeutic options can be considered in this subacute phase. Urgent carotid endarterectomy may be considered if the patient has a severe carotid stenosis with an inadequate collateral

supply through the circle of Willis or the external carotid artery ophthalmic system. In this setting, the resultant stroke can be devastating, while emergency endarterectomy can be highly effective. Carotid endarterectomy for mild to moderate stroke or TIA in the territory of the internal carotid artery has also been proven effective, by the North American Symptomatic Carotid Endarterectomy Trial (NASCET) study, for patients with both 70% to 99% stenosis and 50% to 69% stenosis. But severe stroke in the middle cerebral artery territory in which further worsening would only be minimal, that is, the deficit is almost maximal, is not appropriate for endarterectomy in the subacute phase. If the patient improves in rehabilitation to the point where worsening of the deficit would be problematic, then endarterectomy can be reconsidered. If low-flow stroke is not the issue, surgery can be planned in patients with mild to moderate deficits on an elective basis after careful consideration of the cardiomedical status. The surgical benefit for patients with symptomatic moderate stenosis was statistically significant but small, with only 1.5% absolute risk reduction per year, and therefore surgery should only be considered in centers with low perioperative rates of surgical morbidity. The decision to perform carotid endarterectomy for symptomatic moderate carotid stenosis should be made on an individual basis, taking into account the patient's surgical risk, center-specific perioperative complication rate (which should be less than 2%), and the patient's life expectancy. Because the surgical risk occurs "up-front" during the perioperative period, the benefit from surgery accrues with increased years of life. For the elderly, the risks and benefits must be carefully weighed. When there is symptomatic severe stenosis (70–99% luminal narrowing) the surgical benefit is, by contrast, quite high, and most patients will benefit from surgical rather than medical management.

Carotid stenting has recently gained ground as an alternative to endarterectomy. Advantages include shorter hospital stay, lack of a neck incision, avoidance of general anesthesia, and a lower incidence of cranial neuropathy as a complication. However, two recent randomized trials, in patients with symptomatic carotid stenosis, showed that stenting was inferior to endarterectomy with higher rates of serious periprocedural complications. Stenting is still an option for patients at high risk for complications from endarterectomy, including those with medical comorbidities, unfavorable neck anatomy, and postendarterectomy restenosis. Additional trials, incorporating newer technologies to prevent stent-related embolization, may yet expand the indications for stenting.

Hemicraniectomy may be considered when progressive cerebral edema in the nondominant hemisphere becomes severe enough to compromise cerebral perfusion or cause brain herniation. This operation can prevent herniation and death by relieving intracranial pressure, but is unlikely to restore significant neurological function because it is typically performed in the setting of extensive brain infarction. A pooled analysis of three small trials confirms that hemicraniectomy prevents severe dependency or death. Observational studies suggest very poor outcomes in patients older than 65 years, and it is generally not used in elderly persons.

### Preventive

There are two important aspects of preventive therapy. First, the control and prevention strategies related to the primary risk factors for all stroke subtypes and, second, preventive strategies directed toward the specific stroke or TIA subtype in the particular patient.

**Preventive Strategies for Controlling Primary Risk Factors.** Treatment of hypertension is, by far, the most important aspect of risk factor control. Achieving and maintaining blood pressure treatment targets are probably more important than proposed class effects of the drugs. Control of lipids is also important. Following the Third Report of the National Cholesterol Education Program Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (ATPIII) guidelines for prevention of MI, the primary goal is lowering the low-density lipoprotein (LDL). Risk factor adjustment including diet, exercise, weight reduction, cessation of smoking, and diabetes management are all important first steps. Hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (“statins”) are associated with reduction in the risk of stroke, as well as reduction in the risk of MI. The recent Stroke Prevention with Atorvastatin to Reduce Cholesterol Levels (SPARCL) trial showed that, among patients with large vessel atherothrombotic or lacunar stroke subtypes and LDL >100 mg/dL, high-dose atorvastatin (80 mg every day) was superior to placebo in reducing subsequent stroke. Our practice is to treat all patients with large vessel atherothrombotic or lacunar stroke with statins to lower the LDL to less than 100 mg/dL.

**Preventive Therapy Directed Toward the Specific Stroke/TIA Subtype.** Therapy directed toward preventing the specific stroke subtypes consists of two aspects: (1) antiplatelet versus anticoagulant therapy and (2) surgical strategies.

- *Anticoagulant versus antiplatelet therapy:* Anticoagulant therapy is accepted as standard of practice in the cardiac conditions outlined in Table 64-1; but only in the case of atrial fibrillation has this treatment been proven by randomized clinical trial. The INR goal is 2 to 3, except in certain prosthetic valvular conditions, where an INR of 2.5 to 3.5 is recommended. Warfarin anticoagulation is contraindicated in infective endocarditis and in left atrial myxomatous syndromes because of associated cortical surface mycotic and myxomatous aneurysm with the risk of hemorrhage. In all other possible causes of cardioaortic embolism, as in cases of cryptogenic embolism, debate exists as to the efficacy of anticoagulant therapy. Aspirin or other antiplatelet agents have been prescribed in lieu of anticoagulant therapy, but their efficacy also has not been proven by randomized clinical trials. Stroke and TIA subtypes were not identified in those studies in which aspirin was compared to placebo or to another antiplatelet agent for the secondary prevention of recurrent stroke or TIA after a previous minor primary stroke or TIA. One study in which the primary and secondary stroke subtypes were accurately identified was the Warfarin Aspirin Recurrent Stroke Study (WARSS), which compared the efficacy of warfarin to aspirin in secondary stroke prevention. When all of the stroke subtypes were combined, there was no difference in the risk of stroke with warfarin compared to aspirin. When the data for primary individual stroke subtype were analyzed in terms of secondary stroke prevention, there was a trend in favor of anticoagulant therapy for patients with cryptogenic embolism. For patients with symptomatic intracranial stenosis, warfarin was also recently shown in a randomized trial to be no more effective than aspirin in preventing recurrent stroke. However, when there are recurrent cerebrovascular events on antiplatelet agents, which are common in the setting of high-grade intracranial stenosis, our practice is to then consider anticoagulation, as well as to consider whether intracranial angioplasty with stenting should be performed. In addition, we manage carotid or vertebral dissection with warfarin. The INR goal in all of these conditions is 2 to 3. Generally, for dissection, we continue the warfarin for 6 months; then if ultrasonographic evidence or non-invasive neuroimaging evidence suggests the arteries are open and symptom-free, we switch to aspirin. If the artery has not healed, then one must consider whether to continue warfarin for a period of time and repeat the noninvasive imaging or, at some point, consider switching to aspirin.
- Recent studies have compared the efficacy of aspirin to other antiplatelet agents, typically without consideration of the pathophysiologic stroke subtype. Two randomized trials show that the combination of aspirin with sustained release dipyridamole at a dose of 200 mg twice daily (marketed as Aggrenox) confers an absolute risk reduction of 1% to 1.5% per year compared to aspirin alone. This must be balanced against a risk of throbbing headache that led to higher drop out rates in the aspirin plus dipyridamole group. Clopidogrel was shown in a randomized trial to be slightly better than aspirin (0.5% absolute risk reduction per year) in preventing a combined endpoint of stroke, coronary events and peripheral vascular disease; when stroke endpoints alone were considered, the difference was no longer significant. Three large trials have looked at the combination of aspirin and plavix for chronic prevention of cardiovascular diseases and found that the combination has a relatively high rate of bleed complications compared to single agent therapy, without better efficacy. This combination should, therefore, be avoided except in specific circumstances where the benefit is well accepted, such as following arterial stenting.
- *Surgical therapy:* Carotid endarterectomy is the only widespread surgical therapy available in ischemic stroke. Two clinical settings apply, with different criteria: (1) symptomatic disease and (2) asymptomatic disease. The efficacy of carotid endarterectomy for symptomatic disease is high when there is a 70% to 99% stenosis, but modest when there is a 50% to 69% stenosis. Urgent carotid endarterectomy is also discussed in the section on subacute surgical therapies. Precise assessment of the degree of severity of the stenosis and its effect intracranially is extremely helpful when determining the urgency of timing of surgery. In addition, an image through CTA or MRA is also helpful in identifying the pathology not only in the internal carotid artery origin, but also in the arteries distally and in the arteries providing collateral flow. Neither CTA nor MRA can quantify the degree of stenosis when it becomes hemodynamically significant as well as carotid duplex Doppler and transcranial Doppler. There now exist 100% specific criteria noted by transcranial duplex Doppler for identifying such a lesion.
- *Asymptomatic carotid stenosis:* The clinical utility of endarterectomy or stenting for asymptomatic carotid stenosis and which patients should be treated remain controversial. Two large randomized trials have now reported that endarterectomy is superior to medical therapy for prevention of new stroke. Both of these studies enrolled patients with moderate degrees of stenosis, as low as 60%. Naturally, the event rates in the trials were extremely low. Both trials showed similar modest risk reductions in the surgical group, indicating that the surgical benefit, although statistically significant, is marginal.

Because of the relatively small surgical benefit, patient selection and low perioperative complication rates are essential in order to realize a benefit from endarterectomy for asymptomatic lesions. Younger persons accrue more benefit from surgery because of longer life expectancy. Surgery should be avoided in patients with poorly controlled cardiac or pulmonary conditions, and in those with a short life expectancy. We additionally will use information about the degree of stenosis and status of collateral flow. This despite the fact that asymptomatic endarterectomy trials did not find a correlation between the degree of stenosis and the risk of stroke. The low event rates in those trials probably gave too little power to properly identify this relationship, however. By contrast, natural history studies and the modern symptomatic endarterectomy trials point out that symptoms (low-flow transient ischemia or embolic ischemia, transient or permanent) most often occur as a result of internal carotid artery origin stenosis that is severe enough to produce a pressure drop across it. This occurs between 70% and 75% residual lumen diameter reduction or 1.5 mm actual residual lumen diameter. Duplex Doppler assessment of flow at the bifurcation of the common carotid artery and transcranial Doppler assessment of distal internal carotid artery, ophthalmic artery, and middle, anterior, and posterior cerebral artery stem flow can accurately identify such lesions. Confirmation by CTA and/or MRA eliminates the need, except in rare instances, for conventional intra-arterial angiography and its risks.

Our data from transcranial Doppler and duplex ultrasound studies suggest that a stenosis with a residual luminal diameter of 1.5 mm (i.e., 70–75% stenosis) represents the point at which a pressure drop across the stenosis occurs in most patients; that is, the point at which the stenotic lesion at the origin of the internal carotid artery becomes hemodynamically important. When the stenosis has hemodynamic consequences, the collateral flow through the ophthalmic artery or through the circle of Willis is called into play. If collateral flow is not adequate, low-flow TIAs and infarcts develop. If collateral flow is adequate, patients should remain free of low-flow symptoms (TIA or stroke).

Our concern is that reduced flow in the internal carotid artery, supplemented by good collateral flow distally, may promote the formation of thrombi at the origin of the internal carotid artery; such thrombi may embolize or propagate distally to cause sudden stroke. We, therefore, recommend surgery for asymptomatic patients whose lesions have progressed to this point, that is, those with stenosis of 70% to 75% or more. We identify such lesions on the basis of our 100%-specific criteria for hemodynamic importance, based on duplex and transcranial Doppler ultrasonography, combined with MRA or CTA. Because of the absence of clinical trials that have definitively assessed the surgical benefit for varying degree of stenosis, with adequate statistical power, we feel that this approach is warranted.

- *Carotid artery stenting compared to carotid artery surgery*: Transfemoral angiography with endovascular angioplasty and stenting of internal carotid artery plaque is emerging as an alternative to carotid endarterectomy. Stenting is attractive because it is associated with shorter hospital stay, allows avoidance of general anesthesia, and is not associated with the cranial nerve injury complications that sometimes complicate endarterectomy. A significant concern, however, is the risk of distal embolization of thrombus or fragments of atheroma dislodged during either arterial access, balloon inflation, or stent deployment. An evolving

array of embolization protection devices, deployed distal to the stent, is designed to limit this risk.

Three randomized trials have recently addressed whether stenting can produce results as good as endarterectomy. All of the trials used a noninferiority design, that is, that stenting is not worse than endarterectomy. Two trials, *Endarterectomy versus Angioplasty in Patients with Symptomatic Severe Carotid Stenosis (EVA-3S)* and *Stent-Supported Percutaneous Angioplasty of the Carotid Artery versus Endarterectomy (SPACE)*, showed that, in patients with symptomatic >60% internal carotid artery stenosis, stenting was worse than endarterectomy with regard to 30-day rates of major complications such as stroke and myocardial infarction. By contrast the *Stenting and Angioplasty with Protection in Patients at High Risk for Endarterectomy (SAPPHIRE)* trial, which included only patients who were deemed poor operative candidates for endarterectomy, showed equivalency between stenting and endarterectomy, with slightly lower complication rates in the stenting group. Long-term outcomes are not yet available from any of the trials.

At this time we do not see any clinical situation in which carotid stenting is clearly superior to endarterectomy. For symptomatic lesions that are poorly amenable to surgery, because of poor anatomical factors or medical comorbidities, stenting is a reasonable, possibly safer, alternative. Patients with asymptomatic stenosis and complex, difficult to treat lesions, or severe medical comorbidities, should have neither stenting nor surgery, based on the high periprocedural complication rates from the SAPPHIRE trial. There is a need for additional trials in symptomatic patients that incorporate the newer generation embolization protection devices, which were mostly not used in the EVA-3S and SPACE trials. Additionally, information on long-term stroke risk by stroke subtype, and the risk of in-stent restenosis, is needed before the role of carotid stenting in routine clinical practice can be fully defined. Until that information is available, good surgical candidates should be treated with endarterectomy, rather than stenting, except in the context of clinical trials.

### Treatment and Prevention of Complications of Stroke

Common medical complications of stroke include aspiration pneumonia, deep venous thrombosis, and pulmonary embolism. When in-dwelling bladder catheters are used, then urinary tract infection is an additional concern. All stroke patients with evidence of dysarthria, aphasia, cough, or aspiration should have a formal evaluation of swallowing before being allowed to take food, liquid, or medicines by mouth. Some patients may require placement of a percutaneous gastrostomy feeding tube, which, in most cases, can be removed in 1 to 2 months when the ability to swallow improves. Deep venous thrombosis can be prevented by the administration of subcutaneous heparin or the use of pneumatic compression boots, followed by ambulation as soon as possible.

Patients with stroke-related disability should be evaluated by specialists in physical therapy, occupational therapy, or speech therapy as appropriate. A substantial number of patients may benefit from inpatient rehabilitation following the acute hospital stay. There is evidence from observational studies that patients treated in dedicated stroke units, with experienced physician, nursing and rehabilitation staff, have better outcomes than patients treated in general medical or surgical wards.

Stroke recovery may require 6 months to a year, or even longer, because of the slow nature of neuroplastic changes following brain injury. Late complications of stroke include spasticity, contracture, pressure ulcers, shoulder joint dislocation, and depression. The injection of botulinum toxin in affected muscles has been shown to improve symptoms of stroke-related spasticity.

## INTRACRANIAL HEMORRHAGE

Intracranial hemorrhages are classified according to site of origin. The diagnosis, treatment, and secondary prevention of intracranial hemorrhage depend on the assessment of the underlying specific pathophysiology, analogous to the way in which ischemic stroke diagnosis and treatment depend on identifying the ischemic stroke subtype. There are four locations of origin: intracerebral, subarachnoid, subdural, and epidural. Subdural and epidural hemorrhages are predominantly traumatic and not related to an acute vascular event, and are not considered a form of hemorrhagic stroke. This section will therefore be concerned with intracerebral hemorrhage (ICH) and subarachnoid hemorrhage. ICH may be further divided by location into lobar ICH (arising in the cortex or at the junction of the cortex and the white matter) and deep ICH (arising in the deep hemispheric portions of the brain, including the basal ganglia, thalamus, brainstem, and cerebellum).

### Intracerebral Hemorrhage

#### Deep Hemispheric Hemorrhage

Hypertension is by far the major cause of hemorrhages in deep brain locations. The favored sites are (1) the putamen and adjacent internal capsule, (2) the thalamus, (3) the pons, and (4) the cerebellum. A penetrating artery arising from the middle cerebral stem, basilar artery, or circle of Willis is generally the source of the hemorrhage. These same vessels are also frequently affected by lipohyalinosis and, when occlusion occurs rather than rupture, give rise to lacunar infarction.

Recently, a single family has been reported with a mutation in the *COL4A1* gene, encoding for type IV collagen  $\alpha 1$ , and deep ICH not associated with hypertension. Other features of this disease include migraine with aura, retinal arteriolar tortuosity with retinal hemorrhage, and infantile hemiparesis.

Each of the four sites of ICH produces a characteristic clinical syndrome. For *putaminal hemorrhage*, the eyes are deviated conjugately to the side of the hemorrhage and there is a contralateral hemiplegia. Stupor is evident at the onset in most cases. *Thalamic hemorrhage* has a similar clinical state unless the mass effect is directed downward; in that case, the eyes deviate downward and inward. Unequal pupils and skewed deviation with the eye on the side opposite the hemorrhage being displaced inferiorly and medially is also seen. *Pontine hemorrhage* produces deep coma, quadriplegia, decerebrate rigidity, and impairment of horizontal eye movements with pinpoint pupils. *Cerebellar* hemorrhage presents with vomiting and instability of gait; these may be the only signs. However, forced deviation of the eyes to the opposite side or ipsilateral sixth nerve palsy may be noted. Less frequent ocular signs include blepharospasm, involuntary closure of one eye, and skew deviation. Dysarthria may also occur. Babinski signs and bifacial weakness occur late. Hemiparesis or hemiplegia is

not part of the clinical picture until coma has set in from increased pressure in the posterior fossa.

CT scan has excellent sensitivity for ICH and is the mainstay of diagnosis. There are no clinical signs or symptoms specific for ischemic stroke compared to hemorrhagic stroke, making CT mandatory in all cases. CT angiography, MRA, or conventional angiography can exclude the presence of an associated arteriovenous malformation, and T2-weighted MRI can detect the classical “popcorn” appearance of cavernous malformation. Older patients with a history of hypertension and hemorrhages in a typical location do not need angiographic assessment. Younger patients and those with an atypical appearing hemorrhage should, by contrast, have angiography. Hemorrhages in the basal ganglia that are contiguous, inferiorly, with the subarachnoid space should be investigated with angiography to exclude the presence of a middle cerebral artery bifurcation aneurysm. When hemorrhages occur in atypical locations or in the absence of a history of hypertension, our practice is to also obtain an MRI in 3 to 6 months, following ICH resorption, to screen for an underlying lesion such as a vascular malformation or tumor. Additional acute laboratory assessment should include platelet count, prothrombin time, and partial thromboplastin time. The history, physical examination, and imaging should exclude secondary causes of hemorrhage such as coagulopathy, brain tumor, aneurysm rupture, and hemorrhagic transformation of ischemic infarction.

The size and location of the hematoma determine the treatment and prognosis. Supratentorial hematomas > 5 cm in diameter have a poor prognosis. Infratentorial hematomas > 3 cm in size are generally fatal if they are in the pons. Other factors associated with poor prognosis are the presence of intraventricular blood and worse level of consciousness at presentation.

For cerebellar hemorrhages, neurosurgical consultation is essential because early hematoma evacuation can be life saving. In general, hemorrhages larger than 3 cm in diameter, and smaller hematomas associated with depressed consciousness or brainstem signs (other than nystagmus or ataxia), should be surgically evacuated. For other locations, surgical evacuation is controversial. The Surgical Trial for Intracerebral Hemorrhage (STICH) trial failed to find a benefit for surgical evacuation over medical management. Even so, we consider surgical evacuation or hemicraniectomy for nondominant hemisphere deep ICH accompanied by decreasing level of consciousness caused by increasing mass effect.

General supportive care should be provided. Accumulation of cerebral edema can be problematic by causing raised intracranial pressure (ICP). Osmotic agents including mannitol can be used to lower ICP, but are generally considered temporizing therapy, gaining time while preparing for surgery. Obstructive or communicating hydrocephalus should be treated by external ventricular drainage of cerebrospinal fluid followed, if necessary, by insertion of a permanent ventricular drainage shunt. Seizures may occur and, if the patient is at risk of deterioration from raised ICP, our practice is to administer preventative anticonvulsants, although this practice has not been evaluated in controlled trials.

### Lobar Hemorrhage

Lobar hemorrhages occur spontaneously in the supratentorial white matter and cerebral cortex of all lobes of the brain. The manifestations are dependent on the area of white matter and cortex that are involved. Headache is sometimes present and may be most severe

near the location of the hemorrhage. If the hemorrhage is large, then depressed consciousness may be present. The symptoms usually evolve over minutes or hours, in contrast to embolic ischemic stroke where the onset of symptoms is abrupt. A precise cause of lobar ICH is found in a significant number of cases: amyloid angiopathy and vascular malformations are the most common; metastatic disease is less frequent, but well known. Some proportion of lobar ICH are likely caused by hypertension. Lobar ICH is more readily accessible for surgical evacuation because of their superficial location. A subgroup analysis of the STICH trial showed a benefit for surgery, compared to initial conservative management, for ICH <1 cm from the cortical surface. At our institution, we consider, on an individual basis, surgical evacuation for nonmoribund lobar ICH patients who are deteriorating from mass effect caused by hematoma expansion or the accumulation of perihematomal edema.

**Cerebral Amyloid Angiopathy.** A cause of both single and recurrent lobar hemorrhages in the elderly population, amyloid angiopathy is diagnosed conclusively only by postmortem demonstration of amyloid in the media of cortical and leptomeningeal arterioles and capillaries. But the clinical history of repeated supratentorial lobar hemorrhages and the demonstration of small, 1- to 2-mm areas of hypointensity on MRI susceptibility pulse sequences, indicative of prior small asymptomatic hemorrhages, strongly suggest the diagnosis. These small, silent hemorrhages may be the cause of recurrent focal symptoms sometimes seen in these patients. A clinical–pathological correlation study suggests that cerebral amyloid angiopathy is the cause of approximately 70% of primary lobar ICH in persons aged >55 years. Sporadic amyloid angiopathy is caused by the deposition of beta-amyloid only in the cerebral arteries, without systemic amyloidosis. Extremely rare mendelian causes of cerebral amyloid angiopathy have been discovered and are caused by mutations in the *BR12* gene or the genes encoding the amyloid precursor protein, cystatin, transthyretin, prion protein, or gelsolin.

Other than avoidance of anticoagulants, treatment options remain elusive. There is a high recurrence rate of 10% to 14% per year in sporadic lobar ICH, mostly caused by cerebral amyloid angiopathy, which is significantly higher than the recurrence rate of 2% to 4% per year observed in survivors of deep ICH. Careful control of associated hypertension, if present, seems prudent.

A small number of cases are associated with vascular or perivascular inflammation that frequently responds to a pulse of steroids, although late relapses may occur. Cerebral amyloid angiopathy-associated inflammation typically presents with cognitive impairment, seizure or focal neurological signs rather than hemorrhagic stroke. Asymmetric white matter and gray matter hyperintensities, often with small silent hemorrhages on susceptibility sequence, are observed on MRI. Biopsy is usually indicated to exclude other causes of vasculitis.

**Lobar Hemorrhages Caused by Metastatic Disease.** Cerebral metastases, particularly malignant melanoma, may give rise to hemorrhage. Usually, the metastases are multiple and can easily be demonstrated by MRI or CT scanning, both with contrast.

### Vascular Malformations

Increasingly recognized with advances in neuroimaging techniques, vascular malformations are classified into four types: venous malfor-

mations, capillary telangiectasias, arteriovenous malformations, and cavernous malformations or angioma. Vascular malformations may cause hemorrhage in either deep or lobar locations.

*Venous malformations*, also known as venous angiomas or developmental venous anomalies, consist of anomalous veins that, while not associated with arterial feeders, nevertheless provide functional venous drainage, and are usually asymptomatic.

*Capillary telangiectasias* are small, often punctate, lesions composed of small clusters of dilated capillaries with normal intervening parenchyma. Small capillary telangiectasias in basal ganglia areas or in the brainstem are usually asymptomatic (i.e., discovered at autopsy), but may rarely rupture and produce a hematoma.

*Arteriovenous malformations* and *cavernous malformations* are clinically significant because of their potential for producing hemorrhage and neurologic deficits.

*Arteriovenous malformations* consist of a tangle of abnormal vessels forming an abnormal communication between the arterial and venous systems. Most are developmental arteriovenous fistulas in which the constituent blood vessels enlarge and grow with the passage of time. They vary in size from a small blemish a few millimeters in diameter to a huge mass of tortuous channels composing an arteriovenous shunt of sufficient magnitude to raise the cardiac output. Hypertrophic dilated arterial “feeders” approach the main lesion and then disappear into a network of thin-walled blood vessels, which are the source of rupture. Some (perhaps 10%) may harbor berry aneurysms. Arteriovenous malformations occur in all parts of the brain, brainstem, and spinal cord, but larger ones are most frequently located in the hemispheres.

The chief clinical symptoms and signs are headache, seizures, and findings associated with rupture. When headache occurs (without bleeding), it may be hemicranial and throbbing, like migraine, or diffuse. A hemiplegia may accompany a headache, resembling the syndrome of hemiplegic migraine. Focal seizures that become generalized occur in approximately 30% of cases and are sometimes difficult to control with antiepileptic drugs. In half of the cases, arteriovenous malformations manifest with an ICH. In most of these cases, the hemorrhage is mainly intraparenchymal with a small amount of spillage into the subarachnoid space. Blood is usually not deposited in the basal cisterns, thus symptomatic vasospasm is rare. When the hemorrhage occurs, it may be large leading to death or small, giving rise to focal symptoms. Large supratentorial arteriovenous malformations may be associated with an audible bruit. The bruit is sometimes even self-audible, particularly when the malformation involves the dural vessels (also called arteriovenous dural fistula). Headache at the onset of the rupture is common, and it may be difficult to distinguish it from the headache present in nonruptured arteriovenous malformations.

*Cavernous malformations* represent approximately 10% of all intracranial vascular malformations. Located within the brain parenchyma, without site of predilection, they are composed of thin-walled, dilated vessels, like a mulberry, devoid of intervening normal brain, and often surrounded by a ring of hemosiderin, a residuum of prior hemorrhages. Cavernous malformations may be multiple in as many as 3.6% of patients; in some families, multiple cavernous malformations are inherited as an autosomal dominant trait. Three gene loci have recently been identified: CCM1 (caused by mutation of the *Krit1* gene), CCM2 (caused by mutations of the *Malcavernin* gene), and CCM3 (caused by mutations of the *PDCD10* gene).

The symptoms of cavernous malformations are similar to those of arteriovenous malformations: seizures, headaches, or neurologic deficits associated with rupture. Hemorrhages are usually small and circumscribed, but on occasion can be quite large, or clinically devastating because of their critical location, for example, in the pons. The reported risk of symptomatic hemorrhage varies widely across studies, from as low as 1% per year to as high as 20% per year. The hemorrhages are typically less disabling than primary ICH but, when there are multiple recurrences, are often associated with progressive neurological disability.

The management of patients with vascular malformations is best accomplished by an experienced team approach consisting of neurosurgeons and physicians who can consider both surgical and endovascular approaches, sometimes in combination. Radiosurgical obliteration may also be an option in some cases (i.e., deep, inaccessible lesions associated with repeated hemorrhages or progressive neurologic deficits). Each case requires a unique approach that takes into account the extent and location of the vascular malformation, and the feasibility and safety of the various therapeutic approaches.

### Subarachnoid Hemorrhage

By far the most common cause of atraumatic subarachnoid hemorrhage is rupture of a berry aneurysm. Other less common causes include blood dyscrasia or leukemia, tumors (such as ependymoma or meningioma, glioblastoma, renal cell, or metastasis), peripheral vascular malformation or, rarely, venous sinus disease or meningitis.

Ruptured saccular “berry” aneurysms occur at the branch points of the arteries at the base of the brain and, following rupture, give rise to subarachnoid hemorrhage, or sometimes ICH. Histological examination shows interruption of the internal elastic lamina with an aneurysmal outpouching that appears like a berry. Although they are usually single, they can be multiple in 15% to 20% of cases. The most common sites are the anterior communicating artery, the junction of the posterior communicating artery with the internal carotid artery, the middle cerebral stem bifurcation, the top of the basilar artery bifurcation, the origin of the major branches of the basilar artery, and at the origin of the PICA. Intracranial aneurysms can be associated with coarctation of the aorta and are more common in autosomal dominant polycystic kidney disease.

Prodromal symptoms and signs, prior to rupture, occur in as many as a third of cases. These symptoms may include headache, diplopia, or blurred vision. Pinpoint pain behind the eye with or without a third nerve palsy is the most common and indicates the presence of an aneurysm at the posterior communicating artery–internal carotid artery junction. It represents a medical emergency. Juxtaclinoid aneurysms compress the optic nerve, leading to amblyopia. Supraclinoid aneurysms can be confused with suprasellar tumors, sometimes producing a hypothalamic syndrome. Aneurysms in the vertebrobasilar system can produce occipital headaches and cerebellar or long-tract signs as well as cranial nerve deficits.

Once rupture occurs, the clinical syndromes are best divided into the *hemorrhage onset syndrome* and the *delayed onset syndrome*. The *hemorrhage onset syndrome* consists of a sudden, severe headache with or without loss of consciousness. Nausea and vomiting invariably occur on awakening. If the hemorrhage ruptures into the brain substance, stupor and focal signs appear that relate to the site of the rupture. Anterior communicating artery aneurysmal rupture produces a quiet, slowed or retarded abulic state with a crural pare-

sis, or hemiplegia predominating in the leg, while middle cerebral bifurcation aneurysms rupture into the brain substance and often produce a faciobrachial hemiparesis, with aphasia if the dominant hemisphere is involved. *Delayed clinical syndromes* mainly consist of re-rupture syndromes, hydrocephalus, and the syndromes resulting from cerebral vasospasm. *Re-rupture* is most frequent during the first 72 hours after the initial rupture. Early surgical intervention or intra-arterial obliteration now precludes many re-ruptures. *Fever* ( $\geq 38^\circ\text{C}$ ) in the absence of a discernible infective etiology is common in subarachnoid hemorrhage, and in some instances, may be confused with a florid meningitis. *Hydrocephalus* may be acute in the first day or two after the subarachnoid hemorrhage and might require ventricular drainage. Delayed hydrocephalus presents several days to weeks after the subarachnoid hemorrhage and may require ventriculoperitoneal shunting. Worsening stupor is a sign of both early and delayed hydrocephalus. *Cerebral vasospasm* usually develops between days 4 and 14 following the subarachnoid hemorrhage. Its location and severity have been related to the extent and location of the subarachnoid blood, with thick clot typically present around the artery developing spasm. In 30% of cases, the spasm is severe enough to give rise to ischemic symptoms and infarction may ensue. In middle cerebral stem spasm, the resulting infarction may cause devastating edema. The extent and location of blood in the basal cisterns, postoperatively, may suggest the patients who will have severe enough vasospasm to develop signs of ischemia or infarction.

Management of the patient with subarachnoid hemorrhage from a ruptured berry aneurysm should focus on: (1) medical stabilization, with aggressive treatment of elevated blood pressure and good supportive neurocritical care; (2) early operation or endovascular coiling, in nonmoribund patients, to prevent re-rupture; and (3) prevention and treatment of delayed ischemia caused by vasospasm. The International Subarachnoid Aneurysm Trial (ISAT) showed that, for aneurysms equally accessible for surgical clipping or endovascular treatment with detachable coils, the endovascular strategy was associated with less death or dependency at 1 year. Volume expansion and blood pressure elevation together with calcium channel-blockers are often used to prevent symptomatic ischemia from vasospasm. Oral nimodipine, 60 mg given every 4 hours, has been shown in multiple clinical trials to reduce mortality and the incidence of delayed ischemia. For refractory cases local intra-arterial infusion of vasodilators such as nicardipine, or angioplasty of the affected arteries, may alleviate arterial stenosis caused by vasospasm.

Because of the above complications and the highly technical neurosurgical and endovascular approaches that are available for obliterating the aneurysm, as well as the specialized neurointensive care required, the patient should be managed in a center capable of carrying out these maneuvers.

# Dementia Including Alzheimer's Disease

Cynthia M. Carlsson ■ Carey E. Gleason ■ Luigi Puglielli ■ Sanjay Asthana

Alzheimer's disease (AD) is the most common neurodegenerative disorder projected to afflict more than 13 million Americans and 81 million individuals worldwide in the next 40 to 50 years. The disease is characterized by progressive cognitive and behavioral deficits accompanied by diffuse structural abnormalities in the brain. AD is associated with significant morbidity and mortality and is currently among the 10 most common causes of death in the United States. Unfortunately, the devastations of AD affect both the patient and caregivers, and involve numerous aspects of human life including physical, socioeconomic, psychological, functional, and quality of life. In addition, caring for patients with AD places heavy financial burden on patients, families, and the health care system at large. In the United States, the average annual cost of managing a patient with AD varies between \$18,400 and \$36,000, while, as a nation, we spend close to \$100 billion each year to care for patients with AD. Similar data are reported from other countries as well. In the United Kingdom, more than \$8 billion or 0.6% of the gross domestic product is spent each year to care for patients with cognitive impairments. Recognizing the enormity of the burden of AD, international collaborations between clinicians, researchers, policy makers, patient advocacy groups, the media, and many others have increased public awareness of the global impact of the disease and have laid the foundation for the development of effective preventive and therapeutic strategies as well as improvements in care management for patients with AD.

Recent advances in biomedical research have provided critical knowledge related to the pathobiology of AD and mechanisms underlying neuronal plasticity and death. While current therapies work mainly to slow the inevitable progression of the disease, these newly identified mechanisms now serve as targets to develop effective novel therapies that could either delay or preferably arrest the progression of AD. Moreover, treatment strategies are being developed for primary prevention of AD, especially for individuals at increased risk for the disease. The present chapter includes information on the major aspects of AD, including the pathology, epidemiology, clinical

presentations, diagnosis, management, and potential neuroprotective therapies. Details related to non-Alzheimer types of dementia are discussed in Chapter 67.

## GENETICS OF ALZHEIMER'S DISEASE

Alzheimer's disease is characterized by progressive cognitive and behavioral deficits accompanied by diffuse structural abnormalities in the brain. The common symptoms of the disease include memory loss, confusion, impaired judgment, personality changes, disorientation, and loss of language skills. Based on the onset of symptoms, AD is normally divided into two groups: early- (<60 years) and late-onset (>60 years). Early-onset, also called familial AD (FAD), accounts for approximately 3% of all the cases and has to date been linked to mutations in the genes for the amyloid precursor protein (APP; gene name *APP*) on chromosome 21, presenilin 1 (PS1; gene name *PSEN1*) on chromosome 14, and presenilin 2 (PS2; gene name *PSEN2*) on chromosome 1. Among these genes, more than 160 different mutations have so far been identified, accounting for approximately 40% of all cases of FAD. Most of the mutations (~140) are found in the *PSEN1* gene, while the remaining are almost equally split between *APP* and *PSEN2*. FAD is characterized by early onset (from mid 30s to mid 50s) of cognitive symptoms, but is clinically indistinguishable from late-onset AD.

Late-onset AD (LOAD), also called sporadic AD, accounts for close to 97% of all cases of AD and to date has not been linked with any mutations. Aging is the single most important risk factor for LOAD. Additionally, LOAD has been associated with many other environmental and genetic risk factors, including hypercholesterolemia and other vascular risk factors, history of head trauma, and low educational attainment. Among the genetic risk factors, the  $\epsilon 4$  allele of the apolipoprotein E (*APOE*) gene on chromosome 19 is the only polymorphism consistently found associated with LOAD in both case-control and genetic studies. The *APOE* gene exists as

three major alleles ( $\epsilon 2$ ,  $\epsilon 3$ , and  $\epsilon 4$ ) that encode three different ApoE isoforms: ApoE2, ApoE3, and ApoE4. Interestingly, these isoforms only differ in amino acid sequences either at position 112 and/or 158: E2 (cysteine 112, cysteine 158), E3 (cysteine 112, arginine 158), and E4 (arginine 112, arginine 158). The inheritance of the  $\epsilon 4$  allele confers a major risk for developing AD, while the  $\epsilon 2$  allele confers protection. For example, presence of one copy of the  $\epsilon 4$  allele increases risk of AD by fourfold, whereas inheritance of two copies enhances the risk by almost ninefold. However, unlike genetic mutations associated with FAD, the presence of *APOE4* (or other polymorphisms) is neither necessary nor sufficient to cause AD. Even though the first report of an association between *APOE4* and AD was published over a decade ago, the precise molecular mechanism(s) underlying this association still remain elusive. It is currently unknown if the *APOE4* allele influences the rate of production, clearance, or aggregation of amyloid  $\beta$ -peptide or whether it influences cholesterol metabolism and inflammation that reportedly play a major role in the pathobiology of AD.

In addition to *APOE4*, more than 40 other polymorphisms have been associated with increased risk for LOAD. However, none of these associations has been uniformly confirmed in every population-group studied to date.

## NEUROPATHOLOGY OF ALZHEIMER'S DISEASE

The neuropathological hallmarks of AD include amyloid plaques, neurofibrillary tangles, and amyloid angiopathy accompanied by diffuse loss of neurons and synapses in the neocortex, hippocampus, and other subcortical regions of the brain (Figure 65-1). The predominance of the amyloid plaques versus neurofibrillary tangles or

amyloid angiopathy can differ from one patient to another. However, the neuronal/synaptic loss is a constant feature and eventually the direct cause of dementia. Interestingly, the distribution of the disease pathology seems to follow a region-specific pattern with the amyloid plaques more prevalent in the neocortex and the neuronal/synaptic loss more prevalent in the hippocampus, posterior cingulate, and corpus callosum areas of the brain closely involved with memory formation and higher cortical activities. The amyloid angiopathy is often observed in the “classical” LOAD, but seems to be more prevalent in a small subgroup of FAD (Dutch E693Q and Iowa D694N mutations in the *APP* gene). Finally, AD brains are also characterized by a diffuse and widespread invasion of reactive astrocytes, mostly concentrated in the hippocampus and around areas of neuronal loss; however, this is not specific to AD and can be observed in other neurodegenerative disorders associated with inflammatory and neurotoxic insults.

The dominant component of the plaque core is amyloid  $\beta$ -peptide ( $A\beta$ ) organized in fibrils of approximately 7 to 10 nm intermixed with nonfibrillar forms of the peptide (Figure 65-1). The most characteristic form of the amyloid plaque, the “neuritic plaque”, is characterized by a dense core of aggregated fibrillar  $A\beta$ , surrounded by dystrophic dendrites and axons, activated microglia, and reactive astrocytes. In addition, diffuse deposits of  $A\beta$ , likely representing a prefibrillary form of the aggregated peptide, are found without any surrounding dystrophic neurites, astrocytes, or microglia. These diffuse plaques can be found in limbic and association cortices, as well as in the cerebellum.

The other neuropathological hallmark of AD is a neurofibrillary tangle (NFT) found exclusively in the cytoplasm of neurons (Figure 65-1). The tangles appear as paired, helically twisted protein filaments composed of highly stable polymers of cytoplasmic

**FIGURE 65-1.** Small section of the neocortex from a patient with Alzheimer's disease showing two classical neuropathological lesions of the disease. (A) The modified silver staining shows one dense senile (amyloid) plaque indicated by three arrowheads. The plaque consists of aggregated extracellular deposits of  $A\beta$  fragments surrounded by silver-positive dystrophic neuritis. The arrow indicates a neuron containing neurofibrillary tangles, which appear as dark masses of abnormal filaments occupying most of the cytoplasm. (B) The image shows higher magnification of two neurons containing neurofibrillary tangles (indicated by arrows). (Photograph courtesy of Shahriar Salamat, MD, PhD, University of Wisconsin School of Medicine and Public Health, Department of Pathology and Laboratory Medicine.)

proteins called tau. Tau comprises a group of alternatively spliced proteins found in the cytoplasm that possess either three or four microtubule-binding domains and can assemble with tubulin, thus helping the formation of cross bridges between adjacent microtubules. Tau proteins can be phosphorylated in multiple sites and the degree of phosphorylation is inversely correlated with binding to microtubules. As a result, highly phosphorylated tau proteins dissociate from microtubules and polymerize into filaments forming NFTs. In addition to AD, the abnormal accumulation of filamentous tau is observed in frontotemporal forms of dementia, progressive supranuclear palsy, corticobasal degeneration, and Pick disease. Contrary to prior belief, tau proteins themselves can cause dementia, and multiple mutations in the *tau* gene have been found in frontotemporal dementia with parkinsonism. The possible role of tau proteins in the pathogenesis of AD and their potential interaction with A $\beta$  are still unclear and are discussed in the section below.

## PATHOBIOLOGY OF ALZHEIMER'S DISEASE

### Amyloid Precursor Protein Processing and Generation of A $\beta$

A $\beta$  is a 39 to 43 amino acid hydrophobic peptide proteolytically released from a much larger precursor, the amyloid precursor protein (APP). The generation of A $\beta$  from APP (Figure 65-2) requires the sequential recruitment of two enzymatic activities:  $\beta$ -secretase, also called BACE1 (beta-site APP cleaving enzyme 1), and  $\gamma$ -secretase, a multimeric protein complex containing presenilin, nicastrin, Aph-1, Pen-2, and CD147. The  $\beta$  cleavage is the rate-limiting step and occurs before the  $\gamma$  cleavage. It liberates a large N-terminal fragment (s $\beta$ APP) that is released in the extracellular milieu and a small (~12 kDa) membrane-anchored fragment called  $\beta$ -APP-CTF (or C99). The release of the large N-terminal domain allows subsequent  $\gamma$  cleavage, and liberation of A $\beta$  and the signaling of active intracellular domain of APP (Figure 65-2). Generation of A $\beta$ 40 and A $\beta$ 42 results from  $\gamma$  cleavage of A $\beta$  at positions 40 and 42, respectively. The release of A $\beta$  in the extracellular milieu is followed by oligomerization and aggregation in the form of fibrils and amyloid plaques. Additionally, small A $\beta$  aggregates are also found in the soma of the neurons suggesting that the A $\beta$  fragments can escape secretion and aggregate in the intracellular environment.

The molecular mechanisms underlying the toxicity of A $\beta$  are still being investigated and currently incompletely understood. However, recent research seems to indicate that small A $\beta$  aggregates (oligomers), which represent the "preplaque" neurotoxic species of A $\beta$ , act as the proximate cause of neuronal injury and synaptic loss associated with AD. Additionally, the C-terminal tail of APP can undergo further processing at amino acid 664 of APP695 liberating two small cytosolic fragments, Jcasp (from aa. 649 to 664 of APP695) and C31 (containing the last 31 amino acids of the C-terminus of APP, from aa. 665 to 695). Both these fragments are generated only after  $\gamma$  cleavage, require caspase-mediated processing of APP, and can activate proapoptotic pathways in a variety of cellular systems.

It is widely known that, although the major source of A $\beta$ , APP exerts several important functions in the nervous system. APP com-

**FIGURE 65-2.** Generation of amyloid  $\beta$ -peptide (A $\beta$ ) from amyloid precursor protein (APP). APP is a type 1 membrane protein with a large extracellular domain, a single membrane-spanning domain, and a short cytoplasmic tail. The A $\beta$  region of APP (in yellow) includes the first 12 to 14 amino acids of the membrane domain. (A) Shows a schematic image of APP on the cell-surface of a neuron, whereas (B) provides a closer view of APP processing. The initial enzymatic step for the generation of A $\beta$  requires proteolysis of APP at  $\beta$  site (amino acid 1 of the A $\beta$  region). This event liberates a large N-terminal fragment (s $\beta$ APP) that is rapidly secreted into the extracellular milieu and a small C-terminal fragment ( $\beta$ -APP-CTF) of 99 amino acids (also called C99). The removal of s $\beta$ APP most likely induces a conformational change that allows subsequent cleavage by  $\gamma$ -secretase. Once generated, the A $\beta$  peptides aggregate in the brain in the form of plaques. Further cleavage of  $\beta$ -APP-CTF at the  $\epsilon$  site liberates the signaling active APP intracellular domain (AICD). In addition to the above  $\beta/\gamma$  pathway, APP can also be cleaved at the  $\alpha$  site (between amino acids 16 and 17 of the A $\beta$  region) precluding the generation of A $\beta$ .

prises a group of ubiquitously expressed proteins that are generated from one single gene by differential splicing, resulting in three major isoforms of 695, 751, and 770 residues. The first isoform (APP<sub>695</sub>) is highly abundant in neurons and differs from the others in the absence of a 56-amino-acid domain that is homologous to the Kunitz-type of serine protease inhibitors. Among others, some of the important proposed normal functions of APP include serving as a cell-surface receptor, growth factor, protease inhibitor, cell-cell interaction molecule, coreceptor/partner in the endocytic/lysosomal network, coagulation inhibitor factor, cell-surface scaffold protein, kinesin-interacting molecule for axonal transport, and transcription factor.

### A $\beta$ : Pivotal Role in the Pathogenesis of Alzheimer's Disease

The most critical clinical link between A $\beta$  and AD came from the observation that patients with Down's syndrome (trisomy 21) had a higher propensity of developing a clinical and pathological phenotype resembling AD, thereby suggesting a potential association

between AD and chromosome 21. This observation was further strengthened by the fact that  $A\beta$  was the major component in plaques from both patients with Down's syndrome and AD, and that its genesis was related to a gene (*APP*) located on chromosome 21, close to the obligate Down's syndrome region. Following the identification of APP, several groups found mutations in the *APP* gene that were linked to familial forms of AD. Given that the duplication of the *APP* locus could result in early AD and that Down's syndrome patients with partial trisomy 21 developed AD only when the trisomy was proximal to the *APP* locus, the potential direct relationship between APP metabolism and AD seems strong. Furthermore, causative mutations in the genes that encode for presenilin 1 (PS1) and presenilin 2 (PS2), which are also implicated in the metabolism of APP, have been found and are associated with familial forms of AD, thereby conferring additional strength to the linkage between APP/ $A\beta$  metabolism and AD.

Although the generation of  $A\beta$  from APP seems to be a pivotal step in the pathobiology of AD, it does not explain all the neuropathological changes observed in patients with AD. For example, examination of the brain of transgenic mice expressing human APP harboring one or more FAD-associated mutations reveals presence of amyloid plaques and some synaptic loss and cognitive deficits, but absence of tau pathology and astrogliosis. This suggests that additional biochemical/molecular events are required to develop the full pathological spectrum of AD. To circumvent this issue, several new animal models have been generated where human APP is accompanied by additional genes. These genes include the *presenilins* (harboring FAD-associated mutations), *tau*, and *ApoE*. Recently, several transgenic mice models harboring three or five FAD-associated mutations (respectively called 3X and 5X mice) in two or more genes have been generated. All of these models demonstrated that  $A\beta$  is an essential element for the development of AD-like neuropathology and revealed a close relationship between  $A\beta$  and the phosphorylation/aggregation state of tau. However, none of the mouse models fully reproduce the classical AD-phenotype; thereby again suggesting that  $A\beta$  seems to be necessary but not sufficient to produce the entire spectrum of AD neuropathology.

Transgenic mice expressing the human microtubule-associated protein tau develop the typical tau-related pathology found in individuals suffering from frontotemporal dementia with parkinsonism; however, they do not develop amyloid plaques suggesting that tau is not required for the formation of plaques. Crossing these mice with APP transgenic mice potentiates tau-related pathology and neuronal loss but does not aggravate plaque pathology suggesting that  $A\beta$  acts upstream of tau in the classical AD-phenotype. However, studies from patients with AD, mouse models, and *ex vivo* cellular systems indicate that  $A\beta$  and tau can interact synergistically, thereby fostering their respective aggregation and neuronal loss. The true relationship between  $A\beta$  and tau is more complex than previously thought and likely involves additional molecular and biochemical pathways acting upstream of both  $A\beta$  and tau in the AD brain.

The recent identification of the gene that encodes BACE1, the rate-limiting enzyme in the biosynthesis of  $A\beta$ , prompted the generation of "knock-out" mice that lack BACE1. Crossing these mice with the APP mutant mice models revealed that elimination of  $\beta$  cleavage of APP is sufficient to resolve many aspects of AD pathology, including the synaptic impairment and cognitive phenotype of the animals. Moreover, these approaches indicated that BACE1 re-

resents a viable target for development of effective treatment strategies for AD, given that disruption of BACE1 does not result in a strong phenotype in the mouse. Overall, there is extensive evidence from laboratory research that  $A\beta$  plays a major role in the pathogenesis of AD; however, there are likely additional, yet unidentified, molecular pathways that contribute to the overall pathobiology of AD.

## EPIDEMIOLOGY AND RISK FACTORS FOR ALZHEIMER'S DISEASE

Alzheimer's disease is the most common cause of dementia in older adults, currently affecting more than five million Americans and more than 24 million individuals around the world. Unless effective preventive strategies are identified, it is anticipated that the prevalence of AD will double every 20 years. Of note, the United Nations predicts that the major rate of increase in the prevalence of AD will likely occur in developing countries like India and China that may not possess all the essential resources, public health support system, or medical expertise to care for patients with AD.

There is clear evidence that a number of risk factors significantly enhance the overall risk for developing AD. These risk factors relate to both genetic and nongenetic markers, and are discussed below.

### Aging

Aging is the single most important and validated risk factor for AD. The projected increase in AD prevalence in the coming decades is in part related to recent increases in the average human life span. Almost all of the epidemiological studies indicate that the incidence of AD increases with aging. For example, in the year 2000, the age-specific distribution of patients with AD was 5% between the ages of 65 and 74 years, 18% between the ages of 75 and 84 years, and 45% above the age of 85 years. Additionally, age-associated increases in the amount of amyloid plaques and NFTs in the brains of older persons further underscore a strong relationship between aging and AD pathology. Although not clearly understood, converging findings from recent research provides some clues concerning the potential molecular pathway(s) underlying the association between aging and AD. This pathway acts downstream of the insulin-like growth factor 1 receptor (IGF1-R) and plays a major role in determining both the lifespan and age-associated diseases. In general, activation of IGF1-R signaling accelerates aging and shortens lifespan, while a partial block—as achieved with either genetic or biochemical approaches—delays aging, extends lifespan, and, most importantly, delays the progression of many age-associated diseases, including AD and type 2 diabetes mellitus. Recent biochemical and genetic studies have delineated a precise molecular pathway involving IGF1-R, neurotrophin signaling, BACE1, and APP metabolism, suggesting that pharmacological approaches aimed at IGF1-R signaling might help delay the progression as well as onset of AD.

Aging and IGF1-R signaling are both associated with cerebrovascular dysfunction, which, emerging evidence supports, may play a key role in the development of AD. An increased exposure time to age-dependent vascular risk factors or an interaction between aging and vascular risk factors may in part account for the effects of aging on the pathobiology of AD. Thus, targeting treatment of vascular risk factors may ameliorate some of the age-associated risk for AD.

## APOE Genotype

Late-onset AD is the most common form of the disorder, accounting for more than 90% of all AD cases. Although early-onset AD has strong genetic links, many cases of LOAD are seen in individuals without any clear genetic predisposition. A common polymorphism in the apolipoprotein E (*APOE*) gene is the major determinant of risk in families with LOAD. Of the three common allelic forms (*APOE2*, *APOE3*, and *APOE4*), *APOE4* is associated with up to fourfold increased risk of developing AD among individuals with at least one *APOE4* allele. However, *APOE4* genotype is neither necessary nor sufficient for the development of AD. *APOE4* allele may contribute to AD by influencing processes related to the development of AD, including altering the rate of production, clearance, or aggregation of amyloid  $\beta$ -peptide and/or influencing cerebral cholesterol metabolism and inflammation. Currently, routine genetic testing for LOAD is not recommended. Recent estimates based on twin studies suggest that nearly 50% of LOAD cases may be related to *APOE* allele and other unidentified genetic factors.

## Gender

Although controversial, there is some evidence that AD is more common among women. Specifically in the population-based studies published to date, more than half reported a greater risk of AD in women, while the others found no difference. It is generally believed that the discrepant findings between various studies are likely owing to several important reasons, including methodological differences and a failure to account for the potential gender-related variability in education, occupation, and lifestyle variables that can directly affect the risk of AD. Some data support that estrogen deficiency following menopause may contribute to the development of AD; however, the effects of estrogen replacement therapy on cognition remains controversial.

## Hypercholesterolemia and Vascular Risk Factors

There is mounting evidence that midlife vascular risk factors are associated with an increased risk of AD in later life. In epidemiological studies, hypercholesterolemia, hypertension, hyperhomocysteinemia, obesity, diabetes mellitus, and elevated inflammatory markers have all been associated with enhanced risk of developing AD. Furthermore, *APOE4* allele is related to abnormal cholesterol metabolism suggesting that the increased risk for AD associated with this genotype may be partially mediated through dysregulation of cholesterol. The cholesterol-AD connection is further supported by results from animal studies showing that hypercholesterolemia stimulates the amyloidogenic pathway of APP leading to increased production and deposition of  $A\beta$ . Conversely, decreased levels of cholesterol produce the opposite effect reducing the production and deposition of  $A\beta$ . Not only do some vascular risk factors appear to influence  $A\beta$  metabolism, but conversely, soluble  $A\beta$  has been shown to induce dysfunction in cerebral vessels of rats and in cultured endothelial cells. As both  $A\beta$  deposition and cerebrovascular dysregulation are two early findings in preclinical AD pathology, these processes most likely work synergistically to accelerate neuronal degeneration. Although the evidence supporting an association between vascular disease and AD is increasing, it is presently unclear whether treating these modifiable vascular risk factors will

affect the development or progression of AD. Clinical trials are currently underway to evaluate the potential role of treating these risk factors in preventing or delaying AD progression.

The fact that cerebrovascular diseases such as vascular dementia and cerebral amyloid angiopathy (CAA) share common risk factors with AD supports that their pathologic mechanisms are related. A clear separation between vascular forms of dementia and classical AD based on cognitive impairment is extremely difficult. Typical patients with vascular dementia have a history of vascular disease and show a more pronounced impairment in executive function with only mild memory deficits. The presence of white matter hyperintensities and lacunar infarcts demonstrated by MRI constitutes an important criterion to support the diagnosis of vascular dementia. However, only 2% to 3% of patients with dementia fulfill the diagnostic criteria of pure vascular dementia. In contrast, a large group of patients show an overlapping phenotype with subcortical white matter changes, hypoperfusion, microinfarcts, and amyloid angiopathy. These patients tend to progress into classical AD and will show some degree of amyloid plaques and tau aggregates at autopsy, together with microglia and astrocytic proliferation. CAA is characterized by abnormal accumulation of fibrillar  $A\beta$  (especially  $A\beta_{40}$ ) in the walls of meningeal and cortical arterioles, venules, and capillaries. The damaged vessels undergo spontaneous rupture, and the patients often present with subcortical white matter changes and microhemorrhages. An autosomal dominant form of CAA is caused by a point mutation in the APP gene (Dutch-type) and is a form of FAD. Understanding the overlapping pathologic mechanisms among AD, vascular dementia, and CAA may help to identify common targets for disease-modifying therapies.

## Head Trauma

Several epidemiological studies have indicated that a history of severe or repeated head trauma is a risk factor for cognitive decline and AD. The majority of patients develop AD, although a minority might manifest dementia of Parkinson disease and depression. Neuropathological examination of the brain from patients with a history of head trauma generally reveals changes of diffuse amyloid plaques together with tau pathology, inflammatory response, and loss of cholinergic neurons. A smaller number of patients show diffuse  $\alpha$ -synuclein reactivity, Lewy body-type aggregates, and loss of dopaminergic neurons resembling Parkinson disease. In animals, pathological changes following experimental head trauma reveal transient upregulation of BACE1 together with increased generation of  $A\beta$ . These features are accompanied by tau hyperphosphorylation and increased caspase-mediated cleavage of APP. Thus, head trauma may lead to AD by triggering accelerated neurodegeneration.

## Depression

Depression is a common psychiatric condition in the elderly and widely reported to present with symptoms of cognitive and functional impairment, commonly grouped into the clinical entity of *pseudodementia*. Furthermore, more than 30% of patients with AD develop depression during the course of their illness, and might present with the symptoms of depression as the first clinical manifestation of underlying AD. Thus, a better understanding of the potential relationship between depression and AD is of pivotal clinical significance. Although not confirmed universally, there is converging

evidence from several studies that a history of depression can increase the risk of AD later in life. Findings of a recent meta-analysis and metaregression analysis involving 20 retrospective and prospective studies supported an increased risk of AD in patients with prior history of depression. The pooled odds ratio for developing AD in this analysis was 2.03 for case-control and 1.90 for cohort studies. To date, the precise mechanism(s) underlying the association between depression and enhanced risk for AD is unknown. However, several potential mechanisms have been proposed, including elevated levels of cytokines observed in both patients with AD and depression, increased association of vascular risk factors with the pathobiology of AD as well as depression, and the potential role of *APOE4* allele in enhanced risk for both AD and depression. Clearly, more research is necessary to better understand the biological basis of increased risk of AD in patients with a history of depression.

### Education and Ethnicity

There is some evidence, albeit controversial, from epidemiological studies that higher education may protect against the development of AD. Individuals with elementary level education might be at an increased risk of developing AD, compared to those with high school and college education. Of note, these findings have not been substantiated by all studies and need to be systematically evaluated in larger epidemiological studies. The exact mechanism underlying the neuroprotective effects of higher education is currently unknown; however, based on the “use it or lose it” theory there is suggestion that individuals with higher education might have more neurons to lose before they cross the threshold of developing dementia.

It is generally presumed that AD affects all ethnic groups equally. However, there is some recent evidence that the disease might be more prevalent in certain ethnic groups. In a population based study in the Washington Heights and Inwood communities of New York City, the cumulative incidence of AD was increased twofold among individuals of African-American and Caribbean Hispanic origin. This ethnicity-based incidence of AD did not change following corrections for differences in the number of years of education, or a history of diseases like hypertension, diabetes mellitus, and cardiovascular disease. Although not universally confirmed, other studies also support these findings. In a study in Houston, both the incidence and prevalence of AD were higher among African-Americans and Hispanics than retirees of Caucasian origin. Although speculative, it is possible that the increased risk of AD among the above ethnic groups may be because of a higher incidence of comorbid vascular and cardiovascular diseases and a higher prevalence of *APOE4* genotype.

## CLINICAL PRESENTATIONS OF ALZHEIMER'S DISEASE

The most common symptoms of AD include cognitive deficits and functional impairments. These deficits progress over time and eventually result in loss of activities of daily living, frequently necessitating admission to nursing homes and leading to eventual death. The majority of patients with AD initially present with slowly progressive memory impairments; however, in up to 40% patients the initial presentation might involve nonmemory symptoms like lan-

guage impairments, symptoms of depression, personality changes, extrapyramidal manifestations, and visuospatial deficits. These patients are very likely to be misdiagnosed and require comprehensive evaluation by a physician with special expertise in dementia.

### Typical Clinical Presentation of AD

Slowly progressive memory loss for recent events is the most common clinical presentation of AD. Patients with AD frequently have problems remembering recent conversations, dates, appointments, and may misplace items at home. Many patients are not aware of these deficits and are brought to medical attention by their family members or friends. The memory deficits of AD are generally differentiated from those caused by normal aging by the fact that these deficits are progressive and interfere with daily living activities. Cognitive changes associated with healthy aging, although frustrating, are caused by age-associated decline in mental processing speed and difficulty learning new material. However, these changes are not associated with alterations in day-to-day function. Memory loss leading to a change in functional status is not a part of normal aging and warrants further evaluation.

The second most common clinical presentation of AD is impairment in language function. Seen in up to 40% to 50% patients, these impairments generally start with word-finding problems followed by paraphasic errors and circumlocution. These initial deficits lead to expressive aphasia accompanied later with receptive and global aphasia. Unfortunately, given the impairments in communication, patients with AD having significant language impairments generally progress rapidly and have a poor prognosis.

Impairments in executive function are common early deficits in AD, leading to poor judgment, organization, reasoning and abstract thinking, and resulting in inability to complete complex demanding tasks. Deficits in concentration and attention are other common symptoms seen in patients with AD. These impairments lead to tangential tendencies, disorientation, and an inability to successfully complete daily tasks. Persons exhibiting deficits in visuospatial abilities may have problems with driving, dressing, using eating utensils, and walking.

As the disease progresses, changes in personality are commonly seen in patients with AD and may include increased passivity, lack of interest, restlessness, and overactivity. More than 30% of persons with AD develop symptoms of depression, which may be the first clinical presentation of the disease. Early signs of depression in patients with AD include changes in behavior, loss of appetite, alterations in sleep, social withdrawal, and a decline in physical function. Sundowning, or worsening of behavior and cognitive symptoms in the evening, is also common in patients with AD and may be because of changes in circadian rhythm from loss of sunlight.

In the later stages of the disease, individuals may have increased confusion, dysphagia, poor gait, and repeated falls. In some patients with AD, disruptive behaviors may increase with aggression, agitation, and physical or verbal hostility; in others, these behavioral symptoms lessen with disease progression. The majority of patients become increasingly frail and dependent for self-care and activities of daily living with many patients developing bowel and bladder incontinence. Persons in the late stages of AD may become immobile and bed-bound, which increases their risk of developing pressure sores, malnutrition, and dehydration. The most common causes

of death in patients with AD include pneumonia, urinary sepsis, dehydration, pressure sores, fractures, and malnutrition. The median survival period from the time of diagnosis to death generally varies between 8 and 10 years, although some patients, especially those with FAD, die earlier.

### Atypical Clinical Presentations of Alzheimer's Disease

It is widely reported that between 20% and 40% of patients with AD will initially present with atypical features of the disease. Unfortunately, these patients are commonly misdiagnosed with either a personality or related disorder, and may need to be evaluated by a specialist. As noted earlier, one of the common atypical presentations of AD is impairment in language. These patients are frequently misdiagnosed as having suffered a stroke. The other atypical presentation of AD includes prominent extrapyramidal manifestations. Between 5% and 10% of patients with AD might initially present with features resembling Parkinson disease, consisting of mild rigidity of extremities, hypokinesia, and expressionless face. However, these patients generally do not present with the classical Parkinsonian tremors and do not respond well to dopaminergic drugs. Another atypical feature of AD, seen in approximately 10% patients with AD, includes symptoms of behavioral disinhibition. These patients may make socially unacceptable remarks, become increasingly difficult to live or work with, and may be misdiagnosed with a personality disorder. Finally, less than 5% patients with AD present with symptoms of Balint syndrome, consisting of visual agnosia and ataxia, and complaints of inability to see.

Overall, it is important to recognize that AD can present itself with varied clinical features, and while memory impairment is a critical component of the disease, it is not the only clinical manifestation. Atypical clinical presentations of AD are common and should be evaluated by a physician with special expertise in dementia. Clearly, a misdiagnosis of AD has major serious adverse consequences including emotional, occupational, social, and financial.

## DIAGNOSIS OF ALZHEIMER'S DISEASE

Diagnosis of AD involves a comprehensive medical, psychiatric, and neurological evaluation of a patient with cognitive impairment. To date, there is no clinical, laboratory, genetic, or neuroimaging investigation that can definitively diagnose AD. Thus, the diagnosis of AD is largely based on clinical evaluation. In specialized centers, there is up to 10% to 15% chance that the diagnosis of AD could be incorrect; in a general practice environment, an incorrect diagnosis may be made in approximately 30% to 40% of cases, especially if the initial presentation of disease is atypical. Definitive diagnosis of AD can only be made on neuropathological examination of the brain following death.

While the differential diagnoses for AD are extensive (Table 65-1), in usual practice making a clinical diagnosis of AD involves differentiating whether a patient's memory complaint is related to normal aging, mild cognitive impairment (MCI), delirium, depression, or a true dementia such as AD. Differentiating between these various conditions is critical for identifying whether or not the memory complaint is part of a progressive neurodegenerative disorder and for choosing appropriate treatment strategies. An algorithm for ap-

**TABLE 65-1**

### Differential Diagnosis for Alzheimer's Disease

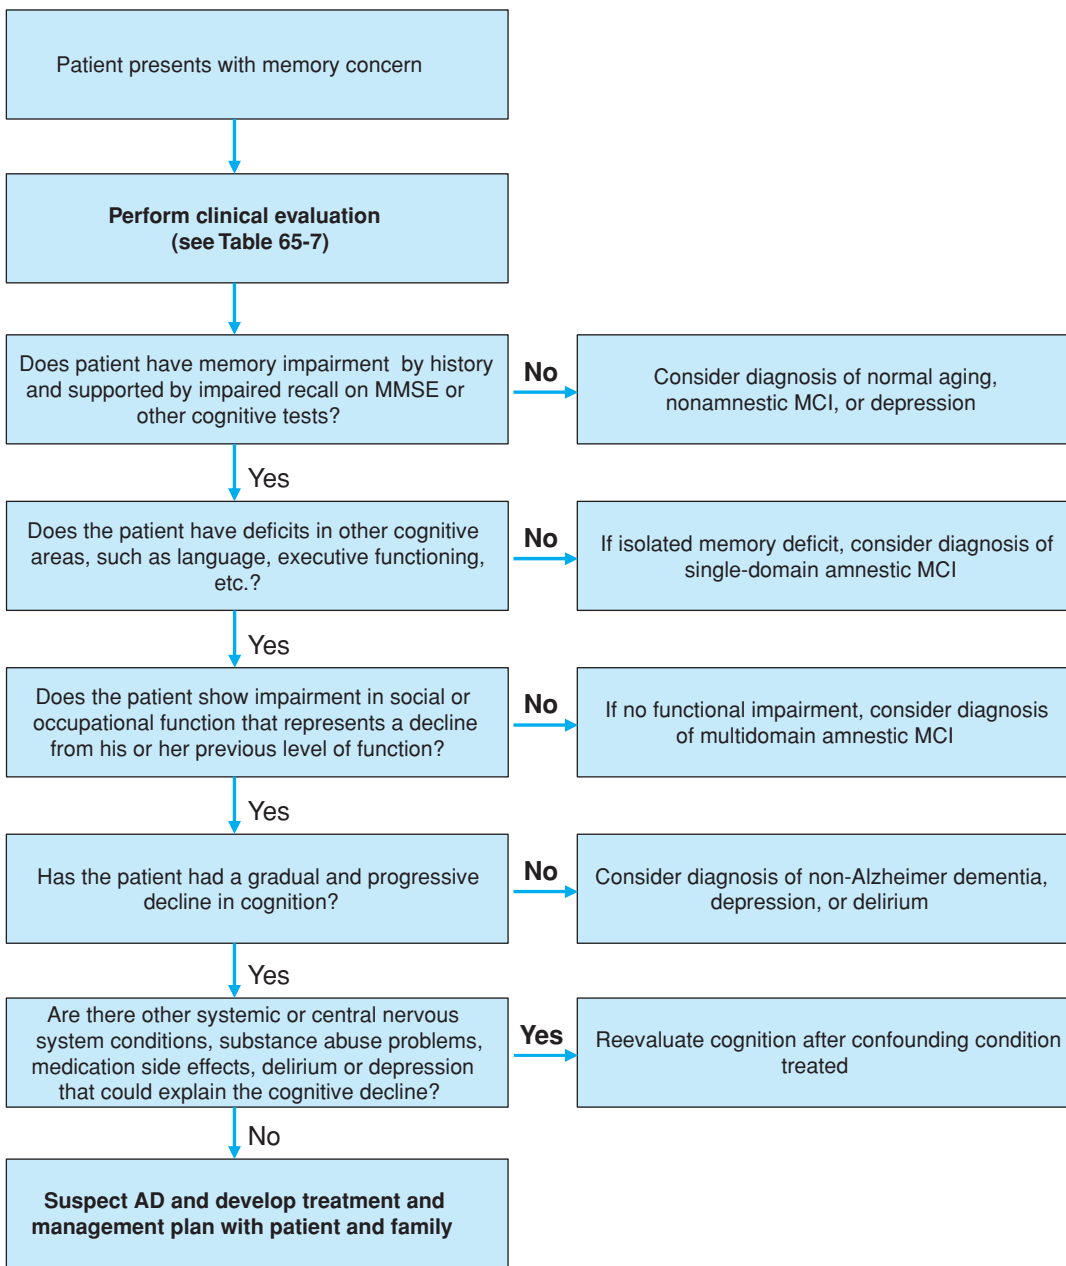

Depression	AIDS (HIV)
Delirium	Chronic meningitis
Dementia with Lewy bodies	Encephalitis
Vascular dementia	Progressive multifocal leukoencephalopathy
Frontotemporal dementia	Neurosyphilis
Progressive supranuclear palsy	Lyme disease
Corticobasilar degeneration	Prion diseases (Creutzfeldt-Jakob disease, bovine spongiform encephalopathy)
Parkinson disease dementia	Drugs
Normal pressure hydrocephalus (NPH)	Alcohol
Huntington disease	Heavy metal toxicity
Alcoholic dementia	Hepatic encephalopathy
Binswanger disease	Wilson disease
CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy)	Metabolic-endocrine disorders
Mass lesions (neoplasms, subdural hematomas)	Uremia
Seizures	Central nervous system vasculitis
Vitamin B-12 deficiency	Nonvasculitic autoimmune inflammatory meningoencephalopathies
Thiamine deficiency	

proaching the patient with memory complaints is shown in Figure 65-3, integrating various established diagnostic criteria.

While a decline in mental processing speed and difficulty learning new material may be seen with normal aging, MCI is considered to be a predementia condition. Seen in up to 15% to 20% of older adults, MCI was originally characterized as a stage of memory impairment beyond normal aging in which other cognitive domains were preserved and daily function remained intact. Original criteria for MCI are outlined in Table 65-2. Findings from several epidemiological studies have indicated that between 12% and 15% of persons each year with MCI will progress to AD or other forms of dementia. MCI criteria have now been expanded to include both patients with memory impairment (amnesic MCI, with single vs. multiple cognitive domains affected) and those in whom memory function is intact, but other cognitive domains are impaired (nonamnesic MCI, single vs. multiple domain). Persons with amnesic MCI are more likely to progress to AD, whereas those with nonamnesic MCI may be more likely to progress to other forms of dementia, such as frontotemporal dementia, dementia with Lewy bodies, or vascular dementia. A history of intact functional status is a critical distinguishing feature between MCI and early AD and requires careful history-taking and collaborative history from family and/or friends.

Delirium is associated with an acute or subacute onset of fluctuating cognitive dysfunction and can be caused by a wide variety of medical conditions and medications. In patients with delirium, a careful history frequently can tease out the temporal relationship between the onset of potentially reversible cognitive symptoms and contributing underlying medical problems or medications. Depression may cause "pseudodementia" by leading to impaired concentration and attention, thus, affecting an individual's ability to attend to tasks on cognitive testing. Dementia is differentiated from the

**FIGURE 65-3.** Algorithm for the clinical diagnosis of Alzheimer's disease.

above-mentioned conditions in that it is a progressive, irreversible process that causes impairment in two or more cognitive domains (such as memory, language, and executive functioning) to the degree that it impairs social or occupational performance. Such changes in cognitive function cannot be attributed to delirium or depres-

sion. Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV) criteria for dementia are listed in [Table 65-3](#). Once a diagnosis of dementia is suspected, the clinician must differentiate between various causes of dementia, discern if it is multifactorial, and decide if there is any reversible component to the cognitive loss that can be addressed.

AD is the most common form of dementia in the United States, accounting for 50% to 90% of all dementia cases. Dementia with Lewy bodies, vascular dementia, and frontotemporal dementia are other common forms of dementia ([Table 65-4](#)). Details of the clinical and pathological features of these dementias are covered in Chapter 67. Differentiating AD from other causes of memory loss can help clinicians choose effective therapies, anticipate behavior changes and other potential complications, and provide patients and caregivers information on prognosis. AD is characterized by a gradually progressive decline in memory and other cognitive abilities to the degree that it impairs social or occupational performance. These cognitive

**TABLE 65-3**

**DSM-IV Diagnostic Criteria for Dementia**

- A. The development of multiple cognitive deficits manifested by both:
  1. Memory impairment (impaired ability to learn new information or to recall previously learned information)
  2. One (or more) of the following cognitive disturbances:
    - a. Aphasia (language disturbance)
    - b. Apraxia (impaired ability to carry out motor activities despite intact motor function)
    - c. Agnosia (failure to recognize or identify objects despite intact sensory function)
    - d. Disturbance in executive functioning (i.e., planning, organizing, sequencing, abstracting)
- B. The cognitive deficits in Criteria A1 and A2 each cause significant impairment in social or occupational functioning and represent a decline from a previous level of functioning.
- C. The deficits do not occur exclusively during the course of a delirium.

*American Psychiatric Association. Task Force on DSM-IV. Diagnostic and Statistical Manual of Mental Disorders: DSM-IV. 4th ed. Washington, DC: American Psychiatric Association; 1994.*

deficits must represent a decline from a previous level of functioning. The diagnosis of AD is a clinical diagnosis, with the only “gold standard” being autopsy confirmation. The most widely used diagnostic criteria for the disorder include DSM-IV criteria and the National Institute of Neurological and Communicative Disorders and Stroke–Alzheimer’s Disease and Related Disorder Association (NINCDS-ADRDA) criteria (Tables 65-5 and 65-6).

In many cases, a clinical diagnosis of AD can be made in a primary care office setting using a careful history, a focused physical examination, cognitive screening tools, and appropriate laboratory data (Figure 65-3 and Table 65-7). A careful history should include collaborative information from the patient, family, caregivers, and/or friends. A patient’s baseline level of functioning may be estimated based on educational background as well as occupational history, including

**TABLE 65-5**

**DSM-IV Diagnostic Criteria for Dementia of the Alzheimer Type**

- A. The development of multiple cognitive deficits manifested by both:
  1. Memory impairment (impaired ability to learn new information or to recall previously learned information)
  2. One (or more) of the following cognitive disturbances:
    - a. Aphasia (language disturbance)
    - b. Apraxia (impaired ability to carry out motor activities despite intact motor function)
    - c. Agnosia (failure to recognize or identify objects despite intact sensory function)
    - d. Disturbance in executive functioning (i.e., planning, organizing, sequencing, abstracting)
- B. The cognitive deficits in Criteria A1 and A2 each cause significant impairment in social or occupational functioning and represent a decline from a previous level of functioning.
- C. The course is characterized by gradual onset and continuing cognitive decline.
- D. The cognitive deficits in Criteria A1 and A2 are not caused by any of the following:
  1. Other central nervous system conditions that cause progressive deficits in memory and cognition (e.g., cerebrovascular disease, Parkinson disease, Huntington disease, subdural hematoma, normal-pressure hydrocephalus, brain tumor)
  2. Systemic conditions that are known to cause dementia (e.g., hypothyroidism, vitamin B-12 or folic acid deficiency, niacin deficiency, hypercalcemia, neurosyphilis, HIV infection)
  3. Substance-induced conditions
- E. The deficits do not occur exclusively during the course of a delirium.
- F. The disturbance is not better accounted for by another Axis I disorder (e.g., major depressive disorder, schizophrenia).

**Clinical Features of Common Dementias**

TYPE OF DEMENTIA	ALZHEIMER DISEASE	VASCULAR DEMENTIA	DEMENCIA WITH LEWY BODIES	FRONTOTEMPORAL DEMENTIA
Must first meet diagnostic criteria for dementia (see Table 65-3)				
TYPICAL COURSE	Gradually progressive	Stepwise deterioration	Progressive cognitive decline with fluctuating cognition, attention, and alertness	Insidious onset and gradual progression
COGNITIVE SYMPTOMS	Memory impairment plus one or more areas of cognitive deficit	Memory impairment plus two or more areas of cognitive deficit	Fluctuating cognitive symptoms May have prominent visuospatial/constructional impairment on cognitive testing	Early decline in social interpersonal conduct (frontal lobe predominance) or language skills (temporal lobe predominance) May not exhibit memory loss symptoms until later in illness
OTHER ASSOCIATED SYMPTOMS/SIGNS		Focal neurological signs and evidence of relevant cerebrovascular disease by brain imaging	Recurrent visual hallucinations Parkinsonism motor features Recurrent falls Syncope Neuroleptic sensitivity Delusions	Early impairment in regulation of personal conduct Early emotional blunting Early loss of insight

**TABLE 65-6****NINCDS-ADRDA Criteria for Clinical Diagnosis of Alzheimer's Disease**

The criteria for the clinical diagnosis of PROBABLE Alzheimer's disease include:

- Dementia established by clinical examination and documented by the Mini-Mental Test, Blessed Dementia Scale, or some similar examination, and confirmed by neuropsychological tests;
- Deficits in two or more areas of cognition;
- Progressive worsening of memory and other cognitive functions;
- No disturbance of consciousness;
- Onset between ages 40 and 90, most often after age 65; and
- Absence of systemic disorders or other brain diseases that could account for the progressive deficits in memory and cognition.

The diagnosis of PROBABLE Alzheimer's disease is supported by:

- Progressive deterioration of specific cognitive functions such as language (aphasia), motor skills (apraxia), and perception (agnosia);
- Impaired activities of daily living and altered patterns of behavior;
- Family history of similar disorders, particularly if confirmed neuropathologically; and
- Laboratory results of:
  - Normal lumbar puncture as evaluated by standard techniques;
  - Normal pattern or nonspecific changes in EEG, such as increased slow-wave activity, and
  - Evidence of cerebral atrophy on CT with progression documented by serial observation.

Other clinical features consistent with the diagnosis of PROBABLE Alzheimer's disease, after exclusion of causes of dementia other than Alzheimer's disease, include:

- Plateaus in the course of progression of the illness;
- Associated symptoms of depression, insomnia, incontinence, delusions, illusions, hallucinations, catastrophic verbal, emotional, or physical outbursts, sexual disorders, and weight loss; other neurologic abnormalities in some patients, especially with more advanced disease and including motor signs such as increased muscle tone, myoclonus, or gait disorder;
- Seizures in advanced disease; and
- CT normal for age.

Features that make the diagnosis of PROBABLE Alzheimer's disease uncertain or unlikely include:

- Sudden, apoplectic onset;
- Focal neurologic findings such as hemiparesis, sensory loss, visual field deficits, and incoordination early in the course of the illness; and
- Seizures or gait disturbances at the onset or very early in the course of the illness.

Clinical diagnosis of POSSIBLE Alzheimer's disease:

- May be made on the basis of the dementia syndrome, in the absence of other neurologic, psychiatric, or systemic disorders sufficient to cause dementia, and in the presence of variations in the onset in the presentation, or in the clinical course;
- May be made in the presence of a second systemic or brain disorder sufficient to produce dementia, which is not considered to be the cause of the dementia; and
- Should be used in research studies when a single, gradually progressive severe cognitive deficit is identified in the absence of other identifiable cause.

Criteria for diagnosis of DEFINITE Alzheimer's disease are:

- The clinical criteria for probable Alzheimer's disease and
- Histopathologic evidence obtained from a biopsy or autopsy.

Classification of Alzheimer's disease for research purposes should specify features that may differentiate subtypes of the disorder, such as:

- Familial occurrence;
- Onset before age of 65;
- Presence of trisomy-21; and
- Coexistence of other relevant conditions such as Parkinson disease.

*Adapted from McKhann G, Drachman D, Folstein M, et al. Clinical diagnosis of Alzheimer's disease: report of the NINCDS-ADRDA Work Group under the auspices of Department of Health and Human Services Task Force on Alzheimer's Disease. Neurology. 1984;34(7):939-944.*

detailed information on the highest level tasks associated with each vocation. In persons who have not worked outside the home or who are retired, questions on hobbies, household management, and other volunteer activities will provide important information on the patient's previous level of functioning. Changes in the person's ability to carry out these tasks should then be ascertained, and the degree to which these impairments affect daily functioning should be documented. Questions about changes in daily functional activities will help the clinician isolate problem areas representing functional decline.

Ascertaining the time course over which the memory symptoms developed is important, as AD is characterized by a gradually progressive decline in cognitive function occurring over years. Frequently, an inciting event that disrupts coping skills, such as a hospitalization or the death of a spouse, will draw the attention of family members

to a person's memory problems. The family may give a history of an acute onset of memory impairment following the inciting event, but careful questioning may identify memory problems preceding that time period and point to a gradually progressive course.

Additional information on safety should be obtained, including inquiries on medication management, kitchen fires, driving, wandering, financial scams, use of power tools, and hunting or other use of firearms. A review of systems should include questions on depression, tremors, rigidity, falls, dysphagia, urinary incontinence, stroke or transient ischemic attack symptoms, waxing and waning level of consciousness, and visual hallucinations.

A past medical history of cardiovascular disease and associated risk factors, coronary artery bypass surgery, head injury, seizures, depression, Parkinson disease, and heavy alcohol use may help guide the clinician in making a diagnosis. A careful substance use and

**Neuroimaging (CT or MRI)****Other tests to consider (based on clinical suspicion)**

- Lumbar puncture for cerebrospinal fluid collection
- Electroencephalogram (EEG)

medication history should be obtained, including specific questions regarding use of alcohol and common over-the-counter anticholinergic medications that can worsen memory, such as antihistamines.

The physical examination should include assessment of general appearance, such as level of attention and cooperation, psychomotor slowing, affect, hygiene, and speech pattern. A neurological examination should screen for focal deficits, increased muscle tone, cogwheeling, rigidity, or tremors. A detailed review of a comprehensive mental status and neurological examination in older adults is described in Chapter 12. Cardiac arrhythmias, carotid bruits, or abdominal or femoral bruits may suggest a predisposition to vascular dementia.

Cognitive testing can be readily performed in the primary care clinic setting using screening tests such as the Mini-Mental State Examination, the Clock Draw Test, and category fluency. In adults with high baseline cognitive functioning, however, these tests may be normal in the presence of obvious functional impairment necessitating referral to a neuropsychologist for more detailed testing. In those with lower educational levels, these cognitive screening tests may suggest impairment, but the history may not suggest any changes in functional status. Thus, it is critical to use age- and education-adjusted norms, and integrate historical information on baseline function to decide if further neuropsychological testing is warranted or if abnormal testing may actually represent the person's baseline

status. In addition, screening for depression is a critical part of a memory assessment. Any suspicion of mood disturbances can be evaluated with a screening tool such as the Geriatric Depression Scale (GDS). These cognitive and affective screening tools can be easily administered by a variety of health care personnel, allowing for their use in a busy clinic setting.

Laboratory data can assist in identifying factors that may be contributing to cognitive decline. Rarely do these factors alone account for the overall cognitive changes that lead to the presentation of a patient with significant memory loss symptoms. Nevertheless, treating such factors may improve cognitive symptoms in patients with severe laboratory abnormalities, numerous comorbid illnesses, or in whom there is an underlying neurodegenerative process. Recommended laboratory tests include vitamin B-12, thyroid stimulating hormone (TSH), electrolytes, complete blood count, liver enzymes, homocysteine, red blood cell folate levels, and a cholesterol panel. If symptoms are atypical or if there are specific risk factors, then a serologic test for syphilis may be performed. In some European countries, routine assessment of cerebrospinal fluid (CSF) for  $\beta$ -amyloid and tau levels is done as part of the clinical evaluation. In the United States, CSF collection is usually reserved for ruling out Creutzfeldt–Jakob disease or other conditions such as normal pressure hydrocephalus (NPH). In most cases, it is recommended that some form of neuroimaging be obtained. Typical findings for AD on neuroimaging can range from a fairly normal scan to diffuse cerebral atrophy. A computed tomography (CT) of the head without contrast is usually sufficient to evaluate for significant cerebrovascular disease, brain tumors, subdural hematoma, or NPH. Magnetic resonance imaging (MRI) can provide more information if lacunar infarcts are suspected. In persons with suspected seizure disorder or Creutzfeldt–Jakob disease, an electroencephalogram (EEG) may be considered. Although positron emission tomography (PET) scans are used frequently in research settings, they are not yet advocated for regular use in clinical practice.

If a patient does not meet the criteria for AD yet clinical suspicion remains, either more detailed neuropsychological testing or repeat testing in 6 months may clarify the diagnosis as the symptoms progress. Persons with suspected MCI should be reassessed on an annual basis as 12% to 15% of individuals with this diagnosis progress to dementia each year. If the symptoms or course of the disease are atypical for AD, the level of functional decline is out of proportion to neuropsychological testing results, or if there are significant behavioral issues that need to be addressed, then referral to a geriatrician, neurologist, or psychiatrist with expertise in dementia is recommended.

### Future Diagnostic Tools

Novel diagnostic tools are continually being investigated for use in the diagnosis of AD. Many of these tools are still mainly used in research settings, but are under continued study to evaluate their role in clinical practice. Current investigations are focusing on how to best identify biomarkers with strong relationships to clinically relevant outcomes in AD that could be used not only for diagnosis, but also for identifying asymptomatic persons at risk for AD. Neuroimaging modalities have shown great promise in documenting not only the late effects of neuronal damage in AD (regional and global cerebral atrophy), but also in identifying earlier *in vivo* pathology (such as *in vivo*

amyloid imaging on PET) and the functional consequences of such pathology (activation patterns on functional MRI). CSF levels of  $A\beta$  and tau have been shown to predict risk for progression to AD in older adults and persons with MCI. With the recent advances in the safety and acceptability of lumbar punctures, CSF markers may eventually find their way into the clinical diagnostic workup of preclinical AD. Some blood and CSF inflammatory markers have also shown some value in predicting risk of cognitive decline. Future research is focusing how these biomarkers may be used in combination with cognitive tests to identify who is at greatest risk for AD, who would benefit most from preventive therapies, and how effective these therapies are in modifying the underlying disease process in asymptomatic individuals.

## MANAGING PATIENTS WITH ALZHEIMER'S DISEASE

Managing patients with AD involves a comprehensive, multidisciplinary team approach including presentation of the diagnosis, initiation of medical therapy, assessment and treatment of concomitant depression and/or behavioral concerns, development of a social support network, education of patients and caregivers, provision of caregiver support, and initiation of appropriate safety measures. While not all medical centers have access to multidisciplinary team resources, effective care can still be given by focusing on providing established medical treatment, identifying a few strategies to maintain patient safety and providing basic education and caregiver support.

### Presenting the Diagnosis

Presenting the diagnosis of AD to a patient is difficult, as it may generate significant emotional responses from the patient and their family and trigger fear of the future. Frequently, patients and family members suspect the diagnosis before it is presented, but how they respond to the news depends on personal coping mechanisms, cultural influences, family dynamics, and their preconceived understanding of AD. Clinicians may help patients and families adjust to this diagnosis by using an empathetic, yet honest approach and by providing them with educational and support resources, including those provided by agencies such as the Alzheimer's Association and the National Institute on Aging Alzheimer's Disease Education and Referral (ADEAR) Center. In addition, the clinician should emphasize the goals of diagnosing AD in order to take steps to protect the patient's memory, delay the progression of the disease, and to maintain the person's safety. In general, it is recommended to tell both the patient and family the diagnosis using the term "Alzheimer's disease", thus, providing patients and families with a starting point for education. Encouraging both persons with the disorder and caregivers to utilize resources such as local support groups and the Alzheimer's Association is an important part of the patient management plan.

### Treatment of Cognitive Symptoms

Acetylcholinesterase inhibitors (AChEIs) are the mainstay of therapy for AD, and until several years ago, were the only medications approved in the United States for the treatment of AD. AChEIs increase the levels of the neurotransmitter acetylcholine in neuronal synapses, thereby enhancing cholinergic activity in the affected brain regions.

**TABLE 65-8****FDA-Approved Medications for the Treatment of Alzheimer's Disease\***

MEDICATION	INDICATION	AVAILABLE FORMULATIONS	DOSE RANGE AND TITRATION
Cholinesterase inhibitors			
Donepezil (Aricept®)	Mild to severe AD	5 and 10 mg tablets 5 and 10 mg oral disintegrating tablets	Tablets or oral disintegrating tablets: 5–10 mg once daily at bedtime May be taken with or without food Begin at 5 mg once daily at bedtime for 4–6 wk then increase to 10 mg daily as tolerated Effective dose: 5–10 mg daily
Galantamine (Razadyne® and Razadyne® ER)	Mild to moderate AD	4, 8, and 12 mg immediate-release tablets 4 mg/mL immediate-release oral solution 8, 16, and 24 mg extended-release capsules	Immediate-release tablets or oral solution: 4–12 mg twice daily Should be taken with meals Begin at 4 mg twice daily for 4–6 wk then increase to 8 mg twice daily for 4–6 wk then 12 mg twice daily as tolerated Extended-release capsules: 8–24 mg once daily Should be taken in the morning with food Begin at 8 mg once daily for 4–6 wk then increase to 16 mg once daily for 4–6 wk then 24 mg once daily as tolerated Effective dose: 16–24 mg daily
Rivastigmine (Exelon®)	Mild to moderate AD	1.5, 3, 4.5, and 6 mg capsules 2 mg/mL oral solution 4.6 mg/24 h and 9.5 mg/24 h patches	Capsules or oral solution: 1.5–6 mg twice daily Should be taken with meals Oral solution may be taken directly or mixed with beverage Begin at 1.5 mg twice daily for 2–4 wk then increase to 3 mg twice daily for 2–4 wk then 4.5 mg twice daily for 2–4 wk then 6 mg twice daily as tolerated Patch: Begin at 4.6 mg/24 h patch daily for 4–6 wk then increase to 9.5 mg/24 h patch daily as tolerated Effective dose: 6–12 mg daily
N-methyl-D-aspartate (NMDA) receptor antagonist			
Memantine (Namenda®)	Moderate to severe AD	5 and 10 mg tablets 4-wk titration pack 2 mg/mL oral solution	Tablets or oral solution: 10 mg twice daily May be taken with or without food Begin at 5 mg once daily for 1 wk then increase to 5 mg twice daily for 1 wk then 10 mg in the morning and 5 mg in the evening for 1 wk then 10 mg twice daily as tolerated (available in a 4-wk titration pack) Effective dose: 20 mg daily

\*Information obtained from product inserts.

Although 18% to 48% of persons may experience improvements in cognition after taking these medications, the majority of patients do not have any noticeable improvement, but instead experience a plateau or slowing of their rate of cognitive decline. This lack of noticeable improvement has led to controversies regarding the benefit of using cholinesterase inhibitors. However, given the chronic nature of AD, delaying the progression of cognitive decline may lead to improvements in quality of life, reduced caregiver burden, and reduced economic cost associated with long-term care.

Four AChEIs have been approved for use in the United States by the Food and Drug Administration (FDA). These medications include tacrine (Cognex®), donepezil (Aricept®), rivastigmine (Exelon®), and galantamine (Razadyne®). Excessive gastrointestinal side effects have made use of tacrine less favorable given the improved safety and tolerability profiles noted with the newer agents. Dosing

recommendations for the commonly used AChEIs are shown in Table 65-8. In general, the most common adverse effects associated with AChEI use are nausea, anorexia, and diarrhea. Gastrointestinal side effects may be alleviated by taking the medications with food. Sleep disturbances are also common, and may improve with altering the dosing schedule.

While used for many years in Europe, the United States' FDA-approved memantine (Namenda®) for use in moderate to severe AD in 2003. Memantine is an uncompetitive N-methyl-D-aspartate (NMDA) receptor antagonist. At high concentrations, memantine can inhibit mechanisms related to learning and memory, but at lower concentrations, it can preserve or enhance memory in animal models of AD. Memantine can protect against the excitotoxic destruction of cholinergic neurons and may inhibit  $\beta$ -amyloid production. In persons with moderate to severe AD, memantine slows the progression

of cognitive decline either alone or when used in conjunction with AChEIs. In addition, studies support that use of memantine showed better outcomes on measures of cognition, activities of daily living, global outcome, and behavior and was well tolerated. While early trials show promising results, additional studies are needed before memantine can be recommended for early stages of AD. In most circumstances, it is appropriate to add this medication to cholinesterase inhibitor therapy in persons with moderate to severe AD. Current prescribing recommendations for memantine are shown in [Table 65-8](#). In persons who do not tolerate cholinesterase inhibitors, memantine may be used as first-line therapy. With use of either AChEIs or memantine, clinicians should educate families on what to expect with use of the medications, namely that they work to delay the progression of the disease and not to significantly improve their cognition. Consideration should be given to the modest expected benefit and cost of both medications per month.

### Disease-Modifying Therapies

Currently there are no FDA-approved disease-modifying therapies available, but research is making progress in identifying pathways that could serve as targets for such therapies. A variety of agents targeting  $\beta$ -amyloid metabolism are in various stages of development, including  $A\beta$  immunotherapy, agents inhibiting  $A\beta$  fibrillization and reducing soluble  $A\beta$ , selective amyloid lowering agents (SALAs), and  $\beta$ - and  $\gamma$ -secretase inhibitors. In addition, potential disease-modifying agents with known cardiovascular benefits, such as statins and omega-3 fatty acids, are currently being studied in large clinical trials.

While clinical trials have not conclusively shown that treating vascular risk factors delays the development or progression of AD, aggressive treatment of vascular risk factors in many patients with memory complaints, including those associated with AD, may be warranted. Vascular risk factor modification has known cardiovascular benefits that may lead to reduction of coronary artery bypass grafting, cerebrovascular disease, and stroke—factors strongly linked to cognitive decline. Trials are underway to clarify if vascular risk factor reduction and improved cerebral perfusion modify the course of AD. Until the completion of such trials, clinicians should follow established cardiovascular prevention guidelines for patients presenting with memory complaints, taking into account the patient's comorbid illnesses, quality of life, treatment costs, and life expectancy.

### Preventive Strategies

Currently there are no established preventive therapies for AD. Evidence supports that future therapies that either delay or prevent the onset of AD may need to be started in midlife in high-risk populations in order to significantly influence the onset and course of the disease. As the underlying pathologic changes that eventually lead to clinical AD begin decades before the onset of symptoms, primary prevention trials with conversion to AD as their primary outcome may prove costly and time-consuming. Integrating biomarkers with strong relationships to clinically relevant outcomes into such primary prevention trials may allow for earlier identification of disease-modifying effects of potential preventive therapies. Given the multifactorial nature of AD, future preventive strategies will most likely target a variety of mechanisms related to disease progression, similar

to that used in cardiovascular disease prevention. Some potential prevention therapies currently under investigation include vascular risk factor modification, anti-inflammatory medications, antioxidants, lifestyle interventions such as exercise, social engagement, and cognitive stimulation, and novel compounds targeting  $A\beta$  metabolism.

### Behavioral Management

AD is frequently associated with behavioral disturbances that include agitation, emotional or physical outbursts, and sexual inappropriate-ness. Such behaviors may be more distressing to family and caregivers than the actual memory decline. Such behaviors may be managed by nonpharmacologic as well as pharmacologic interventions. Nonpharmacological therapies should be explored and exhausted before using pharmacologic therapy, unless the person's agitation threatens his or her safety or living situation. Addressing physical pain or other medical symptoms or distressing situations that could be contributing to agitation is key prior to any pharmacologic intervention. Identifying and correcting physical or emotional stressors may alleviate agitation. Potential medication side effects should be considered to see if they are contributing to agitation symptoms. After nonpharmacologic measures have been tried, consideration may be given to use of low-dose atypical antipsychotics taking into account potential risks associated with these medications. Selective serotonin reuptake inhibitors (SSRIs) may reduce symptoms of sexual inappropriateness. Wandering symptoms typically do not respond to pharmacologic therapy. Taking patients for a walk or giving them busy tasks to do may help reduce wandering. Frequently, it is the behavioral changes associated with AD and other dementias that are most distressing to family members and provide the greatest challenge for primary care physicians who are managing the care of persons with AD. Referral to a multidisciplinary memory disorders clinic is appropriate for patients with significant behavioral concerns. More information is dedicated to this topic in [Chapter 73](#).

### Safety Management

Reviewing common safety concerns in persons with dementia may help identify significant risks and provide an opportunity for educating family members and caregivers on what areas to monitor closely and what safeguards they can take to protect the person with AD. Some patients may require further evaluation to assess driving safety, which can be done through occupational or physical therapy departments or local driving schools. Pill boxes or other similar medication planners may facilitate correct administration of medications and allow family or caregivers to help in setting up the medications properly. Other safety concerns such as proper use of the stove, woodworking equipment, hunting rifles, etc. should be discussed and appropriate supervision arranged.

### Caregiver Support

Evidence is accumulating that the effects of AD are felt not only by the patient but also by the caregivers. Caregivers have increased depression, missed work, and health problems compared to those not caring for a family member with dementia. Use of respite services from family, friends, neighbors, and local adult day centers may allow for caregivers to take the appropriate time needed to maintain their own health and social connections.

## End-of-Life Care

Upon diagnosis of AD, many patients and families have questions as to what to expect in the years ahead. As the rapidity of progression of AD may depend not only on genetic and environmental factors but also comorbid medical conditions, the course of decline can be difficult to predict in some persons. Once on medical treatment for AD and when all potentially reversible contributing factors have been addressed, obtaining repeat cognitive testing will give the clinician an idea of the trajectory of decline of the individual and help inform the family on what to expect in the years ahead. Providing information early in the disease course on end-of-life planning may help smooth this difficult transition later in the disease. Use of respite services and home health aides or family members may help the person with AD stay in the home longer. If the social network of the patient cannot support the patient as the care needs increase, then nursing home placement frequently is necessary. Involving hospice can help with symptom management late in the course of the illness. Involvement in Alzheimer support groups can provide support during the unique grieving process related to dementia, as family and caregivers watch the cognitive and personality transformations in their family member with AD.

## SUMMARY

Alzheimer's disease is the leading cause of dementia worldwide and, unless effective preventive strategies are identified, is expected to significantly increase in prevalence in the coming decades as the population ages. The diagnosis of AD remains a clinical diagnosis that requires careful history-taking, a physical examination, and cognitive testing to document a decline in cognitive and functional abilities. Ancillary laboratory and neuroimaging can help differentiate between various causes of memory loss and different types of dementia. Treatment for AD involves not only pharmacologic therapy with cholinesterase inhibitors and NMDA antagonists, but also

careful assessment of safety, behavioral concerns, and education for the patient, family, and other caregivers. While preventive therapies have not yet been established, newly identified mechanisms of disease pathobiology are being targeted to develop effective novel therapies that could either delay or preferably arrest the progression of AD. Future research may help identify persons at highest risk for AD and develop treatment strategies targeting multiple mechanisms underlying the pathobiology of AD.

*Stanley Fahn*

## DISTINGUISHING BETWEEN PARKINSON'S DISEASE AND PARKINSONISM

The syndrome of parkinsonism must be understood before understanding what is Parkinson's disease (PD). Parkinsonism is defined as any combination of six specific, independent motoric features: tremor at rest, bradykinesia, rigidity, loss of postural reflexes, flexed posture, and the freezing phenomenon (where the feet are transiently "glued" to the ground). Not all six of these cardinal features need be present, but at least two should be before the diagnosis of parkinsonism is made, with at least one of them being tremor at rest or bradykinesia. Parkinsonism is divided into four categories (Table 66-1). PD or primary parkinsonism will be the principal focus of this chapter; not only as it is the one that is most commonly encountered by the general clinician, it is also the one on which much research has been expended and the one we know the most about. The great majority of cases of primary parkinsonism are sporadic, but in the last decade, several gene mutations have been discovered to cause PD (Table 66-2). Whether genetic or idiopathic in etiology, the common denominator is that this group of primary parkinsonism is not caused by known insults to the brain (the main feature of secondary parkinsonism) and is not associated with other motoric neurological features (the main feature of Parkinson-plus syndromes). The uncovering of genetic causes of primary parkinsonism has shed light on probable pathogenic mechanisms that may be a factor in even the more common idiopathic cases of PD. It may even turn out that many of the idiopathic cases will be linked to gene mutations, discoveries yet to be made. Although the term "idiopathic PD" has been applied to primary parkinsonism, the fact that there are known genetic causes should encourage us to adopt the term "primary parkinsonism" rather than "idiopathic parkinsonism."

Three of the most helpful clues that one is likely dealing with a category of parkinsonism other than PD would be (1) a symmetrical onset of symptoms (PD often begins on one side of the body),

(2) a lack of a substantial clinical response to adequate levodopa therapy, and (3) the absence of rest tremor. The presence of any of these features does not necessarily exclude the diagnosis of PD, but the likelihood that the cause belongs to another category of parkinsonism is high. The clinical features suggesting a diagnosis favoring the other parkinsonian disorders and not PD are listed in Table 66-3. One common misdiagnosis is tremor owing to essential tremor, which can even be unilateral, although it more commonly is bilateral. Helpful in the diagnosis is that the tremor caused by PD is a rest tremor, whereas essential tremor is not present at rest, but appears with holding the arms in front of the body and increases in amplitude with intention activity of the arm, such as with handwriting or performing the finger-to-nose maneuver.

PD begins insidiously and gradually worsens. Symptoms, such as rest tremor, can be intermittent at the beginning, becoming present only in stressful situations. Patients with PD can live 20 or more years, depending on the age at onset; the mortality rate is approximately 1.5 times that of normal individuals of the same age. Death in PD is usually because of some concurrent unrelated illness or owing to the effects of decreased mobility, aspiration, or increased falling with subsequent physical injury. The Parkinson-plus syndromes typically progress at a faster rate and often cause death within 9 years. Thus, the diagnosis of PD is of prognostic importance, as well as of therapeutic significance, because it almost always responds to at least a moderate degree to levodopa therapy, whereas the Parkinson-plus disorders do not. While it may be difficult to distinguish between PD and Parkinson-plus syndromes in the early stages of the illness, with disease progression over time, the clinical distinctions of the Parkinson-plus disorders become more apparent with the development of other neurological findings, such as cerebellar ataxia, loss of downward ocular movements, and autonomic dysfunction (e.g., postural hypotension, loss of bladder control, and impotence).

There are no practical diagnostic laboratory tests for PD, and the diagnosis rests on the clinical features or by excluding some of the other causes of parkinsonism. The research tool of fluorodopa

**TABLE 66-1****Classification of the Parkinsonian States**

Primary parkinsonism (Parkinson's disease)
Sporadic
Known genetic etiology (see Table 66-2)
Secondary parkinsonism (environmental etiology)
Drugs
Dopamine receptor blockers (most commonly antipsychotic medications)
Dopamine storage depletors (reserpine)
Postencephalitic
Toxins—Mn, CO, MPTP, cyanide
Vascular
Brain tumors
Head trauma
Normal pressure hydrocephalus
Parkinsonism-plus syndromes
Progressive supranuclear palsy (PSP)
Multiple system atrophy (MSA)
Cortical-basal ganglionic degeneration (CBGD)
Diffuse Lewy body disease (DLBD)
Parkinson-dementia-ALS complex of Guam
Progressive pallidal atrophy
Heredodegenerative disorders
Alzheimer's disease
Wilson disease
Huntington disease
Frontotemporal dementia on chromosome 17
X-linked dystonia-parkinsonism (in Filipino men; known as lubag)

positron emission tomography measures levodopa uptake into dopamine nerve terminals, and this shows a decline of approximately 5% per year of the striatal uptake. A similar result is seen using ligands for the dopamine transporter, either by positron emission tomography or by single photon emission computed tomography; these ligands also label the dopamine nerve terminals. All these neuroimaging techniques reveal decreased dopaminergic nerve terminals in the striatum in both PD and the Parkinson-plus syndromes, and do not distinguish between them. A substantial response to levodopa is most helpful in the differential diagnosis, indicating presynaptic dopamine deficiency with intact postsynaptic dopamine receptors, features typical for PD.

**TABLE 66-3****Criteria to Exclude the Diagnosis of Parkinson's Disease in Favor of Another Cause of Parkinsonism**

	LIKELY DIAGNOSIS
History of:	
Encephalitis	Postencephalitic
Exposure to carbon monoxide, manganese, or other toxins	Toxin-induced
Recent exposure to neuroleptic medication	Drug-induced
Onset of parkinsonian symptoms following:	
Head trauma	Posttraumatic
Stroke	Vascular
Presence on examination of:	
Cerebellar ataxia	OPCA, MSA
Loss of downward ocular movements	PSP
Pronounced postural hypotension not because of concurrent medication	MSA
Pronounced unilateral rigidity with or without dystonia, apraxia, cortical sensory loss, alien limb	CBGD
Myoclonus	CBGD, MSA
Falling or freezing of gait early in the course of the disease	PSP
Autonomic dysfunction not because of medications	MSA
Excessive drooling of saliva	MSA
Early dementia or hallucinations from medications	DLBD
Dystonia induced with low-dose levodopa	MSA
Neuroimaging (MRI or CT scan) revealing:	
Lacunar infarcts	Vascular
Capacious cerebral ventricles	NPH
Cerebellar atrophy	OPCA, MSA
Atrophy of the midbrain or other parts of the brainstem	PSP, MSA
Effect of medication:	
Poor response to levodopa	PSP, MSA, CBGD, Vascular, NPH
No dyskinesias despite high-dose levodopa	Same as above

CBGD, cortical-basal ganglionic degeneration; DLBD, diffuse Lewy body disease, also called dementia with Lewy bodies; MSA, multiple system atrophy; NPH, normal pressure hydrocephalus; OPCA, olivo-ponto-cerebellar atrophy, which can be one form of MSA.

**TABLE 66-2****Genetic Forms of Primary Parkinsonism**

NAME	GENE SYMBOL	PROTEIN	CHROMOSOME
Autosomal Dominant Transmission			
PARK1/PARK4	<i>SNCA</i>	$\alpha$ -synuclein	4q21.3
PARK5	<i>UCH-L1</i>	Ubiquitin C-terminal hydrolase-L1	4p14
PARK8	<i>LRRK2</i>	Leucine rich repeat kinase 2	12p11.2-q13.1
	<i>GBA</i>	$\beta$ -glucocerebrosidase	1q21
Dopa-responsive dystonia		GTP cyclohydrolase 1	14q22.1-q22.2
Autosomal Recessive Transmission			
PARK2	<i>PRKN</i>	Parkin (ubiquitin ligase)	6q25.2-q27
PARK6	<i>PINK1</i>	PTEN-induced kinase 1 (PINK1)	1p35-p36
PARK7	<i>DJ-1</i>	DJ-1	1p36
PARK9	<i>ATP13A2</i>	ATPase	1p32
Tyrosine hydroxylase deficiency			11p11.5

The development of dementia in a patient with parkinsonism remains a difficult differential diagnosis. If the patient's parkinsonian features did not respond to levodopa, the diagnosis is likely to be Alzheimer's disease, which can occasionally present with parkinsonism. If the presenting parkinsonism responded to levodopa, and the patient developed dementia over time, the diagnosis could be either PD dementia (PDD) or diffuse Lewy body disease (DLBD), also known as dementia with Lewy bodies. The nosologic distinction is less of substance and more of useful categorization. The term PDD is used if the symptoms of PD have been present for at least 1 year before dementia develops. The term DLBD is used if the symptoms of PD have been present less than 1 year before onset of dementia, or if dementia presents with the onset of parkinsonism. A major feature of PDD and DLBD is the presence of hallucinations. Without hallucinations, other types of dementias should be considered, including vascular disease, Alzheimer's disease, and frontotemporal dementia. DLBD is a condition where Lewy bodies are present in the cerebral cortex as well as in the brainstem nuclei. The hereditary degenerative disease, known as frontotemporal dementia, is an autosomal dominant disorder caused by mutations of the *tau* gene or the *progranulin* gene on chromosome 17; the full syndrome presents with dementia, loss of inhibition, parkinsonism, and sometimes muscle wasting. PDD is associated with aging and increased duration of PD. The prevalence of PDD is approximately 20%, but the likelihood of developing dementia eventually in a patient with PD is much greater, with the highest estimate around 78%.

Some adults may develop a more benign form of PD, in which the symptoms respond to very low-dose levodopa, and the disease does not worsen severely with time. This form is usually caused by the autosomal dominant disorder known as dopa-responsive dystonia, which typically begins in childhood as a dystonia. But when it starts in adult life, it can present with parkinsonism. There is no neuronal degeneration. The pathogenesis is because of a biochemical deficiency involving dopamine synthesis. The gene defect is for an enzyme, GTP cyclohydrolase 1, required to synthesize the cofactor for tyrosine hydroxylase activity, the crucial rate-limiting first step in the synthesis of dopamine and norepinephrine. Infantile parkinsonism is caused by the autosomal recessive deficiency of tyrosine hydroxylase, another cause of a biochemical dopamine-deficiency disorder. Young-onset PD—less than 40 years of age, but some use a cut-off of 50 years—usually worsens more slowly than those with older onset. But these young-onset patients are more likely to develop motor complications from levodopa therapy (see below).

## PATHOLOGY OF PARKINSON'S DISEASE AND PARKINSON-PLUS SYNDROMES

Parkinson's disease and the Parkinson-plus syndromes have in common a degeneration of substantia nigra pars compacta dopaminergic neurons, with a resulting deficiency of striatal dopamine caused by loss of the nigrostriatal neurons. Accompanying this neuronal loss in the nigra is an increase in glial cells and a loss of the neuromelanin in the nigra, because neuromelanin is normally contained in the dopaminergic neurons. In PD, intracytoplasmic inclusions, called Lewy bodies, are usually present in many of the surviving neurons. It is recognized today that not all patients with PD have Lewy bodies, those with a homozygous mutation in the *parkin* (PARK2) gene,

mainly patients with young-onset PD, have nigral neuronal degeneration without Lewy bodies. Lewy bodies contain many proteins, including the fibrillar form of the protein  $\alpha$ -synuclein. Immunostaining for  $\alpha$ -synuclein is utilized today as the most sensitive histologic method to detect Lewy bodies. Recent research has shown that Lewy neurites ( $\alpha$ -synuclein fibers in axons) first appear in the medulla and the olfactory bulb, and over time become present in a rostral manner up the brainstem, from medulla to pons to midbrain, and then into the thalamus and cerebral cortex. Thus, Lewy neurites (and Lewy bodies) do not start in the substantia nigra, which is located in the midbrain. There are no Lewy bodies in the Parkinson-plus syndromes.

A pathological feature of multiple system atrophy (MSA) is the presence of inclusions in oligodendroglia; these inclusions also contain  $\alpha$ -synuclein. PSP and CBDG contain tau filaments, and these two diseases share similar clinical features, especially in the late stages of these diseases. PSP shows neurofibrillary tangles in the substantia nigra and other nuclei, while CBDG shows ballooned neurons, especially in areas of the cerebral cortex.

## CAUSE AND PATHOGENESIS OF PARKINSON'S DISEASE AND PARKINSON-PLUS SYNDROMES

Other than known genetic causes of PD (Table 66-2), the etiology of these disorders remains unknown. Alterations in the *tau* gene have been implicated for PSP and CBDG. Three of the identified genes causing PD (*PARK1*, *PARK2*, *PARK5*) point to an impairment of protein degradation with a build-up of toxic proteins that cannot be degraded via the ubiquitin–proteasomal pathway. This has led to the concept that perhaps most, if not all, cases of sporadic PD have an impairment of protein degradation. While *PARK1* represents mutations in the gene for  $\alpha$ -synuclein, triplications and duplications of the chromosomal area for the *\alpha*-synuclein gene (*PARK4*) also cause PD, indicating that accumulation of wild-type  $\alpha$ -synuclein, and not just gene mutations of this protein are capable of causing neurodegeneration. A heterozygotic mutation in the gene for the lysosomal enzymes,  $\beta$ -glucocerebrosidase and a lysosomal ATPase (*PARK9*), indicates that faulty degradation of substrates can be an important pathogenic factor. One gene (*PARK6*) is involved with mitochondrial function, suggesting impaired energy metabolism can lead to PD. *PARK7* is a gene for a protein that fights oxidative stress; thus supporting the notion that increased oxidative stress can be a risk factor for PD.

The most common gene mutation causing PD is *PARK8*, especially the G2019S mutation; approximately 5% of familial cases and up to 2% of nonfamilial cases have this mutation. There is ethnic disproportion of specific mutations in the *LRRK2* gene. The G2019S mutation is highly prevalent in North African Arabs, Portuguese, Spanish, and Ashkenazi Jews. In the Chinese, the G2385R mutation is the most common. *LRRK2* is a complex protein with several functional domains, and mutations in any of them can lead to PD. It is not clear how such mutations cause the disease.

Because accumulated  $\alpha$ -synuclein can cause porosity in the synaptic vesicle membrane, resulting in an outward leakage of stored dopamine, the increased cytosolic dopamine can auto-oxidize to form oxyradicals, such as dopamine quinone, to cause cell damage. Other pathogenic mechanisms being considered are (1) damage to the protein degradation properties of lysosomes leading to protein

accumulation and aggregation; (2) other effects from oxidative stress, such as the reaction of oxyradicals with nitric oxide to form the highly reactive peroxynitrite radical; (3) impaired mitochondria leading to both reduced ATP production and accumulation of electrons that aggravate oxidative stress, with the final outcome being apoptosis and cell death; and (4) inflammatory changes in the nigra producing cytokines that augment apoptosis. These concepts on pathogenesis are leading researchers to test agents that affect these potential mechanisms in an attempt to reduce the rate of neurodegeneration in PD.

## EPIDEMIOLOGY AND CLINICAL FEATURES OF PARKINSON'S DISEASE

Although PD can develop at any age, it is most common in older adults, with a peak age at onset around 60 years. The likelihood of developing PD increases with age, with a lifetime risk of approximately 2%. A positive family history doubles the risk of developing PD to 4%. Twin studies indicate that PD with an onset before the age of 50 years is more likely to have a genetic relationship than for patients with an older age at onset.

The early symptoms and signs of PD are rest tremor, bradykinesia, and rigidity; these are related to progressive loss of nigrostriatal dopamine. These signs and symptoms result from dopamine deficiency and are usually correctable by levodopa and dopamine agonists. As PD progresses over time, non-dopamine-related symptoms develop, such as flexed posture, the freezing phenomenon, and loss of postural reflexes; these do not respond well to levodopa therapy. Moreover, increasing bradykinesia that is not responsive to levodopa can appear as the disease worsens. All these intractable symptoms lead to disability.

While the motor symptoms of PD dominate the clinical picture, and even define the parkinsonian syndrome, many patients with PD have other complaints that have been classified as *nonmotor*. These include bradyphrenia (slowness in mental function), decreased motivation and apathy, dementia (discussed above), fatigue, depression, anxiety, sleep disturbances (fragmented sleep and REM sleep behavior disorder), constipation, bladder and other autonomic disturbances (sexual, gastrointestinal), and sensory complaints. Sensory symptoms, including pain, numbness, tingling, and burning, in the affected limbs occur in approximately 40% of patients.

## PRINCIPLES OF THERAPY

Parkinson-plus syndromes respond poorly to medications, so the emphasis here is on the treatment of PD. Certain principles serve as guidelines.

### Neuroprotective Therapy

So far no drug or surgical approach has unequivocally been shown to slow the rate of progression of PD, but if any drug could be proven to delay the progression of the disease process, it should be incorporated early. Two drugs that have suggested evidence in the ability to slow the rate of clinical worsening are selegiline and rasagiline; both are irreversible MAO-B inhibitors with a propargylamine moiety in their chemical structure, which has been found to suppress apoptosis.

### Encourage Exercise to Keep the Patient Mobile

An active exercise program encourages the patients to participate in their own care, allows muscle stretching and full range of joint mobility, and enhances a better mental attitude toward fighting the disease. One of the nonmotor symptoms of PD is the tendency to being passive with decreased motivation. Encouraging activity helps fight these symptoms. Studies in rodents have shown that those in enriched cages allowing exercise have slowed degeneration of dopamine neurons following toxin injections into those neurons, supposedly because of exercise leading to an increase in brain tropic factors.

### Individualize Therapy

No two patients are identical; each presents with a unique set of symptoms, signs, response to medications, and a host of social, occupational, and emotional problems that need to be addressed. The treatment of PD, therefore, needs to be individualized. One takes into account the severity of the patient's symptoms, the degree of functional impairment, the expected benefits and risks of available therapeutic agents, and the age of the patient. Younger patients are more likely to develop motor fluctuations and dyskinesias from levodopa, while older patients are more likely to develop confusion, sleep-wake alterations, dementia, and psychosis.

### Deep Brain Stimulation

Stereotaxic surgical implantation of electrodes with stimulation of the subthalamic nucleus has been shown to reduce motor symptoms of PD, especially bradykinesia, tremor, and rigidity. These are the same symptoms that respond to levodopa. The dopa-nonresponsive symptoms of PD also do not respond to deep brain stimulation (DBS). The best candidates for DBS are younger patients with a very good response to levodopa, but with the uneven response of motor fluctuations and dyskinesias. DBS can provide a smoothing out of the clinical response and allows a reduction of medications.

## MEDICAL THERAPY OF PARKINSON'S DISEASE

Treatment of patients with PD can be divided into three major categories: physical (and mental health) therapy, medications, and surgery. Physical exercise is mentioned above, and should be implemented as soon as the diagnosis is made, but it is useful in all stages of disease. In the early stages of the disease, the joints should be fully stretched to compensate for the tendency of the patient to have a reduced range of motion. In advanced stages of PD, formal physical therapy is more valuable by keeping the joints from becoming frozen, and by providing guidance how best to remain independent in mobility, particularly with gait training. Medications are the mainstay of therapy, but DBS can be appropriate for selected patients as described above.

Dopamine replacement therapy is the major medical approach to treating PD, and a variety of dopaminergic agents are available (Table 66-4). The most powerful drug is levodopa, the immediate precursor of dopamine. Levodopa, an amino acid, can enter the brain, whereas dopamine is blocked by the blood-brain barrier. Levodopa is usually administered combined with a peripheral decarboxylase inhibitor

**TABLE 66-4****Dopaminergic Agents**

Dopamine precursor: levodopa
Peripheral decarboxylase inhibitors: carbidopa, benserazide
Dopamine agonists: pramipexole, ropinirole, rotigotine, apomorphine
Catechol-O-methyltransferase inhibitors: tolcapone, entacapone
Dopamine releaser: amantadine
Peripheral dopamine receptor blocker: domperidone
MAO type B inhibitor: selegiline, Zydys selegiline, rasagiline

(carbidopa and benserazide) to prevent formation of dopamine in the peripheral tissues, thereby increasing levodopa's bioavailability and also markedly reducing gastrointestinal side effects. The brand name Sinemet is a combination of carbidopa and levodopa; the brand name Madopar is a combination of benserazide and levodopa. Such combination drugs are available in standard (i.e., immediate-release) and extended-release formulations. The former allows a more rapid and predictable "on," and the latter allows for a slightly longer plasma half-life, but with a slower and less predictable "on." The combination of the two release formulations can be administered in an attempt to smooth out and extend plasma levels of levodopa. One brand of carbidopa/levodopa is Parcopa that dissolves in the patient's mouth and enters the stomach via swallowing saliva. Its usefulness is for patients who have swallowing difficulties or who need to take a dose of carbidopa/levodopa quickly without delay in a search for liquid to swallow with a tablet. Although its pharmacokinetic profile is similar to a swallowed tablet of carbidopa/levodopa, many patients believe Parcopa works more quickly.

Although levodopa is the most effective drug to treat the symptoms of PD, approximately 60% of patients develop troublesome complications of disabling response fluctuations ("wearing-off" effect) and dyskinesias after 5 years of levodopa therapy, and younger patients (less than 60 years of age) are particularly prone to develop these problems even sooner. Thus, younger patients are often started with a dopamine agonist rather than levodopa (see below).

It should be pointed out that it is not safe to discontinue levodopa suddenly, such action can induce the neuroleptic-like malignant syndrome of fever, sweating, rigidity, and mental confusion and obtundation.

Besides being metabolized by aromatic amino acid decarboxylase (commonly known as dopa decarboxylase), levodopa is also metabolized by catechol-O-methyltransferase (COMT) to form 3-O-methyldopa. Two COMT inhibitors are available: entacapone and tolcapone. These agents extend the plasma half-life of levodopa with only slightly increasing its peak plasma concentration, and can thereby prolong the duration of action of each dose of levodopa. Their clinical indication is to help reduce motor fluctuations, i.e., increase "on" time and reduce "off" time. Because they enhance levodopa's efficacy, these agents can increase dyskinesias and the dosage of levodopa may need to be lowered.

Entacapone is very short acting, and each 200 mg tablet is taken simultaneously with levodopa; entacapone has been combined with carbidopa/levodopa into a single tablet, known as Stalevo. Tolcapone (100 and 200 mg tablets) is more potent and has a longer duration of action; it is taken three times daily. But it is encumbered with a greater likelihood to cause diarrhea and hepatic toxicity. Liver

function must be monitored and the drug stopped if abnormal liver chemistries are seen. Tolcapone is therefore given only if entacapone has been found to be ineffective in controlling motor fluctuations.

After levodopa, the next most powerful drugs in treating PD symptoms are the dopamine agonists. Several of these are available. The ergot compounds of pergolide, bromocriptine, and cabergoline have the potential to induce fibrosis (cardiac valvulopathy and retroperitoneal, pleuropulmonary, and pericardial fibrosis), so these agents are not recommended; indeed pergolide has been withdrawn from the U.S. market. Pramipexole and ropinirole appear to be equally effective at therapeutic levels. Dopamine agonists are more likely than levodopa to cause hallucinations, confusion, and psychosis, especially in the elderly. Thus, it is safer to utilize levodopa in patients older than 70 years. On the other hand, clinical trials have shown that dopamine agonists are less likely to produce dyskinesias and the wearing-off phenomenon than levodopa. But these trials also showed that levodopa provides greater symptomatic benefit than do dopamine agonists. Other problems more likely to occur with dopamine agonists than levodopa are sudden sleep attacks, including falling asleep at the wheel; daytime drowsiness; ankle edema; and impulse control problems such as hypersexuality and compulsive gambling, shopping, and eating.

The newest dopamine agonist is rotigotine, applied via a dermal patch to the upper torso or arms. Rotigotine penetrates the epidermis and dermis and enters the subcutaneous fat where it slowly enters the blood stream. The skin patch is applied once daily, usually after the morning shower, and is removed the next day before the shower; a new patch is applied to a different surface of the skin to reduce the chance of a rash, a common adverse effect. Absorption is steady over 24 hours, and three dose strengths (four in Europe) are available: 2, 4, and 6 mg/day (plus 8 mg/day in Europe). It is useful for those with swallowing difficulties and may help smooth out motor fluctuations and nocturnal akinesia, when the last prebedtime dose of levodopa does not last throughout the night. It is less potent than the other dopamine agonists, but its milder action may offer fewer adverse effects such as mental and behavioral side effects.

Apomorphine may be the most powerful dopamine agonist, but it needs to be injected subcutaneously (or taken sublingually in Europe). It is used to provide faster relief to overcome a deep "off" state.

Amantadine has several actions; it has antimuscarinic effects, but more importantly, it can activate release of dopamine from nerve terminals, block dopamine uptake into the nerve terminals, and block glutamate NMDA receptors. Its dopaminergic actions make it a useful drug to relieve symptoms in approximately two-thirds of patients, but it can induce livedo reticularis, ankle edema, visual hallucinations, and confusion. Its antiglutamatergic action is useful in reducing the severity of levodopa-induced dyskinesias, and in fact, is the only known effective antidyskinetic agent. The dose of amantadine for its anti-PD effect is usually 100 mg twice daily, but its antidyskinetic effect requires higher dosages, usually 300 to 400 mg/day. Unfortunately, the antidyskinetic effect tends to lessen over time. The elderly do not tolerate amantadine well because of mental adverse effects of confusion and hallucinations. Domperidone is a peripherally active dopamine receptor blocker and is useful in preventing gastrointestinal upset from levodopa and the dopamine agonists. It is not available in the United States, but is available in other countries. Monoamine oxidase type B (MAO-B) inhibitors

(selegiline, rasagiline, and Zydys selegiline) offer mildly effective symptomatic benefit and are without the hypertensive “cheese effect” seen with MAO-A inhibitors, and therefore can be used in the presence of levodopa therapy. Although there has been considerable debate about possible protective benefit with selegiline, recent studies evaluating its long-term use indicate that selegiline is associated with less freezing of gait and with a slower rate of clinical worsening compared to placebo-treated subjects. These benefits appear to be separate from its mild symptomatic dopaminergic effect, because all subjects were receiving the symptomatic benefit from concurrent levodopa therapy. Rasagiline is currently undergoing a large clinical trial to test its neuroprotective effect. Selegiline, but not rasagiline, is metabolized to L-amphetamine and methamphetamine. Zydys selegiline is a formulation of selegiline that dissolves under the tongue and is absorbed via the oral mucosa directly into the blood stream, thereby by-passing the gut and liver and not generating the amphetamines. All these drugs can reduce the severity of motor fluctuations with levodopa. They are more likely, however, to increase dyskinesias.

Nondopaminergic agents (Table 66-5) are useful to treat both motor and nonmotor symptoms in PD. Antimuscarinic drugs have been widely used since the 1950s, but these are much less effective than the dopaminergic agents, including amantadine. Because of sensitivity to memory impairment and hallucinations in the elderly population, antimuscarinics should be avoided in patients older than 70 years. They can reduce the severity of tremor. Antihistaminics have mild anticholinergic properties and can serve as alternatives to antimuscarinic drugs in the elderly population. Another alternative agent is the tricyclic amitriptyline, because it also has anticholinergic properties. Muscle relaxants can sometimes reduce muscle tightness and cramping, and might help overcome “off” dystonia and peak-dose dystonia that patients on levodopa therapy sometimes develop. Coenzyme Q10 is currently being tested in a controlled clinical trial to determine if it has protective effects.

Because depression is common in patients with PD, and often precedes the motor symptoms of PD, this mood disturbance needs to be vigorously addressed; the tricyclics and selective serotonin reuptake inhibitors are useful antidepressants. It is not certain if one

type of antidepressant class of compounds is superior to the other in treating the depression accompanying PD. If insomnia is a problem for the patient, using an antidepressant that is also a soporific can be doubly advantageous, such as amitriptyline given at bedtime.

The benzodiazepines can reduce anxiety and stress, and therefore are useful to decrease parkinsonian tremor that is exacerbated by stress. Diazepam is usually well tolerated and does not exacerbate parkinsonian symptoms. Lorazepam and alprazolam are other agents in this class of drugs.

Psychosis induced by levodopa and the dopamine agonists can usually be controlled by quetiapine and clozapine without worsening the parkinsonism. Other antipsychotic agents are more likely to worsen the parkinsonism, therefore, they should be avoided. Clozapine is more effective than quetiapine, but because clozapine treatment requires weekly white blood cell counts, quetiapine should be tried first. Both drugs are soporific and bedtime dosing is helpful to also overcome insomnia. Patients with PD often have no problem falling asleep, but they have frequent arousals (sleep fragmentation), and if they have trouble returning to sleep, a short-acting drug, such as zolpidem, taken when trying to fall back to sleep can be helpful. REM sleep behavior disorder (RBD) is common in patients with PD and MSA, and often precedes the appearance of these disorders. RBD is manifested by patients moving about while dreaming, i.e., acting out their dreams. Normally, dreaming in REM sleep is associated with muscle paralysis, and this is lost in RBD. The bed-partner is the one usually disturbed by the patient with RBD; the patients are unaware that they are thrashing and kicking in their dreams. Clonazepam taken at bedtime is an effective drug to overcome this problem. Excessive daytime sleepiness, due either to disrupted nighttime sleep or to drowsiness from medications (dopamine agonists and levodopa), can sometimes lessen with the administration of modafinil.

Cognitive decline and frank dementia can be helped to a limited and modest degree with centrally active cholinesterase inhibitors, donepezil and rivastigmine, which have undergone clinical trials in PDD. Orthostatic hypotension in PD can be owing to the disease (or to MSA) or to the medications, particularly levodopa, dopamine agonists, and antidepressants. Fludrocortisone and midodrine can overcome this symptom to some extent. Restless legs syndrome (RLS) is common in patients with PD, possibly induced by levodopa therapy, which is known to augment symptoms in patients with RLS (without concomitant PD) who had been placed on levodopa or dopamine agonists. Since RLS can cause nocturnal sleep disturbance, this symptom is worth enquiring about when patients complain of a restless sleep at night. The typical symptom of RLS is an uncomfortable feeling of discomfort in the legs (like crawling ants under the skin) late in the evening or night. Walking around relieves this symptom. Bedtime dose of a dopamine agonist or, if that fails, an opioid can provide effective relief.

**TABLE 66-5**

**Nondopaminergic Agents**

Parkinsonian motor symptoms:

- Antimuscarinics: trihexyphenidyl, benztropine
- Antihistaminics: diphenhydramine, orphenadrine
- Antiglutamatergics (to reduce dyskinesia): amantadine
- Muscle relaxants: cyclobenzaprine, diazepam, baclofen
- Mitochondrial enhancer: coenzyme Q10

Nonmotor symptom control:

- Depression: selective serotonin reuptake inhibitors, tricyclics, ECT
- Anxiety: benzodiazepines—diazepam, lorazepam, alprazolam
- Psychosis (hallucinations, paranoia): clozapine, quetiapine
- Insomnia: quetiapine, zolpidem, benzodiazepine, mirtazapine
- REM sleep behavior disorder: clonazepam
- Excessive daytime sleepiness: modafinil
- Dementia: donepezil (Aricept), rivastigmine (Exelon)
- Orthostasis: fludrocortisone, midodrine (ProAmatine)
- Restless legs: dopamine agonists, opioids (e.g., propoxyphene, oxycodone)

**MOTOR COMPLICATIONS OF LEVODOPA THERAPY**

Many patients on levodopa therapy develop motor complications (Table 66-6). Response fluctuations usually begin as mild wearing-off, which can be defined as when an adequate dose of levodopa does not last at least 4 hours. Typically, in the first couple of years of treatment, there is a long-duration response so that the timing of doses of levodopa is not important. Over time, the long-duration

**TABLE 66-6****Pattern of Development of Response Fluctuations, Dyskinesias, and Other Complications**

Dyskinesias (chorea and dystonia)
Peak-dose dyskinesias
Diphasic dyskinesias (beginning and end-of-dose dyskinesias)
Fluctuations
Wearing off
Delayed "ons"
Dose failures
Sudden, unpredictable "offs" (on-offs)
Early morning "off" dystonia
"Off" dystonia during day
Alertness
Drowsy from a dose of levodopa
Reverse sleep-wake cycle
Behavioral and cognitive
Vivid dreams
Benign hallucinations
Malignant hallucinations
Delusions
Paranoia
Confusion
Dementia

response becomes lost, and only a short-duration response occurs; patients then develop the wearing-off phenomenon. The "offs" tend to be mild at first, but over time become deeper with more severe parkinsonism; simultaneously, the duration of the "on" response becomes shorter. Eventually, some patients develop random, sudden "offs" in which the deep state of parkinsonism develops over minutes rather than tens of minutes, and they are less predictable in terms of timing with the dosings of levodopa. Many patients who develop response fluctuations also develop abnormal involuntary movements, i.e., dyskinesias.

### Treatment of the "Wearing-off" Phenomenon

The wearing-off phenomenon, when mild, may be ameliorated slightly with the addition of selegiline (introduced as 5 mg daily, and increasing to 5 mg twice daily, as necessary) or rasagiline (0.5 mg once daily, and increasing to 1 mg once daily, as necessary). Both MAO-B inhibitors potentiate the action of levodopa, and their introduction can induce confusion and psychosis, particularly in the elderly. A lower dose of levodopa may be necessary. Sinemet CR (continuous release carbidopa/levodopa) can also be effective in patients with mild wearing-off, and one can gradually switch from standard carbidopa/levodopa to Sinemet CR, or use the combination of both immediate- and extended-release formulations. Because it takes more than an hour for a dose of continuous release medication to become effective, most patients will require simultaneous standard immediate release carbidopa/levodopa to obtain an adequate response. One can attempt to utilize standard carbidopa/levodopa alone, giving the doses closer together, but ultimately most patients will develop progressively shorter durations of effectiveness from these doses. So, patients could require as many as six or more doses per day, and then, eventually, dose failures owing to poor gastric emptying often develop.

Dopamine agonists, which have a longer biological half-life than levodopa, can also be used in combination with standard Sinemet or Sinemet CR. The addition of a dopamine agonist tends to make the "off" state less severe when used in combination with carbidopa/levodopa. The addition of a dopamine agonist, however, will likely increase dyskinesias; in this situation the dosage of levodopa would need to be reduced. Rotigotine (Neupro Dermal Patch) might be helpful to reduce mild wearing-off.

Catechol-O-methyltransferase inhibitors (COMTIs) have been found useful for treating wearing-off. Because of entacapone's short half-life, it is given with each dose of carbidopa/levodopa, and is equally effective as rasagiline in reducing the amount of daily "off" time. For those patients who have "offs" at a specific time of day, entacapone can be strategically given just with the dosage of carbidopa/levodopa that precedes this "off" period. Tolcapone, which can be tried if entacapone fails to provide adequate benefit, is taken three times daily with biweekly monitoring of the patient's liver enzymes. A typical dose of tolcapone is to start with 100 mg tid with an increase to 200 mg tid possible should the need arise. Because tolcapone can increase dyskinesia, using 50 mg tid on initiation of treatment for patients who already have dyskinesia is a more gentle approach. The COMTIs are effective immediately, which is a distinct advantage.

Behavioral or sensory "offs" can also occur as do motor "offs," often in the absence of any motor "off," which means a return of parkinsonism. Behavioral and sensory "offs" tend not to be easily recognized, because visibly the treating physician sees no motor changes. Behavioral/sensory "offs" can consist of pain, akathisia, depression, anxiety, dysphoria, or panic, and usually a mixture of more than one of these. Sensory "offs," like dystonic "offs" are extremely poorly tolerated. It is often the presence of one of these sensory and behavioral phenomena, more so than motoric parkinsonian or dystonic "offs," that drives the patient to take more and more levodopa, turning the patient into a "levodopa junkie."

### Treatment of Levodopa-Induced Dyskinesias

Levodopa-induced dyskinesias are involuntary movements and occur in two major forms—chorea and dystonia. Choreic movements are irregular, purposeless, nonrhythmic, abrupt, rapid, unsustained movements that seem to flow from one body part to another. Dystonic movements are more sustained, twisting contractions. Many patients probably have a combination of chorea and dystonia. Dystonia is a more serious problem than chorea, because it is usually more disabling.

*Peak dose dyskinesias* occur when the plasma concentration of levodopa is at its peak, and the brain concentration of levodopa and dopamine is too high. Reducing the individual dosage can resolve this problem. But the patient may need to take more frequent doses at this lower amount, because reducing the amount of an individual dose also reduces the duration of benefit. More frequent dosing of levodopa tends to lead to delayed "ons" and dose failures eventually. A simple approach is to add amantadine, which suppresses the severity of dyskinesias, possibly because of its antiglutamatergic action. Start with a dose of 100 mg bid and increase up to 200 mg bid if necessary. Another approach is to add or substitute higher doses of a dopamine agonist while lowering the dose of carbidopa/levodopa. Dopamine agonists are less likely to cause dyskinesias, and therefore can usually be used in this situation quite safely. But adding the agonist while

maintaining the levodopa dosage will usually result in an increase of dyskinesias. If lowering the dose of levodopa results in more severe “off” states, then the agonists become more important. Sinemet CR is not helpful, because there is the danger of increased dyskinesias at the end of the day as the blood levels become sustained from frequent dosings of this extended release form of levodopa. Once dyskinesias appear with Sinemet CR, they last for considerable duration of time because of the slow decay in the plasma levels. In some patients, peak-dose chorea and dystonia occur at subtherapeutic doses of levodopa, and lowering the dose will render a patient even more parkinsonian. Such patients are candidates for deep brain stimulation (see below under Surgical Therapy).

*Diphasic dyskinesias* are dyskinesias that occur at the beginning and end of dose, not during the time of peak plasma and brain levels of levodopa. They tend to affect particularly the legs with a mixture of chorea and dystonia. Because the mechanism is unclear, treatment of diphasic dyskinesias is difficult. In this situation one should use a dopamine agonist as the major pharmacologic agent with supplementary levodopa.

“Off” dystonia and painful “off” cramps could be listed in both “dyskinesias” and “fluctuations,” because these dystonias occur when the patient is “off.” Dystonic spasms, therefore, can be either a sign of levodopa overdosage, as in peak-dose dyskinesias, or occur when the plasma level of levodopa is low, such as in early morning before the first dose of levodopa. “Off” dystonia can occur anytime when the patient is “off,” but most commonly in the early morning hours upon awakening and when the last prebedtime dose of levodopa has worn off. Usually, the dystonia manifests as painful foot and toe cramps, which are relieved when the next dose of levodopa begins to take effect. Preventing “offs” is the best way to control these painful dystonias. An effective treatment is to use a dopamine agonist as the major pharmacologic agent with supplementary levodopa. Here the rotigotine dermal patch can be particularly useful, by keeping a steady pharmacokinetic level of active drug throughout the day and night. Baclofen has also been reported to benefit some patients. Bedtime Sinemet CR may be useful to prevent early-morning dystonia, but some patients need to set the alarm early to take a dose of standard carbidopa/levodopa in the middle of the night and then fall back to sleep and awaken at their usual time.

## TREATMENT OF NONMOTOR FEATURES

In addition to PD having motor features, a number of nonmotor problems can also occur as complications from dopaminergic therapy. Mental changes of psychosis, confusion, agitation, hallucinations, paranoid delusions, and excessive sleeping are probably related to activation of dopamine receptors in nonstriatal regions, particularly the cortical and limbic structures. Elderly patients and patients with concomitant dementia are extremely sensitive to small doses of levodopa. But all patients with PD, regardless of age, can develop psychosis if they take excess amounts of levodopa as a means to overcome “off” periods.

If hallucinations are mild and not frightening, treatment can begin with the addition of quetiapine, starting with 25 mg at bedtime. The dose should be increased steadily until the hallucinations are brought under control. If quetiapine is ineffective or if the hallucinations are frightening, clozapine needs to be initiated instead of quetiapine, because clozapine is more effective than quetiapine. The

reason clozapine is not the first drug of choice in dopaminergic-induced hallucinations is because clozapine causes agranulocytosis in approximately 1% to 2% of patients. Patients must have their blood counts monitored weekly for this potential complication, and then discontinue the drug if leukopenia develops. Both quetiapine and clozapine often cause drowsiness, so bedtime dosing is recommended. Quetiapine can cause falling, and clozapine, seizures with high doses. The dosing regimen for clozapine is similar to that for quetiapine. Quetiapine and clozapine are labeled as “atypical antipsychotics,” because they usually do not induce or worsen parkinsonism, and therefore can be used in patients with PD. Of the other antipsychotic drugs, olanzapine ranks next as being “atypical,” but this drug will worsen PD, most atypical are quetiapine and clozapine. All the other antipsychotics, regardless if they had in the past been considered to be “atypical,” actually are not, for they all worsen PD.

If the psychosis is severe or if the patient is in an acute delirious state, hospitalization is necessary, with immediate initiation of high doses of clozapine, and some reduction in anti-PD medication. These medications could even be withdrawn temporarily to overcome the psychosis, but this should be done stepwise over a 3-day period to avoid the neuroleptic-malignant-like syndrome that could occur with sudden withdrawal of levodopa.

If hallucinations are mild and the patient can be treated as an outpatient, and the patient does not respond well or tolerate quetiapine and clozapine, then the physician needs to reduce one or more anti-PD medication. All antiparkinson drugs have the potential to induce psychosis, so the less efficacious drugs should be withdrawn first. Accordingly, COMT inhibitors, MAO-B inhibitors, amantadine, anticholinergics, and dopamine agonists should be withdrawn in that order, reserving levodopa as the most effective agent.

*An altered sleep-wake cycle* of drowsiness during the daytime, particularly after a dose of levodopa, and insomnia at night are fairly common in the elderly and often accompany cognitive decline. If a patient becomes drowsy after each dose of medication, reducing the dose may correct this problem. If the patient is generally drowsy during the daytime and remains awake at night, this makes it difficult for the care provider. It is important to get the patient onto a sleep-wake schedule that fits with the rest of the household. Efforts must be made to stimulate the patient physically and mentally during the daytime and force him/her to remain awake, otherwise he/she would not be able to sleep at night. At night, the patient should then be drowsy enough to be able to sleep. If this fails, it may be necessary to use stimulants in the morning and sedatives at night in order to reverse the altered state. This should be done in addition to prodding the patient to remain awake during the day. Modafinil can sometimes be helpful to overcome daytime drowsiness, and one or two doses in the morning and early afternoon can be employed. Drugs such as methylphenidate and amphetamine are usually also well tolerated by patients with PD, and can be considered if modafinil fails. A 10-mg dose of either of these two drugs, repeated once if necessary, may be helpful. To encourage sleep at night, a hypnotic may be necessary in addition to using daytime stimulants. It should be noted that strong sedatives, such as barbiturates, are poorly tolerated by patients with PD. Milder hypnotics, such as benzodiazepines and zolpidem, are usually taken without difficulty. Taking advantage of the soporific effects of quetiapine, clozapine, mirtazapine, and amitriptyline is a good strategy if a patient can also benefit from their other actions of antipsychotic or antidepressant.

*Orthostatic hypotension* can be caused by levodopa, dopamine agonists, and other drugs taken by the patient, such as tricyclic antidepressants. These other drugs should be discontinued. If orthostatic hypotension remains, it can sometimes be managed by using support stockings, NaCl, midodrine (ProAmatine), and fludrocortisone (Florinef), but often the dose of levodopa needs to be reduced.

*Constipation* is common in PD. It may be further aggravated by anticholinergics. Besides changing dietary habits by increasing intake of more fiber and dried fruits, polypropylene glycol (Mira-Lax) can be effective. For those who have bloating because of suppression of peristalsis when they are "off", keeping them "on" with levodopa is beneficial.

*Depression* is a common nonmotor symptom in PD, probably related to the reduction of all brain monoamines in this disease. Depression must be treated, not only for its own sake, but because its presence interferes with a good response to antiparkinson drugs. It often responds to selective serotonin reuptake inhibitors, such as fluoxetine, sertraline, and paroxetine, and those agents like nefazodone and venlafaxine that inhibit both serotonin and norepinephrine. It is not clear if any antidepressant is superior to any other, including the tricyclic antidepressants, such as amitriptyline, nortriptyline, and protriptyline. Because of its anticholinergic and soporific effects, amitriptyline can be useful for these properties as well as for its antidepressant effect. Protriptyline, on the other hand, has no anticholinergic effect and can be useful when this property is not needed. Electroconvulsive therapy can be effective in patients with severe, intractable depression, and it can sometimes transiently improve the motor symptoms of PD as well.

*Impulse control problems* have emerged in the last few years as a complication of dopamine agonists that had not been recognized previously. These consist of behavioral changes such as compulsive gambling, shopping, and eating, and hypersexual desire. Although infrequent, these can be serious problems. So far, the only remedy has been to reduce the dose of the dopamine agonists or stop them altogether.

## SURGICAL THERAPY

Surgery for PD is becoming increasingly available as deep brain stimulation has evolved along with a better understanding of basal ganglia physiology. Stereotaxic DBS has replaced the older technique of lesioning in the brain, because the latter is more risky for inducing permanent neurological deficits. With DBS, the parameters of stimulation, such as voltage and frequency, can be adjusted, and the electrodes could be removed if required. However, DBS is more costly, and frequent adjustments of the stimulators are usually needed. The location of the stereotaxic target is a major factor that needs to be individualized for each patient. The subthalamic nucleus (STN) is the favored target, because this reduces bradykinesia and

tremor, allowing for a reduction of levodopa dosage, thus reducing the severity of dyskinesias as well. The internal segment of the globus pallidus is a more satisfactory target for controlling choreic and dystonic dyskinesias, which in turn would allow a higher dose of levodopa to be used to control the major symptoms of PD. The thalamus, particularly the ventral intermediate nucleus, is the target most successful for controlling tremor, but this target does not eliminate bradykinesia as well as the STN does, so the thalamus is not a preferred choice today. Surgical procedures for patients with PD are best performed at specialty centers with an experienced team of a neurosurgeon, neurophysiologist to monitor the target during the operative procedure, and neurologist to program the stimulators. The patient needs close follow-up to adjust the stimulator settings to their optimum. Patients with cognitive decline should not have DBS, because cognition can be further impaired. Also, intractable symptoms of freezing of gait, loss of postural reflexes, and falling are not benefited. The major benefits of STN stimulation are those symptoms that respond to levodopa. Adverse effects include surgical complications, mechanical problems with the stimulator and leads to the electrodes, infections attacking any of the inserted hardware, and neurologic and behavioral changes. The latter include troubles with speech, dystonic postures, depression, suicide attempts, and cognitive decline. The best candidates are younger patients who can tolerate the penetration of the brain and who have uncontrollable motor fluctuations and dyskinesias.

# Other Neurodegenerative Disorders

Victor Valcour ■ Bruce Miller

Alzheimer's disease (AD) is the most common neurodegenerative disorder encountered by the practicing geriatrician. However, a sizable number of other neurodegenerative diseases will be seen in a typical practice, rendering a working knowledge of these disorders critical for practicing clinicians. This chapter provides an overview of the more common neurodegenerative disorders with emphasis on those that influence behavior and cognition early in the course. We begin by reviewing the clinical approach to neurodegenerative cognitive disorders and then review the clinical presentation, epidemiology, and examination findings of the more common neurodegenerative syndromes. We attempt to link clinical presentation to anatomy and neuropathology whenever possible.

## APPROACH TO THE EVALUATION OF COGNITIVE AND BEHAVIORAL DISORDERS IN ADULTS

The evaluation of neurodegenerative disorders is multifaceted, requiring careful attention to the cognitive, behavioral, and motor history combined with a comprehensive neurological examination aiming to identify the brain regions involved. Isolating anatomy in patients who present with slowly progressive neurodegenerative disorders greatly facilitates the determination of the correct diagnosis.

Emphasis should be placed on the earliest presenting symptoms, whether cognitive, behavioral, or motor in origin. These early features may be critical to the identification of the pathological substrate. As diseases progress, signs and symptoms merge between the different disorders, making diagnosis more difficult. An early history of repeated falls, for example, should warrant concern for progressive supranuclear palsy (PSP) or vascular dementia; although most dementias are associated with basal ganglia involvement later in their disease course, diminishing the value of falls for diagnosis. Likewise, inappropriate behavior and disinhibition are commonly seen in patients with advanced dementia syndromes regardless of disease etiology. However, when these findings are a prominent presenting

feature in the relative absence of amnesic symptoms, frontotemporal dementia (FTD) should be considered more likely.

Cognitive histories should be comprehensive, and must include evaluation of memory, language, visuospatial function, executive functioning, and attention (Table 67-1). The comprehensive history should probe for autonomic symptoms and sleep patterns, with emphasis on symptoms associated with disorders of rapid eye movement (REM) sleep behavior and sleep apneas.

The assessment of behavioral symptoms can be particularly helpful and sometimes critical in non-Alzheimer's neurodegenerative disorders. FTD is the most common cause of dementia in patients younger than the age of 60 years. Behavioral symptoms or personality change are commonly the presenting symptoms of this disorder (see Table 67-4 and discussion later in this chapter). When evaluating for change in personality, the clinician should gain an understanding of premorbid character. The emergence of predominant behavior and personality changes in the absence of episodic memory and perceptual complaints localizes disease to the frontal or anterior temporal lobes.

The neurological examination is a critical component to the assessment of neurodegenerative disorders and typically confirms the clinical impression obtained from the history. The motor examination identifies both pyramidal and extrapyramidal signs as well as features characteristic of FTD, dementia with Lewy bodies (DLB), corticobasal degeneration (CBD), and PSP. Examination of cranial nerves includes an assessment of eye movements and range of gaze. Abnormalities in vertical gaze with a preserved oculocephalic reflex are a characteristic finding in PSP while horizontal gaze abnormalities are more typical of CBD. Abnormalities in saccadic eye movements can be seen in a number of neurodegenerative disorders. Saccadic movements are tested by asking the patient to focus on an object in front of them (such as a pen tip held by the examiner) then to quickly refocus on an item in their peripheral field (such as the examiner's finger) while the examiner watches carefully for saccadic latency (delay in initiation of movement), incomplete saccades (gaze

**TABLE 67-1****Assessment of Major Cognitive Domains in Neurodegenerative Disorders**

<i>Memory:</i> repetitive statements, misplacing items, missed appointment or medications, recalling recent/remote events
<i>Language:</i> speech fluency, comprehension, reading, writing, articulation, word-finding, content of speech, output, spelling
<i>Visuospatial:</i> getting lost, driving, object perception, completing household repairs, parking
<i>Executive:</i> planning, flexibility/rigidity in thinking, organization, multistep tasks
<i>Motor:</i> gait, falls, tremor, dysphagia, weakness, handwriting, coordination
<i>Autonomic:</i> light-headedness, bowel/bladder function, impotence, hypotension

palsy), and interrupted/jerky saccadic movement. Saccades should be tested in all four directions. Ocular pursuit is tested by having the patient track an object, such as the examiner's finger, in both horizontal and vertical directions.

The combination of cognitive history, behavioral history, and neurological examination, with emphasis on earliest symptoms should sufficiently narrow the diagnosis to few neurodegenerative disorders, and in many cases, identify one highly suggested disease. Confirmatory imaging and laboratory work, and standard laboratory tests to exclude treatable etiologies of cognitive impairment can then be completed (Table 67-2).

## DISORDERS ASSOCIATED WITH ALPHA-SYNUCLEIN DEPOSITION

### Dementia with Lewy Bodies

The precise role of alpha-synuclein in health and disease is not fully understood. High concentrations of alpha-synuclein in synaptic regions suggest a role in synaptic plasticity. In DLB, alpha-synuclein accumulates with the brain stem, basal ganglia, and cortex, resulting in a progressive neurodegenerative cognitive and motor disorder. The prevalence of DLB is still uncertain and the coassociation of Lewy body and AD pathology is extremely common in aging dementia populations. Indeed, even with classical AD associated with

Thyroid function

apolipoprotein E4 genotype, more than 50% of subjects show Lewy bodies and genetic disorders that predispose to Lewy bodies often show the coassociation of A $\beta$ -42. Based on autopsy studies, DLB is widely underdiagnosed.

The reported mean onset of disease is 75 years of age with a range from 50 to 80 years and a slight predominance of DLB in men compared to women. The clinical and pathological overlap between DLB and AD and with Parkinson disease dementia (PDD) is well-recognized, resulting in some diagnostic challenges. Accurate diagnosis has clinical implications as patients with DLB compared to AD tend to have more favorable responses to cholinesterase inhibitors and patients with DLB often have sensitivity to neuroleptic medications.

The characteristic features of DLB are cognitive impairment with profound fluctuation, spontaneous Parkinsonism, and visual hallucinations that are often complex. The typical neuropsychological profile differs somewhat from that of AD. DLB often involves greater parietal-occipital lobe deficits and lesser medial temporal lobe deficits. This manifests in testing as better performance on episodic memory tasks, and recognition memory when compared to AD patients. Invariably, memory becomes impaired over time. Combined cortical and subcortical deficits are common and deficits in attention are a core feature of the disease.

The degree of cognitive fluctuation can be so profound as to effect MMSE scores up to 50% from day-to-day. However, eliciting a history of fluctuation can be difficult and is inconsistently reported by caregivers. Clinicians should consider several different approaches, including questions focused on marked alteration in attention, staring spells, daytime sleepiness, and episodes of incoherent speech. On occasion, the fluctuation can be so severe as to result in emergency room evaluation for a transient ischemic attack (TIA) or delirium. Several structured scales exist to assist in assessment of fluctuation, including the One Day Fluctuation Assessment Scale and the Clinical Assessment of Fluctuation.

A common feature of neurodegenerative disorders with alpha-synuclein pathology is REM sleep behavior disorder (RBD) defined as vivid and often frightening dreams that are frequently acted out verbally or motorically. RBD occurs in 85% of DLB cases, compared to 15% of Parkinson disease patients and 60% of patients with multiple system atrophy (MSA). In the DLB diagnostic criteria, RBD is considered a suggestive feature. Autonomic dysfunction is also common and can be profound. When REM behavior occurs in association with severe autonomic symptoms, MSA rather than DLB should be considered. Unexplained loss of consciousness is another supportive feature of DLB and significant depressive symptoms occur in up to 40% of cases.

About two-thirds of DLB cases will exhibit visual hallucinations, misperceptions or, less frequently, delusional misidentification. When delusional misidentification, such as mistaking the spouse, friend, or relative as an impostor, occurs as the first symptoms of a dementia, DLB is highly likely. The visual hallucinations of DLB can be vivid, with distinct colors and the inclusion of human figures and animals. In contrast to the hallucinations sometimes seen with more advanced AD, visual hallucinations occur early in DLB. In one pathology-based study, visual hallucinations corresponded to a greater number of Lewy bodies in the anterior/inferior temporal lobes and to larger deficits in acetylcholine. Visual hallucinations often respond to boosting brain acetylcholine with cholinesterase inhibitors.

Spontaneous Parkinsonism is a hallmark feature of DLB, occurring in up to 70% of cases. Common findings include bradykinesia, axial greater than appendicular rigidity, postural instability, slowed response times, and hypomimia. In contrast to Parkinson's disease, the Parkinsonism of DLB is typically bilateral and less frequently includes tremor. Parkinsonism rarely occurs in isolation as an early finding in DLB although early features of the cognitive syndrome are commonly overlooked. Response to levodopa treatment is less frequent than the response seen in Parkinson disease; however, efficacy data may be biased. Clinicians are more likely to avoid such drugs in DLB patients for fear of adverse effects or aggravations of hallucinations.

Parkinsonism contributes substantially to the disability in DLB and alters the clinical course. Mean survival among postmortem confirmed cases of DLB is 10 years, with a rate of disability at approximately 10% per year, often exceeding that of Parkinson's disease. Cases of rapid progression to death in 1 to 2 years have been described. Risk factors for higher mortality include older age, hallucinations, greater degrees of fluctuation, and neuroleptic sensitivity.

Diagnostic criteria for DLB assist in identification of disease and are particularly useful for research purposes (Table 67-3). In the revised schema, core features include prominent fluctuation, recurrent visual hallucinations, and spontaneous features of Parkinsonism such as rigidity, bradykinesia, and hypomimia. Supportive and suggestive features are also defined. To meet diagnostic criteria for probable disease, two core features or the combination of one core feature and one supportive feature are required. If suggestive features are present in the absence of core features, the term possible DLB is used.

The pathological hallmark of DLB is the presence of neuronal spherical intracytoplasmic inclusions of alpha synuclein, termed Lewy bodies (Figure 67-1). The Lewy bodies seen in DLB are very similar in appearance to those that are seen in Parkinson's disease; however in DLB, the distribution extends beyond the substantia

**TABLE 67-3****McKeith Criteria for DLB\****Central features*

- Progressive cognitive decline with functional impairment
- Prominent memory impairment may not occur early but is usually evident with progression
- Deficits in attention, executive functioning, and visuospatial ability may be prominent early

*Core features*

- Fluctuating cognition with prominent variations in attention and alertness
- Recurrent visual hallucinations
- Spontaneous parkinsonism

*Suggestive features*

- REM sleep behavior disorder
- Neuroleptic sensitivity
- Low dopamine transporter uptake in the basal ganglia (SPECT, PET)

*Supportive features*

- Repeated falls
- Transient, unexplained loss of consciousness
- Severe autonomic dysfunction
- Systematized delusions
- Depression
- Hallucinations in nonvisual modalities
- Relative preservation of medial temporal lobe structures on CT/MRI
- Generalized low uptake on SPECT/PET with reduced occipital activity
- Abnormal MIBG scintigraphy
- Prominent slow wave activity on EEG with temporal lobe transient sharp waves

\*Probable DLB requires two core features or one core feature and at least one suggestive feature. Possible DLB requires one or more suggestive features. Probable DLB should not be based on suggestive features alone. MIBG (metaiodobenzyl guanidine scintigraphy).

Adapted from McKeith IG, Dickson DW, Lowe J, et al. *Diagnosis and management of dementia with Lewy bodies: third report of the DLB Consortium. Neurology.* 65(12):1863–1872, 2005.

**FIGURE 67-1.** Lewy bodies (LB) seen with hematoxylin and eosin staining (left) and alpha-synuclein staining (right).

nigra and locus coeruleus to involve the neocortex and limbic system. Cortical Lewy bodies lack the typical dense core with pale halo appearance that is seen in Parkinson's disease. Other intraneuronal aggregates of alpha-synuclein (Lewy neurites), cortical senile plaques, sparse tau pathology, and spongiform change are all described in DLB. MSA is the third neurodegenerative disease with prominent alpha-synuclein pathology.

Currently, imaging studies do not add substantially to differentiating DLB from other neurodegenerative disorders and are only included as supportive in diagnostic criteria. Structural MRI often identifies less atrophy of the medial temporal lobes in cohorts of DLB compared to AD and variably identifies greater atrophy in the basal ganglia structures and the dorsal midbrain. In group studies, single photon emission computed tomography (SPECT) with  $^{99m}\text{Tc}$ -hexamethylpropyleneamine oxime (HMPAO) tends to show decreased regional cortical brain activity in parietal-occipital regions of DLB compared to AD patients. DLB patients exhibit decreased dopamine transport in the putamen and caudate by dopaminergic SPECT and decreased postganglionic sympathetic cardiac innervation by I-metaiodobenzyl guanidine (MIBG) SPECT imaging. However, the modest performance characteristics of these tests limit their clinical utility.

The clinical course of DLB is often faster than that seen in AD and a drop of 4 to 5 points on MMSE per year is not unusual. Patients with DLB should be treated with cholinesterase inhibitors. Often this results in responses that exceed those seen in AD. Social stimulation and physical exercise to maximize balance and strength should be recommended. Symptomatic treatment with levodopa can be used, if indicated for Parkinsonian symptoms. Patients should be advised to avoid anticholinergic medications, including many common over-the-counter cold remedies. RBD, if severe, can be treated with clonazepam. Atypical neuroleptic medications should be cautiously considered only if intolerable behavioral disturbances emerge.

### Parkinson's Disease Dementia

The temporal relationship between the onset of dementia and the development of Parkinsonism is the primary clinical feature distinguishing DLB from Parkinson's disease dementia (PDD). In PDD, cognitive deterioration occurs in well-established Parkinson disease, typically a decade after motor systems are identified. In contrast, research criteria for DLB require cognitive symptoms that predate Parkinsonism by 12 months; although this "1 year rule" is often difficult to apply in the clinical setting. This temporal distinction is debatably arbitrary as many believe the two disorders represent different points in the spectrum of the same disease and abnormalities in alpha-synuclein accumulation underlie both disorders.

Approximately one-third of older Parkinson's disease patients will develop sufficient cognitive symptoms during the course of their illness to impair function. In pure PDD, the prominent findings include motor and psychomotor slowing, decreased response times, and alterations in concentration and attention. The recognition that medications used to treat Parkinson's disease can affect cognition and the understanding that, as a result of age, a substantial number of Parkinson's patients will develop concurrent AD results in a scenario where cognitive symptoms in this population can be multifactorial. Possible predictors for dementia in Parkinson disease include older

age at onset of motor symptoms, bradykinesia, nontremor prominent PD, bilateral onset of motor signs, and declining response to levodopa. Depression and visual hallucinations may increase risk as well. Patients with DLB typically exhibit a faster clinical decline than do patients with PDD.

### Multiple System Atrophy

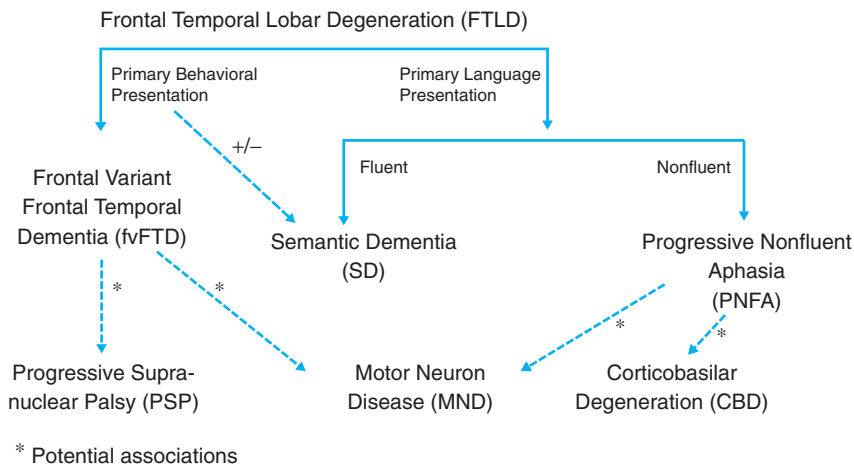

MSA is a sporadic disease marked by degeneration of multiple neurological systems and resulting in relentlessly progressive clinical course. Death typically occurs within 6 to 10 years with an estimated 10-year survival of 40%. Relatively infrequent, the incidence is estimated to be 0.6/100 000 person-years or between 1.86 and 4.9 per 100 000 population. The incidence increases to 6/100 000 person-years among patients older than 50 years of age. The mean age of onset is 54 years. While currently speculated to have a combination of environmental and genetic predispositions, neither has been definitively established. Epidemiological studies suggest a potential risk associated with exposure to pesticides. MSA is about three times more frequent in men than women and limited epidemiological data suggest that it may be less frequent among smokers.

The term MSA was first used in 1969 and encompasses diseases previously labeled as striatonigral degeneration (now termed MSA-P for Parkinsonism), Shy-Drager syndrome, and olivopontocerebellar degeneration (now termed MSA-C for cerebellar). The MSA subtypes are indicative of the predominant neurological component involved. Patients with prominent orthostatic features tend to have decreased survival. Several derivations of diagnostic consensus statements exist with mixed sensitivity.

The presenting symptoms of MSA are variable and include cerebellar findings, autonomic failure, pyramidal findings, and Parkinsonism. Parkinsonism (MSA-P) is prominent in the majority of cases (80%) with cerebellar symptoms (MSA-C) more prominent in about 20% of cases. The more common presenting Parkinsonian features are akinesia, rigidity, and postural (rather than rest) tremor. Autonomic symptoms precede motor symptoms in most cases. Gait instability is common; but falls occur less frequently in early stages than in PSP. In early stages, MSA can mimic Parkinson's disease but more symptoms evolve within 5 years. Gait ataxia, limb kinetic ataxia, and dysarthria are the more frequent presenting symptoms in patients with cerebellar-dominant MSA. The dysarthria caused by cerebellar dysfunction has a characteristic appearance of jerky, intermittently explosive, and slurred output often associated with poor separation of syllables.

Autonomic symptoms include orthostasis, erectile dysfunction, constipation, and urinary incontinence. While orthostasis is common, syncope occurs infrequently. Diagnostic criteria for the orthostatic component of MSA require a 30 mm Hg drop in systolic blood pressure; although in practice, a 20 mm Hg drop in systolic blood pressure or 10 mm Hg drop in diastolic blood pressure is thought to be significant in the absence of appropriate increased heart rate. Occurrence of symptoms suggestive of MSA in an individual younger than 30 years of age or in an individual with a family history of similar disease should raise suspicion for alternative diagnoses.

Most MSA patients complain of sleep problems, commonly sleep fragmentation (53%), early waking (33%), and insomnia (20%). As with other synucleinopathies, RBD is common, occurring in up to 60% of MSA patients. Nocturnal stridor and obstructive sleep

**FIGURE 67-2.** Frontotemporal lobar degeneration and potential associations to other neurodegenerative syndromes.

apnea are also frequent in MSA. Stridor is associated with decreased survival and risk of sudden death.

Brain MRI changes occur in some patients but lack sensitivity and specificity for definitive diagnosis. These findings include hypointensity and atrophy of the putamen on T2-weighted images with a slit-like marginal hypointensity just lateral to the putamen on axial images. A characteristic “hot cross bun” sign has been described in the pons and middle cerebral peduncles thought to be caused by degenerative changes in pontocerebellar fibers. This finding lacks sensitivity and is sometimes seen in Parkinson’s disease limiting specificity. Atrophy of the brainstem, middle cerebellar peduncles, and cerebellum may also be seen. Volumetric analyses of the striatum and brainstem where atrophy is very severe in MSA-P but not simple Parkinson’s disease demonstrate some promise in discriminating these two disorders. Electromyography (EMG) abnormalities at the anal sphincter can be seen in MSA; although the clinical utility for distinguishing MSA from Parkinson’s disease in early stages of disease has not been established.

The hallmark pathology of MSA is cell loss, gliosis, and glial inclusions in multiple neurological systems including the spinal cord and cortex. Prominent abnormalities are also seen in the basal ganglia, substantia nigra, and olivopontocerebellar pathways, as suggested by the terminology, with anatomy reflecting symptoms. On gross inspection, the putamen is shrunken and displays a green-grey discoloration that can appear cribiform when disease is severe. As with DLB and PD, there is an accumulation of alpha-synuclein as half-moon-, oval-, or conical-shaped argyrophilic glial cytoplasmic inclusions.

Treatment is generally symptomatic with about one-third of patients responding to levodopa in the early stages of the disease. Patients should be encouraged to sleep in a lateral decubitus rather than supine position to minimize airway obstruction. Use of positive airway pressure devices should be considered. Invasive means of controlling stridor and apneas have included tracheotomy, but should be approached cautiously within the full context of ethical and quality of life considerations. RBD may respond to low-dose clonazepam at night. Labile blood pressures may develop and should raise concern when symptomatic. Avoiding alcohol, heaving meals, or straining at micturition and defecation is recommended. Elastic stockings and elevating the head of the bed may provide some relief. Pharmacological approaches designed to increase sympathetic

tone (midodrine) or volume expansion (fludrocortisone) may be required. Patients with MSA-C tend to maintain function for a longer period of time than those with MSA-P.

## NEURODEGENERATIVE DISORDERS ASSOCIATED WITH TAU, PROGRANULIN, OR TDP-43 PATHOLOGY

### Frontotemporal Lobar Degeneration Syndromes

Frontotemporal lobar degeneration (FTLD) includes the clinical syndromes of frontal variant FTD (FTD), progressive nonfluent aphasia (PNFA), and semantic dementia (SD). Recent evidence indicates that FTLD is closely related to several other neurodegenerative disorders: CBD, PSP, and motor neuron disease (Figure 67-2).

The core anatomical feature of FTLD is the focal, often asymmetric cortical degeneration of frontal and anterior temporal regions with general sparing of posterior cortical structures. The resultant brain atrophy can be severe, sometimes described as “knife-edge” and the brain can weigh as low as 750 g (Figure 67-3). Patients present with a primary behavioral or language deficit that typically corresponds to the region of greatest brain atrophy and dysfunction. Patients presenting with primary behavioral deficits most commonly

**FIGURE 67-3.** T2-weighted axial (right) and T1-weighted coronal (left) brain MRI in a 59 yr-old woman with pathology-confirmed Pick’s disease.

have frontal variant FTLT (FTD). This can overlap considerably with the two syndromes that present with predominant language deficits, PNFA, and semantic dementia (SD), with the greatest degree of overlap seen with SD. FTD and SD each encompass about 40% of the FTLT syndromes. The neuropathological basis for approximately one-half of these diseases is the abnormal accumulation of tau protein. Recent scientific advances have identified abnormalities in the manufacture of progranulin and TDP-43 protein and are likely to clarify the pathology in the vast majority of non-Tau cases.

Many FTLT patients are misdiagnosed as having AD during life. In addition to changes in personality and behavior, features that should alert physicians to the possibility of FTLT include early abnormalities in social conduct, loss of sympathy and empathy for others, repetitive motor behaviors, or hyperorality. When cognitive testing is completed, suspicion should be raised when abnormalities in executive functioning occur in the absence of prominent amnesic complaints or cognitive features localizing to posterior structures, such as problems with calculations and visuospatial tasks. FTLT is the most common form of dementia, in patients younger than 60 years of age.

Patients who present with isolated language symptoms that exist for at least 2 years in the initial stages of cognitive decline are termed to have primary progressive aphasia (PPA). As a group, patients with PPA have left greater than right atrophy of the perisylvian region, the anterior temporal lobes, and the basal ganglia. Inferior parietal lobule atrophy has also been described. When carefully dissected based on anatomic, symptomatic, and linguistic parameters, it is evident that PPA may be the presenting syndrome of a number of diseases, most frequently PNFA, SD, and a logopenic variant of AD. As the syndrome progresses, patients presenting with PNFA may also develop CBD or PSP and less commonly amyotrophic lateral sclerosis (ALS). Thus, careful attention to the development of motor symptoms is necessary. The emergence of artistic behavior has been described in some patients with primary language difficulty.

Efforts to distinguish various PPA syndromes from each other may have clinical ramifications. Based on apolipoprotein epsilon 4 expression in clinical studies, it appears likely that the logopenic variety of PPA is a language presentation of AD; although pathological confirmation of this correlation is lacking. As the term implies, these patients have decreased speech output. They typically have slow speech with impaired syntactic comprehension and naming. The logopenic variety is associated with short-term phonological memory deficits. These patients exhibit profound echoic memory deficits manifested as forgetting portions of longer phrases during repetition tasks. As pathological studies become available, if confirmed to be AD in etiology, these patients may be amenable to treatment with cholinesterase inhibitors or emerging amyloid-directed treatment strategies.

### Progressive Nonfluent Aphasia

Patients with progressive nonfluent aphasia (PNFA) typically have apraxic, labored speech with errors in grammar, and difficulty with more complex syntax. Speech apraxia is the inability to produce speech caused by difficulty in programming the sensorimotor commands for the positioning and movement of muscles used to produce speech. This leads to difficulty with initiation of speech, sound sub-

stitutions, omissions, transpositions of syllables, and a slower rate of expressing sentences punctuated with inappropriate starts and stops. The errors produced in apraxic speech are typically inconsistent. Patients may display difficulty with articulating multisyllabic words. Speech apraxia is localized to the left anterior insular region.

Anomia is variably present and phonemic paraphasias are frequently observed. Speech output is decreased and dropped words, often articles such as “the” occur. In patients with PNFA, sentences tend to be richer for nouns than verbs. In contrast to patients with SD, these patients maintain single word comprehension and semantic knowledge. Thus, PNFA would be considered less likely in a patient who has preserved articulation, preserved grammar, and who displays deficits in semantic knowledge. Insight into the condition can be exquisitely preserved with PNFA and patients often develop depression. Behavioral problems are uncommon in early stages of disease.

The evaluation of brain MRIs in 11 patients with PNFA using voxel-based morphometry (VBM) identified regions of atrophy that are typically asymmetrically left-dominant with preferential involvement of the inferior frontal lobe, the insular region, and the caudate. Hypometabolism of the left frontal region can be observed on FDG positron emission tomography (PET).

### Semantic Dementia

In contrast to patients with PNFA, patients with SD have fluent speech that is grammatically accurate; but they exhibit the hallmark loss of semantic knowledge. Semantic memory is encyclopedic knowledge of people, objects, facts, and words. Unlike episodic memory, these types of memories are not linked to time or space. Thus, these patients typically do not remember where or when they learned these facts. Eventually individuals lose all knowledge about the fact or word and exhibit features of a multimodality agnosia. Therefore, even when they are provided with the name of the object, the object is not recognized. Early in the disease patients are often aware of word-finding difficulties, but are unaware of comprehension difficulties. Semantic paraphasias are frequent, with supraordinate substitutions of words and common use of nonspecific grouping words such as “stuff” and “things.” Repetition and prosody are preserved as is syntax and verb recognition.

Patients with SD also display surface dyslexia manifest by difficulty pronouncing irregularly spelled words, such as “gnat,” “heir,” or “pint,” when pronunciation does not follow standard phonological rules. On neuropsychological testing, patients with SD have difficulty with category fluency and confrontational naming, particularly with low-frequency words. Often, SD patients have difficulty naming famous people. In contrast to AD, many SD patients have greater deficits for remote compared to recent memory, when memory deficits become involved.

Of all the PPA syndromes, SD has the greatest propensity to include behavioral problems, which are included as supportive evidence in diagnostic criteria. As with FTD, the behavioral issues seen with SD often involve hyperorality, disinhibition, and aberrant motor behavior. Diagnostic criteria include behaviors such as loss of sympathy and empathy, narrowed preoccupations, and parsimony (excessive frugality, stinginess). Rigidity in thinking can be striking. SD patients can develop compulsions and have been described to have visual hypervigilance, such as recognizing a subtle hair out of

place on an examiner or a coin on the street. They may exhibit difficulty in the interpretation of emotions, particularly negative emotions such as sadness, anger, and fear. Emergence of behavioral symptoms correlates with duration of illness, but can also be an early finding. The presence of early behavioral issues in a patient with a PPA syndrome should alert to the possibility of SD.

Anatomic studies may explain why SD patients often exhibit behavioral abnormalities. While SD usually begins in the anterior left temporal lobe, it typically spreads anteriorly to involve the frontal regions. Eventually it spreads to the right medial frontal lobe, the right orbitofrontal lobes, and the right insular region, areas associated with behaviors such as disinhibition and apathy. The absence of behavioral problems in the logopenic variety of PPA and in PNFA may be caused by the general sparing of these same structures in those diseases.

Patients with SD often have ubiquitin-positive, tau-negative inclusions at autopsy. Up to one-third of the patients will also have amyloid plaques. In one small series, the presence of plaques was associated with the absence of behavioral symptoms. The existing overlap in neuropathologies may be because of a lack of sensitivity in our diagnostic acumen, whereby some patients with PPA syndromes have AD.

### Frontal Variant Frontotemporal Dementia

FTD presents with the insidious onset of change in personality and inappropriate behaviors. The mean age of onset is in the mid-fifties. Most commonly, symptoms include disinhibition, poor impulse control, loss of sympathy or empathy for others, and socially inappropriate behaviors (Table 67-4). Patients can develop stereotyped behaviors, defined as repetitive, invariant behaviors that lack purpose. Examples include counting, pacing, organizing, or the repetitive use of catch phrases. Socially inappropriate activities can include shoplifting and other criminal behavior, public urination, offensive

speech, and public masturbation. Perseveration is common. Cravings for sweets are often observed. When associated with the decreased sense of satiety that can occur, large and unhealthy amounts of weight gain result. Hyperorality and oral exploratory behavior can occur.

Patients with FTD are often misdiagnosed as having psychiatric illness. Delusions can occur, often with bizarre or grandiose overtones. Patients exhibit lack of empathy and can have a cold, blunted affect. When the anterior cingulate and medial frontal lobes are involved, apathy can be particularly prominent. Some patients undergo large changes in their beliefs and attitudes, including religious sentiments. In contrast to AD, depression is uncommon in FTD.

Neuropsychological testing demonstrates abnormalities in executive functioning and working memory with general sparing of visuospatial skills and verbal memory. Consequently, the MMSE score can be quite high even among patients with marked functional disability. FTD patients also display problems with set-shifting, concept formation, and abstract reasoning. They may demonstrate disinhibition, impulsivity, and poor judgment during testing. These behaviors can falsely lower verbal memory scores. When closely scrutinized, poor scores on such tests are accompanied by frequent intrusions of novel words and endorsement words that were not part of the original list learned (false positives on recognition testing).

Behavioral symptoms are a common late finding in most dementia syndromes. Thus the emergence of behavior and personality symptoms in a patient with well-established dementia should be looked upon with caution when considering a change in diagnosis to FTD. The importance of first symptom (often the presenting symptom) in the evaluation of patients with neurodegenerative disorders cannot be overstated.

Patients with FTD will typically have profound, usually bilateral, frontal lobe atrophy, with symptom presentation that matches anatomy. Thus, patients with right greater than left frontal atrophy have more severe behavioral symptoms. Stages of atrophy have been described with the earliest stage involving only mild atrophy of the orbital and superior medial frontal lobes and hippocampus. As disease progresses, the anterior frontal and temporal cortices and basal ganglia are increasingly involved. The severity of atrophy increases as disease advances. SPECT and FDG PET techniques have been used to differentiate FTD from AD with PET receiving Food and Drug Administration (FDA) approval for this indication. Both SPECT and FDG PET demonstrate bilateral frontal hypometabolism/perfusion in patients with FTD.

### Pick's Disease

Pick's disease is a pathologic diagnosis and occurs in the minority of clinical cases presenting with signs and symptoms of FTLD. First described in 1892 by a German neurologist, Arnold Pick, the pathological hallmark of Pick's disease are argyrophilic cellular inclusions known as Pick bodies and swollen achromatic neurons termed Pick cells. This is invariably associated with loss of large pyramidal neurons, resulting in a spongiform histological appearance with selective atrophy of the frontal and anterior temporal lobes. Pick bodies are localized to the limbic cortex, paralimbic cortex, and predominantly the ventral aspect of the temporal lobe. The pre- and postcentral gyri are notably spared. The largest concentration of Pick bodies is found in the hippocampus and amygdala. Pick bodies are composed

**TABLE 67-4**

#### Behavior Symptoms Seen in Frontal Variant FTD

Antisocial behavior
Apathy
Change in beliefs (hyperreligiosity, change in attitude)
Cravings (sweets, weight gain)
Criminal behavior (theft, assault, public urination)
Delusions
Disinhibition
Euphoria (inappropriate jocularity)
Hyperorality (oral exploratory behavior in late disease)
Hypersexuality (offensive statements, masturbation)
Impotence and decreased sexual drive
Impulsivity
Loss of empathy (coldness, self-centered)
Obsessive-compulsive behavior
Perseverative behavior
Poor insight
Stereotyped behavior (counting, pacing, repetitive use of catch phrases)

of randomly arranged tau filaments. In AD, tau pathology (neurofibrillary tangles) can spare the dentate gyrus; however, in Pick's disease, this region is heavily involved.

### Other FTLD Neuropathologies

FTLD is associated with tau pathology in about half of cases. The tau gene product has six isoforms, half of which result in three microtubule binding repeats (3Rt) and the other half result in four microtubule repeats (4Rt). Pick's disease is usually associated with 3Rt although there is great variability. PSP and CBD, in contrast, are associated with 4Rt. The clinical features and neuropathology of PSP and CBD are described later in this chapter.

Among FTLD cases that do not stain for tau protein, the histopathology will typically indicate a variable pattern of neuronal loss and gliosis without characteristic features such as neurofibrillary tangles or Pick bodies. Historically, the term dementia lacking distinctive histology (DLDH) has been employed; however, new discoveries led to the reclassification of many such cases to FTLD-U (ubiquitin) and it remains unclear if the DLDH diagnostic classification will be archived. FTLD-U may account for over 50% of all nontau FTLD cases. In these cases, neuronal inclusion bodies with prominent ubiquitin staining are seen in the absence of other characteristic features. These inclusion bodies stain negative for tau and are localized throughout the neocortex and within anterior horn cells. This pathology has been identified in patients with and without concurrent motor neuron disease.

A number of proteins have been identified within the ubiquitin inclusions of FTLD-U including neurofilament, p62, HSP70, and, most recently, the TAR DNA-binding protein (TDP)-43. It is estimated that TDP-43 captures up to 50% of the cases previously categorized as DLDH. Additionally, there is overlap between FTLD and hippocampal sclerosis. In a series published from the Mayo clinic, 70% of patients with hippocampal sclerosis showed FTD pathology.

Our understanding of the genetics of FTLD is evolving. Early research revealed a mutation in the microtubule-associated protein tau (MAPT) found in patients with a familial form of FTD associated with Parkinson's disease (FTDP-17). Recently, a mutation in the progranulin (PRGN) gene (close to the tau gene) was identified and four differing classes of mutation have since been described. This mutation appears to account for up to 11% of sporadic and 25% of familial FTD cases. To date, the pathological characterization of this mutation and the clinical phenotype remain incompletely described. In one series of two families, the onset of disease ranged from 35 to 75 years and the clinical findings were variable, including language impairment, behavioral changes, or Parkinsonism.

Other isolated cases of FTLD-related mutations have been described, including valosin-containing protein gene (VCP) and charged multivesicular body protein 2B (CHMP 2B). Patients with the VCP mutation develop a rare disease with inclusion body myopathy, early Paget's disease of bone, and FTD (IBM-PDB-FTD).

### Treatment of FTLD

Treatment approaches for FTLD are generally aimed at symptom management as there are no solid data regarding disease-modifying approaches. Potential treatments that deserve further investigation include memantine and possibly lithium, based on small nonran-

domized trials or tissue models. Selective serotonin reuptake inhibitor (SSRI) medications may be beneficial for behavioral symptoms, including carbohydrate craving and compulsions. If delusions are problematic, atypical neuroleptics can be considered. There is no theoretical basis for the use of cholinesterase inhibitors, which could aggravate agitation. Attention to caregiver issues is important as the stressors often differ from those seen in typical AD. The different social and behavioral issues presented to FTLD compared to AD caregivers and the younger age of both patients and caregivers in FTLD can result in a feeling of isolation in typical AD support groups.

### AMYOTROPHIC LATERAL SCLEROSIS (ALS, LOU GEHRIG'S DISEASE)

ALS was first identified in 1869 by the French neurologist, Jean-Martin Charcot who described a progressive neurodegenerative disease with mixed upper and lower motor neuron signs and symptoms. The disease's name is derived from myelin pallor identified in the lateral aspects of the spinal cord representing axonal degeneration from upper motor neurons as they descend to the limbs. In the United States, the disease is best known as Lou Gehrig's disease, named after the famous baseball player who died of the disease in 1941. It occurs with an incidence of approximately 1 to 2/100 000 patients each year with a nearly 2:1 male to female predominance. About 5000 people develop ALS annually. As with FTLD, peak incidence occurs in mid-life; however disease can be seen in advancing ages.

ALS is inherited in an autosomal-dominant manner in up to 10% of cases. In 2% of cases, risk has been traced to a mutation in Cu/Zn superoxide dismutase 1 (SOD1). Most cases are sporadic and the etiology remains elusive. Intriguing small clusters of cases have been described, including a recent case report involving three amateur Italian soccer players. The neuropathology of ALS includes neuronal cytoplasmic inclusions of a ubiquitinated protein, most commonly seen in lower motor neurons. Recently, these inclusions were shown to contain the 43-kDa TAR DNA-binding protein (TDP-43), the same protein that has been identified in FTLD-U. This finding is consistent with a previously recognized association between ALS and FTD. In this study, TDP-43 immunoreactivity was seen in all case of sporadic ALS and all cases of familial ALS that did not have an identified SOD1 mutation.

Patients with ALS typically present with complaints of weakness in one or more limbs, resulting in unexplained tripping or dropping of items. Clumsy fine finger movements lead to difficulty with tasks such as buttoning clothes or writing. Patients often complain of cramping. Bulbar symptoms such as speech slurring, difficulties with swallowing, and hoarseness occur in many patients. Bulbar symptoms are presenting symptoms in about 25% of cases and more commonly occur in older patients. Patients may complain of difficulty chewing or swallowing. Up to 45% of patient will develop a pseudobulbar affect characterized by episodes of uncontrolled laughter or crying, often in inappropriate settings. Many patients have symptoms of a slowly progressive behavioral syndrome including apathy, lack of insight, and loss of empathy.

The neurological examination identifies both upper and lower motor neuron abnormalities. Muscle atrophy is seen, usually in the hands and often noted at the thenar or hypothenar eminence. Fasciculations and weakness are noted as lower motor neuron findings.

Upper motor neuron findings include mild spasticity, hyperreflexia, and abnormal plantar responses. EMG is diagnostic for ALS.

The clinical course is relentlessly progressive with only a 50% survival at 3 years. Mild muscle weakness progresses to inability to walk, difficulty with speaking, and dysphagia. The FDA has approved riluzole for treatment of ALS, which extends survival and delays the need for ventilation support. Treatment is otherwise directed at symptom control and quality of life. This is best achieved with a multidisciplinary approach, including ancillary services such as physical therapy, respiratory therapy, and social work.

## CORTICOBASAL DEGENERATION

Asymmetric Parkinsonism, often with a rigid akinetic arm, is the prototypical finding in CBD. Many patients will report a “useless” arm or gait problems. While speech or behavior concerns less often represent the first symptoms, this presentation does occur and CBD should be considered in any patient with symptoms consistent with FTLT, particularly those who present with PNFA. Occasionally, language will be the only symptom for the first 2 years of the disease, rendering CBD a potential diagnosis in patients presenting with PPA syndromes.

The mean age of disease onset for CBD is in the mid-sixties. A few series suggest that women may be more commonly affected than men. CBD is generally sporadic in occurrence; although familial cases have been described in association with both tau and progranulin mutations. Many cases are not correctly diagnosed during life.

In one series, common early findings included unilateral limb rigidity (75%), bradykinesia (71%), and postural instability (45%). The asymmetric Parkinsonism of CBD can be severe and usually involves the upper more than the lower extremities. As disease progresses, other limbs become involved. Severe upper limb dystonia typically results in internal contracture of the limb with the fingers clutching the thumb with flexion at the wrist. An alien limb phenomenon sometimes occurs with the limb not only levitating, but often hooking onto clothing or grabbing other body parts and behaving as if it were no longer under the control of the patient. On occasion, the alien limb will conflict with actions of the other hand. Simple levitation of the lower extremity is described as well, but is less specific to CBD. Focal reflex myoclonus that is typically present first in the fingers, then in the hand, can be elicited with distal percussion.

Concurrent cortical sensory loss is seen without deficits to peripheral sensory modalities. This is discriminated by testing for agraphesthesia, agnosia, or problems with two-point discrimination. Bilateral limb apraxia is common and apraxia of opening or closing the eyes can occur. Close evaluation of eye movements will often reveal saccadic latency with normal velocity, often in the horizontal plane. Supranuclear vertical gaze palsy can occur.

In one study, dementia was identified in about one-third of patients with CBD; however, this likely underestimates the frequency of cognitive features as nearly all had some manifestation of impairment in higher cortical function. Typically, cognitive impairment manifests with abnormalities that localize to the frontal and parietal lobes such as difficulty in executive functioning, calculations, and visuospatial ability. Behavioral problems are common and include depression (nearly three-quarters of patients), apathy, irritability, and

agitation. Falls and dysphasia are also common. Constipation and urinary urgency occur.

CBD shares many neuropathological abnormalities with FTD and PSP, suggesting the possibility that they represent a spectrum of similar diseases linked by underlying tau pathology. Ballooned neurons throughout the neocortex associated with neuronal loss and astrocytic tau-staining plaques are the diagnostic histological features of CBD. Unlike Pick's disease, the distribution of ballooned neurons is extensive and involves both the primary sensory and motor regions. Pick bodies are absent. Commonly, the superior frontal lobes and the parietal lobes are most heavily affected and are reflected in patterns of neuropsychological testing. Secondary degeneration of the corticospinal tracts occurs. Grossly, asymmetric atrophy of the parasagittal superior frontal gyrus and superior parietal lobule are common, with relative sparing of the temporal and occipital regions.

The treatment of CBD is symptomatic as disease-altering therapies are not known. Levodopa is beneficial in the minority of patients. Muscle relaxants and physical therapy with range of motion exercises can be useful. Clonazepam may be instituted for myoclonus. There is no theoretical basis for the use of cholinesterase inhibitors in this disease.

## PROGRESSIVE SUPRANUCLEAR PALSY

PSP, also referred to as Steele-Richardson-Olszewski syndrome, is a progressive neurodegenerative disease with prominent extrapyramidal motor findings and supranuclear ocular abnormalities. Patients with PSP present to both movement disorder clinics, resulting from motor abnormalities, and behavioral clinics, resulting from cognitive or psychiatric symptoms. The frequency of PSP in the general population is around 1 in 100 000, increasing to 7 in 100 000 among people older than 55 years. Diagnosis typically occurs in the sixth to seventh decade of life. There are only a few published reports of familial cases, suggesting that an autosomal dominant gene plays only a small role in the disease.

The initial descriptions of PSP emphasized abnormalities in movement with nearly all patients exhibiting early gait abnormalities and 60% presenting with falls as the first manifestation of disease. Patients often pivot with turns and have a tendency to fall backwards. Increased tone (axial more than appendicular) and dysphagia (affecting 46% in the first 5 years) are other common motor findings while bradykinesia is seen in only about a quarter of autopsy-proven cases. Spastic dysarthria results in slurred speech. Ultimately patients become mute.

Eye movement abnormalities are the hallmark feature of the disease, with vertical supranuclear palsy a critical feature for diagnosis. While vertical gaze palsy can be upward or downward, downward gaze palsy has greater specificity for PSP. The oculocephalic reflex for vertical movement is preserved early in disease despite the vertical gaze palsy. Square wave jerks, and both latency and hypometria of eye movements are often seen, typically greater with command (saccadic movements) rather than to pursuit. A decreased blink rate and a furred brow can be noticed when interviewing the patient.

The cognitive features of disease are variably described in early disease but are often present when sought. They are commonly identified if neuropsychological testing is completed, but are often overlooked in the clinical setting of frequent falls and prominent

movement abnormalities. The pattern of cognitive dysfunction is characterized by abnormalities localizing to the frontal and temporal lobes and subcortical structures. Thus, slowing of cognitive performance and below expectation performance in verbal fluency and executive functioning tasks are often documented, typically with retained verbal and visual memory performance. Behavioral symptoms of apathy, compulsions, perseveration, and utilization behavior are common features. This pattern of neuropsychological and behavioral findings is similar to what is seen in FTD, consistent with the findings that the pathology of the two entities overlap considerably.

Treatment of PSP is focused on control of symptoms. Occupational therapy to address speech and visual limitations can be successful. Prevention of falls is critical, but often challenging as impulsivity and lack of insight can limit the effectiveness of therapeutic interventions. Levodopa can be helpful in some patients with PSP, but eventually loses its efficacy. Survival is between 6 and 10 years at the time of diagnosis.

### SPINOCEREBELLAR ATAXIA SYNDROMES

Spinocerebellar ataxias (SCA) are a heterogeneous group of disorders with prominent, progressive cerebellar involvement. The current classification system corresponds to the order to which gene mutations have been identified. A comprehensive database, including scientific reviews and a listing of laboratories, that will evaluate for mutations is available at [www.geneclinics.org](http://www.geneclinics.org).

The SCA genetic mutations that have been identified to date are associated with expansion of repeated trinucleotides and are inherited in an autosomal-dominant manner. However, penetrance can vary greatly. The length of the polyglutamine repeat appears to be a major determinant of age for disease onset in an inverse manner. Genetic analyses are estimated to identify only 40% to 60% of familial and less than 25% of sporadic cases. The likelihood that a gene mutation will be identified decreases with older age (>40 years of age). The prevalence of SCAs is between 1 and 4/100 000 with variation by region caused by founder effects [SCA 2 (Cuba), SCA 3 (Azores), and SCA 10 (Mexico)]. These disorders most commonly present in the third decade of life with some presenting in youth; however, the range of age extends into older ages for many SCAs.

Phenotypic overlap is common in SCA syndromes; however, progressive cerebellar disability often presenting early in disease is a common feature. SCA syndromes often affect the noncerebellar portions of the nervous system, particularly as the disease progresses, with neuropathology identified in the brainstem, basal ganglia structures, and cortex. Such clinical symptoms include oculomotor features (SCA 1, 2, 3), retinopathy (SCA 7), seizures (SCA 10, 17), peripheral

neuropathy (SCA 1, 2, 3, 4, 8, 18, 25), or cognitive and behavioral deterioration (SCA 17, dentatorubral pallidolusian atrophy [DRPLA]).

Other neurodegenerative disorders should be considered in patients with progressive cerebellar dysfunction, including mitochondrial diseases, Huntington's disease, leukodystrophies, Frederick's ataxia, MSA, prion disease, and the premutation associated with Fragile X syndrome. Paraneoplastic processes should be considered in patients presenting with subacute cerebellar dysfunction. While scattered clinical reports describe benefits for some SCAs, treatment is generally aimed at symptom management, physical and occupational therapy, and genetic counseling.

### CONCLUDING REMARKS ON NON-ALZHEIMER'S DISEASE NEURODEGENERATIVE DISORDERS

Scientific advances have remarkably altered our understanding of non-AD neurodegenerative disorders in the past decade; however, large gaps remain. In many cases, neuropathology can now be identified facilitating the process of linking disease syndromes by pathological substrate and supporting an in-depth understanding of disease. In such cases, clinical researchers can then begin to accurately describe the clinical presentation of pathology-proven cases to provide clinicians with clues to neuropathology. When combined with emerging noninvasive diagnostic tools, such as PET imaging with novel ligands such as the Pittsburg compound B, which binds to the protein in amyloid plaques, we can achieve the ultimate goal of promoting pathology-driven treatment approaches.

# Traumatic Brain Injury

*Sterling C. Johnson*

Traumatic brain injury (TBI) is common among the elderly mainly through the association with falls. TBI in the elderly presents special issues for the clinician to consider in the management of these patients, including a higher risk of poor recovery and psychiatric and neuropsychiatric comorbidity. This chapter will review the epidemiology of TBI, mechanisms of injury, features on brain imaging, cognitive and psychosocial outcomes, and postacute management, with particular attention to research and practice with geriatric patients.

## EPIDEMIOLOGY

TBI is craniocerebral trauma associated with decreased consciousness, cognitive or neurologic abnormalities, skull fracture, or intracranial injuries. More than 5.3 million Americans have disabilities related to TBI. With approximately 1.6 million incident cases per year, resulting in 1.2 million emergency department visits, 290 000 hospitalizations, and 51 000 deaths, TBI is a common cause of morbidity and mortality. Approximately 444 per 100 000 population are evaluated in the emergency department for TBI. In adults older than 85 years, the incidence of TBI-related emergency department evaluations is more than double the average (see [Figures 68-1 and 68-2](#) for age breakdown). The annual incidence of hospitalized trauma or death is 101 per 100 000. The incidence of mild TBI across all ages (not resulting in hospitalization or death) is 392 TBI-related emergency department visits per 100 000 population.

The economic consequences of TBI are alarming. The annual costs of TBI are approximately \$60 billion. Estimates for the cost of lifetime care for a person with severe TBI range between \$600 000 and \$1.9 million. These estimates do not account for lost income of the patients, and time and lost earnings of family members who care for patients with TBI. Nor do these include the opportunities these victims have lost and their reduced quality of life.

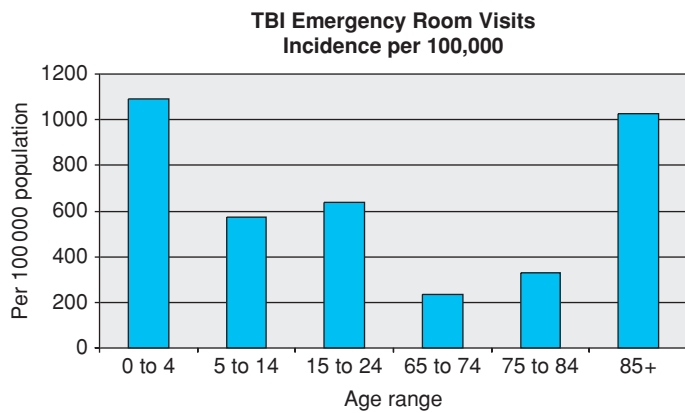

## ETIOLOGY

The older patient may have a number of age-related existing risk factors or conditions that increase vulnerability to both TBI and unfavorable outcome. These risks include, but are not limited to, cognitive slowing/impairment, orthopedic/mobility issues, visual acuity, balance difficulty, and neurologic and cardiac diseases. These issues increase risk for falls and motor vehicle accidents, the two major etiologies for TBI. These and other etiologies of injury are categorized in [Figure 68-3](#). It is estimated that 28% to 36% of TBI are because of falls, followed by motor vehicle accidents (19%), being struck by or against an object (18%), assault (10%), others (11%), and unknown (10%). In the general population, men are twice as likely to sustain TBI as women, although this difference is negligible in the elderly.

## Falls

Up to 60% of nursing home residents fall each year as do one-third of older adults in the community. It is significant to note that approximately half of all TBIs in the elderly are attributable to falls. In addition to being the most common mechanism of TBI, falls produce the highest rates of TBI hospital admissions. People aged 65 to 74 years are three times as likely to be hospitalized from a TBI-related fall as young adults. The risk ratio doubles for ages 75 to 84 years (7.6 relative risk) and doubles again for adults 85 years and older (16.4 relative risk). Similarly, the length of hospital stay is longer in the older adult, and the likelihood of being discharged to home is poorer. In adults older than 85 years, the rate of home discharge is 30%; for patients aged 75 to 84 years, the rate is 41%; at age 65 to 74 years, the rate is 54%; and in adults younger than 65 years the rate of home discharge is 86%.

Because falls account for the majority of injuries, an assessment of risk for falls is an important part of the geriatric evaluation. Risks

**FIGURE 68-1.** Incidence of emergency department (ER) visits with a TBI-related ICD-9 coding. Adults older than 85 yrs have high rates of TBI-related ER visits as do infants and toddlers. (This graph is derived from Jager TE, Weiss HB, Coben JH, Pepe PE. Traumatic brain injuries evaluated in U.S. emergency departments, 1992–1994. *Acad Emerg Med.* 2000;7(2):134–140.)

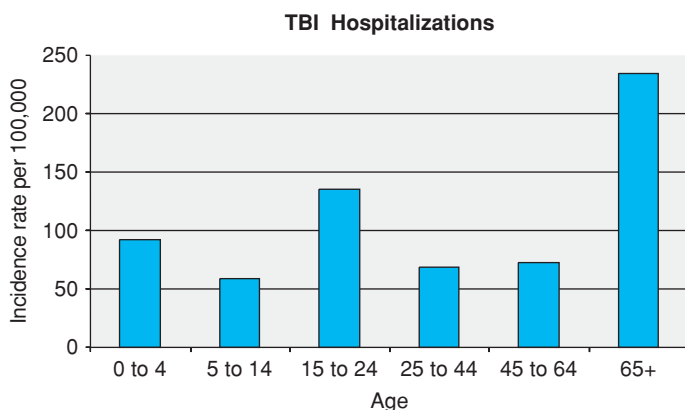

such as the following should be considered: chronic neurological, sensorial, or musculoskeletal disease; alcohol use, acute illness and delirium, episodic hypotension, and potential medication effects; as well as activity and environmental risks. More on falls and their prevention are covered in another chapter.

### Motor Vehicle Accident

Motor vehicle accident is the most common etiology of injury in the young adult. In the older adult, motor vehicle accident is the second most frequent etiology. Collisions are often at lower speeds but may still result in substantial injury. Key risks for motor vehicle accident include visual acuity and cognitive ability, particularly in the domain of attention—distractibility.

### Mortality

TBI-related death in the elderly is increasing. A CDC study found that for persons older than 75 years, the rate is 60 per 100 000 population. Falls, firearms, and motor vehicles were the most common causes. In hospitalized elderly patients with TBI, the rate of mortal-

**FIGURE 68-2.** When TBI occurs in the older adult, it results in greater rate of hospitalization compared with other age groups.

### Incidence by injury type

**FIGURE 68-3.** Etiology of TBI. Falls and motor vehicle accidents are the main causes of injury across all ages.

ity is high for subdural hematoma (33%), followed by contusions (25%) and diffuse axonal injury (11%).

## TYPES OF BRAIN INJURY

The circumstances, location, severity, and outcomes after brain injury are quite variable, although, some broad categorizations can be made regarding the mechanisms of injury (Table 68-1). Gennarelli indicates that there are two principal mechanisms of primary brain tissue damage in TBI: contact and acceleration/deceleration. Contact-related injury is the result of the head coming in forceful contact with an object (such as the floor or windshield), or contact between the brain and the inner surface of the skull. Contact injuries tend to result in cerebral contusions and hematoma at the point of contact. Not infrequently *contra coup* lesions occur opposite to the site of contact as the brain rebounds from the initial impact against the skull. Acceleration/deceleration injuries are the result of tensile shearing and straining forces acting on the tissue at the sudden moment of the impact. Such forces may tear blood vessels surrounding the brain, resulting in epidural or subdural hematoma or in

**TABLE 68-1**

### Traumatic Brain Injury Mechanisms

Primary injury
Skull fracture
Cortical contusions and arachnoid–pial layer lacerations
Intracranial hematoma
Diffuse axonal injury
Diffuse microvascular injury
Cranial nerve injury
Secondary injury
Hypoxia and ischemia
Edema
Increased intracranial pressure
Infection

**FIGURE 68-4.** A 52-yr-old male 14 months post injury. The patient was involved in a low-speed motor vehicle accident and sustained a skull fracture with right frontal epidural and subdural hematomas (that were subsequently evacuated surgically) and right frontal contusions. The T2\*-weighted scan in the left panel is negative for diffuse axonal injury. The image on the right is FLAIR T2 and highlights the right frontal lesion with associated gliosis and encephalomalacia around the edges.

widespread (diffuse) shearing of axons and microvasculature within the brain, which is termed diffuse axonal injury. The incidence of hematoma is very common in elderly patients with TBI, as a result of the fact that the proportion of brain volume to cranial volume is significantly smaller in the older adult, and the microvasculature is more brittle. These two factors may combine to yield more brain movement within the cranium at impact and higher incidence of hematoma owing to strain on the vessels, even with seemingly mild impact.

Focal effects of trauma can be observed in variable locations throughout the brain, depending on the specifics of the injury. However, contusions are more frequently observed in the polar, inferior, and lateral frontal and temporal lobes. For example, the lesion in [Figure 68-4](#) is large, but focal to the frontal lobe. Another mechanism for the increased rate of contusions in these areas is actual movement of the brain over the bony anterior and middle fossa and forward motion frontal impact sustained in motor vehicle accidents.

Extra-axial hemorrhages (epidural, subdural, and subarachnoid hematomas) are common in TBI, particularly in the elderly, and the presence of hemorrhage may impact the quality of outcome. A classic lucid period may be described in which the patient exhibits an impact-related alteration in consciousness, followed by a period where consciousness is regained, followed by secondary deterioration of consciousness as the hematoma evolves. Elderly have a higher rate of secondary hematoma even though the initial impact/injury may be mild. On computed tomography imaging, an epidural hematoma is an extra-axial biconvex ovoid mass of blood. Its biconvex shape is caused by blood accumulation in the epidural space, compressing the dura mater onto the brain, causing mass effect. Acute subdural hematoma involves blood accumulation between the dura and brain parenchyma. On computed tomography, subdural hematoma has a characteristic crescent shape. The inner boundary of subarach-

noid hematoma is more irregular—characterized on imaging with blood accumulation that conforms to the sulcal and gyral pattern of the brain. Between 40% and 80% of patients with acute subdural hematoma have an initial Glasgow Coma Scale (GCS) in the severe range (8 or less). In severe cases of high-speed or penetrating injury, lacerations of the meninges may be present, owing to depressed skull fracture or rotational forces of the injury or from the penetrating object.

The diffuse effects of moderate-to-severe TBI can be seen throughout the white matter, indexed on gradient-echo MRI by small punctate hypointensities reflecting paramagnetic hemosiderin in the parenchyma, caused by microvascular shearing ([Figure 68-5](#)).

Secondary injury from diffuse axonal injury may involve a cascade of events, including defective axonal transport, swelling, and separation of proximal and distal segments of the axon for more than 12 to 24 hours. Further secondary injury may result from increased intracranial pressure, causing increased hypoxia and ischemia, and poorly regulated, excitotoxic release of glutamate and other excitatory neurotransmitters.

### Severity of Injury

The GCS was developed by Jennett and Teasdale in 1974 and is still in wide use today to characterize the depth of coma, a major indicator of injury severity. The GCS is scaled from 3 to 15 ([Table 68-2](#)), with 3 being completely nonresponsive and 15 being completely alert, oriented, and following commands. Often the patient is necessarily intubated in the field, making an accurate assessment of GCS difficult.

Duration of loss of consciousness and duration of posttraumatic confusion are also important markers of injury severity, which may help predict eventual outcome (see outcomes section below). Guidelines to appraise injury severity are given in [Table 68-3](#).

**FIGURE 68-5.** Diffuse axonal injury. The patient was involved in a high-speed motor vehicle accident 3 months prior to this scan. The patient's initial GCS at the scene was 5 and 3 following intubation. After 24 hours, the GCS was 7. At 3 weeks postinjury, the GCS was 11. By 4 weeks, the patient's GCS was finally at 15. Day of injury imaging indicated a small left frontal epidural hematoma, left frontal contusions, and prominent diffuse axonal injury. This gradient-echo T2\*-weighted axial series of images highlights areas of hemosiderin deposition, a blood byproduct containing iron, and therefore results in punctuate areas of signal loss (dephasing) on the image. The multifocal pattern of hemosiderin suggests microvascular shearing and diffuse axonal injury. The multifocal lesions mainly appear at gray–white matter junctions.

## OUTCOMES

TBI may result in a variety of adverse outcomes along several overlapping dimensions, including dependence, cognitive outcome, neuropsychiatric outcome, psychosocial outcome, and medical comorbidity. There are several factors that affect these various outcomes after TBI (Table 68-4), including characteristics of the injury and characteristics of the patient. These factors may interact. For example, an older patient in the prodromal phase of Alzheimer's disease (AD) may exhibit progressive symptomatology of AD, which may have been instigated by the TBI but cannot readily be attributed to brain injury alone. This concept is especially relevant to age-associated brain disorders in the elderly. Studies of people at risk of AD indicate that amyloid deposition and neuronal loss may occur

gradually and be fairly asymptomatic until a certain threshold is reached. A brain injury, even if mild, may be sufficient to lower the threshold. Additional information on this topic is provided in the section on dementia and TBI below.

## Global TBI Outcome and Age

TBI can result in long-standing cognitive, personality/emotional, and interpersonal deficits that often interfere with successful rehabilitation, resumption of employment and other activities, interpersonal relations, and quality of life. A common finding is that elderly have *poorer* global outcome from the injury than their younger counterparts with similar injuries. The Glasgow Outcome Scale (GOS), a simple five-point scale ranging from death to good recovery (Table 68-5), is the predominant outcome instrument for global outcome. However, this measure is quite course—and there is considerable variability at the best outcome. Despite its limitations, this scale has been used in the largest number of patients and trials. In a recent pooled analysis of the International Mission for Prognosis and Clinical Trial (IMPACT) data involving more than 8700 patients with GOS outcome scores, results indicated that age is one of the most powerful prognostic indicators of GOS outcome, as is acute GCS motor score, pupil response, and computed tomography findings. In the case of severe injury, the chance of a GOS good recovery is

**TABLE 68-2**

### Glasgow Coma Scale

Best eye response (E)	Spontaneous	4
	To speech	3
	To pain	2
	None	1
Best motor response (M)	Obeys commands	6
	Localizes to pain	5

Access to social and rehabilitation services	

unlikely in the geriatric patient. Three studies have found that among patients older than 65 years who sustained severe injury (GCS >8), none exhibited a good recovery on the GOS. Another study found that only 6% of patients older than 65 years exhibit good recovery after severe TBI. A fifth study suggested that good recovery was possible after severe injury if the patient regained consciousness within 72 hours. Even when the injury is mild or moderate, the elderly have poorer GOS outcome.

With regard to rehabilitation outcomes, an important study of TBI model systems data found that patients older than 55 years experienced a doubling in the length of rehabilitation stay and associated costs, while only attaining half the rate of functional recovery of their younger counterparts. These patients also had greater cognitive impairments at discharge and higher rates of nursing home placement.

**TABLE 68-5****Glasgow Outcome Scale**

OUTCOME	SCALE	DESCRIPTOR
Death	1	
Vegetative state	2	Unable to interact with environment; unresponsive.
Severe disability	3	Conscious, but dependent—in need of supervision/assistance every day as a result of physical and cognitive impairments. Ranges from total dependency to assistance with one or more ADLs.
Moderate disability	4	Independent but with a disability. Basic ADLs are intact, but the patient is impaired in occupational and/or social functioning. Able to work in a supported environment.
Good recovery	5	The patient has mild to no residual deficits and has the capacity to resume independent occupational and social activity.

ADLs, activities of daily living.

Less research has been done with fine-tuned neuropsychological assessment of outcome, and studies tend to be much smaller. A review of major cognitive domains that are affected in TBI follows.

### Executive Dysfunction

The selective vulnerability of the frontal and temporal lobes to injury gives rise to a preponderance of neuropsychological deficits involving frontal systems, including executive functions, working memory, speed of processing, episodic memory, and aspects of personality. All have been shown to be related to severity of injury. The precise definition of executive function is itself a matter of debate and some confusion. The executive functions are those that promote self-directed action. Self-monitoring, self-regulation, inhibition, introspective reflection, decision making, and planned and goal-directed activity are executive functions. Working memory and attentional capacity such as imperviousness to distraction and sustained attention are necessary components, but not sufficient by themselves for executive function. However, these capacities are conveniently operationalized into a quantifiable psychometric instrument (such as digit span, n-back, or serial 7s), and there is a great deal of research on these components of executive function. Executive functions and components are best assessed with a comprehensive neuropsychological evaluation, although some bedside tests such as clock draw, verbal fluency, and digit span, and go–no go tests may be useful to get a feel for the extent of the problem.

### Speed of Processing

Speed of information processing is one of the most frequently observed deficits after TBI. For example, one study found patient's reaction time in a simple motor choice paradigm to be significantly slower than that of matched young adults. Another study assessed speed of information processing and attention in a group of 60 patients with severe TBI and controls. When speed of processing was statistically controlled, differences between patients and controls in focused and divided attention became nonsignificant, suggesting that slowed information processing was accounting for most of the difference. A similar finding was observed for planning and flexible problem solving in patients with severe TBI in the chronic stage of recovery. When speed was controlled, performance was equivalent between patients and controls. A factor analysis of a battery of neuropsychological test scores in survivors of TBI indicated that the most prominent factor was decreased perceptual and motor speed. Speed of processing also declines with age, and thus the older patient with TBI may have unusually slow cognitive processing speeds, which may greatly limit their range of activities and quality of social interactions.

### Attention/Distractibility

The ability to allocate attention between multiple tasks and working memory are affected in TBI. For example, Baddeley's original model of working memory, which has been frequently proposed to help explain executive difficulties, states that a central executive process or supervisory attentional system within the prefrontal heteromodal cortex regulates the allocation of limited attentional resources. This system appears to be facilitated by D2 dopamine networks within the dorsolateral frontal lobe and is particularly vulnerable to trauma

through either direct contact (contusion to the lateral frontal lobe) or disconnection via acceleration/deceleration injuries.

### Memory Dysfunction

Memory complaints from patients are extremely common following TBI, and measured impairment seen on neuropsychological tests is frequently observed, including difficulty at the encoding or acquisition stage, as well as difficulty in retrieval of information. Whether these complaints and deficits are secondary to the more salient attentional, processing speed and executive deficits or whether these are a primary result of hypoxic and excitotoxic injury to the hippocampus is still somewhat unresolved and may vary depending on the nature and severity of the injury.

### Personality/Emotional Functioning

The personality changes accompanying TBI vary depending on the injury location, severity, and preinjury personality factors. Prigatano has summarized the literature in detail on this point. Common overlapping descriptors of personality in patients with TBI include irritability/anger, impatience, impulsivity, poor social judgment, inappropriate social behavior, rapid mood swings, loss of drive, fatigability, and/or depression. Major ways of relating to the world following TBI have been described as “childishness” (self-centered behavior, insensitivity to others, or immature behaviors), “helplessness/dependence” (requiring supervision and inability to make important decisions or set goals), and “lack of insight/awareness” of any of the above difficulties. These patterns frequently overlap and have been collectively labeled “frontal lobe personality.”

### Self-Awareness

TBI results in very abrupt changes that may not be easily, and often only slowly, accommodated into one’s stable sense of self. Characteristics of impaired self-awareness can be varied depending on injury location and severity. Acutely, patients with TBI may be unaware that they have deficits from the injury. Later, the patient may admit to some deficits but fail to appreciate the impact of these deficits on daily functioning. Prigatano et al. found that patients with TBI frequently underestimated their behavioral limitations, abnormalities in social interaction, and emotional dyscontrol when compared to a family member’s rating of the patient’s abilities, while more objective criterion-based competencies such as ADLs, laundry, and shopping may be areas where the patient’s insight is more accurate. Critically, a syndrome of impaired self-awareness will significantly complicate or impede the rehabilitation process or treatment adherence, since patients may not perceive the need for such treatments. Damage to the anterior prefrontal regions (behind the forehead) has been associated with impaired self-awareness for social interaction, judgment, and planning. These are the very areas that are commonly injured in TBI.

## NEUROPSYCHIATRIC OUTCOME

One recent study compared 120 adults with TBI between the ages of 18 and 65 years to a group of 45 adults older than 65 years. Psychiatric symptoms were assessed 1 year later. The study found that the younger group had double the proportion with psychiatric

disorders (32%) compared to the older group (16%). Further, the younger group was more likely to experience irritability and sleep difficulty, while the older group was more likely to experience poor memory, dependence, and slowness of thinking. This finding is consistent with prior research, indicating that aging with TBI may predispose patients to higher incidence of psychiatric symptoms later in life. Prevalence of major depression is higher (18% prevalence), as is memory difficulty (75%), concentration (53%), personality changes (65%), and increased social isolation (68%).

### TBI AND SUBSEQUENT BRAIN ATROPHY AND COGNITIVE AGING

Previous neuroimaging research has demonstrated that TBI results in diffuse cerebral atrophy and that these changes can be observed within months of injury. However, the brain continues to undergo changes over the next year or longer, which are beyond the rates of normal aging (Figure 68-6). However, limited research has been conducted on patients further post injury. Furthermore, the effect of TBI on cerebral integrity during the aging process is not well understood. Studies in normal aging have demonstrated that gray matter volume peaks in adolescence and then decreases over time. In contrast, it has been suggested that white matter volume peaks much later, between the ages of 40 and 50 years. Since diffuse axonal injury affects white matter, one might expect TBI prior to accumulation of maximal white matter to alter its normal trajectory as the brain ages.

It is well accepted that aging results in gradual cognitive decline in many domains. One of the questions that needs to be addressed is whether TBI accelerates normal age-related cognitive decline (a rate of aging by TBI interaction). No studies have directly addressed this, but some studies have begun to approximate an answer. A 2006 study examined cognitive outcome after 30 years in 61 patients with TBI. The study found that older subjects showed significantly greater cognitive decline over the follow-up period. Whether the

**FIGURE 68-6.** Patients with TBI show significant decline in global brain volume, here termed percent brain volume change or %BVC, more than a 1-yr interval, while matched controls do not. The notches in the box plot are the 95% confidence interval. The mean, fifth, 25th, 75th, and 95th percentiles are also shown.

rate of change exceeded the rate of change associated with normal aging was not directly assessed. The cognitive areas that exhibited the greatest declines were mental arithmetic, visuospatial reasoning, and immediate memory.

## DEMENTIA AND TRAUMA

Dementia is defined as loss of cognitive functions in multiple domains, one of which is memory, which are severe enough to impair occupational or social functioning. Head trauma is an etiology of dementia and is designated as such in the Diagnostic and Statistical Manual of Mental Disorders-IV. After a single injury, dementia, if present, is expected to be nonprogressive. In the elderly, neural loss because of TBI may serve as a “stressor” to a preexisting asymptomatic neurodegenerative process such as AD.

### Does Trauma Increase the Risk of AD?

The single greatest risk factor for dementia is age. The apolipoprotein (APOE) gene and other genes increase the risk of dementia, as does neurological history such as trauma. The APOE gene may play a role in multiple age-related diseases. APOE is lipid transporter, and the gene coding for APOE has three alleles: e2, e3, and e4. By far, the most common allele is e3. Persons with the e4 allele (approximately 15% of the general population) are at higher risk of dementia and cerebral vascular diseases, while e2 may be somewhat protective. The risk of dementia in TBI survivors has not always been clear-cut, but when studies include APOE status, the risk becomes somewhat clearer. For example, one large study of 236 community-dwelling older adults found that TBI by itself was not associated with risk of AD, while APOE4 was associated with a twofold increase. However, patients with APOE4-positive TBI had a 10-fold increased risk for AD. Elderly with APOE4 may also have a longer length of coma and earlier age of onset of dementia than non-APOE4 carriers. Another study examined patients with TBI at 6 months postinjury and found that patients with the APOE4 allele were twice as likely (57% vs. 27%) to have outcomes of 1 to 3 on the GOS (death, vegetative state, or severe disability).

Two related concepts of brain vulnerability are of interest here in explaining individual differences in decline to subsequent dementia. *Brain reserve* and *cognitive reserve* address the lack of measurable cognitive decline in the presence of brain disease or age. *Brain reserve* posits that, in the presence of tissue compromise, some brains have greater capacity to rely on spared heteromodal neurons and pathways to compensate in several possible ways, including activation of latent pathways and formation of new synapses. *Cognitive reserve* posits that age and disease-related declines may be protected against by higher premorbid cognitive ability and resources; those that are higher functioning premorbidly may have a greater repertoire of cognitive compensatory strategies to draw upon postinjury or may simply have farther to decline before testing in the impaired range.

## POSTACUTE MANAGEMENT OF GERIATRIC PATIENTS WITH TBI

The geriatric patient post TBI presenting in the clinic may have difficulty with mobility and pain and have several less obvious problems

including cognitive impairment, mood, anxiety and comorbidity-related issues, and decreased social and physical inactivity. A careful comprehensive assessment is warranted.

## Neuropsychological Assessment

Cognition decline and affective dysfunction are not specific to TBI and may, in fact, co-occur in several neurological diseases and medical conditions. Neuropsychological evaluation may be helpful in making the differential diagnosis. Such an evaluation will identify cognitive profiles that are indicative of specific diagnoses and will identify patterns of strengths and weaknesses in order to inform and help maximize the effectiveness of treatments. Such an evaluation may also help prevent a misdiagnosis of Alzheimer dementia.

## Neuropsychiatric Disturbances

Behavioral disturbances can have a negative impact on cognitive functioning, relationships with family and significant others, treatment compliance and motivation, and reintegration into the patient’s social community. Common neuropsychiatric sequelae are provided in Table 68-6. A thorough clinical interview with the patient and with one or more other sources such as a spouse and adult child is important, in order to identify neuropsychiatric issues. Collateral sources are important because the patient may give an unreliable history and may have inaccurate insight into the extent of deficits and their effects on others in the patient’s life.

When treatable neuropsychiatric disorders are present, it is important to try alternatives to medication when possible. Patients with TBI may be particularly prone to side effects and exaggerated and paradoxical responses to medications. Geriatric patients with TBI are even more vulnerable to adverse responses. Environmental changes may be helpful in some cases, such as increasing social engagement for depressed patients or reducing stressors in the environment that may be adding to agitated behavior. Supportive counseling may be tried for treatment of depression and anxiety. When psychotropic medication is warranted, the drug should be started with the lowest possible dose and titrated up. It has been shown that benzodiazepines

**TABLE 68-6**

### Neuropsychiatric Sequelae

Dementia as a result of trauma; risk for Alzheimer’s disease
Posttraumatic confusion
Isolated cognitive disorders: Aphasia, apraxia, amnesia, anosognosia, and executive function
Compartment disorders: Apathy, disinhibition, paranoia, irritability, and lability
Affective disorders: Depression or mania
Anxiety disorders: PTSD, panic, generalized anxiety, and obsessive
Psychotic disorders: Hallucinations and/or delusions
Sleep disorders: Insomnia and hypersomnia
Fatigue

and traditional antipsychotic medications hamper recovery in the geriatric patient, so alternatives with less sedating properties are preferred.

Depression in the elderly patient with TBI has a 30% to 77% prevalence rate. Studies have suggested that demographic (such as marital status and socioeconomic status) or injury characteristics (such as time since injury) are unrelated to postinjury depression. Both a more severe injury and a preinjury psychiatric history do predict postinjury depressive symptoms. Suicide risk is much higher in older adults with TBI, and suicidal ideation should be assessed. Anxiety disorders postinjury are also common. Post-Traumatic Stress Disorder (PTSD) is the most frequent with prevalence rate of 20% to 30%; generalized anxiety disorder and panic disorder are also common. Identification and treatment of these neuropsychiatric sequelae of TBI may contribute greatly to rehabilitation outcome, interpersonal dynamics with family and care providers, and community integration.

## Pain

TBI may cause neuropathic pain as a result of CNS injury as well as nociceptive pain resulting from tissue damage. The older patient may have preexisting conditions such as arthritis that augment their discomfort. Physical modalities such as ice, heat, activity, and comfortable positioning are preferable interventions, followed by non-narcotic analgesics. For neuropathic pain, newer anticonvulsants may be advantageous.

# Epilepsy

*Ilo E. Leppik*

## DEFINITION OF EPILEPSY AND SEIZURES

There is currently a debate within the medical community regarding the precise definition of epilepsy. In the past, it was accepted that a person should not be diagnosed as having epilepsy until that individual had two or more seizures. However, with current diagnostic tools, brain pathology can be readily identified, and studies have shown that persons with certain conditions, such as stroke or brain tumor, have a high probability of having more seizures after a single seizure. As a result, many epileptologists, including prominent members of the ILAE (International League Against Epilepsy), are proposing that epilepsy be defined as a condition of the central nervous system predisposing to seizures. Thus, a single seizure associated with specific pathology would be sufficient to initiate treatment to prevent further seizures. This is of particular importance to the geriatrician because many persons with seizures in this age group have identifiable brain pathology.

Seizure classification is based on the functional anatomy of the brain. The smallest seizures are termed simple partial seizures. These do not involve loss of consciousness, and the manifestation of the seizure reflects the function of the area of brain from which these originate. Thus, clonic activity of the right hand (minor motor seizure) originates from an epileptogenic zone in the left motor cortex. Simple partial seizures can be motor, sensory, visual, olfactory, or psychic (de ja vue; brief panic). Because patients are alert during these seizures, they are able to remember what happened. This history can be of great value in localizing the area of brain from which the seizures originated. Complex partial seizures usually originate from the temporal lobes. During the seizure, a person will perform automatic activities such as lip smacking, unbuttoning, wandering aimlessly, or other semipurposeful behaviors. Because memory is mediated by the temporal lobes, persons have no memory for the event. A simple partial seizure can evolve into a complex partial seizure, and both can excite the whole brain and evolve into a generalized tonic-clonic

seizure (convulsion; “Grand Mal”). Persons with these seizures are described as having localization-related epilepsy, and most elderly have this type of epilepsy.

## INCIDENCE AND PREVALENCE OF EPILEPSY AND USE OF AEDs

### Incidence in Community-Dwelling Elderly

Until a few decades ago, epilepsy was mostly a disorder of children. However, as the population of persons older than 65 years has increased, the demographics have changed dramatically. The incidence of epilepsy (new cases per 100,000) in the United States and developed countries now forms a U-shaped curve (Figure 69-1). The incidence of epilepsy is higher in the elderly than in any other age group and rises with each decade after the age of 55 years. Because of the rapid growth in their numbers and their propensity to develop epilepsy, elderly persons will represent an increasingly large group of patients needing expert care for this disorder. In the United States, approximately 181,000 persons developed epilepsy in 1995, and approximately 68,000 of these were older than 65 years. Similar high incidence rates have been reported from the Netherlands, and in Finland new cases of epilepsy in elderly now outnumber those in children.

### Prevalence in Community-Dwelling Elderly

An estimate of the prevalence of epilepsy (active cases in a population) can be from a study of veterans. Of a total of 1,130,155 veterans 65 years and older identified from the national database of 1997–1999, 20,558 (1.8%) were identified as having epilepsy by having an ICD-9-CM code representative of this condition. Approximately

**FIGURE 69-1.** Age-specific incidence of epilepsy by gender in Rochester, MN, during 1935–1984. (Constructed from data in Hauser WA. *Seizure disorders: the changes with age. Epilepsia. 1992;33(suppl 4):S6–S14.*)

80% were receiving one antiepileptic drug (AED), and 20% were being treated with two or more. Phenytoin was used as monotherapy by almost 70%, whereas phenobarbital was used as monotherapy by approximately 10%. Another 5% were using phenobarbital in combination, mostly with phenytoin. Carbamazepine (CBZ) was used by just more than 10%, and newer AEDs (gabapentin and lamotrigine [LTG]) were used by less than 10% (levetiracetam was not available at the time of the survey). Smaller studies of AED used in community-dwelling elderly patients who are non-veteran administration (VA) patients have found a similar distribution of AED use with phenytoin, by far the most widely used AED in the United States in this population. Studies from Europe show a much different pattern of AED use, with CBZ or phenobarbital being used more frequently than phenytoin. There is no evidence upon which to base this pattern of use; hopefully studies will be done in elderly to delineate the best treatments.

### Prevalence in Nursing Home Elderly

Recently, a surprisingly high rate of AED use in nursing homes has been identified, with cross-sectional studies indicating that as many as 10% of all nursing home residents are being prescribed an AED. In one study, phenytoin was used by 6.2% of the residents, followed by CBZ (1.8%), phenobarbital (1.7%), clonazepam (1.2%), valproic acid (0.9%), and all other AEDs combined (1.2%); these percentages exceed 10.5% owing to AED polytherapy. In approximately 6%, the indication is seizure or epilepsy. AEDs such as valproate and CBZ are often used for modification of behavior. If these results are extrapolated to the approximately 1,500,000 elderly residents in U.S. nursing homes (NHs) in 2000, then as many as 150,000 people were likely to have been receiving an AED. Of note, this prevalence in nursing homes is approximately five times that of AED use in the community-dwelling elderly. But the most striking difference between community-dwelling elderly and the nursing home population is the finding that the younger residents are much more likely to be prescribed an AED than the oldest. Analysis by subdivision into those 65 to 74 years of age (“young old”), those 75 to 84 years of age (“middle old”); and those 85 years or older (“old”) and further subdivisions by the elderly healthy (EH) who have epilepsy, the elderly with multiple medical problems (EMMP), and the frail elderly, usually in nursing homes (FE), as shown in Table 69-1, are useful in analyzing results and deciding on therapy.

**TABLE 69-1**

#### Categorization of Elderly with Epilepsy

Young old healthy EH	Middle old healthy EH	Old old healthy EH
Young old multiple medical problems EMMP	Middle old multiple medical problems EMMP	Old old multiple medical problems EMMP
Young old frail FE	Middle old frail FE	Old old frail FE

A sample from one nursing home study had the following age group distribution: young old 15%, middle old 36%, and old old 49%. Age was inversely related to AED use. Of the young old, 23.7% were prescribed an AED, 16.4% for seizure indication, and 7.3% for other indications. In the middle old, 12.2% had an AED, 8.3% for seizure and 3.9% for other, whereas the old old had only 5.8% use, 3.7% for seizure and 2.1% for other (Figure 69-2). This finding was unexpected and is just the opposite of the rate of epilepsy in the community. The reason for this reversed pattern is not known but may be related to the severity of the medical conditions in the younger nursing home residents.

### Prevalence at Time of Admission to Nursing Homes

In a study of admissions using a longitudinal design to explore AED use at the time of admission, approximately 8% of the admissions group used one or more AEDs at entry, and among these, greater than half had an epilepsy/seizure disorder indication. This demonstrates that the prevalence of epilepsy is approximately three to four times higher in this cohort than in the general community and that these persons have a high rate of developing epilepsy just prior to nursing home entry.

**FIGURE 69-2.** AED use among nursing home elderly by age group and seizure indication. Young old are much more likely to be treated with an AED than the old old, the inverse of what is observed in community-dwelling elderly. (Constructed from data from Garrard J, Cloyd J, Gross C, et al. *Factors associated with antiepileptic drug use among elderly nursing home residents. J Gerontol A Biol Sci Med Sci. 2000;55:M384–M392.*)

## Incidence After Admission to Nursing Homes

The study of prevalence at admission also included a follow-up cohort ( $n = 9516$ ) of those in the admissions group who were not using an AED at NH entry. This cohort was followed up for 3 months after their individual admission dates or until NH discharge, whichever occurred first. Among this group, 3% had an AED prescribed within 3 months of admission. Indications associated with the initiation of AEDs during this period included epilepsy/seizure (1%) and manic depression or other psychiatric diagnoses (2%); a crude estimate of the incidence would be 600/100,000 per 3 months, compared to the approximately 160/100,000 in the community-dwelling elderly. Thus, many persons admitted without a diagnosis of epilepsy are diagnosed as such after entry, and the incidence of newly diagnosed epilepsy within the nursing home far exceeds that in other populations.

These studies demonstrate that, in addition to epilepsy incidence being higher in the elderly overall, there is acceleration in the incidence prior to entry to a nursing home, and an even higher incidence after admission. The causes of this have not been studied but clearly as the individual becomes frailer, the probability of developing seizures and or epilepsies increases.

## CAUSES

In the elderly, the most common identifiable cause of epileptic seizures is a previous stroke, which accounts for 30% to 40% of all cases. Approximately 10% of persons with a stroke will have a seizure within the first few months, and the overall incidence rises to approximately 20% by 2 years. Hemorrhagic strokes are more likely to produce seizures than ischemic strokes. Sometimes a transient ischemic attack (TIA) will produce seizures whose pattern is similar to the deficit of the TIA, but the clue is that seizures usually last only a few minutes. Brain tumor, head injury, and Alzheimer's disease are other major causes. However, in a large number of cases, the precise cause cannot be identified and the etiology is labeled cryptogenic (crypt = hidden; genic = cause).

## DIAGNOSIS

### History

A clear distinction must be made between epileptic seizures, those arising from brain pathology, and nonepileptic seizures, those in which a seizure is caused in a normal brain by some alteration in physiology, such as hypoxia. Thus, other causes of seizures, such as cardiac insufficiency, metabolic conditions, convulsive syncope (micturition syncope and cough syncope), and additional conditions must be eliminated before it can be concluded that the event was an epileptic seizure. The evaluation after a single seizure must, therefore, be comprehensive. A thorough history must be obtained, focusing on events of the last day or so, to identify any precipitating or provoking factors. Epileptic seizures are usually unprovoked. An electrocardiogram (EKG) to rule out cardiac conditions is essential. Laboratory tests for metabolic disorders should be done. A review of prescription drugs, over-the-counter agents, and natural product

use must be obtained. Many natural products designed to simulate weight loss or improve memory may have proconvulsant properties. Withdrawal from benzodiazepines or alcohol can provoke seizures, and methamphetamine and cocaine may cause convulsions. A drug screen should be considered.

## CT and MRI Scans

Structural studies to explore for intracerebral hemorrhage, brain tumor, and encephalomalacia should be done. A CT scan is appropriate as the initial emergency study. Because its modality is x-rays, it is effective in detecting tissue contrasts. Thus, it is effective for detecting blood, areas of encephalomalacia, and calcified lesions. However, the MRI is much more sensitive for detecting subtle changes in brain tissue and should be done if obvious pathology is not detected by the CT scan. Glial tumors are often not well visualized by CT, nor are small changes in the hippocampus.

## Electroencephalogram

An electroencephalogram (EEG) serves many useful roles in the diagnosis of epilepsy. A person with epilepsy has abnormal electrical discharges in between seizures (interictal activity). These can be detected by an EEG, just as abnormalities can be found on an EKG in between clinical cardiac events. The interictal patterns can confirm the presence of physiologically abnormal brain, thus cementing the diagnosis of an epileptic as opposed to a nonepileptic seizure. In addition, it can identify the epileptogenic region, providing additional clues to the etiology. Also, the degree of interictal activity can provide a clue as to the severity of the epilepsy. It is recommended that an EKG rhythm strip be obtained during an EEG to help identify artifacts and provide additional evidence to exclude a cardiac cause for the seizure.

## TREATMENT

### Deciding to Treat

After a single seizure, the decision to initiate treatment with an AED must be made on the basis of assessing the risk for additional seizures. Given the risks associated with additional convulsions, there is probably a greater urgency to treat. In an elderly person with a history of stroke or an identified CNS lesion, a single seizure would meet the newer proposed definition of epilepsy as a condition of the central nervous system predisposing to seizures, and treatment is warranted. A more complicated decision arises when the evaluation of a single seizure does not identify CNS pathology and the EEG is negative. In these cases, a more intensive search for nonepileptic seizures must be performed, and treatment may reasonably be deferred until a second seizure occurs. In addition, the elderly population is heterogeneous, and broad statements about elderly may not be relevant to each individual patient. Treatment in the elderly carries more risks than in younger persons because they may experience more side effects, have a greater risk for drug interactions, and be less able to afford the costs of medications. In addition to their use in epilepsy, AEDs are prescribed for a variety of other disorders affecting the elderly, including pain and psychiatric disorders. As a cause of adverse

reactions among the elderly, AEDs rank fifth among all drug categories. Unfortunately, very little research has been done in this vulnerable population, and only general recommendations can be made at this time.

### Clinical Pharmacology of AEDs in the Elderly

Drug concentration at the site of action determines the magnitude of both desired and toxic responses. The unbound drug concentration in serum is in direct equilibrium with the concentration at the site of action and provides the best correlation with drug response. Three of the major AEDs (valproic acid, phenytoin, and CBZ, respectively) are highly bound, and binding is frequently altered. Thus, for these AEDs, measurement of unbound (free) levels may be important to avoid errors in therapy.

The age-related physiological changes that appear to have the greatest effect on AED pharmacokinetics involve protein binding and the reduction in liver volume and blood flow. Reduced serum albumin and increased  $\alpha$ 1-acid glycoprotein (AAG) concentrations in the elderly alter protein binding of some drugs. By the age of 65 years, many individuals have low normal albumin concentrations or are frankly hypoalbuminemic. Albumin concentration may further be reduced by conditions such as malnutrition, renal insufficiency, and rheumatoid arthritis. The concentration of AAG, a reactant serum protein, increases with age; further elevations occur during pathophysiological stress such as stroke, heart failure, trauma, infection, myocardial infarction, surgery, and chronic obstructive pulmonary disease. Administration of enzyme-inducing AEDs also increases AAG. When the concentration of AAG rises, the binding of weakly alkaline and neutral drugs such as CBZ to AAG can increase, causing higher total serum drug concentrations and decreased unbound drug concentrations. Because of the complexity of confounding variables and the lack of correlation between simple measures of liver function and drug metabolism, the effect of age on hepatic drug metabolism remains largely unknown.

Renal clearance is the major route of elimination for a number of the newer AEDs. It is well known that an elderly person's renal capacity decreases by approximately 10% per decade, but this also is highly dependent on the general state of health.

Despite the theoretical effects of age-related physiological changes on drug disposition and the widespread use of AEDs in the elderly, few studies on AED pharmacokinetics in the elderly have been published. The available reports generally involve single-dose evaluations in small samples of the young old (65–74 years). There is a lack of data regarding AED pharmacokinetics in the oldest old (>85 years), individuals who may be at greatest risk of therapeutic failure and adverse reactions.

### Variability of AED Levels in Nursing Homes

Studies have shown that in compliant patients, the variability of AED concentrations over time is relatively small. One study of phenytoin showed that in younger institutionalized patients, the variability between serial measurements over time was in the order of 10%. In the same study, compliant clinic patients had variability of approximately 20%. Approximately 5% of this can be accounted for by measurement instrument variability, although laboratories not following rigid quality control standards may have a much larger variability. The remainder of the variability arises from day-to-day alterations in

absorption and metabolism or differences in AED dose content. The variability for CBZ and valproate is in the order of 25%, possibly because of their shorter half-lives and, thus, increased variability from sampling times. An analysis of serial phenytoin levels from nursing home patients across the United States who had no change in dose, no change in formulation, and no additions of other medications found that some had a difference of two- to threefold from the lowest to the highest. Interestingly, some had very little fluctuation. Similar but less severe fluctuations were observed for CBZ and valproate. These findings suggest that the elderly frail nursing home residents may have much greater variability in absorption of drugs. Factors, which contribute to this, must be identified and strategies developed to minimize this phenomenon.

### Clinical Trials of AEDs in the Elderly

All major AEDs have an FDA indication for use for the seizure types most likely to be encountered in the elderly. However, there are little data relating specifically to these drugs in the elderly, and those that are available have been limited to community-dwelling elderly. One post hoc study of the veteran administration hospital (VAH) cooperative study of CBZ and valproate found that elderly patients often had seizure control associated with lower AED levels than seen in the younger subjects. However, side effects were also observed at levels lower than those seen in younger. This suggests that the elderly need a different “therapeutic range” than those quoted for younger adults. A multicenter, double-blind, randomized comparison between LTG and CBZ in elderly patients (mean age 77 years) with newly diagnosed epilepsy in the United Kingdom showed that the main difference between the groups was the rate of drop out as a result of adverse events, with a rate for LTG of 18% compared to a rate of 42% for CBZ. The VA Cooperative Study in the United States, an 18-center, parallel, double-blind trial on the use of gabapentin, LTG, and CBZ in patients 60 years or older, found that efficacy did not differ, but the main finding favoring the two newer AEDs was tolerability.

### Choosing an AED for the Elderly

At the present time, there are little data regarding the clinical use of AEDs in the elderly. The paucity of information makes it very difficult to recommend specific AEDs with any confidence that the outcomes will be optimal. A drug choice optimal for the EH group may not be appropriate for the EMMP or FE group, owing to differences in pharmacokinetic or pharmacodynamic properties among these groups. Phenytoin is still the most commonly used AED in both community-dwelling and nursing home elderly in the United States, although expert opinion may disagree with this practice. In the next section, discussion is based first on the most commonly used AEDs for which there are more data (often negative) and then on an alphabetical review of the newer AEDs. A summary of the properties of most AEDs is in [Table 69-2](#).

#### Phenytoin

It is effective for localization-related epilepsies and, thus, has an efficacy profile appropriate for the elderly. Phenytoin has a narrow therapeutic range, is approximately 90% bound to serum albumin, and undergoes saturable metabolism, which has the effect of producing

**TABLE 69-2****AEDs Used for Treatment of Epilepsy in the Elderly**

DRUG	PROTEIN BINDING (%)	ELIMINATION	COMMENTS
Carbamazepine	75–85	Hepatic CYP 3A4/5	Levels increased by erythromycin, propoxyphene, and grapefruit juice Decreases levels of calcium channel-blockers (diltiazem and verapamil) Decreases effect of warfarin Decreases tricyclic antidepressant levels
Gabapentin	<10	Renal	Elimination correlates with creatinine clearance No drug interactions
Lamotrigine	55	Hepatic–glucuronide conjugation	Levels decreased by inducing agents—carbamazepine, phenytoin, some hormones, and others yet to be determined Levels increased by valproate
Levetiracetam	<10	Renal	Very water soluble; IV formulation available No drug interactions
Phenobarbital	50	Hepatic Renal	Induces metabolism of many drugs Very sedative IM and IV available
Phenytoin	80–93	Hepatic CYP 2C9 CYP 2C19	Protein binding decreased with reduced serum albumin and renal failure Decreases levels of calcium channel-blockers (diltiazem and verapamil) Complicated interaction with warfarin Decreases tricyclic antidepressant levels Interacts with diabetes and arthritis medications Decreases effectiveness of cancer chemotherapy IV formulation available. Fosphenytoin can be given IM or IV
Valproic acid	87–95	Hepatic Multiple pathways	Protein binding decreased in elderly Inhibits glucuronidation and may increase levels of lamotrigine and other drugs Decreases platelet function IV formulation available

large changes in serum concentrations, with small changes in dose or absorption. The binding of phenytoin to serum proteins correlates with the albumin concentration. A number of studies have also shown that phenytoin metabolism appears to be reduced in the elderly. Thus, in the elderly, an initial daily dose of 3 mg/kg may be appropriate, rather than the 5 mg/kg/d used in younger adults. This 3 mg/kg dose is only 160 mg/day for a 52-kg woman, or 200 mg/day for a 66-kg man. As a result of the high protein binding of phenytoin, unbound phenytoin concentrations are a better indicator of efficacy and toxicity than total concentrations. Measurement of unbound phenytoin concentrations is recommended for elderly patients who have: (1) decreased serum albumin concentration, (2) total phenytoin concentrations that are more than 15 mg/L, (3) a low total concentration relative to the daily dose, or (4) total concentrations that do not correlate with the clinical state, such as apparent toxicity. A range of 5 to 10 mg/L total may be more appropriate as a therapeutic range for the elderly because of decreased protein binding and increased sensitivity to side effects.

Phenytoin has many drug–drug interactions and should be used cautiously in patients with EMMP receiving other medications. Selective serotonin reuptake inhibitor (SSRI) antidepressants may inhibit the cytochrome 2C family of P450 enzymes responsible for metabolizing phenytoin. Fluoxetine and norfluoxetine are more potent inhibitors of this enzyme, followed by sertraline and paroxetine. The latter two SSRI antidepressants may prove to be a safer choice

in the elderly. Coumadin has a very strong and complicated interaction with phenytoin and concomitant use should probably be avoided.

Phenytoin has some effects on cognitive functioning, especially at higher levels. In addition, phenytoin may cause imbalance and ataxia. In a study of elderly, among the various lifestyle, demographic, and health factors, which contributed to an increased risk, phenytoin was the only drug that was associated with a significant increase in fractures. However, this study could not determine if this was caused by falls from ataxia or seizures or was an effect of bone changes. In spite of its limitations, phenytoin is the least expensive major AED. This and its long record of use may account for it presently being the most widely used AED in the United States.

### Carbamazepine

It is effective for localization-related epilepsies and, thus, has an efficacy profile appropriate for the elderly. Two studies of new-onset epilepsy in elderly found it to be as effective as LTG, but it had a higher incidence of side effects.

Apparent clearance of CBZ has been reported to be 20% to 40% lower in the elderly as compared to adults. Decreases in clearance result in a prolonged elimination half-life. These changes in CBZ pharmacokinetics indicate that lower and less frequent dosing in elderly patients may be appropriate.

CBZ has some significant drug–drug interaction with medications that inhibit the cytochrome P450 enzyme, CYP 3A4. Among the inhibitors are erythromycin, fluoxetine, ketoconazole, propoxyphene (Darvon), and cimetidine (Tagamet). At least one food (grapefruit juice) has been identified to interact with CBZ, causing increases in CBZ serum concentrations. Patients with EH will need to be cautioned about these and should be instructed to inform the physician whenever they are beginning a new medication, including over-the-counter medications. Many other drug interactions occur, so CBZ is one AED which will need to be used cautiously in patients with EMMP receiving other medications. CBZ can also induce the CYP 3A4 system, reducing the effectiveness of other drugs.

CBZ may cause imbalance and ataxia. It is possible that patients with EMMP, especially those with CNS disorders, may be more sensitive to these effects. One of the major concerns with CBZ is its effect on sodium levels. The hyponatremia associated with CBZ is more pronounced as a person becomes older. This may become more problematic if a person is on salt restriction or a diuretic. Because of the mild neutropenia associated with CBZ use in younger adults, the effects of this AED on hematopoietic parameters in the elderly will need to be studied. CBZ is also known to affect cardiac rhythms and should be used cautiously, if at all, in persons with rhythm disturbances. CBZ is a moderately priced drug and should not present a significant cost issue.

### Valproate

This drug has both antiseizure properties and behavioral control effects. Valproic acid, like phenytoin, is associated with reduced protein binding and unbound clearance in the elderly. As a result, the desired clinical response may be achieved with a lower dose than usual. A nationwide elderly nursing home study showed that valproic acid dose and total valproic acid concentrations decrease within the elderly age groups. If the albumin concentration has fallen or the patient's clinical response does not correlate with total drug concentration, measurement of unbound drug should be considered. Because of its effects on mood stabilization, it may be especially appropriate for elderly with a dual diagnosis.

### Phenobarbital

This AED is effective for localization-related epilepsies and is the least expensive of all of the AEDs. However, its side effects of worsening of cognition and depression make it an undesirable drug for the elderly, especially in the nursing home setting.

### Gabapentin

It is effective for localization-related epilepsies. It is not metabolized by the liver, but rather renally excreted; therefore, there are no drug–drug interactions. Thus, it may be especially useful in patients with EMMP. There is a reduction of renal function with advancing age, so doses may need to be adjusted in patients with both EH and EMMP. Levels must be monitored after initiation and doses adjusted accordingly. However, gabapentin does appear to have some sedative side effects, especially at higher levels, and the elderly may be more sensitive to this problem.

In the elderly its half-life may be longer because of decreased renal elimination. Because gabapentin is effective in treating neuralgic

pain, it would be additionally beneficial for someone suffering from both epilepsy and pain.

### Lamotrigine

LTG is effective for localization-related epilepsies. It is primarily metabolized by the liver using the glucuronidation pathway, not the P450 system, and this pathway may be less affected by age. Based on a study of 150 elderly subjects, the dropout rate owing to adverse events was lower with LTG (18%) than with CBZ (42%). LTG subjects had fewer rashes (LTG, 3%; CBZ, 19%) and fewer complaints of somnolence: 12% for LTG and 29% for CBZ. LTG clearance is increased by approximately two to three times with coadministration of phenytoin and CBZ, whereas LTG clearances decrease twofold when valproic acid is coadministered.

### Levetiracetam

It has been approved as adjunctive therapy for partial-onset seizures in adults. It is extremely water soluble. This allows rapid and complete absorption after oral administration. Levetiracetam is not metabolized by the liver and, thus, is free of nonlinear elimination kinetics, autoinduction kinetics, and drug–drug interactions. Lack of protein binding (<10%) also avoids the problems of displacing highly protein-bound drugs and the monitoring of unbound concentrations. Lack of drug interactions would make it useful for treating elderly patients with epilepsies, EMMP.

Levetiracetam also appears to have a favorable safety profile. It was initially studied as a potential agent for treating cognitive disorders in the elderly, and thus a considerable amount of data regarding its tolerability in this age group are available.

### Pregabalin

This drug is related to gabapentin but is more potent with doses generally one-fifth those of gabapentin needed for therapeutic effect. Its absorption also appears to be more predictable because of the lower amounts needed for being transported across the intestinal system. Although it may prove to be a favorable AED for the elderly, its cost and lack of experience may limit its use.

## Dosing of AEDs in the Elderly

Compliance is a potential challenge in the elderly because of multiple medications, memory problems, and visual problems. In general, once- or twice-daily dosing is preferable, and even the AEDs with short half-lives in younger adults can be given less often in elderly. Reducing staff time spent administering multiple daily doses of medication to many patients may reduce errors and cost. In general, the elderly need lower doses than younger persons because (1) metabolism is slower and the same dose could give higher levels and (2) the elderly may need lower levels for seizure control and avoidance of toxicity.

### Alternative Routes of Administration

All of the commonly used AEDs have liquids or suspensions available. These were developed primarily for pediatric use, but these can be used if a person has difficulty swallowing pills or capsules. These can also be administered by way of a nasogastric tube. Blood levels

should be monitored if switching from one formulation to another to assure that adequate levels are being maintained.

Unfortunately, few AEDs are available for intramuscular (IM) or intravenous (IV) use. Phenytoin for IV infusion has a pH of 12, contains 40% propylene glycol, and can cause venous sclerosis, hypotension, and cardiac arrhythmias. It cannot be given IM. A much safer and better-tolerated phenytoin prodrug, fosphenytoin, is available and can be given IM or IV. Of the other AEDs, Phenobarbital can be given IM or IV, but valproate and levetiracetam have only IV indications.

## Drug Interactions with Non-AEDs

Concomitant medications taken by elderly patients can alter the absorption, distribution, and metabolism of AEDs, thereby increasing the risk of toxicity or therapeutic failure. Comedications are frequently used by patients in nursing homes receiving AEDs (Table 69-3). No data are available for elderly outpatients. Calcium-containing antacids and sucralfate reduce the absorption of phenytoin. The absorption of phenytoin, CBZ, and valproate may be reduced significantly by oral antineoplastic drugs that damage gastrointestinal cells. In addition, phenytoin concentrations may be lowered by intravenously administered antineoplastic agents. The use of folic acid for treatment of megaloblastic anemia may decrease serum concentrations of phenytoin, and enteral feedings can also lower serum concentrations in patients receiving orally administered phenytoin.

Many drugs displace AEDs from plasma proteins, an effect that is especially serious when the interacting drug also inhibits the metabolism of the displaced drug. Several drugs used on a short-term basis (including propoxyphene and erythromycin) or as maintenance therapy (such as cimetidine, diltiazem, fluoxetine, and verapamil) significantly inhibit the metabolism of one or more AEDs that are metabolized by the P450 system. Certain agents can induce the P450 system or other enzymes, causing an increase in drug metabolism. The most commonly prescribed inducers of drug metabolism are phenytoin, phenobarbital, CBZ, and primidone. Ethanol, when used chronically, also induces drug metabolism. The interaction between antipsychotic drugs and AEDs is complex. Hepatic metabolism of certain antipsychotics such as haloperidol can be increased by CBZ, resulting in diminished psychotropic response. Antipsychotic medications, especially chlorpromazine, promazine,

trifluoperazine, and perphenazine, can reduce the threshold for seizures. The risk of seizures is directly proportional to the total number of psychotropic medications being taken, their doses, any abrupt increases in doses, and the presence of organized brain pathology. The patient with epilepsy taking antipsychotic drugs may need a higher dose of antiepileptic medication to control seizures. In contrast, central nervous system depressants are likely to lower the maximum dose of AEDs that can be administered before toxic symptoms occur.

## CONCLUSIONS

The incidence of epilepsy is higher in the elderly than in any other age group, and, with the increasing number of elderly, the prevalence of epilepsy will be greater in older adults. Nursing homes have a much higher incidence and prevalence of epilepsy than community-dwelling elderly. Doses and blood levels generally need to be lower in the elderly for best outcome. The FE in nursing homes may have much greater variability in blood levels over time with stable doses with the older AEDs. Newer ones have not been studied. Of the newer AEDs, gabapentin, LTG, and levetiracetam are the most widely researched and used and have advantages such as less protein binding and fewer drug interactions. Cost may be one barrier to more extensive use. Much more research is needed, however, to determine the best treatments for the EH, EMMF, and FE cohorts.

# Late-Life Mood Disorders

Dan G. Blazer

## INTRODUCTION

Among the mood disturbances, depression is the most frequent cause of emotional suffering in older adults. Depression decreases the quality of life of the elderly, increases functional decline, and, when severe, is associated with a shortened life expectancy. Bipolar disorder, although much less frequent, can be most burdensome to the elderly and a difficult management problem for the clinician. Therefore, the diagnosis and treatment of mood disorders are among the most important and challenging tasks facing the geriatrician and other health-care providers.

During the past few years, a significant effort has been generated to better understand these common and frequently disabling maladies. We have learned much about the causes of late-onset depression. The evidence base for therapy has increased dramatically for both major depression and bipolar disorder. This chapter begins by first exploring current case definitions. Next, both clinical and community-based epidemiological studies are examined so that the reader appreciates the burden of depression across multiple settings. This is followed by extant evidence that informs us of the origins of late-life depression from a biopsychosocial perspective. The chapter concludes with a review of current therapies for depressed older adults. These therapies range from medications and electroconvulsive therapy (ECT) to family interventions.

## THE SUBTYPES OF LATE-LIFE MOOD DISORDERS

Although clinicians frequently disagree about exact case definitions of late-life mood disorders, the most cogent subtypes are presented below, subtypes relevant to clinical practice. Naturally, clinicians encounter frequent overlap of subtypes. For example, the acute and usually self-limiting episodes of major depression may be accompanied by chronic and less severe mood disturbances, such as dysthymia.

In addition, the symptoms of late-life mood disorders often overlap with other psychiatric and physical disorders. Therefore, these case definitions or subtypes may be more useful for coding and communication than for actual patient care. These do remind the clinician, however, of the variation in symptom presentation and the necessity to tailor treatment strategies to the individual.

*Major depression* is the “bread and butter” diagnosis for moderate-to-severe, yet self-limited, mood disorders in late life. To be diagnosed with major depression according to the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (DSM-IV), the older adult should exhibit most of the time for at least 2 weeks one or both of two core symptoms—depressed mood and/or lack of interest or pleasure in usual activities—along with four or more of the following symptoms: a feeling of worthlessness or inappropriate guilt, a diminished ability to concentrate or make decisions, fatigue, psychomotor agitation or retardation, insomnia or hypersomnia, significant decrease or increase in weight or appetite, and recurrent thoughts of death or suicide ideation. See [Table 70-1](#) for a description of how the symptoms of major depression may vary with older adults compared to younger adults.

Although not a current diagnosis in DSM-IV, *minor, subsyndromal, or subthreshold depression* is a useful diagnosis for older adults with clear yet less severe depressive symptoms than those with major depression, and criteria are presented in the Appendix of DSM-IV. The diagnosis of minor/subsyndromal/subthreshold depression can be made in at least two ways. First, to meet criteria in DSM-IV, subjects must experience one of the core symptoms for major depression plus one to three additional symptoms. Another means by which the diagnosis of minor depression can be made is to administer a symptom screen for depression (such as the Center for Epidemiologic Studies Depression Scale). If the subject scores 16 or higher on this scale (a score that signifies clinically significant depressive symptoms) yet does not meet criteria for major depression, then the diagnosis of minor/subsyndromal/subthreshold depression can be made.

TABLE 70-1

**Diagnostic Criteria for Major Depression and Description of How Symptoms May Vary Compared to those in Younger Adults**

SYMPTOM	DESCRIPTION
Depressed mood and/or lack of interest or pleasure in usual activities	The older adults may be more likely to express a loss of pleasure than to specifically complain of depression
Feelings of worthlessness or inappropriate guilt	Less common in older adults than in younger adults
Diminished ability to concentrate or make decisions	Often manifested as a complaint of memory problems—adults of all ages with moderate-to-severe depression complain of problems with concentration and memory, but depressed elders, in contrast to younger adults, exhibit impairment on psychological testing even when they do not have a comorbid dementing disorder
Fatigue	Common regardless of age
Psychomotor agitation or retardation	Older persons may exhibit either of these symptoms
Insomnia or hypersomnia	Older persons rarely, if ever, exhibit hypersomnia—a symptom that is much more common in adolescence and young adults
Significant decrease or increase in weight or appetite	Older adults rarely gain weight or experience an increase in appetite during a depressive episode
Recurrent thoughts of death or suicidal ideation	Although thoughts of death are not uncommon in older adults, suicidal ideation among depressed elders is less frequent than among the depressed who are younger

*Dysthymic disorder* is usually less severe than major depression but much longer lasting than either major depression or minor depression. To meet criteria for dysthymic, the older patients must experience moderate symptoms of depression for at least 2 years or longer. Although dysthymic disorder rarely has its onset in late life, it frequently persists from midlife into late life.

Depression in the elderly, as noted above, is often *comorbid* with both physical and psychiatric conditions, especially among the oldest old. Elders suffering from myocardial infarction and other cardiovascular conditions, diabetes, hip fracture, urinary incontinence, kidney disease, and stroke are more likely to suffer from depression than the general population of elders. When depression is comorbid with physical health problems, the clinician must distinguish between symptoms that are appropriate to the physical condition and those that either may be exaggerated or are not typical of the physical health problem. For example, an older person with cardiovascular disease may experience difficulty sleeping. If the sleep disturbance is to be considered a signal of depression, then the sleep problem should not simply represent the difficulty sleeping experienced by, for example, a person with shortness of breath or angina.

Depression is also frequently present among older adults with dementing disorders, such as Alzheimer's disease and vascular de-

mentia. The assessment of depressive symptoms in patients with dementia is problematic. One problem is the overlap between symptoms of depression and those that are the behavioral or emotional manifestations of the underlying dementia syndrome. For example, apathy and social withdrawal occur frequently in dementia and mild cognitive impairment. On the other hand, patients suffering from dementia are less likely to experience other symptoms, such as psychomotor agitation. Nevertheless, patients with dementia are no less likely to endorse a depressed mood. Given the frequency of depressive symptoms in Alzheimer's disease, some investigators and clinicians have proposed a "*depression of Alzheimer's disease*." To meet criteria for this syndrome, patients must first be diagnosed with dementia of the Alzheimer's type and exhibit at least three depressive symptoms such as depressed mood, anhedonia, social isolation, poor appetite, poor sleep, psychomotor changes, irritability, fatigue or loss of energy, feelings of worthlessness, and suicidal thoughts.

Episodes of major depression in late life can be of either *early onset* (that is, the first episode occurs before the age of 60 years and the current episode represents a relapse) or *late onset* (the first episode occurs after the age of 60 years). The symptoms of the depressive episode rarely differentiate early versus late onset. Nevertheless, a careful history may reveal factors that are associated with an earlier-onset disorder, such as long-standing personality disorder, a family history of psychiatric illness, or significant psychosocial stressors, such as a difficult employment history. One variant of late-onset depression is vascular depression, a subcategory of depression owing to vascular lesions in the brain. Vascular depression can be diagnosed only with the assistance of brain imaging. Nevertheless, elders experiencing this variant reveal more problems with verbal fluency, psychomotor speed, and especially executive cognitive functioning. Executive functioning is characterized by an ability to plan ahead, initiation, and perseverance.

*Psychotic depression* across the life cycle is much less frequent than nonpsychotic depression, yet is relatively more common in late life than earlier in life. For example, psychotic depression may be diagnosed in between 20% and 45% of hospitalized depressed elderly patients. Symptoms of late-life psychotic depression include a depression associated with delusions or hallucinations. These delusions or hallucinations may be "mood congruent" (delusions or hallucinations whose content is entirely consistent with the depressive themes of inadequacy, guilt, disease, death, and nihilism) or "mood incongruent" (the content of the delusions or hallucinations did not involve these depressive themes). As noted below, psychotic depression frequently will only respond to aggressive therapy such as electroconvulsive treatment.

*Bipolar disorder* is much less frequent than a unipolar major depression in late life. In addition, symptoms do not typically present with the classic cluster (i.e., hyperactivity, decreased sleep, flight of ideas, grandiose delusions, and hypersexuality). Mania may present with the predominant symptom of paranoia and fragmentation of ideas. A syndrome of reversible cognitive impairment, which appears much like an Alzheimer's type of dementia, can also be seen. The symptoms include confusion, agitation, and incomprehensible loud verbalizations. Yet another presentation of bipolar disorder is irritability and anger without evidence of an elated affect. Finally, bipolar disorder may present as a "dysphoric mania." These patients experience agitation and sleep problems but do not express feelings of elation or grandiosity but rather an uncomfortable "depressed" mood.

## THE EPIDEMIOLOGY OF LATE-LIFE MOOD DISORDERS

The frequency of clinically significant depressive symptoms among community-dwelling older adults in most studies ranges from approximately 8% to 16%. Depressive symptoms may be more frequent among Latinos than among Caucasians and African-Americans. Major depression is more common among women compared to men, a difference that persists into late life. Depressive symptoms are more frequent among the oldest old, yet the higher frequency is generally explained by factors associated with aging, such as a higher proportion of women (women experience a higher frequency of depressive symptoms than men), increased physical disability, increased cognitive impairment, and lower social economic status. Overall, the frequency of depressive symptoms is no higher among older adults than among adults in young adulthood or midlife. Depressive symptoms, as assessed by usual screening instruments, are somewhat less frequent in African-Americans and more frequent among Latinos.

The prevalence estimates of major depression in the community are quite low, ranging from 1% to 4% overall with a higher prevalence among women, yet with no significant racial or ethnic differences. The frequency of bipolar disorder in community populations is low regardless of age (less than 0.5%). On psychiatry inpatient units, however, the frequency of mania in older adults may be as high as 5% overall and 9% of the persons having a mood disorder. Dysthymic disorder and minor depression are somewhat more frequent (4–6% for dysthymic disorder and 4% for minor depression). The frequency of major depression in hospitalized older adults on medical and surgical services usually ranges between 10% and 12%; in long-term care facilities between 10% and 15% experienced major depression. Between 5% and 10% of older adults visiting primary-care providers meet criteria for a diagnosis of major depression. Clinically significant depressive symptoms among hospitalized patients ranged between 20% and 25%, and as high as 35% of older adults in long-term care facilities experience the symptoms. Therefore, the burden of mood disorders is much higher in inpatient and long-term care facilities than found in the community.

## THE OUTCOME OF MOOD DISORDERS IN LATE LIFE

Data from a 6-year follow-up of community-dwelling elderly in the Netherlands estimate that approximately 23% of subjects diagnosed with major depression recovered and remained recovered, 44% experienced a fluctuating course, and 33% experienced persistent and moderate-to-severe depressive symptoms. Data from a long-term study of major depression in a clinical setting reveal similar results. Thirty-one percent recovered and remained well, 28% experienced at least one relapse but recovered, 23% recovered only partially, and 17% experienced persistent depressive symptoms throughout the 6 years of follow-up. Predictors of partial remission include comorbidity, major depression and dysthymia, poor social support, and functional limitations.

Many factors adversely influence the outcome of late-life depression. In turn, late-life mood disorders can complicate the course of comorbid problems. For example, depression is a major cause of weight loss in late life, and weight loss can adversely influence the

outcome of many chronic medical illnesses. In turn, depression increased the risk for heart failure, a decrease in bone mineral density, and the prognosis of persons experiencing a myocardial infarction. Depression is also associated with disability over time. Disability is also a risk for depression. Physical disability among the depressed can lead to a higher number of negative events, the restriction of social leisure activities, isolation, and reduced quantity and quality of social support. Severe depression associated with cognitive decline, even if the cognitive impairment remits, is a risk for Alzheimer's disease.

Nonsuicide mortality is a significant adverse outcome resulting from severe late-life depression. Both severity and duration of depressive symptoms increase the risk for mortality in elderly population studies. Even so, the causes of higher mortality rates in older adults may not be secondary to depressive symptoms themselves but rather factors associated both with depression and mortality, such as older age, medical comorbidity, smoking, and body mass index as well as chronic diseases and functional impairment.

Suicide frequency increases for white men, with peaks reaching rates as high as 62 per 100 000 in the 65 years and older age range. In contrast, suicide rates among elderly women are lower than for women in midlife. Persons attempting suicide are more likely to be widows (widowers), to live alone, to perceive their health status to be poor, to experienced poor sleep quality, to lack a confidante, and to experience stressful life events such as interpersonal problems in one's marriage. Suicidal ideation is high among older adults, ranging from 5% to 10% (usually expressed as a wish to not live longer, not active suicidal intent).

Suicide rates in the United States have declined in recent years, reversing earlier trends. From 1987 to 2002, the rates among older persons declined from 21.7 to 15.6 per 100 000. This decline mirrors the lower rates in the 45 to 64 years age group documented during the late 1970s. These two declines suggest a so-called period effects rather than cohort effect. Namely, events during the 1970s and 1990s could be operating to buffer the negative impact of depression and other factors that may increase risk for suicide in the elderly. For example, the stock market created wealth and more economic security for many Americans during the 1990s. A more controversial explanation is that the introduction of selective serotonin reuptake inhibitors (SSRIs), prescribed to more than 10% of older adults in the United States may have reduced the burden of depression such that suicide rates decreased.

## ORIGINS OF LATE-LIFE MOOD DISORDERS

### Biological Origins

Older adults appear to be at greater risk of major depression biologically, such as depression resulting from vascular changes, even though the frequency of depression is either lower or similar to that among younger adults. Older adults may therefore be protected psychologically because of factors such as cumulative wisdom and perhaps relatively protected from social risk. Genetic influences appear to account for less than 20% of the variance in total depression scores in twin studies, a minimal contribution compared to other factors. Most hypothesized genetic markers for late-life depression have not been substantiated in controlled studies. Even so, some unique possibilities of mutations or polymorphisms are being investigated for

their contribution to late-life depression. For example, a rare disease, CADASIL (cerebral autosomal-dominant arteriopathy with subcortical infarcts and leukoencephalopathy), results from a mutation in the notch 3 gene. Depression is one of the initial symptoms of this condition.

Underactivity of serotonergic neurotransmission has been the focus of much research on the pathophysiology of depression in younger adults. Although serotonin activity (specifically receptor binding) decreases dramatically throughout midlife, there is less decrease from midlife to late life. Given that enhancement of serotonin neurotransmission has been a key to the development of antidepressant medications, these findings are of importance to the pathophysiology of late-life depression, although the specifics of the mechanisms have yet to be worked out. Polymorphisms in the serotonin transporter gene may influence antidepressant response to SSRIs. A single-nucleotide polymorphism in the rate-limiting enzyme of neuronal serotonin synthesis has been identified. This functional single-nucleotide polymorphism in older adults has been found to be associated with a significant decrease in response to SSRI antidepressant therapy.

Depressive symptoms can lead to increased cortisol secretion, which, in turn, inhibits neurogenesis, leading to hippocampal volume loss, which, in turn, may mediate the core symptoms of depression. Early-life stress may produce a permanent hypersensitivity to stress, with the production of ongoing HPA dysregulation, and, with repeated episodes of major depression plasticity, may decrease, giving rise to permanent damage. As described above, a vascular-based depression has been proposed, resulting from cortical ischemic events. These ischemic events are documented via magnetic resonance imaging (MRI) as white matter hyperintensities. The symptoms of vascular depression resemble those of frontal lobe syndromes secondary to structural abnormalities in areas associated with the limbic–cortical–striatal–palatal–thalamic–cortical pathways.

The hereditary predisposition to manic episodes is significant, regardless of age. Yet this predisposition does not appear to be as great in late life compared to earlier in the life cycle, especially for first-onset bipolar disorder. Despite the biologic predisposition to developing late-onset bipolar illness, life events can also contribute to the onset of manic episodes. More than half of persons who experience late onset of mania report a life event severe enough to disrupt usual activities of daily living. Clinicians should be especially vigilant in reviewing medications and their patients to present with manic episodes. Corticosteroids, levodopa, decongestants, bronchodilators, thyroid replacement, and antidepressant medications all can contribute to the onset of a manic episode. Finally, traumatic head injuries are thought to contribute to bipolar disorder as well.

## Psychological Origins

A number of psychological factors have been suggested as contributing causes to depressive symptoms and disorders in the elderly. Older patients with personality disorders do not recover from depression as quickly, nor do they experience as long the remission as those without. One reason is that personality styles often modify the way in which the older adult adjusts to stressful events, such as medical illnesses.

Cognitive distortions have also been proposed as potential causes of late-life depression. The cognitive–behavioral psychotherapies (described below) are based on this theory. Specifically, older adults

may overreact to life events or misinterpret these events and, therefore, exaggerate the negative outcome. For example, the older adult may ruminate excessively about a negative event or catastrophize the event. A frequent cause of ruminating or catastrophizing is family conflicts or perceived slights from family members (the basis of interpersonal psychotherapy as described below). Self-efficacy and a higher sense of mastery, in contrast, are associated with fewer depressive symptoms.

## Social Origins

A number of social factors have been associated with late-life mood disorders, including stressful life events, bereavement, chronic stressors or daily hassles, socioeconomic status, and social support. Investigators have found a strong association between more severe stressful events, such as bereavement or life-threatening illness and major depression. Older adults lacking confidence are especially vulnerable to such stressful events. Stressful events, however, may be attenuated among older people for at least two reasons. First, the elderly usually gain experience through the life cycle that prepare them to manage the impact of such an event. This increased capacity for managing stressful events assumes that the older adult is cognitively intact and functions at a relatively normal level. In addition, older adults often have anticipated the events that confront them. For example, the death of a spouse for an 80-year-old woman may be a tragic but not an unanticipated event. She has seen many of her peers experience similar losses. Following the loss of a loved one, depression is more frequent but it is not the usual outcome. Older persons exposed to chronic strain are also at greater risk of developing depression. The most common and frequently studied example of such strain is caregiving (especially for demented). Financial strain has also been associated with increased frequency of depressive symptoms. In general, socioeconomic disadvantage and the perception that one's basic financial and tangible needs (such as adequate housing) are inadequate have been associated with a higher frequency and persistence of depressive symptoms.

Social support has long been associated with protection against the onset and persistence of depressive symptoms. The most robust relationship between social support and depression is the perception that one's social network and interactions with network members are limited or negative. Adequate social support, on the other hand, can modify the negative impact of stressful events and other risk factors for depression. For the most part, older adults perceive their support to be adequate (and therefore when support is perceived to not be adequate, clinicians should be especially attentive).

Given that the frequency of depression in the elderly is no higher than at other stages of the life cycle, yet biological risk for depression may be increased, some have suggested that psychological factors may modify the biological and social risk for depression. One example of a psychological factor modifying a biological risk is "wisdom." Wisdom is a nebulous concept, yet may be loosely defined as an expert knowledge system concerning the fundamental and practical aspects of life, such as a knowledge and ability to judge both the meaning and the conduct of life. Investigators have suggested five characteristics of wisdom: a rich factual knowledge, a rich procedural knowledge (that is, having an ability to assess, for example, what strategies might best solve a given problem), lifespan contextualization (that is, learning to integrate life experiences), relativism of values and life priorities (that is, a tolerance for differences in one's

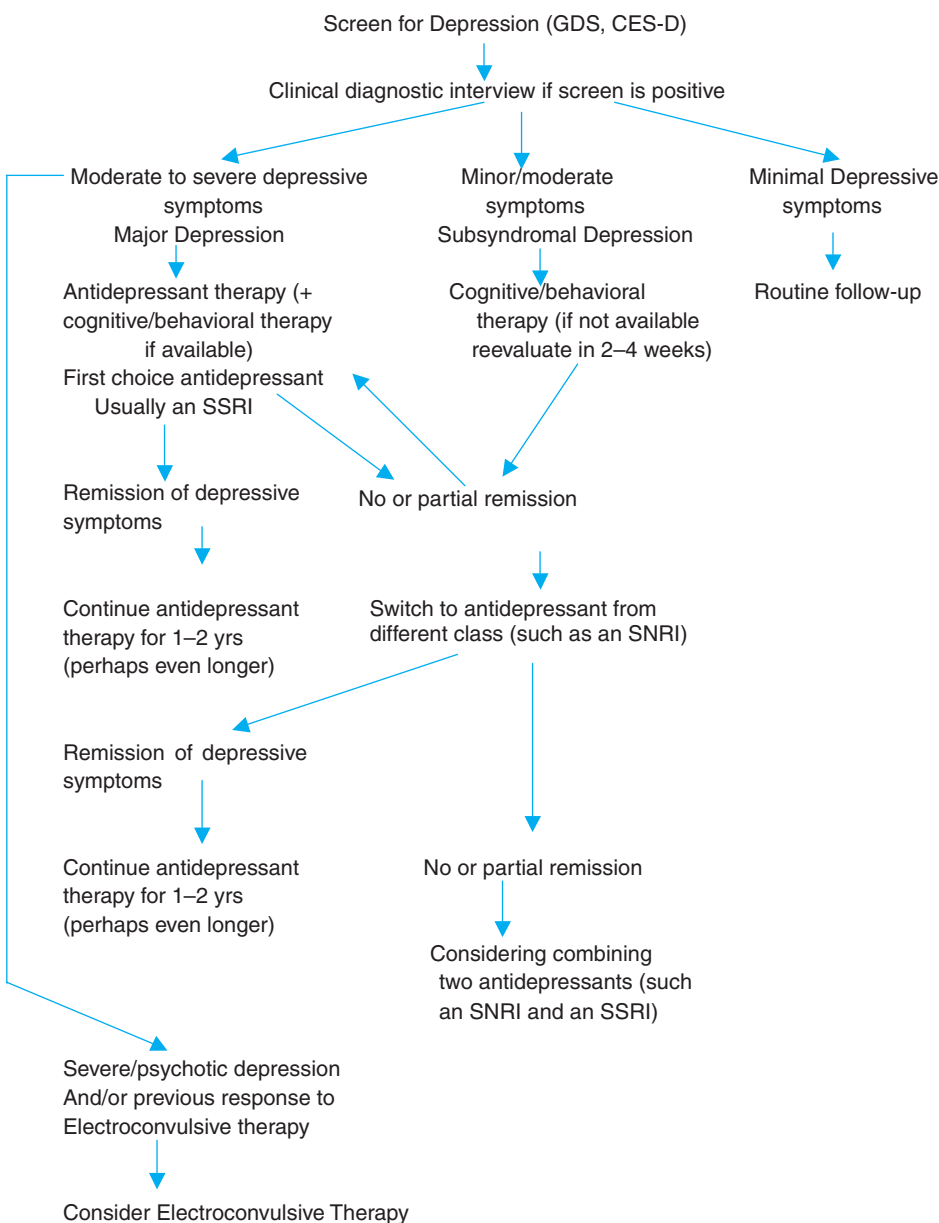

sociocultural environment), and a recognition and ability to manage uncertainty.

## THE DIAGNOSTIC WORKUP OF LATE-LIFE MOOD DISORDERS

The diagnosis of late-life mood disorders derives primarily from a careful history (see [Figure 70-1](#)). The clinician should focus on not only present symptoms but also past history (especially history of previous episodic symptoms similar to those presenting at the time of the interview). Family history, medication history, recent life events, changes in social and economic status, and recent physical problems will inform the clinician of not only the diagnosis but also potential causes of the mood disorder. The diagnosis of depression can be made in older adults without comorbid disorders, using the diagnostic criteria for major depression in DSM-IV-TR. Yet, as outlined in [Table 70-1](#), older adults are less likely to endorse a depressed mood,

rarely report weight gain (a symptom that is frequent among depressed younger adults), rarely complain of excess sleeping, are less likely to express feelings of worthlessness or inappropriate guilt, and are less likely to report suicidal thoughts.

Screening scales, such as the Geriatric Depression Scale and the Center for Epidemiologic Studies-Depression Scale, can complement the history and provide screening in busy clinics, especially primary-care clinics. Screening for depressive symptoms should be supplemented with screening for cognitive functioning using scales such as the Mini-Mental State Examination. Screening in primary care is critical, for not only is the frequency of depression high but suicidal ideation may range from 1% to 5% of all older adults attending a clinic. The success of screening in primary clinics, however, is mixed for busy physicians. These physicians, although accepting the responsibility for treating older adults with mood disorders, often perceived their clinical skills as inadequate. One reason for these feelings of inadequacy is that uncomplicated major depression makes up only approximately 15% of those depressed persons receiving

**FIGURE 70-1.** The diagnosis and treatment of depression in the elderly.

TABLE 70-2

## Diagnostic Workup of the Depressed Older Adult

ROUTINE DIAGNOSTIC TESTS	ELECTIVE DIAGNOSTIC TESTS
Screen for depressive symptoms using commonly used symptom screening scales such as the Geriatric Depression Scale or the Center for Epidemiologic Depression Scale	Magnetic resonance imaging can be used to establish the diagnosis of subcortical white matter hyperintensities, a clue to the presence of a vascular dementia
The key to the diagnosis of late-life mood disorders is a thorough present and past history and mental status examination	Screens for vitamins and minerals, such as vitamin B-12 and folate deficiency, when deficiency is suspected
Cognitive function can be evaluated by administering a brief cognitive screen such as the Mini-Mental Status Examination	Polysomnography is used infrequently in routine diagnostic workups for late-life mood disorders but may be used when a sleep abnormality cannot be explained
Laboratory tests can be used to screen out comorbid medical conditions that may contribute to the depressive disorder or that may provide baseline data for the prescription of antidepressant medications	T <sub>3</sub> and T <sub>4</sub> as well as TSH may be ordered to rule out undiagnosed thyroid dysfunction

primary care. Recent studies have suggested that the effectiveness of treating late-life depression in primary care can be significantly augmented by case managers who maintain close contact with mental health professionals.

Clinicians should be aware of potential bias in the diagnostic process. For example, older men are less likely to be referred to primary-care physicians or mental health specialists for symptoms of depression. Older men are also less likely to endorse core depressive symptoms and to have received prior depressive treatment. The discomfort felt by depressed older men is more likely to present more as somatic symptoms and interpersonal stress rather than in emotional terms. In other words, men may be less likely to recognize their feelings. They also are less likely to accept a diagnosis of depression and perhaps therapy, if the diagnosis is made. Some symptoms of depression may be endorsed more frequently by older adults who are both depressed and cognitively impaired. The symptoms include greater emotional withdrawal and psychomotor retardation. The cognitively impaired depressed, however, are probably no less likely to endorse a depressed mood than those without cognitive impairment.

Laboratory tests are ordered primarily to augment the history and physical examination, for there is no biological marker for most subtypes of late-life depression. The one exception is vascular depression, where the presence of subcortical white matter hyperintensities on magnetic resonance imaging assists in the diagnosis. Routine laboratory tests, especially a chemistry screen and an electrocardiogram, should be obtained when antidepressant medications are prescribed. Elective tests include thyroid screens for undiagnosed thyroid dysfunction, polysomnography if significant sleep abnormalities cannot be explained, vitamin B-12 and folate assays when vitamin deficiency is suspected, and magnetic resonance imaging to establish the diagnosis of vascular depression (Table 70-2).

## TREATMENT OF LATE-LIFE MOOD DISORDERS

### Biological Therapies

Antidepressant medications are the foundation for the treatment of moderate-to-severe late-life depression. In terms of efficacy, virtually all antidepressant medications are equal (see Figure 70-1). There-

fore, the choice of an antidepressant medication is usually based on side effects that the clinician wishes to avoid. For this reason, the SSRIs have become the treatment of choice. Nevertheless, collision should recognize that these medications are not without side effects. Antidepressant medications and their doses are presented in Table 70-3. Antidepressants are most effective in treating moderate-to-severe depression (typically major depression). For less severe symptoms of depression, antidepressant therapy coupled with counseling/psychotherapy has not proven to be of great benefit. Perhaps for this reason, a number of alternative therapies have been described for depression, such as St. John's wort (*Hypericum perforatum*).

Most of the SSRIs have been demonstrated to be efficacious in treating older adults, including fluoxetine, sertraline, paroxetine, citalopram, and fluvoxamine. Escitalopram is probably an effective drug, but it has not been demonstrated efficacious in clinical trials, specifically for the elderly. Other new-generation antidepressants that have been shown to be efficacious in the elderly include mirtazapine, venlafaxine, and bupropion. Duloxetine, recently entering the market, has not been specifically proven effective in the elderly. Clinicians should not neglect the older antidepressants for some patients, such as nortriptyline and desipramine. These drugs are equally efficacious but, in many elders, cause adverse side effects, which limit their use. Nevertheless, some elders do well on these older drugs, and, if they respond without adverse side effects, there is no reason to switch to the newer agents.

Side effects of the antidepressant medications vary by category (and no category is without side effects). The SSRIs may lead to agitation, insomnia, gastrointestinal disturbances, weight loss, sexual dysfunction, and elevated levels of tricyclic antidepressants if combined therapy is instituted. A rare but most troubling side effect of SSRI therapy is SIADH (syndrome of inappropriate antidiuretic hormone secretion). This syndrome can emerge, suddenly leading to profound electrolyte imbalance (specifically a dramatic decrease in sodium). The tricyclic antidepressants frequently cause anticholinergic effects such as dry mouth, urinary incontinence, and constipation. Postural hypotension is a more serious side effect, possibly leading to falls.

Clinicians must be realistic about expectations for the period of recovery from a moderate-to-severe episode of depression in the elderly. Although most antidepressants are thought to demonstrate their effectiveness within 4 to 6 weeks, the actual time from the beginning of therapy to the subjective report by the patient that

TABLE 70-3

## Pharmacotherapy for Late-Life Depression

ANTIDEPRESSANT	STARTING DOSE (mg)	AVERAGE DAILY DOSE (mg)	SIDE EFFECTS
<i>Tricyclics</i>			
Nortriptyline	25	25–100	Anticholinergic effects (such as dry mouth, constipation, and urinary retention), postural hypotension, and possible cognitive dysfunction
Desipramine	25	25–100	
<i>SSRIs</i>			
Paroxetine	10	10–40	Agitation, insomnia, gastrointestinal disturbances, SIADH, weight loss, sexual dysfunction, and elevated blood levels of tricyclics
Sertraline	50	50–200	
Fluoxetine	10	10–40	
Citalopram	10	10–20	
Escitalopram	10	10–20	
<i>Other antidepressants</i>			
Trazodone	50		Sedation and priapism
Bupropion	75		Agitation and insomnia
Venlafaxine	37.5		Nausea, vomiting, headache, and hypertension
Mirtazapine	7.5		Sedation and weight gain
Duloxetine	40		Orthostatic hypotension, nausea, and hypertension

they truly feel “back to normal” may take months and even up to a year in severe depression. Although biological symptoms may abate fairly quickly, such as sleep problems, the subjective sense of well-being and interest in life take much more time to return to normal. One reason is that the depressed persons when recovering require some time to reintegrate into their usual life activities and are often hesitant to return to past activities after a prolonged episode of depression.

Antipsychotic medication is the first-line treatment for acute agitated behavior in the manic patient. The drugs of choice are the new-generation (or atypical) antipsychotic medications. Olanzapine (5–10 mg) and risperidone (2–4 mg) are most frequently used among older adults. These newer agents, in contrast to the older antipsychotic agents, such as haloperidol, have become treatment of choice primarily because of fewer extrapyramidal side effects. Nevertheless, these newer agents can lead to weight gain and especially in a propensity toward diabetes mellitus.

Lithium carbonate has been the cornerstone for the prevention of the current manic and depressive episodes in bipolar disorder, yet the drug does present potential significant toxicity in late life. The usual dose is 300 to 600 mg daily. In younger adults, the normal range for a lithium level is between 0.8 and 1.2 mEq/L. In older adults, lithium can be maintained in the range of 0.4 to 0.6 mEq/L. Renal status of the older adults should be determined before lithium therapy is instituted by obtaining a chemistry screen. If compromised renal function is suspected, then a 24-hour creatinine clearance can be obtained.

Given the potential for side effects with lithium, antiepileptic medications have been used frequently to treat older adults with bipolar disorder. Valproic acid (400–800 mg/day) is the preferred agent by most clinicians. Gastrointestinal problems are the major side effect limiting use of this drug. Other agents that have been prescribed for prevention of manic episodes include carbamazepine (200–600 mg/day), clonazepam (0.5–1.5 mg/day), lamotrigine (100–200/d), and gabapentin (900 mg/day).

Clinicians face challenges in treating depressed older adults who do not respond to antidepressant medication. Older adults with

psychotic symptoms and who have responded previously to ECT do not respond well to antidepressants but often do respond to a second course of ECT. Although the response of older adults experiencing depression may be slightly less optimal than with young adults, some suggest that ECT is actually a superior treatment in late life compared to midlife. A higher percentage of moderately to severely depressed older adults receive ECT compared to younger adults primarily because older adults are more likely to be treatment resistant to antidepressant therapy. Memory problems persist as the primary adverse reaction to ECT, although these problems are usually transient and clear within a few weeks following treatment. A new procedure could replace ECT for older adults, namely, repetitive transcranial magnetic stimulation. The advantage of transcranial magnetic stimulation is that it does not require anesthesia and does not produce a seizure. Finally, exercise has been shown to be effective in treating mild-to-moderate symptoms of depression (but is not a treatment that can replace antidepressant therapy for moderate-to-severe depression). ECT may also be effective in bringing about a remission of a severe and pharmacologically resistant episode of mania.

### Psychological Therapies

A number of psychotherapies have been explored in the treatment of late-life depression, especially cognitive/behavioral therapy and interpersonal psychotherapy. These therapies, unlike more long-term and subjective approaches to therapy (such as psychodynamic therapy), can be manualized and can be administered by clinicians with Masters-level training. Cognitive/behavioral therapy is an educational approach to therapy during which the therapist focuses on thoughts expressed by the patient that may perpetuate depression. The goal of therapy is to teach the older adult that these thought patterns can be changed. One approach to reversing these negative thoughts is by using a daily record of thoughts and then “stepping back” and examining the rational response to these thoughts (thoughts are usually precipitated by an adverse event). For example, an older woman may wait for a call on a Sunday night from

her daughter and the call does not come. She may feel sad and abandoned, thinking that her daughter does not love her anymore. Upon a rational reflection, however, she recognizes that her daughter may have been busy during the evening and by late evening does not wish to disturb her mother and will call the following evening. Interpersonal psychotherapy is a therapy similar to cognitive/behavioral therapy, which focuses on four areas thought to cause or maintain depression: grief (such as the death of a loved one), role transitions (such as movement to a retirement community), interpersonal deficits (such as a propensity to express anger inappropriately), and interpersonal disputes (such as a conflict with a neighbor). Through an educational approach, older adults are instructed to implement adaptive means for confronting each of these problems.

A combination of psychotherapy and pharmacotherapy has been demonstrated to be more effective in bringing a depressive episode into remission, as well as preventing recurrence during the first year following remission. Recent studies, however, suggest that pharmacotherapy is, by far, more valuable than combined therapy in preventing recurrence during longer periods of time. The Improving Mood Promoting Access to Collaborative Treatment (IMPACT) study was developed to test whether placing a health specialist in a primary-care physician's office in order to influence the use of combined therapy is more effective than usual care in reducing the burden of late-life depression. Older adults in the treatment group (compared to the control group) were less likely to express suicidal ideation, to experience reduction in depressive symptoms, and to experience less functional decline.

### Working with the Family of the Depressed Older Adult

Therapy for the depressed older adult almost always involves some interaction with the family. Family members usually accompany the older adult to the office, and the depressed elder rarely prohibits the physician from discussing the depressed mood with the family member. And the physician should take advantage of this opportunity. Initially, the family can provide valuable additional information about the duration, severity, qualitative differences they witness in the depressed elder compared to her/his usual state, and information about life events that may have contributed to the depressive episode. The physician also can address issues of concern to the family. When the physician takes time to discuss care with the family, hospitalization may be avoided and acute changes in behavior during the course of therapy may alert the clinician to problems such as adverse side effects from medications.

Families often can benefit from an explanation of symptoms that the elder is experiencing, for they are not accustomed to their loved one, for example, sitting all day in a chair. They also can benefit from guidance regarding how to manage behaviors. For example, how far should the family push the patient to become more physically active or engage in social activities? Finally, families should be educated about the risk for suicide. Families can help reduce suicide risk by restricting the behavior of the depressed elder, such as limiting access to medications, removing weapons from the house, or limiting driving to times when someone else is in the automobile. At the same time, families should be assured that there is no absolute method to prevent suicide and that the best the clinician and family can do is reduce suicide risk.

### Evaluating and Managing Suicidal Risk in the Depressed Older Adult

When working with the depressed older adult, evaluation and management of suicidal risk are critical. Asking the older adult about suicidal ideation or behavior is of value but cannot be relied on as the best means for evaluation. The physician can ask a series of questions to determine increased risk:

1. Do you feel that life is worth living?
2. Have you ever thought about harming yourself? (Ask question #3 if the answer is yes.)
3. If you were to attempt to harm yourself what means would you use?
4. Have you ever tried to harm yourself?

If the older adult has considered a specific means for harming himself/herself (such as taking pills or shooting oneself) then the risk is increased.

Of greater value, however, in the evaluation of risk for suicide is the accumulation of known risk factors. In other words, the best evaluation for suicidal risk parallels the evaluation for risk of chronic disease events such as a myocardial infarct. A person is at greater risk of a myocardial infarct if the person has high cholesterol, is overweight, has a history of heart disease in the family, has diabetes, does not exercise, and so forth. Older adults are at greater risk of suicide if they are male, are in late-late life, are Caucasian, have lower income, are socially isolated, are divorced or widowed, are bereaved, are suffering from a comorbid medical illness, are diagnosed with depression in the past, are abusers of alcohol, and have a history of previous suicide attempts. Some clinicians believe that developing a suicidal contract (the patient agrees not to harm herself/himself until the clinician is contacted to discuss the emotional pain) prevents suicide. This is not the case, although a suicide contract may reduce risk somewhat.

If the physician determines that the older adult is at significant risk of suicide, then hospitalization is imperative. Acute suicidal risk is usually short-lived and therefore hospitalization for a few days is sufficient to both implement a comprehensive program of treatment and "ride out" the time of greatest risk. During hospitalization, privileges can be gradually increased and the patient gains confidence to return to the usual activities. Once the patient is discharged from the hospital, medication should not be prescribed in sufficient quantity that filling one prescription would provide the patient with enough medications to make a serious suicide attempt by overdose.

# Schizophrenia

Danielle L. Anderson ■ Peter V. Rabins

## DEFINITION

Schizophrenia is a pervasive, debilitating disease characterized by positive symptoms of hallucinations, delusions, and thought disorder (also referred to as psychosis), and negative symptoms of chronic social dilapidation. Emil Kraepelin first distinguished schizophrenia (then termed dementia praecox) from bipolar psychosis more than 100 years ago, by contrasting the long-term deteriorating course of delusions and hallucinations characteristic of schizophrenia to the intermittent course of bipolar illness. Schizophrenia remains a clinical diagnosis made on the basis of the individual's psychiatric history and mental status examination, as no laboratory or imaging studies can validly diagnose it.

## Inclusion Criteria

Schizophrenia is described in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* as two or more of the following symptoms active for a minimum of 1 month's duration (unless adequately treated) as well as the continuing presence of a symptom for 6 months: delusions, hallucinations, disorganized speech, disorganized behavior, and negative symptoms along with a significant disturbance of the individual's functioning that results in disturbances in occupation, social interaction, or the management of one's self-care. These symptoms of schizophrenia can be characterized as either positive or negative.

## Positive Symptoms

The positive symptoms of schizophrenia consist of abnormalities of sensory experience and cognitive processing. These manifest as hallucinations, delusions, bizarre behavior, or formal thought disorder. *Hallucinations* are perceptions in the absence of physical stimuli. In schizophrenia, auditory hallucinations usually predominate, but, in

patients with late-onset schizophrenia, olfactory, visual, tactile, or gustatory hallucinations may be present. In schizophrenia, the hallucinated voices are described as coming from outside the person's head and providing a running commentary on the patient's behavior. At times, these speak directly to the individual or converse with each other. Voices that tell the individual what to do are referred to as command hallucinations.

*Delusions* are fixed, false, idiosyncratic beliefs and consist of ideas and beliefs that are persecutory, bizarre, or grandiose. The idea that the person is being controlled by outside forces is common.

Bizarre behavior may be observed in the person's appearance (odd/inappropriate layering of clothing) or in their aggressive, agitated or repetitive/stereotyped behavior (for example, flipping the light switch multiple times or repeated closing and opening the door). *Formal thought disorder* includes illogical or incoherent speech in the absence of aphasia. It manifests as tangentiality, loose associations (a lack of logical connection between sentences), or derailment (the sudden loss of train of thought).

## Negative Symptoms

The negative symptoms of schizophrenia result in a decline in the person's baseline social, interpersonal, and volitional activity. People with schizophrenia often have a diminished range of facial expression, a phenomenon termed affective flattening; poor eye contact, and decreased expressive gesturing. Spontaneous speech decreases and speech latency increases. Individuals with schizophrenia become less social and form few close relationships with others. As the disease progresses, avolition and apathy become common and impair work and school performance, grooming, and hygiene.

## Clinical Course

Schizophrenia often has a prodromal period during which individuals become socially awkward and isolative. Negative symptoms

emerge, and work or school performance gradually declines. Positive symptoms and bizarre, disorganized behavior then manifest more overtly. For example, people with schizophrenia frequently speak and laugh when they are by themselves, symptoms that are thought to represent patients' responses to internal stimuli such as hallucinations. The negative symptoms often result in a lowered socioeconomic status, leading to unemployment, estrangement from family members, and even homelessness.

### Exclusion Criteria

Schizophrenia is not the only cause of hallucinations and delusions. For this reason, patients presenting with psychotic symptoms need to be fully evaluated and all other potential causes of these ruled out before a diagnosis of schizophrenia is made. The presence of prominent mood symptoms during the psychotic episode indicates the likelihood of a mood disorder or schizoaffective disorder. The presence of hallucinations or delusions with subacute onset of fluctuating disturbance of consciousness and attention suggests a delirium. In the elderly, psychosis often occurs in the setting of dementia; the presence of memory loss and either aphasia, apraxia, agnosia, or loss of executive function should raise the possibility of dementia, since individuals with schizophrenia generally remain oriented to their surroundings. Hallucinations and delusions can also be induced by exogenous substances (e.g., medications, illicit drugs, and toxins) or general medical conditions such as seizure disorder, brain tumor, and encephalitis.

### Associated Symptoms

Abnormal psychomotor activities such as rocking, pacing, immobility, or repetitive stereotyped behaviors can impair social functioning. Hallucinations can impair concentration owing to the distraction produced by aberrant experiences. Demoralization and anhedonia, a loss of interest and enjoyment in activities, may also be found. Mortality is increased in schizophrenia; 28% of the increase in early death is attributed to suicide and 12% to accidents. The prognosis is worse in patients with impaired insight into their illness.

### Age of Onset (Table 71-1)

#### Early Onset

The lifetime prevalence of schizophrenia is 1%. Although schizophrenia occurs with equal frequency in men and women, the age of onset is earlier in males, with a peak age of onset between 10

and 25 years. Women have a bimodal age distribution with a first peak between 25 and 35 years and another peak in late middle age. The disease tends to have a more severe course in males with greater predominance of negative symptoms, and females tend to retain their social and premorbid function. However, patients with early-onset schizophrenia who live into late life usually have a many-year history of illness with prominent negative symptoms and an inability to live independently.

#### Late Onset

A consensus of international experts has identified two diagnostic forms of late age disease: late-onset schizophrenia, with onset after the age of 40 years, and very-late-onset-schizophrenia-like psychosis, with onset after the age of 60 years.

Schizophrenia beginning after the age of 40 years is characterized by prominent positive symptoms, but fewer negative symptoms than early-onset schizophrenia. However, thought disorder is rare in the late-onset condition. In addition, individuals with late-onset schizophrenia are less likely to have a family history of schizophrenia than those with early onset and are more likely to be female. Compared to the cognitive deficits seen in early-onset patients, late-onset illness is characterized by relatively intact learning, abstraction, and cognitive flexibility. Very-late-onset schizophrenia frequently occurs in the setting of sensory impairment (decreased auditory acuity and low vision states) and social isolation. It is important to note that late-onset schizophrenia is responsive to lower levels of antipsychotics than early-onset schizophrenia.

## DIFFERENTIAL DIAGNOSES

### Mood Disorders

Mood disorders include both major depressive disorder and bipolar affective disorder. In both, depressive episodes characterized by a loss of vital sense (a sense of physical discomfort, sleep disorder, appetite loss, poor self-attitude [lack of self-confidence, self-blame, and guilt], and sad mood. Bipolar affective disorder differs from major depressive disorder in that those affected also experience manic episodes. Although psychosis is not required for diagnosis, it can occur during either severe depressive or manic episodes.

One important distinction between psychosis in mood disorders and schizophrenia is that in the psychosis of mood disorders, symptoms are present only during severe mood episodes and resolve when the mood disturbance resolves. Although those with schizophrenia may experience mood symptoms during the course of their illness, psychosis is the dominant feature that persists regardless of mood disturbance. Another clinically useful distinction is that the delusions of mood disorder are congruent with the patient's mood state. For example, in mania, grandiose delusions accompany euphoric or elevated mood, while, in depression, self-blaming, self-deprecating, and guilty delusions parallel a sad mood.

### Schizoaffective Disorder

Schizoaffective disorder is similar to schizophrenia in that psychotic symptomatology is prominent and may persist between episodes, but there is also a prominent disturbance in mood. Thus, the diagnosis of schizoaffective disorder requires a period of psychosis, lasting at

**TABLE 71-1**

#### Differences Between Early- and Late-Onset Schizophrenia

	EARLY ONSET	LATE ONSET
Age of onset	Teens–early adult	Fifth decade or later
Family history of schizophrenia	Frequently a positive family psychiatric history	Rare
Gender	Equal prevalence between men and women	Predominantly women
Symptom type	Negative and positive	Mostly positive symptoms; thought disorder rare
Prognosis	Poor	Moderate

least 2 weeks in the absence of any mood disturbance. However, criteria for a mood disorder must also be met for a predominant portion of the active and residual periods of the disease.

## Dementia

Twenty percent to 30% of individuals with dementia experience hallucinations, and 30% to 40% develop delusions during the course of their illness. The cognitive deficits reflect a drop from the individual's prior level of functioning and cause impairment in activities of daily living. In the case of Alzheimer's dementia, the most common form of dementia, the onset is gradual, typically begins with memory deficits, and progresses to death over the course of 10 years. Although schizophrenia may include cognitive deficits, these are less severe than in dementia and progress more slowly.

## Delirium

Delirium is characterized by an acute or subacute onset of cognitive impairment and a disturbance of attention and cognition. Fluctuation over the course of the day is common. Misperceptions of environmental stimuli, referred to as illusions, and visual hallucinations are also common. Delirium is usually because of a toxic, metabolic, or infectious disorder that needs identification and treatment in order to resolve. Delirium's acute onset and fluctuating cognitive deficits distinguish it from schizophrenia.

## Delusional Disorder

Delusional disorder is characterized by a single, prominent delusion, which is described as "nonbizarre," that is, plausible, and has been present for at least a month. The individual with delusional disorder usually remains fully functional apart from the dysfunction that results directly from the delusion. The negative symptoms found in schizophrenia are absent in delusional disorder, and the individual with delusional disorder behaves normally when the delusion is not being acted upon or discussed.

## Substance-Induced Psychotic Disorder

Hallucinations and delusions may be a result of intoxication or withdrawal of substance use. Sedatives (barbiturates and benzodiazepines), alcohol, and stimulants (amphetamines and cocaine) are common causes. These are not seen in withdrawal from opiates.

## Schizophreniform Disorder and Brief Psychotic Disorder

The criteria to fulfill schizophreniform and brief psychotic disorder are the same as in schizophrenia, except for shorter illness durations than schizophrenia. Schizophreniform disorder lasts between 1 and 6 months, while brief psychotic disorder lasts anywhere from 1 day to 1 month. Social and occupational impairment is not required in these disorders.

## Ictal Psychosis

Schizophrenia-like psychosis occurs in complex partial seizures, particularly those of the temporal lobe. A nonconvulsive status epilep-

ticus can rarely mimic schizophrenia, but the symptoms are present only hours to days. Automatisms of the mouth and lips and eye fluttering can be seen. In these cases, an EEG will show active seizure activity. Psychosis also occurs postictally and following a flurry of seizures lasting an average of 70 hours. A seizure disorder is often present at least 10 years before the manifestation of interictal psychosis. Postictal suppression may be seen on EEG.

## ETIOLOGY

### Genetic

First-degree relatives of individuals with schizophrenia have a 10 times greater risk of developing schizophrenia than the general population, and twin studies show higher concordance rates among monozygotic twins than dizygotic twins. Nonetheless, monozygotic twins are 50% discordant, suggesting that environmental factors contribute as well. The heterogeneity of the disorder suggests that multiple genetic loci contribute a vulnerability to schizophrenia. Genetic vulnerability plays less of a role in late-onset schizophrenia.

### Developmental

Persons born in the winter and early spring are more likely to develop schizophrenia than those born in late spring and summer. While no clear explanation for this has emerged, potential hypotheses include seasonal variability in diet or higher rates of prenatal virus exposure at different times of the year. Observational studies suggest that a complicated fetal history may predispose to the development of schizophrenia. This suggests a potential etiologic role for maternal exposure to influenza virus during pregnancy, perinatal hypoxia from obstetric complication, nutritional deprivation in utero, and autoimmune processes in the pregnant mother.

Brain structural abnormalities found in schizophrenia include a larger right temporal horn and third ventricle as well as decreased amygdala, hippocampus, and parahippocampal gyrus volumes. These changes are felt to represent a reduced synaptic density. Since synaptic density is maximal at the age of 1 years and decreases until adolescence, one etiologic theory postulates that synaptic pruning is excessive in schizophrenia and leads to the emergence of symptoms during late adolescence and early adulthood. Neuronal disorganization within the hippocampus has also been found and has been suggested to represent that disorganization may be the result of impaired neuronal migration during development.

## TREATMENT

### Antipsychotics

#### Typical Antipsychotic

The first antipsychotic, chlorpromazine, was originally developed as an antihistamine and found by chance in the 1950s to reduce psychotic symptoms in individuals with schizophrenia. The primary mechanism of action of antipsychotic drugs is believed to be D2 dopamine receptor blockade in the mesolimbic dopamine pathway,

which travels from the ventral tegmental area of the midbrain to the nucleus accumbens. Since all neuroleptic drugs effective for schizophrenia cause D2 blockade, overactivity of the mesolimbic dopamine pathway is hypothesized as a necessary element in the development of the positive symptoms of schizophrenia. However, D2 blockade is not specific to the mesolimbic pathway, and antipsychotic drugs also block three other dopamine pathways, thought to cause many of the observed side effects of these drugs. Dysfunction of the mesocortical pathway traveling from the ventral tegmental area of the brainstem to the cortex is thought to be responsible for the negative and cognitive deficits found in the disorder. Dopamine blockade of the nigrostriatal dopamine pathway projecting from the substantia nigra to the basal ganglia, a part of the extrapyramidal nervous system that modulates motor movement, causes symptoms similar to those found in Parkinson's disease (increased muscle tone with cogwheel rigidity, shuffling gait, masked facies, and resting tremor). These are referred to as extrapyramidal symptoms. Extrapyramidal symptoms are especially impairing in the elderly, since the resultant shuffling gait may lead to falls in an already susceptible population. A decrease of dopamine in the basal ganglia is thought to cause *akathisia*, a severe feeling of restlessness, accompanied by pacing, shifting weight from foot to foot when asked to stand still, and difficulty remaining seated, and *dystonia*, persistent (tonic) involuntary contractions of muscles, most commonly of the neck and tongue. Dystonia is less common in the elderly but may present as lateral flexion at the hips ("Pisa syndrome"). Another side effect of neuroleptics that can become persistent and disabling is *tardive dyskinesia*, thought to result from the upregulation of dopamine postsynaptic receptors in the nigrostriatal pathway leading to persistent, repetitive, abnormal movements of the tongue, face, and lips. Choreoathetoid movements of the limbs, head, or trunk can also develop. The elderly, females, and individuals with brain injury are more susceptible to tardive dyskinesia. Tardive dyskinesia may resolve weeks or months after discontinuation of the medication, but often persists.

The final dopamine pathway is affected. Dopaminergic neurons from the hypothalamus project into the pituitary gland in

the tuberoinfundibular pathway and inhibit the secretion of prolactin. As a result, neuroleptics can elevate prolactin levels and cause galactorrhea. In postmenopausal women, neuroleptics can cause an increased rate of bone demineralization.

Antipsychotics also affect muscarinic-cholinergic, alpha 1 adrenergic, and histaminergic receptors. Histaminergic blockade causes weight gain and sedation. Sedation, blurred vision, dry mouth, and constipation result from blockade of the muscarinic-cholinergic receptors. Alpha 1 adrenergic inhibition causes dizziness, drowsiness, and orthostatic hypotension. Since all of these increase susceptibility to falls and hip fractures, frequent monitoring in elderly patients is crucially important.

### Atypical Antipsychotics

The atypical or second-generation antipsychotics antagonize serotonergic receptors in addition to dopamine receptors. These are thought to be more effective against the negative symptoms of schizophrenia and may cause less extrapyramidal symptoms. However, recent studies have shown a 1% to 2% increase in mortality in the elderly with dementia who are taking drugs in this class. The mechanism by which this occurs is not known, and it is uncertain whether this pertains to elderly individuals with schizophrenia.

Better cognition, social interaction, and fuller affect are reported with the use of atypical antipsychotics in younger individuals, but whether this is true of the elderly is not known.

Currently, there are six atypical antipsychotics available for clinical use. Although these are all considered atypical, these vary in their side-effect profiles and receptor affinities (Table 71-2). There is increasing concern over metabolic syndrome as a potential side effect of antipsychotics. Therefore, patients taking atypical antipsychotic drugs should be monitored for high blood pressure, obesity, high cholesterol, and insulin resistance. Patients taking olanzapine may be at higher risk than those taking other atypicals.

Neuroleptic malignant syndrome (NMS) is a life-threatening complication, which may occur with either typical or atypical antipsychotics. It is characterized by severe muscle rigidity and

**TABLE 71-2**

#### Commonly Used Pharmacotherapeutic Agents for Schizophrenia

ANTIPSYCHOTIC	STARTING DOSE (mg)	USUAL DOSE RANGE (mg/day)	PREDOMINANT SIDE EFFECTS	RECOMMENDED MONITORING
Haloperidol	0.25	0.5–4	EPS, TD, and dystonia	Monitor for EPS
Clozapine	6.25–12.5 bid	25–150	Agranulocytosis (1%–2%), sedation, tachycardia, decreased seizure threshold at doses greater than 600 mg, and sialorrhea	Weekly granulocyte counts, enforced by manufacturer
Risperidone	0.25–0.5 qd	0.25–3	Hypotension, sedation, and EPS	Monitor for EPS
Olanzapine	2.5 qd	2.5–10	Sedation, weight gain, and metabolic syndrome	Cholesterol and fasting blood sugar level every 6 months
Quetiapine	12.5–25 qd	25–200	Sedation and postural hypotension	Orthostatic blood pressures with dose increases
Ziprasidone	20 qd	40–80	QTc prolongation and cataracts	EKG at baseline and after dose increase, yearly ophthalmologic examination
Aripiprazole	5	5–15	Hypotension	

EPS, extrapyramidal symptoms; TD, tardive dyskinesia; EKG, electrocardiogram.

Note: Monitoring for all antipsychotics should include monitoring for EPS, weights, cholesterol, and fasting blood sugar level every 6 months for metabolic syndrome.

autonomic instability typified by elevated temperature, tachycardia, and elevated or labile blood pressure. Mutism, changing levels of consciousness (as seen in delirium), elevated white blood cell count, incontinence, and dysphagia may also be seen. Creatinine phosphokinase levels are raised when muscle rigidity is present. NMS is felt to result from the abrupt decrease in dopamine from neuroleptic use. Management of this syndrome includes stopping the neuroleptic drug, protecting the kidneys from muscle breakdown products with intravenous fluids, supportive medical measures, and, occasionally, administration of the dopamine agonists bromocriptine or dantrolene.

### Psychosocial Treatments

Individuals with schizophrenia obtain benefit from psychosocial intervention in addition to drug therapy. To combat noncompliance, education and support should be given to individuals with schizophrenia as well as their family members. Supportive and behavioral therapy can be offered. Vocational and social skill training may be used to promote independence and quality of life.

## NONPSYCHOTIC DISORDERS THAT CAN BE CONFUSED WITH SCHIZOPHRENIA

### Charles Bonnet Syndrome

Charles Bonnet syndrome is a condition in which vivid visual hallucinations and generally good insight into the false nature of these hallucinations occur in the setting of poor vision. There is an absence of delusions. The poor vision, usually central, results from conditions such as macular degeneration or cataracts. If vision improves, the hallucinations often remit. Often the visions seen are figures or objects that are diminutive in size, termed Lilliputian hallucinations. Patients with this condition often do not report their hallucinations to health-care providers for fear of being labeled crazy.

### Delusional Parasitosis (Ekbom Syndrome)

Delusional parasitosis is a condition in which the affected individual has a delusion of infestation by parasites. The individual visits multiple physicians with this complaint, is unshaken by negative test results, and often brings in skin scrapings and nail clippings as proof. Patients may try to kill the parasites by pouring kerosene, rubbing alcohol, insecticide, or other irritants over their skin. Some

may physically pick or scrape at themselves. This condition will sometimes respond to antipsychotics.

### Diogenes Syndrome

Diogenes syndrome is a condition of self-neglect. The affected individual tends to live in domestic squalor and be socially withdrawn. A tendency to hoard items (sylligomania) with no clear purpose may also be present. These individuals are reluctant to seek treatment, resist help when it is offered, and may remain undetected for years.

### Hallucinations in Grief

Hallucinations commonly occur during the grief reactions of deceased loved ones. Patients report that they hear the voice of a loved one or see them pass by. This is more appropriately termed an illusion, as it usually consists of misinterpretation of stimuli. However, true hallucinations may occur and are even socially normative in some cultures.

### Organic Delusional Disorder

Organic delusional disorder is characterized by a delusion that is the result of a metabolic, toxic, or neurologic abnormality. This disorder has a wide range of delusional content as well as potential causes (e.g., HIV, seizure disorder, brain damage, drug use, Alzheimer's, and Huntington's). Sudden onset, association with physical symptoms characteristic of the disorder, lack of a typical course, and lack of personal or familial psychiatric history suggest a nonpsychiatric etiology and should prompt further evaluation.

## SUICIDE

Elderly individuals account for a significant proportion of death by suicide in the United States. Recent statistics from the Centers for Disease Control (CDC) indicated that 14.6 persons per 100,000 aged 65 years or older died by suicide, with the highest risk group being males aged 85 years or older. Within that group, the rate of suicide was 51 per 100,000. Although the overall suicide rate in the elderly population has slightly decreased since 1999 (15.9 per 100,000), nonetheless, death by suicide remains a significant concern.

### Factors Associated with Suicide

The majority of suicides occur within the context of a mood disorder with the remainder related to some form of psychiatric disorder including substance abuse, personality pathology, or schizophrenia. In the general population, risk factors for suicide include living in a rural area, owning firearms, and unemployment. For elderly adults, the risk factors vary based on age- and health-related issues. [Table 72-1](#) outlines the risk factors for suicide as well as protective factors that may decrease the possibility of suicidality in elderly patients. With relation to depressive episodes, there is inconclusive evidence discerning between whether late onset (after age 60 years) or early onset, or prior or current depressive episodes are associated with increased risk.

Suicide is a complex construct with both biological and psychological etiologic factors. While there is limited information regarding biological components of suicide, the serotonergic system has consistently been implicated in suicide through mechanisms separate from affective disorders. Hydroxyindoleacetic acid, a serotonin metabolite, is significantly associated with suicide. Lower concentrations of hydroxyindoleacetic acid have been found to correlate strongly with suicide lethality, that is, patients with lower concentrations of

hydroxyindoleacetic acid have been found to make more lethal suicide attempts. Regarding serotonin receptors, there tends to be an abnormality in the prefrontal cortex of patients who completed suicide, as evidenced by decreased presynaptic serotonin transporter sites. Also, compared to patients with no suicidal tendencies, patients with suicidal tendencies have increased serotonergic neurons in the dorsal raphe nucleus. The noradrenergic system has also been implicated in suicide, with research showing high noradrenalin levels in the prefrontal cortex and lower levels in the brainstem. In examining the dopaminergic system, while it has been found to be abnormal in patients with depression, there is too little research to conclude its association with suicide. Thus, research is required to further elucidate the psychiatric contributions to suicide as well as understand the connectivity between psychological, biological, and social factors.

### Evaluation and Assessment

Evaluating and assessing suicide may be difficult in geriatric patients, as they may be prone to not discuss those feelings and thoughts. As such, the role of the clinician is to form a strong, trusting bond with the patient in order to comprehensively assess suicidal ideation, intent, and plan of action. The evaluation is an integral part of the treatment process, as it opens up discussion between the patient and clinician, thereby allowing prevention through decreasing access to available means of suicide, building trust, facilitating a supportive therapeutic relationship, and tailoring treatment interventions.

To increase the reliability of the interview, structured suicidal assessment scales can be used. A commonly used scale is the Scale for Suicide Ideation, which is a 19-item clinician-rated measure that assesses suicidal thoughts and behaviors for the prior 7 days and for the worst points in life as determined by the patient. The Scale for Suicide Ideation thoroughly measures many components of suicide, including suicidal plan, behavior, preparation for attempt, and

**TABLE 72-1****Risk and Protective Factors Related to Elderly Suicide**

RISK FACTORS	PROTECTIVE FACTORS
<ul style="list-style-type: none"> <li>• Increased pessimism</li> <li>• Increased helplessness</li> <li>• Initial week of admission to inpatient unit</li> <li>• Discharge week from inpatient unit</li> <li>• Prior affective disorder</li> <li>• Current affective disorder</li> <li>• Medical comorbidity</li> <li>• Functional disability</li> </ul>	<ul style="list-style-type: none"> <li>• Perceived social support</li> <li>• Feeling useful</li> <li>• Realistic outlook</li> <li>• Positive future outlook</li> <li>• Achieving goals</li> <li>• Close interpersonal relationships</li> <li>• Successful adjustment to aging</li> </ul>

anticipation of attempt. Also, a recent scale developed specifically for use in an elderly population is the Geriatric Suicide Ideation Scale. The Geriatric Suicide Ideation Scale is a 66-item multidimensional measure of suicide in geriatric patients, which assesses four factors including suicide ideation, death ideation, loss of personal and social worth, and perceived meaning of life. This measure will require further study given its newness, but, thus far, it has strong psychometric properties, is easy to administer, has standardized administration and scoring procedures, and is sensitive to suicide detection.

Just as important as clarifying risk factors, within the assessment it will be of utility to identify protective factors. Protective factors (see [Table 72-1](#)) are adaptive for the patient and help to decrease the potential suicide completion. For example, research has found that having a positive future orientation, which involves constructively thinking about the future, generating positive future outcomes, identifying and nurturing goals, and identifying reasons for living, can help decrease suicide. Although [Table 72-1](#) lists those protective factors that have been identified in elderly patients, it is essential to enquire and assess for patient-specific protective factors, which could include hobbies, prior therapeutic treatments, and high self-worth. Once identified, protective factors should be reinforced by the clinician in order to become concrete within the patient, which may aid in the treatment process.

## Management and Treatment

Managing and treating geriatric patients with suicidal tendencies initially involves three steps. The first is to diagnose and treat the current psychiatric disorder. The second step is to assess the suicidal intent and lethality with an emphasis on prevention. And the third is to construct a specific treatment plan tailored to the patient. Guidelines for managing suicide in adults were provided by the American Psychiatric Association's (APA) practice guidelines for the assessment and treatment of patients with suicidal behavior.

For elderly adults, specific guidelines for treating and managing suicide were provided from the Prevention of Suicide in Primary Care Elderly: Collaborative Trial (PROSPECT). The primary goal of PROSPECT, a National Institute of Mental Health-funded, randomized, controlled trial, was to assess the effectiveness of an intervention (treatment by a psychiatric specialist) in preventing and reducing suicidal ideation and behavior. The study found that the intervention, relative to treatment as usual (with additional screening), was effective in decreasing suicidal ideation and depressive symptoms. [Table 72-2](#) shows the PROSPECT general recommendations

**TABLE 72-2****PROSPECT\* Recommended Guidelines and Management Techniques for Working with Patients with Suicide***Guidelines while working with patients with suicidal ideation*

- Be attentive
- Stay calm and nonthreatening
- Provide the patient with space and time to vent
- Be collaborative, use a team approach
- Be willing to say the word "suicide"

*Management techniques for patients with high risk*

- Directly assess the frequency and content of suicidal ideation and risk factors
- Explore the initial problem
- Have the patient describe reasons for and against suicide
- Assess the patient's access to means
- Provide the patient with education regarding depression including its etiology, prognosis, and treatment
- Decide how to manage an increase in suicidal ideation through either a formal contract or some other formality
- Provide education regarding alcohol and illicit substances and encourage their discontinuation
- Meet with the patient weekly at minimum if suicidal ideation is present
- Write prescriptions for no more than 1 week until suicidal risk has decreased
- Provide family education regarding suicide, including how to appropriately respond to the patient and assuring the living environment is safe (i.e., remove firearms)
- Provide supportive and collaborative interaction with the patient

At each treatment assess hopelessness, suicidal ideation, and substance abuse

\*PROSPECT, Prevention of Suicide in Primary Care Elderly: Collaborative Trial.

Data from Brown GK, Bruce ML, Pearson JL. High-risk management guidelines for elderly suicidal patients in primary care settings. *Int J Geriatr Psychiatry.* 2001;16:593-601.

for working with patients with suicide as well as management techniques for patients at high risk.

Many geriatric patients who are suicidal are usually seen by their primary-care physician, and, as such, it is important for their physician to be knowledgeable of suicidal signs and symptoms and treatment strategies. Many of the patients with suicidal ideation may also present with depression; thus, psychiatric treatment may commence with an antidepressant, psychotherapy, or a combination of both. Using cognitive behavior techniques to help the patient reframe his/her thoughts, constructing positive future orientations, and developing adaptive coping strategies may help to mitigate the risk of suicide. Overall, suicide is a significant risk in elderly adults, but, with proper care including comprehensive assessment, development and implementation of patient-specific treatment, and ongoing effective management, the risk of suicide may be lessened.

## ANXIETY DISORDERS IN THE ELDERLY

The most common anxiety disorders in late life are generalized anxiety disorder and phobias. Agoraphobia without panic disorder has been described as occurring late in life, but obsessive compulsive disorder and panic disorder are generally thought to persist from earlier adulthood when present. Anxiety disorders in the elderly are commonly associated with depression. Studies looking at nursing

home populations have found a prevalence ranging from 9.9% to 13.2%. It has also been shown that the presence of depression and anxiety can significantly impact the well-being of nursing home patients. Posttraumatic stress disorder (PTSD) has also been described in the elderly.

### Treatment Options for Anxiety

Commonly used medications for anxiety spectrum conditions include selective serotonin reuptake inhibitors, other antidepressants, and benzodiazepines. As anxiety and depression are so commonly comorbid conditions, pharmacological treatment with antidepressants is often helpful for both conditions.

Benzodiazepine use in the elderly may be associated with some unique concerns. The indication for these drugs is similar to that for the general adult population. Studies have shown that their use is often more common in the institutional setting, and the actual indication for use is often something other than an anxiety disorder. When using benzodiazepines in the elderly, it is important to remember that pharmacological properties are influenced by age, and agents with longer half-lives and active metabolites are more likely to cause adverse events. Studies have shown that the elderly are more sensitive to the sedating effects of benzodiazepines on the central nervous system. Other adverse events documented have included dependence, cognitive impairment, paradoxical agitations, and psychomotor impairment and falls.

### Posttraumatic Stress Disorder

PTSD in the elderly has been discussed in the literature, often in the setting of natural disaster and veterans of war. More than 50% of male veterans are predicted to be older than 65 years by the year 2020. Symptoms of PTSD may occur shortly after the event or may not develop until many years later. There is often a history of previous trauma in individuals with PTSD, and life stressors can bring about a relapse of symptoms. Treatment involving psychotherapy and psychopharmacology is similar to the general adult population, and studies looking at differences are lacking. However, anxiety disorders may impact the treatment outcomes for patients who are depressed. One study examining older adults in an outpatient setting showed a slower response to treatment in geriatrics with comorbid PTSD. Nonetheless, treatment can be effective and will require appropriate diagnosis and management.

## LATE-LIFE PSYCHOTIC DISORDERS

Psychosis is a mental disorder often marked by a law of contact with reality and may affect individuals at any age. Geriatric health-care specialists face a particular challenge in the management of psychosis in the older patient. One of the most disenfranchised groups in health care is the elderly with psychotic disorders. The impact of psychotic disorders in the elderly is significant in both financial costs and quality of life. With national health-care costs skyrocketing, the impact on families, caregivers, and the patients' quality of life is immeasurable. Psychotic episodes increase the risk of hospitalizations and mortality. Behavioral disturbances, are common in psychotic illness and may pose a significant threat to the safety of the elderly patient and those around them.

### Clinical Presentation

The psychotic older person in a distressed state is likely to present first to a primary-care physician or geriatrician, rather than seek mental health services. As the primary-care clinician sorts through the history, the clinician may detect something odd in the nature of the person's complaints. For instance, the history may reveal a heightened suspiciousness toward family, children, or neighbors. Patients may feel that people are stealing from them or trying to control them. The patient's paranoia may further limit access to in-home attendants, visiting nurses, and other social service professionals. Fears of loss of autonomy and loss of mental and physical capacity can culminate in a frank paranoia. In one of the more familiar clinic scenarios, persons may present to their primary-care physician with vague somatic complaints. Upon further questioning, older persons may blame their symptoms on some implausible occurrence such as a noxious gas being pumped into their home by forces or people often unknown.

Psychosis in the older person can be a symptom of either an acute or a chronic illness. Acute psychotic symptoms are often the sequelae of a general medical condition such as infection, trauma, metabolic abnormality, or medication side effect. The psychotic symptoms in these instances noted may be more accurately described as being part of a delirium. Chronic or persistent psychotic symptoms may be consistent with a DSM-IV diagnosis. There are two distinct categorizations. The first is a primary diagnosis of psychosis including a delusional disorder, mood disorder with psychotic features, or schizophreniform illness. The second category includes psychosis as a specified feature of a dementia or because of a chronic general medical condition, such as a head trauma, Parkinson's disease, and a seizure disorder. Most of the further discussion in this section will cover psychosis in the elderly related to more persistent symptomatology. Often these psychotic episodes are diagnosed as part of a late-onset schizophrenia, schizophrenia-like illness or part of a dementia.

### Epidemiology and Terminology

The onset of schizophrenia typically occurs in the late teens to early twenties. In adults younger than 60 years of age, the yearly incidence of schizophrenia is approximately one in 10 000 individuals, with a lifetime risk of 0.8. A minority of the population first experience psychotic symptoms in their later years. The majority of these older individuals with late-onset psychosis are diagnosed with schizophrenia. There are different ages of onset used to define early- and late-onset manifestations of psychotic illness. Swiss psychiatrist Manfred Bleuler's studies of late-onset schizophrenia involved individuals who developed the illness after the age of 40. Most of the subsequent English studies used an onset after the age of 60. The latter group is often referred to as having very-late-onset schizophrenia.

The term "*paraphrenia*" is used interchangeably with late-onset schizophrenia. Paraphrenia was a term used to identify a true *late-onset* schizophrenia as being different from a chronic schizophrenia of *early onset*. Physician Emil Kraepelin originally used paraphrenia to describe an illness in which the patient experiences suspiciousness, frank paranoia, and possible hallucinations but tends not to suffer significant deterioration as seen with negative symptomatology. Late-onset schizophrenia tends to be associated less with deterioration of personality and affect, which may increase the chance of achieving a good treatment response and better prognosis.

## Risk and Comorbidity

Several comorbid conditions are linked with schizophrenia. Some of the conditions include depressive disorders, cognitive impairment, obsessive-compulsive disorder, aggressive disorder, and substance abuse. Each of these entities may have profound negative effects on treatment effectiveness and overall progress. Specific numerical breakdowns in the literature show depression as having 25% prevalence in schizophrenia. Obsessive-compulsive disorder has a 3.5% to 15% probability of occurrence in schizophrenia. Substance abuse is subdivided with 35% of the schizophrenic population using alcohol, 20% using cocaine, 15% using marijuana, 3% using heroin, and 70% to 90% using nicotine. In the nicotine addicted, nicotine use typically increases p450 enzyme activity, resulting in the need for upward dose adjustment in some neuroleptic medications to achieve therapeutic effect. Concerning aggression, there is a five- to sixfold higher probability for violence in patients with schizophrenia.

Moreover, the presence of sensory deficits and female gender seems to increase the risk of developing late-life psychosis. Sensorineural hearing loss has documented ties to the development of psychosis in the elderly adults. In addition, patients with late-onset schizophrenia are more likely to be women, with women having more severe positive psychotic symptoms (i.e., systemic persecutory delusions) and less severe negative symptoms (i.e., affective flattening and social withdrawal).

## Psychosis in Dementia

Psychotic symptoms often present within the course of a dementing illness. The symptoms may vary widely from case to case and may only appear intermittently throughout the illness course. The psychosis of a dementia may pose serious problems for the caregiver. Approximately 50% of patients experience delusions or hallucinations within the first 3 years after a clinical diagnosis of Alzheimer's dementia. Paranoid delusions are often the most common psychotic symptoms to appear in Alzheimer's dementia, with visual hallucinations being second, followed by a lower incidence of auditory hallucinations. The patient with Alzheimer's dementia may provide a history of seeing people or animals moving freely throughout their home. Charles Bonnet syndrome is an example of this type of visual hallucination seen in Alzheimer's dementia. The patient with Alzheimer's may describe seeing people who are fully realized often, except for some unusual feature. These unusually perceived hallucinatory objects may appear to float from place to place or may be abnormally smaller in stature (Lilliputian). The patient with dementia may suffer other disturbances in perception, which involve disorientation to time and space. Reduplicative paramnesia is a curious phenomenon seen in some patients with dementia. It is a delusional belief that the person's present environment has either been duplicated or been moved from another location. The patient may strongly insist that the current hospital room is located in the patient's hometown or even connected to the patient's home in some physical way. This may often be considered as confusion or simple disorientation, but, in fact, it is a form of delusional misidentification.

## Treatment Considerations

When approaching a patient with psychosis of unknown history, the clinician should first rule out a physical or systemic illness, in-

cluding drug intoxication, neurological or vascular events, metabolic abnormalities, systemic infections, sepsis, and postoperative states. These conditions can cause delirium, complicate diagnosis, and impede timely treatment of psychotic symptoms. Remission of the psychosis will likely depend on adequate treatment of the underlying acute medical illness.

Once it is determined that the patient with psychosis is medically stable, the clinician may administer treatment using both nonpharmacologic and pharmacologic methods. In the nonpharmacologic approach, it is important to establish a working rapport. A good working rapport with the older patient who is paranoid may prove difficult, but establishing good rapport can result in reaching a more favorable treatment outcome. There is usually no need to confront patients about their psychotic or delusional symptom. The clinician and the patient can respectfully disagree about the source of the problem and still work together to maximize the patient's ability to function.

The most comprehensive treatment plans use pharmacologic approaches in conjunction with nonpharmacologic ones. The atypical antipsychotics (e.g., olanzapine, risperidone, and ziprasidone) have been the drugs of choice for the past few years. These typically have fewer of the side effects associated with the older antipsychotics (e.g., haloperidol, chlorpromazine, and thioridazine) such as tardive dyskinesia, dystonic reactions, parkinsonian symptoms, and anticholinergic and orthostatic hypotensive effects.

However, atypical antipsychotics should be used more cautiously for a number of reasons. There is an increased risk of developing type II adult-onset diabetes and dyslipidemias with atypical antipsychotic use. Recently, the Food and Drug Administration (FDA) issued a public health advisory that cautions about the use of atypical antipsychotics in the older patients with dementia for treatment of behavioral disturbances and agitation. The FDA stated that atypicals are associated with an increase in mortality (mostly owing to cardiac events and pneumonia). For example, atypical antipsychotics have been found to be associated with increased rates of mortality in patients with Alzheimer's disease. However, a Finnish study showed no associated increase in mortality with atypicals in the elderly patient with dementia. Thus, additional analysis of the data concerning safety and efficacy of these drugs is warranted. As a result of mixed findings, some clinicians have returned to using small doses of the first-generation antipsychotics, while others continue to use atypicals, and follow metabolic markers (i.e., fasting glucose, lipid profiles, and weight) on a monthly basis for the initial visits, then every 8 to 12 weeks during the stable dosing and maintenance phases.

## ALCOHOL AND SUBSTANCE USE IN THE ELDERLY

The consumption of alcohol is common in American culture. The use of alcohol has been linked to many contrasting facets of the human experience such as social activities and religious rituals. It has also had its place in sometimes harmful rites of passage and patterns of self-destructive behaviors. Because of the ubiquitous nature of the alcoholic substance, it tends to illicit very different attitudes from health-care professionals than other potential substances of abuse. When considering these cultural issues and attitudes regarding the geriatric population in a medial setting, the existence of alcoholism can sometimes be overlooked simply because the elderly are often not considered to be alcoholics.

## Geriatric Substance Abuse Prevalence

Research in the area of geriatric substance abuse is a relatively new area of interest. Even though abstinence is the most common drinking pattern among the elderly, recent data suggest that there is still a need for concern. Studies of community-dwelling older adults show prevalence estimates of problem drinking in 1% to 15% of individuals. Males tended to drink more and were more likely to have problem drinking. For example, one outpatient study found that 8.6% of geriatric patients with mental illness meet criteria for alcohol dependence. When examining lifetime prevalence, the numbers were even higher, with one study of short-term rehabilitation nursing home patients showing that 49% of individuals had a diagnosis of alcohol dependence at some time in their life, and 18% had active symptoms in the prior year. One hypothesis suggests that the number of elderly patients with substance dependence may increase in the near future. People who are currently in their thirties, forties, and fifties grew up between 1950 and 1970, which was a time of increased substance use and dependence, a factor that could contribute to elderly substance abuse. Substance use may continue or may resurface in this population, as it faces the stressors typically associated with late life including loss of a loved one, retirement, and loss of independence.

## Diagnosis and Classification

A proper history is essential to diagnosing alcohol dependence. All patients should be initially asked how much alcohol they drink and whether or not they are an everyday drinker. It is often helpful to ask in a nonjudgmental fashion and reiterate that this information is very important to their medical evaluation and necessary to provide good treatment. A particularly useful and popular validated screening tool for use in the medical setting is the CAGE questionnaire. The CAGE questionnaire has four component questions represented by the four letters of the name: (1) Have you tried to **C**ut down on your drinking? (2) Are you **A**nnoyed when asked to stop drinking? (3) Do you feel **G**uilty about your drinking? (4) Do you need an **E**ye-opener drink when you get up in the morning? The CAGE questionnaire focuses on the diagnosis of alcohol dependence. It, in and of itself, is not complete in evaluating a patient but can provide a useful starting place. Further history obtained can include a history of medical illness related to alcohol use, recent social stressors, and a family history of substance dependence. Medical evaluation into medical consequences of alcohol use can also be helpful.

When defining a pattern of alcohol consumption, it is important to distinguish two things: problem/at-risk drinking and dependence. For persons aged 65 years and older, at-risk drinking is considered to be more than seven standard drinks per week or more than three drinks per occasion. A standard alcoholic drink is defined as 1.5 ounces of 80 proof (40%) alcohol (e.g., vodka), 4 to 5 ounces of wine, or 12 ounces of beer. The multitude of different containers that alcohol is available in and the accuracy of the history can make it difficult to accurately estimate use. At-risk drinking, even in the absence of psychological dependence, can be concerning, as it may lead to acute injury and trauma and long-term medical and social complications. In mental health care, dependence is a disorder of substance use defined by the DSM-IV-TR as the presence of three or more of the following symptoms in a given year: withdrawal; tolerance; spending more time obtaining, using, or recovering from

the substance; using more or longer than intended; unsuccessful attempts to control use; and continued use despite psychological and/or physical problems caused by the use.

## Therapeutic Interventions

In the early stages of treatment, it is important to determine if an individual is at risk of alcohol withdrawal, a potentially life-threatening complication of discontinuing alcohol consumption. This can occur clinically in the settings as someone seeking help for at-risk drinking or dependence, or in the acute care or institutional setting when the individuals no longer have access to their usual supply of alcohol. Symptoms of alcohol withdrawal can include tremor, restlessness, elevated pulse and blood pressure, delirium, and/or seizure. The acute symptoms of withdrawal generally peak by 72 hours after the last drink consumed and can require treatment for up to 7 days (or longer if delirium is present). The course of withdrawal is often worse in individuals with a history of previous withdrawal and multiple comorbid medical problems. The elderly are more likely to have withdrawal symptoms for a longer period of time, but there is no evidence that being elderly alone puts one at risk of a more complicated course or a longer duration of treatment. Proper management of withdrawal is a critical first step in treatment and includes medical assessment and stabilization, pharmacologic treatments, and proper vitamin supplementation (including the proper use of thiamine supplementation to prevent the development of Wernicke–Korsakoff syndrome). Wernicke–Korsakoff syndrome is a brain disorder caused by alcohol-associated thiamine deficiency, which can result in memory impairment, hallucinations, changes in vision, and/or loss of muscle coordination.

Benzodiazepines are the agents of choice to treat and prevent alcohol withdrawal. Their cross tolerance at the type A gamma-aminobutyric acid receptors with ethanol is likely the basis for this. Barbiturates have been used effectively in the past but now have largely been abandoned because of their less favorable side-effect profile and lack of controlled evidence-based studies. When choosing a benzodiazepine for use in alcohol withdrawal, it is important to consider the half-life of the drug and the route of metabolism. In the elderly, an agent that is shorter acting and less extensively metabolized by the liver can sometimes be more favorable, as long as the medication is dosed appropriately to the half-life. This can be important to prevent the buildup of multiple CNS active metabolites that may increase the chance of oversedation, especially in patients with multiple medical comorbidities. Chlordiazepoxide, diazepam, lorazepam, and oxazepam are all commonly used agents in adults. Lorazepam and oxazepam are both metabolized via glucuronidation in the liver to inactive metabolites that are renally excreted, making them favorable shorter-acting agents in persons with functional liver insufficiently and intact renal functioning.

Once patients with at-risk consumption or dependence are identified and acute therapies initiated, the implementation of brief interventions has been shown to be cost-effective ways of further directing treatment. These have been studied in the general adult population extensively, and there have also been two studies in the geriatric population. Types of interventions included brief (10–15 minutes) counseling visits and telephone follow-ups. Older adults have been shown to be good candidates for treatment, especially when age-appropriate care is provided. There are limited data on randomized treatment outcomes. In one recent study, 1652 patients older than

50 years were admitted to a rehabilitation center for the treatment of alcohol dependence. The center used treatment programs designed to cater to older adults and found postdischarge rates of abstinence similar to that of middle-aged adults.

### Clinical Approach and Management

When working with patients who suffer from alcohol and other substance disorders, it is important to keep some practical approaches in mind. Motivational interviewing approaches have been shown to be more effective in leading to reduced intake than more confrontational approaches that are common in the medical setting. Motivational interviewing itself is a specific therapeutic intervention, but its philosophy and techniques can be applied to brief interactions in any setting. It emphasizes the use of empathetic listening and encouraging patient-directed discussions about making behavior changes, rather than simply providing instructions to the patient. This process of beginning a discourse on change (referred to as “change talk”) can be effective in leading to patients initiating changes in their behavior. It is helpful to begin such interactions with an assessment of whether or not the patients feel that their drinking is a problem and, if so, how confident they are to make a change. This may help identify early barriers to change. Other techniques include exploring the benefits and drawbacks to both changing and not changing, presenting the patient with data (i.e., laboratory results and standards of at-risk drinking), and correcting false perceptions. This is not meant to imply that persons should be vague or superficial in their expression of concern, but merely that the approach taken can lead to distinctly different results. Such techniques have been applied to other situations as well, including smoking cessation and medication compliance.

Treating addiction with medication is a new area of growth. For many years, the only available pharmacologic intervention was disulfiram. Its use in the elderly has been rare because of its potential for adverse events. More recently, naltrexone has been approved by the FDA for the treatment of alcohol dependence. It has mainly been studied in the general adult population, but one study of veterans aged 50 to 70 years showed similar results, with improvement in relapse to heavy drinking. The most recent medication to be approved for the treatment of alcohol withdrawal is acamprosate, but it has not been studied so far in the elderly.

Mental health comorbidity with substance dependence is common. Older alcoholics frequently have comorbid depression and may be at a greater risk of suicide. Alcohol abuse or dependence has also been shown to be higher in patients with cognitive impairment. It is also important to consider when mental health referrals would be warranted.

### Other Addictive Substances and Treatment

Outside of alcohol and nicotine, the abuse and dependence of other addictive substance in the elderly has mainly been found to be prescription medications such as opiate analgesics and benzodiazepines. However, elderly adults have also been found to abuse illicit substances including marijuana, cocaine, amphetamines, and other stimulants. Again, because of the general misperception that elderly adults do not abuse illicit substances, there is a dearth of information in this arena.

There is a growing problem of misuse of prescription drugs in the elderly, and one estimate suggests that by 2020 the nonmedical use of prescription drugs will increase to 2.7 million. Presently, one in four elderly adults uses a medication with some abuse potential. Factors that are associated with drug use in the elderly are female gender, social isolation, past history, and exposure to addictive substances. Patients with complex medical histories or with a history of dependence are at higher risk of developing benzodiazepine dependence, which may increase with age. Not all patients using benzodiazepines will become psychologically dependent on them, but it has been documented that tolerance decreases with age and they will likely be physiologically dependent on them (i.e., at risk of withdrawal if the medication is abruptly discontinued). It is important to remember to discuss issues of abuse, dependence, and withdrawal when providing informed consent for medication use.

## PERSONALITY PATHOLOGY IN THE ELDERLY

With the advent of the International Society for the Study of Personality Disorders and subsequently the *Journal of Personality Disorders*, interest and research in personality pathology has increased. Historically, personality disorders (PDs) were governed by psychodynamic theories and explanations; however, with changes in theory and practice, PDs have been explained and understood from other perspectives. For example, biological research with twin studies suggests that approximately 40% to 60% of the variance in personality is genetic.

The majority of PD research has taken place in the context of younger individuals from infancy to adulthood, with little examination of elderly adults. Many reasons have precluded a thorough investigation into geriatric PDs, including professional disagreement in valid diagnosis measures, problems in DSM-IV-TR nosology, and the difficulty associated with obtaining a comprehensive psychiatric history from the elderly patient. The latter difficulty is most problematic, as PDs are established based on lifelong behavior patterns. However, assessing PDs in geriatric patients could aid in the development of appropriate treatment algorithms and increase the knowledge of age-associated personality changes.

### Personality Disorder Classification

According to the DSM-IV-TR, PDs are categorized into three distinct clusters based on similarities. Cluster A (odd and eccentric) consists of the paranoid, schizoid, and schizotypal PDs; cluster B (dramatic, emotional, and erratic) contains the antisocial, borderline, histrionic, and narcissistic PDs; and cluster C (anxious and fearful) includes the avoidant, dependent, and obsessive-compulsive PDs. This categorization has received criticism as a result of limited validity, meeting criteria for multiple PDs, and limited diagnostic utility.

Diagnosing elderly patients with an Axis II diagnosis can be difficult because of comorbid medical and psychiatric diagnoses, neurocognitive impairment, and psychosocial changes. Without an accurate longitudinal history, which is the basis for monitoring personality development and change, a reliable PD diagnosis could be difficult to make, as there would be limited evidence regarding personality formation, adaptation, rigidity, and associated impairment.

## Prevalence

The prevalence of PDs in elderly patients has been found to vary depending on hospitalization status. In community residents, the rate was found to range between 2.8% and 13%, between 5% and 33% for elderly outpatients, and between 7% and 61.5% for elderly inpatients. In a meta-analytic review of 16 studies between the years of 1980 and 1997, an overall prevalence rate of 20% was found for all PDs in persons aged 50 or older.

The two clusters of PDs that elderly patients tend to fall into are cluster A (i.e., schizoid) and cluster C (i.e., obsessive-compulsive), and very rarely do elderly patients present with PDs in cluster B (i.e., histrionic). Cluster B disorders tend to dissipate, whereas clusters A and C tend to remain stable or increase as people age. For example, in an empirical study assessing PDs in five different age groups using a self-reported personality check list, patients 50 years and older reported more schizoid and obsessive-compulsive PDs relative to younger cohorts.

The majority of PDs are diagnosed in elderly patients with major affective disorders; however, caution must be taken as PDs should not be diagnosed within the context of an Axis I disorder such as major depressive disorder or bipolar disorder.

## Age-Associated Personality Changes

Personality tends to form from infancy to young adulthood and then begins to remain stable throughout adulthood, with fluctuations depending on various traits or mood states. Trait characteristics are considered to be consistent, reliable determinants of human behavior, which occur regardless of state. State characteristics are those behaviors that are modified (i.e., over- and underexpressed) based on changes in state such as mood or environment.

As people age, personality characteristics may be expressed differently because of environmental, interpersonal, social, functional, or medical changes. In regard to the big five personality traits (neuroticism, extraversion, openness, agreeableness, and conscientiousness), older adults tend to show an increase in agreeableness and conscientiousness and a decrease in neuroticism and openness. Older individuals have been found to be less impulsive and risky and more inhibited. However, there tends to be high stability of earlier personality traits owing to underlying genetic components, with some variability in personality being an adaptive and protective quality. Personality changes, though, can also be a foreshadowing of complications. For example, there is some evidence to support that significant changes in personality may be an indication or a consequence of an organic pathology such as frontotemporal dementia or an aneurism.

## Treatment Strategies

There exists no evidenced-based treatment for elderly patients with personality pathology. Treatment for elderly patients with PDs may involve a collaborative team approach that uses a biopsychosocial paradigm. As PDs may be more common among geriatric patients with a major affective disorder, treatment of the mood disorder will be paramount, in order to help alleviate the accompanying PD. However, in general, patients with PDs may be difficult to treat because of noncompliance with treatment recommendations or possible treatment resistance. Nonetheless, based on the associated functional, social, and overall impairment, treatment strategies may include supportive psychotherapy, psychiatric medication management, and a focus on activities of daily living. These treatment regimens may help to remit the PD and the comorbid mood disorder in turn, increasing the quality of life and functionality of geriatric patients.

# Management of Agitation in Dementia

*Marcella Pascualy* ■ *Eric Petrie* ■ *Lucy Y. Wang* ■ *Suzanne B. Murray* ■ *Elaine Peskind*

## INTRODUCTION

Dementia affects at least 10% of patients older than 60 years and more than a third of patients older than 80 years. It is estimated that, by the year 2030, 14 million Americans will have Alzheimer's disease (AD), the most common disease underlying late-life dementia and the leading cause of nursing home placement in the elderly.

Neuropsychiatric behavioral symptoms are frequent in patients with dementia. It is estimated that between 61% and 92% of patients with AD will develop disruptive agitation during the course of their illness. Agitation is characterized by excessive verbal and motor behaviors, which suggest that the patient is distressed. Disruptive agitation includes such behaviors as hitting, biting, screaming, constant requests for attention, repetitive vocalizations, verbal threats, and forced motor activity like pacing. In 20% to 30% of cases, agitation is accompanied by psychotic symptoms such as hallucinations and delusions.

Agitation adversely affects quality of life for both the patient and the caregiver. More than 70% of caregivers consider the management of disruptive agitated behaviors to be the most challenging aspect of the caretaking process. Along with sleep disturbances, it is the major precipitant of institutionalization. In the nursing home setting, the management of agitation requires a high caretaker-to-patient ratio, further increasing the public health burden of this costly disease, which is presently estimated at \$100 billion per year.

## PATHOPHYSIOLOGY

The effects of AD on brain function and a number of neurotransmitters may contribute to the pathophysiology of neuropsychiatric behavioral symptoms in AD. In a fluorodeoxyglucose-positron emission tomography study mapping psychosis in AD, hypometabolism in the right prefrontal cortex was associated with delusions. Sin-

gle photon emission computed tomography studies in patients with AD, with aggressive behaviors, demonstrated abnormalities in the right anterior medial temporal region.

Changes in a number of neurotransmitter systems likely contribute to the pathophysiology of agitation in AD. There is severe loss of cholinergic neurons in the basal forebrain nucleus basalis of Meynert and reductions in choline acetyltransferase (the synthetic enzyme for acetylcholine with a corresponding cholinergic deficit). In large clinical trials of acetylcholinesterase inhibitors (AChEIs; drugs that inhibit the enzymatic breakdown of acetylcholine and act to ameliorate the cholinergic deficit), there was a decreased incidence of emergent behavior problems in mild-to-moderate AD and a reduction in these behaviors in moderate-to-severe AD. These findings suggest that a subsyndromal "anticholinergic delirium" may contribute to the development of neuropsychiatric behavioral symptoms in AD. A caveat is that persons with severe disruptive agitated behaviors were excluded from trials of AChEIs. The role of AChEIs in the treatment of disruptive agitated behaviors is discussed below.

Loss of serotonergic neurons in the dorsal raphe nuclei results in a deficit state, which may be associated with depressive symptoms, irritability, and anxiety. Loss of dopaminergic neurons in the substantia nigra is variable, but there is little evidence for loss of dopaminergic function in AD.

Despite severe loss of neurons in AD in the locus ceruleus, the nucleus of origin of noradrenergic neurons, central nervous system (CNS) noradrenergic function is increased. Cerebrospinal fluid norepinephrine (NE) concentrations in the later stages of AD (when disruptive agitation is common) are elevated compared to age-matched controls. Administration of the alpha-2 antagonist drug yohimbine (which increases CNS noradrenergic outflow) acutely precipitated disruptive agitation in community-dwelling patients with mild-to-moderate AD who had no previous agitation or other behavior problems. Postmortem brain tissue studies in AD have demonstrated both upregulation of tyrosine hydroxylase (the rate-limiting synthetic enzyme for NE) in surviving locus ceruleus

neurons and upregulation of postsynaptic alpha-1 receptors. Upregulated postsynaptic beta-adrenergic receptors may also contribute to behaviorally relevant increased noradrenergic responsiveness.

## ASSESSMENT OF THE AGITATED PATIENT (see Table 73-1)

### Clearly Define and Document the Problem

Disruptive agitation is a middle- to late-stage phenomenon in AD. As in the careful approach to any medical symptom in late life, it is important to first define and quantify the specific problem behavior in order to elucidate the etiology and intervene effectively. It is essential to clearly characterize and document the nature and frequency of the disruptive behavior so that a baseline record is established. This will serve as a frame of reference to determine whether subsequent interventions have been beneficial. Defining in detail the aberrant behavior frequently requires interviewing several caregivers to obtain an accurate appraisal of the problem. Specifically, ask if the patient has been aggressive or assaultive toward the caregiver. Often, caregivers are embarrassed to give an accurate history of the agitated behavior because they feel that they have tolerated more than they should have. They also may feel embarrassed for the patient. Ask the caregivers if they feel that they are at risk of being harmed. In questioning the caregiver, one needs to identify any events or situations that may precipitate or aggravate the behavior, e.g., disruption in the patient's daily routine, being left alone, or being exposed to new and unfamiliar situations. It is important to determine whether the agitated patient is experiencing psychotic symptoms, such as auditory or visual hallucinations or delusional thinking, which may be contributing to the behavioral disturbance. Affective and anxiety disorders must also be considered in the differential diagnosis. A survey of the patient's sleep pattern is useful to ensure that sleep disturbance (e.g., caused by inadequately treated pain, poor sleep hygiene, or sleep apnea) is not the cause of day- or nighttime agitation. Uncontrolled or inadequate pain management is a frequent cause of agitation at any time. Occult medical illnesses (e.g., urinary tract infections, pulmonary infections, hypoxia, and electrolyte imbalances) may also be precipitants of disruptive agitation in AD.

The following is a list of useful questions for caregivers when assessing the agitated patient:

1. Can you tell me what happens when the patient becomes agitated?
2. Has the patient been aggressive or assaultive? Do you fear that you or the patient will be injured?

3. What is the frequency of the behavior? How many times per day/per week does the agitated behavior occur?
4. How long do the episodes last?
5. What is happening immediately before the behavior begins? Can you link the behavioral disturbance with any particular activity, like bathing, dressing, eating, or dispensing medications? Does it happen only when certain people approach the patient? Does it happen during particular times of the day or night?
6. Has the patient appeared sad or anxious to you? Does the patient seem to be experiencing psychotic symptoms like hallucinations or paranoid delusions when the behavior occurs?
7. How are you managing this behavior? How does the patient respond to these interventions?

### Assess the Impact on the Caregiver

It is especially important to evaluate the impact of the patient's behavior on the well-being of the caregiver. When combined with the physical, emotional, and financial demands of caring for someone with dementia, a behavior that by itself may not seem that distressing or frequent can overwhelm the caregiver who then becomes the one in need of care and support. Often, the caregiver is also elderly and frail. Caregivers often neglect their own physical and emotional health. Careful listening to the caregiver is valuable because it serves to identify these issues and having someone understand their problem also provides support to the caregiver. This helps to establish a positive therapeutic alliance, which greatly increases the likelihood that the caregiver will comply with subsequent treatment recommendations.

Interventions that will reduce care burden should also be considered. Such interventions may include having patients attend adult daycare centers for a few hours to days a week or recruiting family members to participate in assisting with care, thereby allowing caregivers respite and time to attend to their own emotional and other needs. The caregiver should receive a referral to the local chapter of the Alzheimer's Association, which can provide support services and information about community resources, respite care facilities, and caregiver support groups. These interventions are particularly helpful because these will reduce caregiver burden and may prevent or delay institutionalization. Caregivers who perceive themselves as "more burdened" tend to consider themselves less healthy, report a history of poor interactions with the patient, and describe the patient as having a greater number of agitated behaviors. A referral of the caregiver to individual psychiatric treatment may be advisable and helpful. If there is concern or evidence of neglect and/or abuse, further investigation is warranted and a referral to an adult protective agency may need to be considered.

### Medical Workup: Rule Out Delirium

Delirium is a common cause of agitation in patients with dementia owing to their advanced age and underlying brain pathology. It is important to remember that signs and symptoms of delirium, which may manifest as acute changes in cognition and/or an acute onset or increase in agitated behaviors, may be the only indicators of an underlying systemic illness. Therefore, a high index of suspicion for delirium and underlying medical condition(s) is necessary when assessing the patient with dementia who is agitated.

The fundamental features of delirium are fluctuating disturbances of attention and level of consciousness that usually develop over a short period of time. The etiology of delirium tends to be multifactorial. Common causes of delirium include systemic medical illnesses, electrolyte disturbances, and medication or substance intoxication or withdrawal.

It is particularly difficult to diagnose delirium in the context of dementia because both disorders have several features in common. Shared features include evidence of cognitive impairment such as memory disturbances, language deficits, disorientation, perceptual abnormalities (including hallucinations), and agitation. Medically healthy elderly patients with dementia, however, are alert, without disturbances in level of consciousness. Typically, their cognitive deficits have developed insidiously and progress slowly. In contrast, in patients with deliriums, the level of consciousness fluctuates and cognitive deficits usually develop acutely. For example, in AD one can generally expect, on average, a three-point per year drop in the Mini-Mental State Examination score. If a patient with AD exhibits a sudden deterioration in cognitive function and/or a larger drop in Mini-Mental State Examination score, an explanation for this decline must be pursued and delirium needs to be considered in the differential diagnosis.

The following approaches are often valuable in assessing the patient having delirium in the nursing home or inpatient setting. Careful reading of the nursing staff's progress notes will often highlight changes in the patient's level of consciousness. The medication list should be systematically reviewed, and any recent medication changes should be noted. It is important to consider whether medication dosages are appropriate for the elderly, to investigate the possibility of drug–drug interactions, and to identify medications with anticholinergic side effects, a common culprit in delirium (Table 73-9). The use and frequency of prn or “as-needed” medications should be determined, especially for psychoactive medications such as sedative hypnotics, antipsychotics, and analgesics.

The assessment of the patient having delirium also requires a physical and neurological examination and laboratory studies to rule out systemic medical problems such as infection, congestive heart failure, electrolyte imbalance, or endocrine diseases. A careful workup may reveal a urinary tract infection or an occult carcinoma as the cause for the delirium and agitation. Once the underlying cause is corrected, the patient's mental status and behavior should return to baseline. Short-term, low-dose, intravenous haloperidol in the hospital setting or an oral atypical antipsychotic in the outpatient setting should be considered for management of significant agitation in the context of delirium. It is important to recognize, however, that recent studies have shown that persistence of delirium is common and resolution may require weeks to months.

### Rule Out Primary Psychiatric Disorders

Recurrence or exacerbation of a primary psychiatric illness like schizophrenia, bipolar disorder, major depressive disorder, or panic disorder in the patient with a history of one or more of these disorders may explain current psychotic, affective, or anxiety symptoms. These episodes may present with atypical features in the patient who has now developed dementia. As the onset of bipolar disorder in old age is extremely rare, symptoms suggestive of a first episode of mania or hypomania should prompt a workup for causes other than bipolar disorder, such as delirium or partial-complex seizures. Appropriate

medication treatment should be instituted, starting at geriatric doses and slowly titrating up with close attention to the development of side effects and potential worsening of cognition.

### Depression

Although estimates of the prevalence of major depression in AD vary widely, it is clear that depressive signs and symptoms are common. Depression has been associated with an increased risk of dementia and AD, but it is unclear whether it represents a true risk factor or is, instead, a prodromal symptom of incipient dementia. In either case, depression itself can further impair cognitive functioning and causes excess cognitive disability in the patient with dementia. This can make it more difficult for patients with dementia to process and judge events, thereby causing their responses and reactions to be more impaired and unpredictable. In the context of a severe depression, the patient may develop psychotic symptoms and psychomotor changes that can be mistaken for a worsening dementia or delirium. However, in our clinical experience caring for patients with AD, this is a rare occurrence. Apathy and language impairment complicate the diagnosis of depression in dementia. Apathy is the commonest early behavior change in AD and is not helpful in distinguishing between dementia and depression. In the middle to late stages of dementia, patients often have language deficits, which may limit their ability to give information regarding their mood state. The best indicators of depression in patients with dementia are persistent saddened mood, tearfulness, and depressed appearance. Vegetative signs such as sleep, energy, and appetite disturbance are less reliable. Knowledge of a past history of depression may be helpful in identifying patients at increased risk of a recurrence. An antidepressant trial is a reasonable diagnostic strategy in difficult to discern cases—a low index of suspicion for depression in the patient with dementia is appropriate.

### Anxiety Disorders

Anxiety disorders are relatively common in the elderly and are usually accompanied by agitation. Rates for anxiety disorders in this age group are high, between 15% and 20%, and tend to go unrecognized. The most common anxiety disorders include phobias, generalized anxiety disorder, and panic disorder. An exacerbation of preexisting posttraumatic stress disorder may also be responsible for symptoms of anxiety and agitation in patients with dementia. Traumatic memories and dissociative/reexperiencing episodes (“flashbacks”) may become more frequent and intense and difficult to distinguish from current events in patients with dementia because of their cognitive impairments (e.g., disorientation, short-term memory loss, impaired executive function, and confusion) and the fact that long-term memories for distant events are generally intact until late-stage dementia. For this reason, inquiring about a history of trauma exposure is often helpful when evaluating the patient with dementia who is agitated. Other disorders associated with anxiety symptoms in elderly patients with dementia include depression and Parkinson's disease. Given the high rates of anxiety disorders in the elderly, clinicians should actively consider these diagnoses in the patient with dementia who is agitated.

### Psychotic Symptoms

Psychotic symptoms occur in approximately 20% to 30% of patients with AD and often contribute to the development of disruptive

agitation. Delusions tend to be more common than hallucinations in AD; hallucinations (particularly visual hallucinations) are more common in patients with Lewy body pathology. Delusions in the patient with AD are often cognitively based. Memory deficits may lead to delusional beliefs that misplaced objects have been stolen. Symptoms of agnosia (failure to recognize the identity of objects or persons despite intact perceptual abilities) may result in a number of misidentification syndromes: that the identity of a person has somehow changed, that a person has been replaced by an imposter (Capgras syndrome), or that the patients' houses are not their homes. Less commonly, patients may develop the delusion that their spouses have been unfaithful or that the patients are being poisoned. Such delusions may cause distress for both patient and caregiver. Hallucinations are more likely to be visual than auditory and tend to occur more frequently in the moderate-to-severe stages of AD. In many instances, the hallucinatory experiences are unobtrusive and do not cause distress to the patient, so medication intervention is not warranted. The presence of visual hallucinations early in the course of dementia suggests presence of Lewy body pathology. The presence of hallucinations has been associated with increased cognitive decline, institutionalization, and mortality. Systematized, grandiose, nihilistic, or bizarre delusions are uncommon and should alert the clinician to the development or recurrence of another psychiatric disorder, such as late-life schizophrenia, delusional disorder, or major depression with psychotic features.

## MANAGEMENT OF AGITATION (see Table 73-2 and Table 73-3)

### Identify Target Symptoms

Certain behaviors respond better to medication intervention than others. In general, auditory hallucinations, delusions, irritability, uncooperativeness with care, physically aggressive behaviors, and forced motor activity such as pacing tend to respond better to medication intervention. Repetitive, nonaggressive behaviors such as aimless wandering, repetitive vocalizations, and hoarding are less responsive. Some behaviors may be more effectively targeted by utilizing distraction, modifying the patient's environment, or modifying the caretaker's mode of interaction with the patient. Patients who wander need to be provided with a safe environment in which to do so.

**TABLE 73-2**

### Management of the Agitated Patient

Identify target symptoms
↓
Set realistic goals

Nonpharmacological intervention
↓
Pharmacological intervention
↓
Reevaluate need for continued intervention

**TABLE 73-3**

### Management of Major Psychiatric Symptoms

PREDOMINANT NEUROPSYCHIATRIC SYMPTOMS	CONSIDER
Psychotic symptoms	Antipsychotic (haloperidol, risperidone, olanzapine, and quetiapine)
Dangerous aggression	Adrenergic antagonist Antipsychotics Short-acting benzodiazepine ( <i>only short term and in case of emergency</i> )
Hypomanic symptoms	Valproic acid Carbamazepine
Prominent mood or anxiety symptoms or irritability	Selective serotonin reuptake inhibitor

### Set Realistic Goals

It is important to remember that the primary reason to treat disruptive agitation is to relieve suffering in the patient. However, realistic goals on the part of the clinician and caregiver are necessary, particularly with respect to the likelihood of response of the target behaviors to the intervention. It should be stated clearly that the goal of treatment is to decrease the frequency and severity of the agitated behaviors. Total eradication of the disruptive behaviors is only occasionally achieved and often represents an unrealistic expectation. The preferred therapeutic goal is to achieve sufficient improvement so that the quality of life of the patient and the caregiver is enhanced and that, for patients in the home setting, institutionalization is forestalled.

### Therapeutic Interventions

#### Nonpharmacological Interventions

It is important to institute nonpharmacological management first, if possible, in order to minimize the possible adverse effects of psychotropic medications in elderly patients and to optimize the likelihood of a positive response. Nonpharmacological interventions address potential psychosocial and/or environmental reason(s) for the development of agitation. There are three main theoretical models of psychosocial contributions to the etiology of behavioral disturbances associated with dementia: the *"unmet" psychosocial needs model*, the *reduced stress-threshold model*, and the *behavioral/learning model*.

The *"unmet needs" model* emphasizes the identification and resolution of underlying needs that are believed to be causing the inappropriate behavior. These may include sensory deprivation, boredom, loneliness, pain, and the need to empty bladder or bowel. Commonly described interventions include appropriate sensory stimulation, good lighting, provision of sensory aids (e.g., eyeglasses and hearing aids), a safe place to wander, social interactions, pain control, and frequent toileting.

The *reduced stress-threshold model* is based on the assumption that, because their impaired cognition limits their ability to process and cope with environmental stimuli (e.g., sound, light, and motion), patients with dementia have a lower threshold at which these stimuli become overwhelming, resulting in symptoms of disruptive agitation. The primary intervention in this model is to reduce the level of

environmental stimulation with which patients with dementia have to contend, with the expectation that this will decrease their level of agitation.

*The behavior/learning model* assumes that there is a connection between antecedents, behavior, and reinforcement that has been learned. In this model, disruptive agitated behaviors are learned through reinforcement by caregivers, who provide attention when problem behaviors occur. A modification of the usual intervention (reinforcement) is required to change the behavior. For example, caregivers should be encouraged to provide attention and positive emotional responses to desired behaviors and attempt not to respond to problem behaviors, in the hopes of increasing the former and extinguishing the latter.

These models are not mutually exclusive, and several of them can be applied concurrently, depending on the specific behaviors and precipitating circumstances.

Educating caregivers about the nature of neuropsychiatric behavioral symptoms of dementia can be a useful first step. It may be helpful to explain to the caregiver that it is common for patients with dementia to be repetitive, to wander, to misplace items, and to accuse others of stealing because of their memory deficits and impaired reasoning ability. This may prevent the caregiver from interpreting these behaviors as reflecting intentional stubbornness or disruptiveness, thereby making it easier for the caregiver to tolerate these challenging behaviors and eliminate the need for pharmacological intervention.

In instituting nonpharmacological management, it is useful to first appraise current interventions, supporting those who have been successful and discouraging others who are ineffective or appear to aggravate the problematic behavior. As noted above, there is value in identifying circumstances that precipitate or exacerbate the agitation. It is particularly common for patients with dementia to become agitated if their routine is disrupted, if the environment is too stimulating, or if they are approached by strangers or relatives they do not recognize or who they believe are trying to harm them. Avoiding or minimizing these situations is often the best intervention. Patients who are cognitively impaired also tend to become agitated when others are trying to help them during activities of daily living (particularly bathing, dressing, and toileting), so allowing the patient to remain as independent as possible in these activities is important. Examples include person-centered showering (an intervention focused on resident comfort and preferences) and the towel bath (an in-bed bag bath method in which the resident remains covered at all times), which have been shown to be effective methods of reducing agitation, aggression, and discomfort during bathing. A patient who has difficulty dressing but still preserves some abilities may benefit from having clothing and shoes that use Velcro fasteners rather than buttons, zippers, or laces. Similarly, providing utensils with large handles and/or cutting food into bite-size portions may allow patients to continue to feed themselves. Some patients become agitated when they are asked to take their medications, so crushing the pills and diluting them in juice may avoid this source of agitation. Liquid forms of medications are also helpful in patients with swallowing difficulties who are at risk of aspiration. Other types of interventions that have shown some effectiveness in reducing agitation include exercise training, aromatherapy, pet therapy, and music therapy. Given the relative poor response rates in the treatment of agitation, it is important to be “creative” and develop individualized interventions whenever possible.

Since patients with AD gradually become aphasic, it is essential to use simple and clear language and use visual cues to improve communication and minimize frustration. Caregivers should be reminded to approach patients with dementia from the front to avoid startling them. They should stay at more than an arm’s length away to prevent being injured. One should also be cautious when bending down to talk to a patient in a wheelchair, who may respond by hitting or kicking. Instituting predictable routines, eliminating unnecessary stimulation and novelty, maximizing the patients remaining abilities, and approaching the patient cautiously can all help reduce episodes of agitation.

The issue of wandering and getting lost, with the attendant increased risk of physical harm and death, is of extreme concern to caregivers and often precipitates institutionalization. Although unattended patients have higher rates of getting lost, many patients who get lost are in the presence of a caregiver or are living in a professional care setting. Therefore, caregivers need to be made aware that all persons with dementia are at risk of becoming lost, even if the individual has never wandered in the past. While signs on doors may help to orient patients and the use of safety alarms and difficult-to-open key latches may decrease the likelihood of the patient getting lost, continuous supervision is the best preventive measure. To facilitate the location of patients with dementia who do become lost, the Alzheimer’s Association administers the nationwide “safe return” program that provides patients with identification bracelets, necklaces, or clothing tags and offers 24-hour assistance in locating lost patients.

### Pharmacological Interventions

If a general medical cause for agitation has been ruled out and non-pharmacological interventions have been unsuccessful, psychotropic medications need to be considered. Unfortunately, there is no pharmacological regimen with proven good efficacy. In many instances, it is necessary to institute a period of trial and error before an effective medication intervention is identified for the individual patient.

Historically, nursing home residents have been overprescribed psychotropic medication and have been left on them indefinitely. Antipsychotics are the third most frequently used class of drugs in skilled nursing home facilities. The use of psychotropic and sedative medications in the nursing home setting is now regulated by the Omnibus Budget Reconciliation Act (OBRA-1987). The OBRA establishes guidelines for the use of psychoactive medications in the nursing home setting. OBRA regulations allow antipsychotic use only for psychotic symptoms or in dementia for dangerous symptoms. The use of hypnotics is restricted to 7 days of continuous use. The need for continued pharmacologic intervention needs to be periodically reviewed, and polypharmacy should be avoided.

### Antipsychotics

Antipsychotics have traditionally been the cornerstone for treatment of agitation in dementia. Until fairly recently, “conventional” or “typical” antipsychotics were widely used. However, the “atypical” antipsychotics have recently gained popularity because of their improved side-effect profile and tolerability, and their usage in the elderly has increased markedly since their introduction into the market. Antipsychotics are used “off-label” for the management of agitation in dementia; these are not approved by the U.S. Food and Drug

Administration (FDA) for the treatment of behavioral symptoms in patients with dementia.

### Efficacy

Two meta-analyses including 12 randomized clinical trials (RCTs) and two additional RCTs evaluating conventional antipsychotics have shown modest efficacy and significant adverse side effects. A slight benefit for haloperidol with aggression was found. In this same study, six RCTs of atypical antipsychotics were analyzed, and the authors concluded that risperidone and olanzapine had the best evidence for what was described as modest efficacy. In a Cochrane meta-analysis of nine studies, the authors found that there was significant improvement in aggression with risperidone and olanzapine and significant improvement in psychosis with risperidone.

The Clinical Antipsychotic Trials of Intervention Effectiveness was a multicenter effectiveness trial of atypical antipsychotics in patients with agitation and psychosis associated with AD who resided in the community. The study enrolled 421 participants. The study demonstrated that the response to atypical antipsychotic therapy was no greater than that achieved by placebo (improvement was observed in 32% of patients assigned to olanzapine, 26% of patients assigned to quetiapine, 29% of patients assigned to risperidone, and 21% of patients assigned to placebo). In addition, the adverse effects offset the modest improvements. A caveat to these conclusions is that Clinical Antipsychotic Trials of Intervention Effectiveness was designed to study the effectiveness of atypical antipsychotic treatment in community-dwelling patients with AD. It is unclear if these results also apply to nursing home patients with more severe dementia and behavioral impairment.

### Mortality Risk and Antipsychotics

In April 2005, the FDA completed a meta-analysis of 17 placebo-controlled trials (only four studies were in the public domain) of aripiprazole, olanzapine, quetiapine, and risperidone and found the risk of mortality to be 1.6 to 1.7 times greater in treated versus untreated elderly patients with dementia, primarily owing to cardiovascular or infectious causes. The FDA reported, in a public health advisory that prompted a “black-box” warning, that the use of all second-generation (“atypical”) antipsychotic medications for the treatment of behavioral symptoms in elderly patients with dementia is associated with increased mortality. Although the FDA findings were confirmed in an independently conducted meta-analysis, four observational studies did not replicate the finding of increased mortality with atypical antipsychotic treatment. In summary, atypical psychotics and possibly typical antipsychotics may be associated with a small increased risk of death.

### Cerebrovascular Adverse Events and Antipsychotics

The evidence regarding increased cerebrovascular adverse events (mainly stroke, transient ischemic episodes, and cases of loss of consciousness or syncope), associated with the use of typical and atypical antipsychotic drugs is conflicting. A positive association was initially found in a pooled analysis of 11 RCTs, mainly nursing home clinical trials of risperidone and olanzapine for patients with dementia, performed by regulators who had access to unpublished data. A larger number of subjects with vascular and mixed dementias

were included in the risperidone studies compared with the olanzapine studies, which likely accounted for the increased incidence of cerebrovascular adverse events in the risperidone group. When serious cerebrovascular adverse events like stroke were examined separately, the relative risk of risperidone treatment was not significantly higher than placebo. Other large observational administrative health database studies have also failed to demonstrate an increased risk of stroke in elderly patients treated with risperidone or olanzapine. In summary, pooled RCTs suggest an increase in cerebrovascular adverse events with olanzapine and risperidone; this may not include an increased rate of serious events such as strokes. Further studies are needed to confirm these findings.

### Antipsychotics and Mortality in Patients with Dementia with Possible Lewy Body Pathology

Demented patients with Lewy body pathology experience more frequent and severe extrapyramidal motor symptoms as side effects of typical and atypical antipsychotic medications. In the most recent consensus criteria for the clinical diagnosis of dementia with Lewy bodies, “neuroleptic sensitivity” constitutes a “suggestive” feature, which, in the presence of one or more “core” features (i.e., dementia, parkinsonian motor signs, visual hallucinations, fluctuating attention, and alertness), supports a diagnosis of probable dementia with Lewy bodies. Neuroleptic sensitivity in patients with dementia with Lewy bodies has been associated with increased mortality in several studies. Therefore, instituting antipsychotic treatment in patients with symptoms of Lewy body pathology should be avoided whenever possible. When necessary, quetiapine is the preferred antipsychotic agent because of its low propensity for causing extrapyramidal motor symptoms and efforts should be made to limit administration to the lowest effective dose.

In summary, given the modest efficacy and the risk for significant and serious adverse effects, antipsychotics should only be used when nonpharmacologic interventions have failed and other pharmacologic interventions have been considered.

### Other Side Effects of Antipsychotics

Elderly patients are at increased risk of developing troublesome adverse effects of antipsychotic medications, including extrapyramidal motor symptoms, sedation, tardive dyskinesia, and metabolic syndrome. Peripheral anticholinergic effects, such as dry mouth, constipation, and urinary hesitancy can complicate the care of the elderly patient with dementia. Central anticholinergic effects can worsen impairment of memory and other cognitive abilities and induce delirium. Oversedation and pseudoparkinsonism can increase the risk of falls and complications such as fractures and head injury. The clinician also needs to be alert to the development of antipsychotic-induced akathisia, an uncomfortable urge to move about that can increase pacing and other agitated behaviors. Low-potency antipsychotics, such as chlorpromazine and thioridazine, carry the added risk of orthostatic hypotension and cardiac toxicity and should be avoided.

In summary, given the modest positive efficacy found with antipsychotics and the increased risk of mortality, these should be prescribed only for patients with significant psychotic symptoms that are disturbing to the patient and/or aggressive behaviors that may result in harm to the patient or others. However, it is also important

**TABLE 73-4****Selective Serotonin Reuptake Inhibitors—Dosages in the Elderly**

DRUG	STARTING DOSE (mg)	RANGE (mg)
Citalopram (Celexa <sup>®</sup> )	10	10–40
Escitalopram (Lexapro <sup>®</sup> )	5	5–20
Fluoxetine (Prozac <sup>®</sup> )	5	5–60
Paroxetine (Paxil <sup>®</sup> )	10	10–40
Sertraline (Zoloft <sup>®</sup> )	12.5–25	25–100

Each patient should be carefully assessed and dosing adjusted accordingly.

not to undertreat, because appropriate antipsychotic medication use can reduce patient distress or decrease potentially harmful behaviors. Maintaining a common sense approach where one weighs both benefits and risks in a collaborative process involving the patient's caregiver(s) will greatly facilitate the provision of good patient care. If medication treatment is deemed necessary, low-dose atypical antipsychotics are recommended. The general rule in dosing is to start low and go slow, *but* go up as necessary until symptoms improve or side effects intervene (Table 73-7). In dementia with features of Lewy body pathology and in Parkinson's disease, quetiapine is the preferred agent because of its low incidence of extrapyramidal motor side effects. Patients and families should be clearly informed of the potential risks of antipsychotic treatment, including increased mortality, and detailed documentation of such discussions recorded. If the patient responds favorably, periodic attempts should be made to lower or discontinue the medication to see if continued treatment is necessary for control of the original target symptoms.

### Antidepressants

A recent review of five RCTs of antidepressants (sertraline, fluoxetine, citalopram, and trazodone) showed *no efficacy* for treatment of agitation, with the exception of one study that found patients treated with citalopram had improvement in the total behavioral score. The study did not separate psychotic from aggressive behaviors, so it is unclear if citalopram would be effective in patients with psychotic symptoms alone.

Because these have a relatively benign side-effect profile, selective serotonergic reuptake inhibitors (SSRIs) are considered the agents of choice for depressive and anxiety disorders in dementia (Table 73-4). One study in patients with AD found that sertraline was superior to placebo in reducing depressive symptoms. The atypical antidepressants, such as venlafaxine, mirtazepine, and bupropion,

**TABLE 73-6****Atypical Antidepressants—Dosages in the Elderly**

DRUG	STARTING DOSE	RANGE (mg)
Bupropion (immediate release) (Wellbutrin <sup>®</sup> )	75–100 mg every morning or twice daily	150–450
Bupropion (XL) (Wellbutrin XL <sup>®</sup> )	100–150 mg every morning or twice daily	150–450
Trazodone* (Desyrel <sup>®</sup> )	12.5–25 mg every evening	50–200

Each patient should be carefully assessed and dosing adjusted accordingly.

\*Trazodone is used for sleep although it is FDA approved for depression only.

have been less well studied in this population (Tables 73-5 and 73-6). Two multicenter trials with citalopram demonstrated efficacy in the management of depressive symptoms in patients with AD with mild side effects.

Pharmacological properties are important in selecting among SSRIs for elderly patients. In the elderly patient, the development of common SSRI side effects, particularly nausea, diarrhea, and anorexia, can be problematic because of subjective discomfort as well as the increased potential for deleterious effects from weight loss in this often frail population. Fluoxetine is often poorly tolerated in the elderly, even at low doses, because its prominent activating effects and the long half-lives of fluoxetine and its primary metabolite, nor-fluoxetine, complicate dosage adjustment. Paroxetine suffers from relatively greater anticholinergic side effects compared to other SSRIs. Sertraline offers the advantage of a relatively short elimination half-life. SSRIs also exert prominent effects on the activities of hepatic microsomal enzyme systems that metabolize other medications. This requires careful attention to the potential for drug–drug interactions. Citalopram has the fewest such effects and may be preferred in patients on multiple medications for physical illnesses. However, it is important to consider that SSRIs are also highly protein bound and may competitively inhibit protein binding and thereby alter the pharmacodynamic effects of other medications. This is particularly important in the case of medications that have a low therapeutic index, like warfarin.

Trazodone, a serotonergic antidepressant with prominent alpha-1 blocking activity and sedative properties, has been used by clinicians for the control of agitation and sleep disturbance. However, its potent alpha-adrenergic blocking activity can cause orthostatic hypotension and priapism. The only RCT that evaluated trazodone in the management of agitation in dementia showed no benefit over placebo.

Because tricyclic antidepressants (e.g., nortriptyline and desipramine) have significant anticholinergic side effects and may cause

**TABLE 73-5****Serotonin Norepinephrine Reuptake (SNRI) and Mirtazapine—Dosages in the Elderly**

DRUG	STARTING DOSE	RANGE
Venlafaxine (SNRI) (Effexor <sup>®</sup> )	18.75–37.5 mg every morning or twice daily	75–150 mg twice daily
Venlafaxine extended release (SNRI) (Effexor XR <sup>®</sup> )	37.5 mg every morning or twice daily	75–100 mg twice daily
Duloxetine (SNRI) (Cymbalta <sup>®</sup> )	10–20 mg every morning or twice daily	20–60 mg once to twice daily
Mirtazapine* (Remeron <sup>®</sup> )	7.5–15 mg every morning evening	15–60 mg every evening

Each patient should be carefully assessed and dosing adjusted accordingly.

\*Available as rapidly dissolving sol-tab preparation.

Each patient should be carefully assessed and dosing adjusted accordingly.

\*Administer lower doses at night and divide higher doses throughout the day.

†The intravenous route is preferred for delirium in the hospital setting as a result of lower incidence of extrapyramidal symptoms.

orthostatic hypotension and cardiac rhythm disturbances, their use in the elderly is discouraged. Treatment of neuropathic pain in the elderly is probably better treated with anticonvulsants rather than low-dose tricyclics for this reason.

### Anticonvulsants (see Table 73-8)

The effectiveness of mood stabilizers in controlling irritability, aggression, impulsivity, and mood instability in bipolar disorder prompted their use in patients with dementia who are agitated. As is true for the use of most agents in this clinical context, the use of anticonvulsants is based mainly on case reports. Large, well-controlled RCTs have not supported their efficacy for treating disruptive agitation in dementia.

### Carbamazepine

The development of oversedation, confusion, and ataxia limits the use of carbamazepine in the elderly. Carbamazepine has been investigated in two small RCTs for its impact on agitation and aggression in dementia with mixed results. An additional recent randomized multisite trial in 51 nursing home patients with dementia and agitation showed improvement in all agitation measures compared to placebo. Side effects were significantly greater in the carbamazepine group compared to placebo. Of note, carbamazepine carries a “black-box” warning for hematologic toxicity, and its propensity for inducing hepatic drug-metabolizing enzymes makes it problematic.

### Valproate

Valproate is extensively used in the treatment of bipolar affective disorder. Initially, case studies/series suggested possible efficacy in the treatment of agitation related to dementia. Subsequent random-

mized trials failed to show benefit with respect to primary outcome measures of agitation. A meta-analysis of three RCTs investigating valproate showed no efficacy for either short- or long-acting preparations.

### Gabapentin

A small case series of gabapentin as a treatment for agitation associated with dementia showed mixed results as far as effectiveness. In addition, adverse events, including gait instability and sedation, were significant. These limited data do not support the use of gabapentin in dementia.

In summary, the evidence does not support the use of valproate for treatment of agitation in dementia, and there is insufficient evidence to support the use of carbamazepine or gabapentin. The use of anticonvulsants in the treatment of agitation in the demented elderly patient may have a role on a case-by-case basis, especially if they have failed other treatments. When utilizing these medications, a low-dose approach is recommended to avoid serious side effects. Hematologic toxicity and drug interactions are particularly concerning for carbamazepine, considering that many elderly patients with dementia are on multiple medications. Valproate, even at low dose, causes significant sedation. The lack of proven efficacy in randomized controlled trials should be considered when contemplating the use of these medications in this population.

### Acetylcholinesterase Inhibitors

Two meta-analyses and six additional RCTs of AChEIs (tacrine, donepezil, galantamine, and rivastigmine) for the treatment of neuropsychiatric symptoms in dementing disorders have been published. Five of these studies showed statistically significant, albeit modest, benefits. Whether the behavioral responses are secondary to cognitive improvement is unclear. Based on these data, the AChEIs may have a role in the treatment of behavioral symptoms in patients with AD and other dementias, including vascular dementia and Lewy body spectrum dementia.

The theorized reason for efficacy in this broad range of dementia types lies in neuropathologic evidence for a common pathology of

**TABLE 73-8****Anticonvulsants—Dosages in the Elderly**

DRUG	STARTING DOSE	RANGE
Divalproex sodium (Depakote®)	10–15 mg/kg bid or tid 125 mg bid	Target trough level: 45–100 µg/mL
Carbamazepine (Tegretol®)	100 mg bid, increase by 100–200 mg every 2–4 d	400–1200 mg bid Blood level: 4–12 µg/mL

cholinergic neuronal degeneration, which is likely to contribute to both cognitive and behavioral symptoms. AChEIs counteract this by inhibiting acetylcholinesterase, an enzyme that breaks down acetylcholine in the synaptic cleft, resulting in a relative increase in intrasynaptic acetylcholine for stimulation of both postsynaptic nicotinic and muscarinic receptors.

Donepezil, rivastigmine, and galantamine are generally well tolerated; the most common side effects are gastrointestinal disturbances, including nausea, vomiting, and diarrhea. Anecdotal evidence suggests that severity of gastrointestinal side effects may be attenuated when AChEIs are coadministered with memantine. AChEIs are contraindicated in patients with severe asthma or obstructive pulmonary disease, bradycardia (resting heart rate <50), cardiac conduction abnormalities, or peptic ulcer disease.

In summary, AChEIs should be considered in the treatment approach for patients with dementia who are agitated. Although the full treatment effects on behavioral symptoms have not been fully elucidated, the known benefit in delaying cognitive symptom progression, the modest improvement of neuropsychiatric symptoms seen in clinical trials, and the tolerable side-effect profile of these medications make them reasonable tools for addressing agitation. However, it should be made clear that AChEIs are a long-term strategy for reducing disruptive agitated behaviors; these are not an appropriate approach for acute management of severe disruptive agitation.

### Antiadrenergic Approaches

As noted earlier, enhanced behavioral responses to NE in AD may contribute to the pathophysiology of disruptive agitation. Because it is not clear which postsynaptic adrenergic receptor class (beta-adrenergic, alpha-1 adrenergic, or both) might mediate the expression of disruptive agitation, we have developed pilot data using the beta-adrenergic antagonist propranolol and the alpha-1 adrenergic antagonist prazosin.

We previously demonstrated that propranolol (mean dose  $10 \pm 5$  mg/day) was superior to placebo on total Brief Psychiatric Rating Scale scores and Clinical Global Impression of Change (CGIC), and propranolol was well tolerated. However, behavioral (but not antihypertensive or bradycardiac effects) of propranolol appeared to dissipate with long-term treatment in several patients, thus limiting drug effectiveness. In these latter patients and in those medically ineligible for inclusion in the propranolol study, open-label low-dose prazosin (1–5 mg/day) appeared even more effective than propranolol, was well tolerated, and positive effects were sustained for at least 6 to 12 months of follow-up.

Eleven patients with advanced AD or AD/CVD who had severe disruptive agitation for at least 1 month (i.e., physically aggressive behavior, resistiveness to care, verbally abusive behavior, pacing, and/or nighttime restlessness/thrashing in bed) were treated open label with prazosin (1–5 mg/day). Prazosin was started at 1 mg qhs for 2 days to avoid “first-dose” hypotension and increased by 1 mg/day every 5 days. Other psychotropic medications were held constant. All patients were without delirium and were medically stable. Before and after 8 weeks of treatment, subjects were rated by a research psychiatrist with input from the nursing home staff on the CGIC regarding frequency and severity of disruptive agitated behaviors and its impact on patient function and demands on staff. Nine of 11 patients were rated as “markedly improved” or “moderately improved” on the CGIC. Among them, five had no or minimal improvement during treatment with an atypical antipsychotic (olanzapine, risperidone,

or quetiapine). The other two patients were rated on the CGIC as between “moderately improved” and “minimally improved.” Nursing home staff and the patients’ primary-care physician elected to continue maintenance prazosin after the 8-week point in 10 of the 11 patients. There were no cardiovascular or other troublesome adverse events. These open-label data suggest that the alpha-1 adrenergic antagonist prazosin may be a promising treatment for disruptive agitation in dementia. A placebo-controlled trial is currently underway.

### Benzodiazepines

Benzodiazepines have a limited role in the management of agitated behavior in dementia. Their use should be circumscribed only to emergency situations in which severe agitated behavior places the patient or others at risk of injury and has proven unresponsive to systematic trials of alternative medications. Under these circumstances, patients may benefit from a time-limited trial of a short-acting benzodiazepine, like lorazepam, oxazepam, or temazepam. These medications are preferred to long-acting preparations because these do not accumulate with repeated dosing and because their metabolism is not affected by age and liver disease. In contrast, long-acting benzodiazepines, such as diazepam, should be avoided because the parent agent and its active metabolites have extremely long half-lives, which lead to accumulation. Low-dose lorazepam is our preferred choice. All benzodiazepines may worsen cognitive functioning and increase the likelihood of falls and fractures.

### Gonadal Hormones

The utility of hormonal treatments for agitation in patients with dementia is still being clarified. It has been theorized that increasing estrogen activity or decreasing androgen activity in patients with aggressive dementia can reduce problematic behaviors. Consistent with this theory, several case reports have suggested that estrogen administration or the use of gonadotrophin-releasing hormone agonists (leuprolide and goserelin) in men may be beneficial. Small randomized placebo-controlled trials of estrogen treatment have yielded mixed results. One study that included both men and women favored the estrogen arm, whereas another study that included only men found no significant differences from placebo. This second study also observed “rebound” aggressive behavior in subjects whose estrogen was discontinued upon completion of the study. There are several case reports of high-dose estrogen, decreasing aggressive behavior in women with severe dementia. Progestin preparations such as Depo-Provera have been reported to control sexually inappropriate behavior in men with dementia. Given the mixed results of previous studies, further research is needed to determine the value of this treatment approach.

### General Guidelines for the Selection of Pharmacological Interventions

The recommended strategy for effective yet safe and tolerable treatment is to add or change only one medication at a time, thereby making the source of improvement, deterioration, or emergence of side effects more easily apparent. Always start at recommended geriatric doses and titrate up slowly.

Several clinical guidelines are helpful when choosing a psychoactive agent for the treatment of agitation. Patients with AD who are

agitated, who have not responded to nonpharmacologic interventions, should be placed on an AChEI. If psychotic symptoms such as hallucinations or paranoid delusions are a prominent feature, an antipsychotic is a good first choice. Physically aggressive behavior, uncooperativeness with care, and forced motor activity may respond to the alpha-1 adrenergic antagonist prazosin. If the clinical presentation is marked by dangerous aggression, a benzodiazepine may be required acutely but only for short-term use and then an antipsychotic or prazosin should be considered. An SSRI may be useful in the presence of prominent mood or anxiety symptoms and/or irritability. A trial of gonadal hormones including antiandrogen approaches may be beneficial for male patients exhibiting inappropriate sexual behaviors. The need for continued pharmacologic management of disruptive agitation in the nursing home setting must also be reviewed periodically, weighing risks and benefits, keeping in mind that these behaviors often are episodic in nature and may change or even disappear over the course of the dementing illness, particularly in the very late stages of the disease, when patients may no longer exhibit any behaviors. Justification for the chosen intervention must clearly be documented on an ongoing basis.

## CONCLUSION

The management of the elderly patient with AD who is agitated and other dementing disorders requires a comprehensive biopsychosocial approach. Nonpharmacological interventions should always be instituted first. If the symptoms persist and are distressing to the patient or are potentially harmful, then careful deliberation—weighing risks and benefits—should be carried out before initiating pharmacological management, particularly with antipsychotics. It is also important to keep in mind that these behaviors often are episodic in nature and may change or even disappear over the course of the dementing illness regardless of interventions. In many cases, a combination of both nonpharmacological and pharmacological interventions is necessary in order to decrease symptoms, improve quality of life, and delay institutionalization.

# Effects of Aging on Cardiovascular Structure and Function

*Dalane W. Kitzman* ■ *George Taffet*

## PRINCIPLES OF AGING BIOLOGY PERTINENT TO THE CARDIOVASCULAR SYSTEM

As the aging process begins after maturation, deteriorative, regenerative, and compensatory changes develop over time and result in diminished physiological reserve capacity and an increased vulnerability to challenges, particular disease, and, as a result, a decrease in the ability to survive. Importantly, aging itself does not result in disease; however, it does lower the threshold for the development of disease and can intensify and accelerate the effects of disease once initiated. The increased vulnerability with age to external or internal challenges is one of the tenets of geriatrics and gerontology and is called homeostenosis.

These concepts are particularly relevant to aging of the human cardiovascular system, especially older persons living in developed countries. In these populations, it is particularly important to screen for clinical and subclinical disease, particularly atherosclerosis, as well as to consider other cultural and environmental factors that are distinct from aging yet can mimic aging effects. These can manifest in human populations studies as cohort and period effects, can be subtle or overt, and are easily confused with aging. It has been proposed that a true age-related change should be absent in young persons, increase with age, be universally present in very old persons, and not be related to any known, definable disease.

In some early human aging studies, subjects with clinical and subclinical disease were not excluded, leading to an overestimation of the effects of aging on the cardiovascular system. Coronary atherosclerosis is highly prevalent in western societies and is one of the important disorders that can be occult and can significantly affect cardiac function. Systemic arterial hypertension is even more common. Therefore, reasonable screening for these two most common disorders is prudent to separate aging from disease.

In addition to the effects of subclinical disease, there are additional effects of physical inactivity. Humans and many animals become in-

creasingly sedentary as they age. For example, rats given free access to a running wheel will run 20 km per week when they are young, but this decreases to less than 7 km per week when approaching the age of 23 months. Many older people are even less active. Another increasingly important life-style-related factor relatively new to civilization is obesity. Adipose tissue owing to excess caloric intake has numerous effects involving nearly all physiological systems, including cardiovascular, and obesity increases substantially with age. Thus, the changes that are seen in an older population reflect the combination of all these factors, period, cohort, lifestyle, and disease-related changes, as well as the biological effect of age itself. It is often challenging to precisely separate and discern, both qualitatively and quantitatively, the latter from the former. However, awareness of the important nuances of normal aging can help avoid most errors.

## AGING OF THE VASCULATURE

### Age Changes in Arterial Structure

With age a number of ultrastructural changes occur in the aorta, and all appear to contribute to increased stiffness. Elastin becomes fragmented in the internal elastic lamina and media perhaps because of inappropriate activation of matrix metalloproteinases. Calcification of the media is also seen. Collagen increasingly becomes cross-linked, making a stiff matrix, especially in the subendothelium.

Irregularities in size and shape of endothelial cells are seen at areas of turbulence, and high cellular turnover occurring at those sites suggest that replicative or cellular senescence may be occurring at those sites. Further evidence of this “in situ” replicative senescence may be provided by manipulations that inhibit telomere shortening. In endothelial cells with persistently long telomeres, age-associated abnormalities may be significantly reduced.

The aortic lumen diameter increases with age, as do vessel length and wall thickness. Because the aorta is fixed proximally and distally, the increase in length results in the tortuous, ectatic, and rightward-shifted aorta seen often on chest X-rays of older persons.

Angiogenesis is impaired in the old vascular tree in response to ischemia or chemical signals. Explants of arteries from old animals have decreased spouting of microvessels and decreased vascular invasion of implants. There is no deficit of smooth muscle cell proliferation, but endothelial cell proliferation is impaired. The impact on this is uncertain because neovascularization of myocardial infarcts or dermal wounds, which may be a bit slower in old rats, is ultimately similar for young and old rats.

### Functional Changes of Aging Arteries

The older conduit artery may be less responsive to vasoactive substances. For example, nitric oxide (NO) is a vasorelaxor and (at least in the rodent) contributes to the balance that dictates resting arterial tone. Aortic strips isolated from older animals have higher NO synthase activity but produce less NO. Old aortas will relax appropriately when exposed to direct NO donors (nitroprusside) but are less responsive to agents whose effects are mediated by NO such as acetylcholine. Similarly, forearm arterial blood flow is increased less in older individuals in response to acetylcholine compared to younger and athletically active older individuals. As NO is produced from circulating arginine, with age a relative increase in arginase (a scavenging enzyme that competes for arginine) results in reduced arginine availability for the endothelium, explaining the relatively poor efficacy of arginine supplementation. Isoform-specific arginase inhibitors are not yet available, but genetically induced decreases in Arginase protein attenuate age-related changes in arterial function, making this a promising area for research. Again, the response to direct acting agents is the same in old and young. While the reasons for this paradox remain unclear, the net result is that the old artery is contracted and, again, stiffer.

Old arteries are also tonically contracted by an age-related increase in receptors to endothelin-1 and circulating levels of this potent vasoconstrictor. This results in a decreased maximum response to added endothelin in older persons. Exercise training appears to decrease basal endothelin-1 levels and restore its responsiveness.

Arterial wall stiffness can be measured noninvasively as pulse wave velocity (PWV), augmentation index, distensibility, and systolic and pulse blood pressure. PWV increases twofold from age 20 to 80 years, independent of blood pressure. A stiffer artery wall allows pressure to reflect from periphery to the heart while the aortic valve is still open, increasing the load on the heart, and thus PWV is a physiologically relevant parameter. Augmentation index, another measure of the impact of aortic stiffness, increases fourfold over that same age range, contributing to the increase in systolic pressure that occurs with age. For men in the Framingham study, systolic BP increased 5 mm Hg per decade until the age of 60 years; then the slope shifted to 10 mm Hg per decade. For women, systolic BP started lower but shifted to the higher slope earlier. Over the same age range, diastolic BP increases a little and then decreases, so overall it remains unaltered (80 in men, 70–80 in women). Older athletes have lower systolic pressures and PWVs than sedentary old people, but young people were still better than the old athletes. In fact, PWV correlates inversely with maximum oxygen consumption ( $VO_{2max}$ ) in healthy people of all ages.  $VO_{2max}$  is strongly associated with measures of

vessel stiffness, particularly PWV, which may be a true contributor to the age-related decline in exercise capacity via a number of mechanisms, including increased load on the left ventricle as well as altered peripheral blood flow distribution. However, this has not been fully explored.

As noted above, at least one mechanism for the increase in arterial stiffness involves nonenzymatic glucose cross-links between vessel collagen molecules. ALT-711 (alagebrium) is a prototypical cross-link breaker and is effective in decreasing PWV and augmentation index as measures of vessel stiffness in older primates and people. Interestingly, plasma advanced glycosylation end products correlate with PWV in normals and hypertensives.

The net result of these changes is reduced compliance and increased impedance, leading to increased systolic blood pressure and little, if any, effect on diastolic blood pressure.

### Aging and Atherosclerosis

In addition to the changes in the matrix, old smooth muscle cells appear to be less differentiated and proliferate more readily. In studies of smooth muscle cells isolated from young and old rat aortas, the freshly isolated old cells grew more rapidly and migrated more rapidly in comparison to those isolated from the young rat. The smooth muscle cells appear to have polyploidy, which may be another marker of dedifferentiation. While atherosclerosis is not a normal age-related change, especially in species other than man and possibly pigs, the higher propensity to proliferate may increase the probability of developing atherosclerosis if the environment is right.

It is important to understand that age-related changes in large arteries are different from atherosclerosis. First, atherosclerosis is essentially unique to western man; it has been difficult to reproduce the complicated plaque characteristic of advanced disease in humans, in animal models including genetically engineered mice. Atherosclerosis is heterogeneous compared to the age-related changes that occur quite uniformly throughout the conduit arteries. Atherosclerosis leads to a compromise of the vessel lumen compared to the relative dilation of the large vessels with age. The severity of atherosclerosis is related to blood turbulence and shear stress, whereas age-related changes have no such localization. Atherosclerosis clearly has an inflammatory component; none of the activation of white cells typical of atherosclerosis is seen in the age-related process. Cholesterol is a cofactor in atherosclerosis; it has no clear-cut role in age-related changes. Together, age-related changes are termed arteriosclerosis, but regrettably this term is often misused to indicate atherosclerosis, leading to confusion.

Nevertheless, it is clear that the functional and structural changes in the large arteries make the older person or animal at high risk of atherosclerosis, given the proper setting. If older rabbits are switched to atherogenic diets, the resulting lesions are more severe after an interval than young rabbits exposed for a similar duration. Thus, the aged arterial wall provides a more fertile ground for atherosclerosis to occur. And because both atherosclerosis and diabetes mellitus also increase large artery stiffness, these disease processes are multiplicative with age in increasing PWV, systolic blood pressure, and pulse pressure and their ultimate effects on the heart.

The impact of aortic stiffening and its clinical manifestations, increased systolic blood pressure and widened pulse pressure, are well appreciated. In addition to the recognition that increased systolic blood pressure and widened pulse pressure are risk factors for

stroke, renal failure, and heart disease, the more rapid propagation of pressure waves by the stiff aorta may induce left ventricular (LV) hypertrophy and early fibrosis within the myocardium via increased load, as well as altered ventricular–vascular coupling. If the PWV is high enough, early pressure wave reflections return while the aortic valve is still open, increase workload, and induce hypertrophy. Importantly when the pressure waves return later (as in the young), these may improve coronary artery perfusion by increasing the pressure in the proximal aorta.

## AGING CHANGES IN THE HEART

Substantial changes occur with aging in myocardial composition, cardiac structure, and cardiovascular function at rest and during exercise. The changes in anatomy are summarized in [Table 74-1](#).

### Changes in Myocardial Composition

#### Myocyte hypertrophy

Cardiomyocyte hypertrophy has been recognized and seen as a part of the response to the pressure reflections and increased afterload described above. However, this should be interpreted in light of the clear evidence that the heart is renewing itself, continuously repopulated from stem cell population resident and/or sequestered in the bone marrow. The cellular hypertrophy associated with age may mark depletion of the process, as the youngest cells, those most recently differentiated into cardiomyocytes, are thought to be the smallest and in the mouse heart the heterogeneity of myocyte size increases dramatically with age. Interestingly, the largest cells are also the most vulnerable to stress.

#### Myocyte Degeneration

The loss of myocytes with age is greater than the ability to repopulate the heart, and loss is by both apoptosis and necrosis. The total number of cardiomyocytes may be reduced across the lifespan by 50% in healthy human and animal hearts. As above, those cardiac myocytes that remain are increased in size and are much more variable in size. Nearly universal findings in hearts from elderly individuals are focal basophilic degeneration, a result of abnormal glycogenolysis, and lipofuscin, a “wear and tear” pigment, which results in a macroscopic darkened appearance to the aged myocardium, which has been termed brown atrophy. Lipofuscin occupies up to 10%

of myocardial volume in very elderly hearts. While profound, these changes are not detectable by routine diagnostic techniques, such as cardiac ultrasound, and their functional significance is not currently known.

However, older cardiomyocytes are intrinsically stiffer. This may be the contribution of active stiffness in part because of an increased leak of calcium from the SR with age, as well as passive stiffness as a result of viscoelastic changes within the cell. Each mitochondrion has its own genome, with relatively sparse ability to correct mutations. A number of investigators report that MitoDNA deletions may increase with age. The implications of this finding remain uncertain, as the number of mitochondria per myocyte is approximately 1000.

Nowhere is cellular dropout more impressive than in the sinoatrial node. The volume of the sinoatrial node decreases with age. The number of pacemaker cells is reduced (90% by the age of 70 years), with most volume replaced by fat. More modest cellular losses occur at the A-V node, and minimal changes are present in distal conduction system. The dropout of sinoatrial nodal cells is accompanied by a decrease in the slow, L-type calcium channel that is critical to initiation of depolarization. The sensitivity of the older sinoatrial node to calcium channel-blockers appears to increase in the older guinea pig pacemaker.

#### Connective Tissue

Diffuse foci of fibrosis are seen microscopically in the myocardium owing to an increase in interstitial collagen. The fibrous tissue appears in a delicate pattern, unlike the patches of fibrosis seen after acute injury, such as that seen after myocardial infarction. The fibrosis does not appear to be related solely to either ischemia or hypertension, although both of these disorders accelerate the process. Quantitatively, collagen content essentially doubles in the old rat heart. These changes may partly underlie age-related alterations in Doppler diastolic filling, which are discussed later.

#### Senile Cardiac Amyloid

Amyloid deposition is seen to varying degrees in the majority of hearts from persons older than 90 years but is uncommon before the age of 60 years. It is easily recognized at autopsy, particularly along the left atrial endocardium. Its significance is incompletely understood but might also contribute to LV diastolic stiffness seen by Doppler.

#### Adiposity

With aging, there is deposition of adipose, particularly in the right ventricular epicardium and the atrioventricular groove. This is most pronounced in women and in the obese. These observations from autopsy studies correlate with the well-known epicardial and pericardial fat stripes that superficially mimic pericardial effusion on echocardiography. In the Framingham study, the incidence and size of the echocardiographic clear spaces in the area of the pericardium increased significantly with age and were seen in the posterior as well as anterior regions. Previously thought to be an inert epiphenomenon, emerging data suggest that this adipose infiltration within the myocardium and grossly in the epicardium may have consequences for cardiac function, not surprising, given accumulating data indicating that adipose cells are metabolically and hormonally

**TABLE 74-1**

### Normal Age-Related Changes in the Anatomy of the Heart

- Increased heart weight, LV mass, and LV wall thickness; mild hypertrophy
- Fibrosis, collagen accumulation in the myocardium
- LV cavity size decreases, shortening of long axis, rightward shift and dilatation of the aorta, dilation of left atrium, and senile septum
- Calcific and fatty degeneration of valve leaflets and annuli
- Coronary artery dilation and calcification
- Conduction system: fibrosis and loss of specialized cells and fibers; 75% of pacemaker cells in sinoatrial node lost; fibrosis of A-V node and left anterior fascicle

active and can generate a range of factors including cytokines. This is an exciting area of research.

## Changes in Cardiac Structure

### Mass

In an autopsy study of 765 normal hearts evenly distributed by age and gender from age 20 to 99 years from subjects without a history of hypertension or evidence of significant coronary atherosclerosis, indexed mean heart weight in men was not age related and was consistently greater than in women. For women, however, the indexed mean heart weight increased significantly with age. This interaction of gender and age was confirmed in a study in 111 healthy subjects using 2-D guided M-mode echocardiographic measurements of LV mass. Furthermore, in seminal work by Gardin et al., when data from healthy men and women were combined, echocardiographic LV mass was found to increase 15% from age 30 to age 70 years. These age and gender trends in echocardiographic LV mass were confirmed more recently by Gardin et al. with an analysis of data from the Cardiovascular Health study (CHS), an NHLBI-funded population-based, observational cohort study of more than 5000 persons aged  $\geq 65$  years.

Not surprisingly, there is a substantial impact of body size, particularly weight and lean body mass, on LV mass. In a healthy subgroup of participants in CHS, when weight was adjusted for, there was an approximately 1 g/yr increase in LV mass from age 65 to 80 years. In the healthy subgroup of the Framingham study, when obese persons were excluded, there was a minimal influence of age on LV mass.

### Ventricular Wall Thickness

In the large autopsy study described above, right and left ventricular free wall thicknesses remained relatively constant with age, while ventricular septal thickness increased with age for both men and women. However, wall thickness measurements at autopsy may not correlate well with those made in living subjects, where measurements can be made in systole and diastole. In most echocardiographic studies of healthy subjects, mild age-related increases in both ventricular septal and LV free wall thickness have been found in women and men.

A frequent finding at autopsy and on echocardiograms of persons without apparent heart disease is mild disproportionate thickness of the basal ventricular septum. This has also been called sigmoid ventricular septum and senile septum. This finding may be the result of hypertension rather than biological aging. It has potential clinical relevance in that it can confound to some degree the diagnosis of hypertrophic cardiomyopathy in elderly patients.

### Chamber Size

There is disagreement in the literature of the effect of aging on chamber size. Some investigators have found a decrease in LV internal diastolic and systolic dimensions with age, by echocardiography in live subjects or direct measurement in autopsy studies. Others have shown no age-related change in LV size.

Most echocardiographic and autopsy studies have found a significant age-related increase in left atrial size in subjects without

apparent cardiovascular disease, with an increase in left atrial dimension between ages 30 and 70 years. The cause of age-related left atrial dilation is unknown, but it may have consequences for specific disorders that are common in the elderly, such as atrial fibrillation.

### Aorta

A uniform finding in all studies, including large population-based studies such as the Framingham study, has been a substantial age-related increase in aortic diameter, particularly the aortic root. The degree of change, 22% between age 30 and 70 years, is sufficient that nomograms for aortic root diameter should probably be adjusted for age. The thickness of the aortic wall also increases significantly with age, probably independent of atherosclerosis, and the pulsatility (compliance) of the aorta decreases. These changes are most discernible by ultrasound with transesophageal and intravascular echocardiography.

### Valves

The cardiac valves undergo several significant age-related changes. When measured directly at autopsy, the thicknesses of normal aortic and mitral leaflets increase, particularly along the closure margins. This is associated microscopically with collagen deposition and degeneration, lipid accumulation, and focal dystrophic calcification in the leaflets and annuli.

In those subjects most affected, this is recognized clinically and echocardiographically as aortic valve sclerosis, valve thickening without significant hemodynamic dysfunction. In the CHS study, this was found in 26% of participants and was related to male gender and hypertension. The relationship between these presumably age-related degenerative changes and the development of clinical aortic stenosis is incompletely defined. It was found in CHS that echocardiographically defined aortic sclerosis was independently associated with a 1.5-fold increased risk of cardiovascular mortality, calling into serious question whether this should be considered a normal age-related change.

Although not normal, age-related degenerative calcification of an otherwise normal-appearing tricuspid aortic valve may apparently result in progressive aortic stenosis and is currently the most common cause of aortic stenosis requiring valve surgery. The relationship between expected, near-universal age-related thickening and mild calcification of the aortic valve leaflets and the development of degenerative calcific aortic stenosis in a subset of elderly persons is unclear.

Microscopic deposits of calcium accumulated in the mitral annulus are expected with aging. However, gross mitral annular calcification should generally be considered a disease process. Relatively little is known about the true natural history of mitral annular calcification. It has been reported to be present in up to 40% of hearts from women older than 90 years, and there is a large (4 to 1) female predominance. Echocardiographically, it is often associated with modest degrees of mitral regurgitation but rarely with stenosis. A high incidence of atrioventricular block and bundle branch block has been described.

The circumferences of all four cardiac valves, measured at autopsy, increase with age in normal hearts from women and men, and this appears to be associated with collagen degeneration and

lipid accumulation in the valve annuli. This is most notable for the semilunar valves than the atrioventricular valves. In the case of the aortic annulus, this normal age-related dilatation has been confirmed in living subjects with echocardiography.

It is likely that annular dilatation contributes to the age-related increase in valvular regurgitation documented by Doppler in healthy, normal, asymptomatic subjects. By the age of 80 years, 90% of apparently healthy subjects had multivalvular regurgitation, and the aortic valve was affected earliest and to the greatest extent. The degree of valvular regurgitation caused by normal aging is always trivial or mild, central, and associated with normal (for age) appearing leaflets.

As in aortic stenosis, there is an association between this normal age-related change and an important cardiovascular disorder. Age alone is the strongest risk factor for isolated severe aortic regurgitation, and idiopathic dilatation of the aortic annulus is the most common cause of aortic regurgitation in patients undergoing aortic valve surgery. This disease may be an exaggeration of an expected age-related degenerative change exacerbated by systemic hypertension, and there is most likely an additional, contributing factor as yet unidentified.

An interesting, although unanswered, question is whether these normal age-related changes in the cardiac valves, individually or collectively, increase the risk for infective endocarditis.

### Pericardium

Wavy bands of collagen bundles comprise the normal pericardium. The straightening of these wavy bands allows a degree of distensibility when pericardial pressure or volume increases acutely. With aging, these bands of collagen become straighter and the pericardium becomes thicker. This causes the pericardium of older subjects to be stiffer. The significance of this aging change is unknown, but it could impact diastolic compliance in the elderly. As discussed above, the degree of epicardial and pericardial fat increases with age, particularly in women and obese persons, and the resultant echolucent spaces seen on echocardiography can superficially mimic a pericardial effusion.

### Atrial Septum

The atrial septum thickens and becomes stiffer with advancing age, probably owing to fatty infiltration and fibrosis. This causes the atrial septum to become less mobile with phasic respiration. This phenomenon is helpful in echocardiographic diagnosis. The finding of a thinned, hypermobile atrial septum by echocardiography in an elderly person should raise the suspicion of fenestrated atrial septal aneurysm, patent foramen ovale, or atrial septal defect and lead to careful color Doppler and a peripheral venous injection of agitated saline contrast. An exaggerated form of the age-related fatty infiltration is found essentially exclusively in older patients and is called lipomatous hypertrophy of the atrial septum. It can mimic the appearance of an intracardiac tumor but is recognizable by its characteristic dumbbell shape.

A probe-patent foramen ovale is seen in approximately 35% of normal hearts younger than 30 years and in 20% by age 80 years. While paradoxical embolism is usually considered in the context of an atypical stroke in a person younger than 55 years, it likely is

a contributor, although of unknown proportion, to strokes among the elderly. Because of this, injection of venous agitated saline contrast, a relatively benign procedure, is often used as an adjunct to echocardiographic imaging in older patients referred with atypical stroke.

### Coronary Arteries

With aging, the coronary arteries tend to become more dilated and tortuous, possibly because of hemodynamic drag. Coronary collaterals may also increase in number and size with age, but it is not clear whether this is independent of atherosclerosis. While atherosclerosis is always considered a disease process, Mönckeberg's medial calcification (arteriosclerosis) probably represents an age-related degenerative process. It is a nearly universal finding in the very old and is independent of gender. In the peripheral vasculature, it may contribute to the age-related elevation in systemic systolic blood pressure and arterial impedance. A syndrome often seen in elderly patients and those with end-stage renal failure is the triad of cardiac calcifications involving the aortic cusps, mitral annulus, and coronary arteries, called the senile calcification syndrome. In these older persons, no evidence of altered calcium metabolism has been found, and, although a relationship with elevated serum cholesterol levels has been described, the etiology is not known.

### Overall Appearance

It has been stated that a characteristic geometric configuration is imparted to the elderly heart by these age-related changes, particularly those observed in the cardiac chambers: shortening of the long-axis dimension, a mild decrease in the internal systolic and diastolic LV dimensions, dilatation and rightward shifting of the aortic root, and dilatation of the left atrium. These changes, as well as the mild regional calcification seen in the aortic and mitral valve annuli, are so characteristic that these can be used as clues to help detect the age group of patients during blinded readings of echocardiograms.

### Changes in Cardiac Function with Age at Rest

Since there are significant changes in the anatomy of the cardiovascular system, discussed above, and since aging is accompanied by significant changes in function in most other organ systems, one would expect alterations in cardiac physiology as well. Several important age-related changes have already been discussed briefly above, including changes in valvular function and the potential anatomic substrates for altered diastolic function. While the effect of age on cardiac function has long been a topic of research efforts, only recently have studies been able to be performed using adequately robust techniques combined with appropriately defined reference populations. However, it is still true that little information is available regarding how these changes in function impact on the epidemiology, presentation, diagnosis, prognosis, and therapy of cardiovascular disease. Changes with age in cardiovascular function are summarized in [Table 74-2](#).

Most studies of cardiovascular function at rest show either no substantial change in cardiac output, stroke volume, heart rate, and ejection fraction with aging or mild-to-moderate and significant increases in systemic and pulmonary arterial blood pressure, with

**TABLE 74-2****Normal Age-Related Changes in Cardiovascular Physiology**

- Peak cardiac output declines
- Peak heart rate declines
- Peak ejection fraction declines
- LV stiffness increases and diastolic relaxation decreases
- Valvular regurgitation develops
- Prolongation of PR, QRS, and QT; left axis deviation
- Arteries stiffen and aortic impedance increases
- Systolic blood pressure increases

resultant increases in left and right ventricular afterload as shown in Table 74-3.

### Heart Rate and Rhythm

There is no change in resting heart rate with adult aging. However, as will be discussed further later in the section on exercise, there is a clear and marked decrease in maximum heart rate in response to exercise that is highly predictable and can easily be estimated by a simple equation. For men,  $(220 - \text{age})$  predicts the target maximum predicted heart rate for exercise testing. Women have lower peak heart rate in youth and more gradual fall in maximum; thus, a correction factor of 0.85 is often used.

The age-related change in heart rate is perhaps the most substantial change in cardiac function, both in magnitude and in consequence. Although its mechanism(s) are not fully understood, a number of studies have been performed. In the presence of the beta-adrenergic antagonist, propranolol, and the parasympathetic antagonist, atropine, given to ablate both sympathetic and parasympathetic input to the heart, the intrinsic heart rate is seen. Intrinsic heart rate decreases by 5 to 6 beats/minute each decade of age so that the resting heart rate in an 80-year-old is not much slower than the intrinsic heart rate. This means that, at rest, the parasympathetic nervous system is not actively slowing the heart, and, as would be expected, the increase in heart rate after atropine is less than half that in the young.

There is also decreased response to sympathetic agonists. Administration of isoproterenol to healthy young and old people demonstrated that the chronotropic effects of this sympathomimetic agent were markedly attenuated in the old. At doses that increased heart rate by 25 beats/minute in young healthy males, heart rate increased by only 10 beats/minute or less in older persons.

Further supporting the decline in maximal heart rate as a primary age-related biological change is that it cannot be significantly modified by even vigorous exercise training, suggesting that it is not a secondary consequence of an age-related decline in physical activity level. Also, it does not appear to be caused by inadequate sympathetic stimulation, as serum norepinephrine and epinephrine are increased rather than decreased at rest in normal elderly. Further, with stress or exertion these catecholamines increase even more than in young persons under similar stress.

Perhaps as a direct reflection of the decreased parasympathetic nervous system input and decreased responsiveness to what autonomic input is present, there is a significant decrease in heart rate variability. Heart rate variability is a measure of the variations in instantaneous heart rate (or RR interval). This results in a decrease

in complexity, which may not seem important in itself but correlates with the decrease in physiological reserve. Any loss of complexity may then render the older persons or animals less likely to tolerate challenges to their homeostasis. Furthermore, the loss of complexity with age occurs in a number of physiologic systems and is forestalled by interventions like exercise training, which improve robustness.

In highly screened older people to exclude potential confounding effects of disease, the prevalence of atrial premature beats reaches 88% on 24-hour ambulatory monitoring. Because there is no association with cardiac risk over the next decade with the presence of even frequent atrial premature beats (APBs), this is thought not to reflect subclinical coronary artery disease. At exercise testing, isolated ventricular ectopic beats occurred in more than half of highly screened elders older than 80 years. Therefore, this increase in ectopy of both atrial and ventricular origin is thought to be normal aging process.

### Diastolic Function

Increased LV stiffness associated with aging using invasive techniques was first described in young and old beagles. Ten years later, similar findings were identified by invasive techniques in humans. In between these two developments, there was the advent of spectral Doppler echocardiography, which greatly expanded our ability for noninvasively assessing LV diastolic filling. All studies, including the large population-based databases from the Framingham study and the CHS, have uniformly found that diastolic LV filling is substantially altered in older normal subjects. In addition, similar changes with aging are found in rats, dogs, and mice.

The age-related changes in the pulsed Doppler diastolic mitral flow pattern that have been observed in humans are reduced early (E) and increased late atrial (A) flow velocities and decreased E/A ratio. Klein et al. expanded these findings by documenting an age-related increase in early deceleration time and isovolumic relaxation time, important parameters that were not included in many previous papers or in the population-based studies. The finding of a normal age-related change in early deceleration time may be particularly relevant, since this parameter predicts intrinsic LV chamber stiffness. In addition, the report by Klein et al. showed that similar age-related changes take place in pulmonary venous flow, with increased peak systolic flow velocity, decreased diastolic flow velocity, increased peak atrial reversal flow velocity, and increased percentage of forward flow in systole.

It is well known that these Doppler indexes of diastolic filling may be altered early in the course of a variety of disorders that are common and sometimes unrecognized in the elderly and are significantly influenced by a number of physiological variables, including LV mass and chronotropic, inotropic, and loading states, which may also be altered by aging. Thus, it had been questioned whether the age-related alterations in Doppler diastolic filling indexes were simply secondary to these or whether they occurred independent of cardiovascular disease and other confounding physiological variables. In a study of old and young healthy volunteers, rigorously screened for cardiovascular disease, comprehensive Doppler echocardiography, radionuclide ventriculography, and invasive measurements of right heart and left atrial pressures were performed. The old and young subject groups were closely matched for LV mass, volumes, ejection fraction, and end-systolic wall stress; left atrial size and heart rate; and right atrial, pulmonary arterial, pulmonary capillary wedge, and systemic arterial pressures. Despite this, there persisted the characteristic

age-related alterations in Doppler LV filling. In univariate and multivariate regression analyses, peak early and atrial flow velocities were not related to any of the potentially confounding variables measured once age was taken into account. A complementary study showed that even though substantial changes in Doppler filling patterns were inducible by gravitationally induced alterations in LV load, filling patterns in elderly subjects were still distinguishable from those of young subjects. Taken together, these studies suggest that an altered Doppler diastolic LV filling is a primary, biologic effect of aging, intrinsic to the aged human heart, and not explicable by other physiological and pathological changes that frequently accompany the aging process and reflect a true alteration in LV diastolic function.

Since normal healthy elderly are expected to have an altered pattern of Doppler LV filling, what then should be considered abnormal? First, the large population-based databases have yielded important data that have been underappreciated and are significantly underused in current practice. In the CHS, among subjects aged 65 to 100 years, with no indicators of cardiovascular disease, the upper and lower 95% confidence limits for the E/A ratio included 0.65 to 1.45 for women and 0.64 to 1.56 for men. Similar results were found in a smaller group of healthy elderly subjects in the Framingham study. Therefore, findings obtained in elderly patients during basal conditions that fall outside this range should be considered abnormal, regardless of age. Second, the pattern of LV filling is helpful. Certain patterns, such as the pseudonormalized and restrictive patterns, can be more easily discerned from normal and can be more specific for disease when found in the elderly than in younger patients, because these differ more from the expected pattern. The more recent introduction of mitral annulus tissue Doppler has significantly boosted the ability to assess LV diastolic function noninvasively because the annular velocity measures are relatively load dependent. As would be expected, based on the above study, age alters the tissue Doppler velocities as well. Unfortunately, age-related normative reference data are relatively sparse.

In isolated papillary muscles from older rat hearts, the change in pattern of contraction and relaxation is clearly seen: slower force generation and relaxation with no change in peak force. In addition, the inotropic and lusitropic (facilitating relaxation) responses to sympathetic stimulation are also decreased with age. Cardiac contraction and relaxation are dictated by calcium fluxes. For contraction a small amount of calcium enters the cells via the slow L-type calcium channels and stimulates the release of 10- to 20-fold more calcium from the sarcoplasmic reticulum (SR). Active relaxation includes the calcium reuptake by the cardiac SR after contraction and extrusion from the cell by the Na–Ca exchanger and the sarcolemmal Ca pump. Ninety percent of calcium cycles in and out of SR. Calcium reuptake into the SR is decreased by almost 50% in old hearts from rats and mice, and the content of the SR Ca ATPase pump is decreased in old human hearts as well. This slows cardiac relaxation and results in smaller stores in the SR for release in the next contraction. To a small extent, compensation occurs in other calcium fluxes in that the SL Ca ATPase activity is increased in old rat hearts.

The significance of these age-related alterations in diastolic filling has not been fully established. An atrial gallop (S4) is a normal finding on physical examination in those older than 75 years, a manifestation of the increased contribution of left atrial systole to ventricular filling. Brain natriuretic peptide (BNP) elaboration and release by the left ventricle also increases mildly with age, a possible

reflection of altered diastolic function with age; however, it may also reflect known age-related reduction in renal clearance of the peptide. Altered diastolic filling may play a role in reduced exercise capacity seen in normal older subjects, the lower threshold for expression of diastolic heart failure, and the poorer prognosis in older patients with heart failure.

Gene therapy, increasing the content of the SR Ca ATPase has markedly improved the function of old rat hearts. The age-related changes in diastolic function can also be modified and improved by exercise training. In old rats trained on treadmill for 1 to 2 months improved SR calcium uptake and cardiac relaxation to that seen in young sedentary rats. Similarly, changes in early filling, which is dependent on active relaxation, are also seen in humans after 6 months of endurance training. In addition, recent data suggest that humans who put themselves on a diet comparable to the caloric restriction diets have better diastolic function than age-matched controls, corroborating experiments in experimental animals. While this approach may not be highly practical, only 5 years of caloric restriction is needed to produce the change.

### Systolic Function

In healthy humans, no age-related changes in measurable, overall LV contractility, assessed by the ejection fraction, fractional shortening, or mean velocity of circumferential fiber shortening, have been reported in those studies in which it has been measured. Wall motion abnormalities should not be considered normal, even in the very elderly. In CHS, the prevalence of unexpected wall motion abnormalities, in the absence of history and symptoms of coronary heart disease, was 0.4% in women and 0.5% in men.

The contraction and relaxation of the older left ventricle are not uniform. In older people, segments of the heart have started to relax while others are still contracting. As LV pressure must be low before filling can start, this prolonged contraction shortens the time available for filling to occur.

Age-related alterations in several Doppler measures of aortic outflow have been demonstrated. Aortic peak flow velocity, time-velocity integral, and acceleration are reduced with advancing age. While these hemodynamic factors relate to LV systolic performance, these are also substantially affected by afterload, which is known to increase with aging.

A recent report suggests that the inotropic (contractility) as well as lusitropic (diastolic function) responses to dobutamine decrease.

### Possible Implications of the Age-Related Changes in Resting Cardiovascular Function

As noted in the introduction, aging decreases one's ability to tolerate challenges to homeostasis. This is most evident in the cardiovascular system. For example, the mortality and probability of developing heart failure after a myocardial infarction increase dramatically with age. While, clearly the pathogenesis of atherosclerosis and the myocardial infarction itself is not normal aging, the response to the systemic challenges produced by the infarction may well be impaired because of the aging process. Consistent with this, there is an age-related increase in mortality after experimental infarction in mice and rats. We suggest that homeostenosis, the depletion of reserves, may be the cost of invoking compensatory mechanisms just to maintain homeostasis.

Similarly, acute hypertension is poorly tolerated in the old. Old (18 months) and adult (9 months) rats had afterload increased by constriction of the aorta. Immediate early response gene signals were attenuated in the old rats. Decreased skeletal actin expression after pressure overload was present, and skeletal actin expression precedes cardiac actin expression in most models of hypertrophy. Atrial natriuretic peptide stimulates excretion of water and sodium by the kidney. Atrial natriuretic peptide (ANP) is only expressed by the atria in normal young hearts, but ANP is a marker of stress and compensation when seen in the ventricles. In the old rat, ANP is elevated in the ventricles at baseline and could not be further stimulated after additional stress. This suggested that the hypertrophy response was already invoked as part of aging in the older rats and was therefore not available to respond to the acute stress.

While the normal heart is unlikely to ever be exposed to ischemia, ischemic preconditioning is adaptation of the young heart that is not present in the old heart. Young hearts, if repeatedly exposed to brief episodes of ischemia, tolerate longer episodes well with less resultant damage, by possibly increasing levels of heat-shock proteins, opening ATP-gated potassium channels, stimulating the TNF-alpha cascade, and activating antioxidant enzymes. Old hearts cannot make this adaptation, perhaps contributing to the increased mortality after myocardial infarct in the old, but exercise training, caloric restriction, and certain growth factors mitigate it.

The responsiveness is decreased to some cardioactive drugs, including atropine, dobutamine, and other beta-adrenergic active agents. These agents may require higher doses to reach a desired effect in the old. Congestive heart failure becomes increasingly common, reaching a prevalence of more than 10% and being the most common reason for hospitalization of Medicare beneficiaries. The syndrome of heart failure with normal ejection fraction, the most common form among older persons, is likely facilitated by the above and below discussed age-related changes in diastolic function and myocardial composition additive to the arterial and myocardial changes caused by hypertension and other diseases.

Age-related changes in vessels and the heart do not by themselves produce disease, but, because of the changes in compliance, systolic hypertension is incredibly common. Finally compensation for these changes makes the old CVS more prone to decompensation in response to other insults.

### Effect of Age on the Cardiovascular Response During Exercise

If aging affects cardiovascular performance even at rest or with moderate stress, such as dobutamine infusion, one would expect this to be magnified and become even more apparent during exercise. This is indeed the case. Exercise capacity can be quantified objectively by measurement of maximal oxygen consumption ( $VO_{2max}$ ) during exercise. It is solidly established that normal aging is inescapably accompanied by a reduction in  $VO_{2max}$ . While the age at which this decline begins is unclear, it is probably variable and begins early in adult life. The reduction in  $VO_{2max}$  is independent of gender and changes in body size. The magnitude of the decline is approximately 3% to 8% per decade and can be modified but not completely halted or reversed by exercise training.

A study from the Baltimore Longitudinal Study on Aging (BLSA) in 1988 showed results that the authors interpreted as showing a decline at the lowest part of this range (3%) and attributed the majority of this change to loss of muscle mass. In addition, an oft-cited study

in 1984 using subjects from the BLSA and subsequent reviews and commentaries have implied that these cross-sectional estimates for the age-related decline in  $VO_{2max}$  were probably substantial overestimates of the true longitudinal decline and that declines in multiple measures of exercise cardiac function, including cardiac output, were relatively modest or were even preserved with aging. However, such conclusions were at substantial variance with all other studies performed before and since as shown in Table 74-4, and this difference was attributed to rigorous screening. However, a subsequent report from the BLSA in 2005, which examined a large number of subjects, both sedentary and well conditioned by training, during a 7.9-year period of follow-up showed that, in actuality, the decline in exercise capacity ( $VO_{2max}$ ) among older persons was actually more accelerated and greater in magnitude than all previous estimates. In addition, another subsequent report from the BLSA in 1995 showed that, in contrast to the original study in 1984, both men and women do, indeed, have substantial age-related declines in exercise cardiac output, accompanying and contributing to a 40% decline in  $VO_{2max}$ . This is in accord with all other reports from other studies. Thus, there is now uniform agreement that aging, even in the absence of any identifiable disease, is associated with substantial declines in overall cardiovascular performance and reserve capacity, including maximal cardiac output.

By the Fick principle for oxygen, only a limited number of factors could be responsible for a decline in  $VO_{2max}$ . The following equations are pertinent to this discussion:

$$\begin{aligned} VO_2 &= \text{cardiac output} \times \text{arteriovenous oxygen difference} \\ \text{Cardiac output} &= \text{stroke volume} \times \text{heart rate} \\ \text{Stroke volume} &= \text{end-diastolic volume} - \text{end-systolic volume} \end{aligned}$$

The arteriovenous oxygen difference (AVO) is determined by a number of noncardiac factors, including peripheral vascular and skeletal muscle mass and metabolic function. Thus, if  $VO_{2max}$  declines with aging, there must be a decline in peak cardiac output or AVO or both during exercise.

Measurement of cardiac output in healthy human subjects during exercise is challenging methodologically. Investigators have used a variety of techniques, including direct Fick (probably the most reliable), dye dilution, equilibrium-gated radionuclide angiography, and gas rebreathing (Table 74-4). Each of these methods uses a number of variables to derive the cardiac output measurement. Direct measurement of AVO by oximetry, however, is quite accurate and reliable. Most investigators who have measured AVO during maximal exercise have documented no difference or increased AVO in elderly compared with young subjects. By simple algebra, this suggests that the age-related decline in  $VO_{2max}$  must be because of reduced cardiac output. This has, indeed, been the finding reported by virtually all investigators.

The largest modern published study that used invasive techniques in order to directly measure all components of the Fick equation in healthy human subjects over a substantial age range was reported by Higginbotham et al. The subjects had a very low probability of coronary disease as they were all aged  $\leq 50$  years, were asymptomatic volunteers, and had normal electrocardiograms and radionuclide angiograms during exercise. Yet even over the short age range observed by Higginbotham et al., maximal cardiac output, measured by the Fick technique, declined significantly. These healthy subjects had the expected age-related decline in  $VO_{2max}$  and heart rate. Stroke volume was calculated by dividing cardiac output by heart rate. Cardiac

output was measured by a gold standard technique, using the blood samples from systemic and pulmonary arteries along with measured  $\text{VO}_2$ , and was confirmed by another high-fidelity technique, thermodilution by indwelling pulmonary catheter. They found that stroke volume, ejection fraction, and end-diastolic volume were unchanged with aging or showed a slight downward trend. Thus, the well-established age-related decline in maximal heart rate was translated into reduced maximal cardiac output, since stroke volume was unchanged. Similar results have been obtained by others in groups of older human subjects, both men and women, and in beagles. Furthermore, an invasive study confirmed those results in a group of older (age 66 years) versus younger (age 28 years) healthy subjects, as shown in Figure 74-1. These data indicated that both cardiac output and systemic AVO were reduced in older versus young healthy subjects and contributed to their 28% age-related reduction in  $\text{VO}_{2\text{max}}$ .

Thus, the reduced  $\text{VO}_{2\text{max}}$  and exercise capacity seen with aging are caused predominantly by reduced exercise cardiac output. That the heart should be responsible for the age-related exercise limitation is not surprising, since it has been observed that the skeletal muscles have a greater capacity for work than can be supported by the cardiac output. The primary mechanism of the age-related decline in exercise cardiac output is primarily the age-related reduction in maximal heart rate. Reduced maximal exercise heart rate appears to be a universal observation and to meet the criteria for a basic biological aging phenomenon. Its mechanism is unclear but may be related, in part, to an age-related decline in beta-adrenergic sensitivity.

Although reduced maximal heart rate is the primary mechanism for reduced maximal exercise cardiac output and oxygen consumption in elderly subjects, younger subjects in whom exercise heart rate is limited, either by congenital complete heart block or by beta-adrenergic blockade, stroke volume is increased and partially compensates for the reduced heart rate via the Frank-Starling response (increased end-diastolic volume). The effect of aging on end-diastolic volume and the Frank-Starling mechanism during exercise is not clear, since repeated studies from one group using invasive techniques described above show no change with aging and studies from another group suggest end-diastolic volume at peak exercise increases with aging and another showed no change. However, regarding peak exercise stroke volume, most studies show that older subjects have shown either no change or a modest decline in stroke volumes at maximal exercise with aging compared to younger subjects, including in women in the BLSA. An age related decline in Frank-Starling reserve would be consistent with observations suggesting increased LV diastolic stiffness owing to aging.

A lower stroke volume in the elderly could be because of higher end-systolic volume as well as lower end-diastolic volume. LV end-systolic volume was higher and ejection fraction was lower at peak exercise in older than in younger subjects in most studies in which these were measured. Thus, systolic LV function reserve is reduced with aging as well. Reduced stroke volume could also result partially from increased afterload, since systolic blood pressure, aortic impedance, and systemic vascular resistance are higher during exercise in old than in young healthy subjects. When afterload is taken into account, maximal stroke work is fairly similar in young and old subjects.

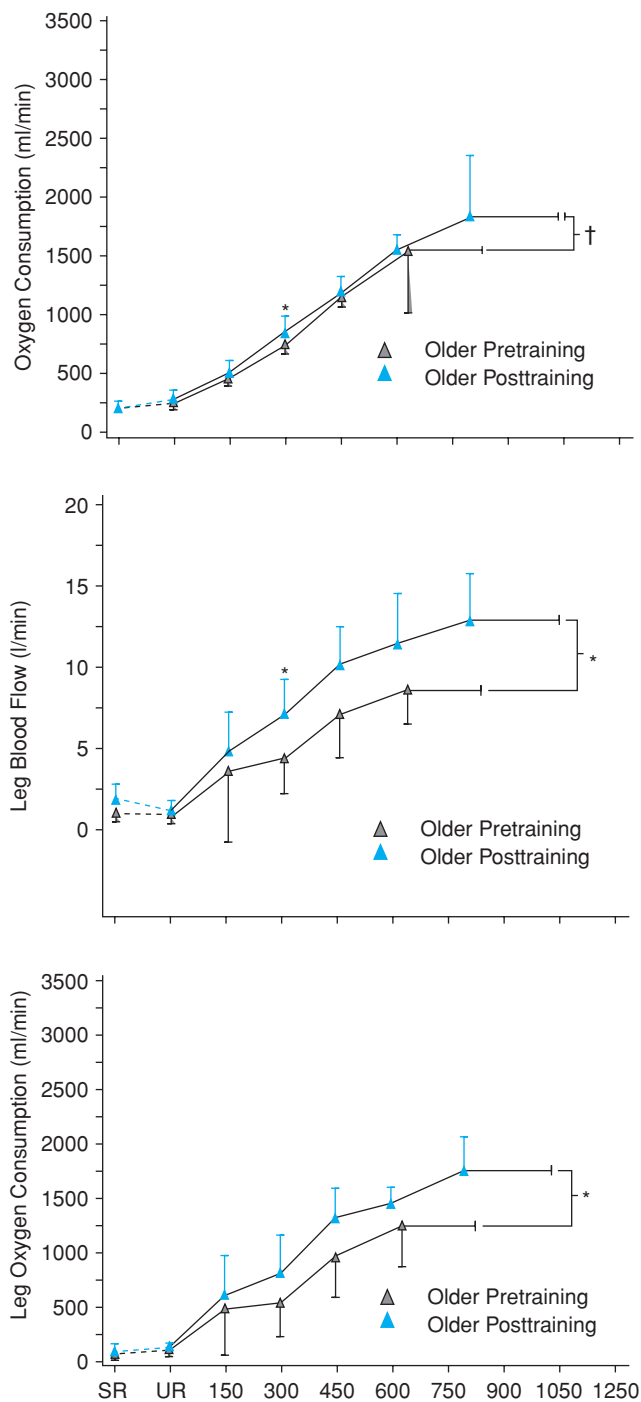

In evaluating elderly patients for coronary heart disease, particularly with radionuclide angiography, it should be recognized that in healthy elderly the LV ejection fraction does not increase as much from rest to peak exercise as it does in young healthy subjects. In fact, a flat response in elderly men and a mild decline in elderly women

**FIGURE 74-1.** Oxygen consumption by expired gas analysis, cardiac output by the direct Fick technique, and systemic arteriovenous oxygen difference by direct oximetry at supine rest (SR), upright rest (UR), and during maximal exercise in younger and older healthy volunteers. Note that there are substantial and significant reductions in older compared to younger subjects in all measures, including maximal cardiac output † $p < 0.01$  \* $p < 0.05$ . (Modified from Beere PA, Russell SD, Morey MC, et al. *Circulation*. 1999;100:1085–1094.)

should be considered normal. However, it is important to note that development of wall motion abnormalities would not be considered normal, even in the presence of a mild nonspecific decline in ejection fraction.

There has been less information regarding peripheral cardiovascular function with aging, including systemic arterial function, which is required to efficiently deliver oxygenated blood to working muscle,

**FIGURE 74-2.** Leg blood flow measured by indwelling catheter, and leg oxygen consumption by expired gas analysis during supine rest (SR), upright rest (UR), and during exercise in older healthy volunteers before and after aerobic exercise training. After exercise training, there is a 28% improvement in maximal body oxygen consumption, and this is accompanied by a 50% improvement in leg arterial blood flow and leg oxygen consumption during exercise † $p < 0.01$ . \* $p < 0.05$  (Modified from Beere PA, Russell SD, Morey MC, et al. *Circulation*. 1999;100:1085–1094.)

and working muscle itself. The study by Beere et al. extended prior work by using a pediatric thermodilution pulmonary artery catheter inserted into the femoral vein, in order to acquire the best available measures of leg blood flow, oxygen consumption, and AVO. Their findings indicated that, in addition to reduced peak exercise cardiac

output, older men have reduced exercise leg blood flow. The study also repeated the detailed measurements of central and peripheral cardiovascular functions following exercise training. Their results confirmed the findings of a number of previous investigators that exercise training can improve  $\dot{V}O_{2\max}$  by 15% or more and thereby “reverse” some of the age-related decline in physical work capacity. Furthermore, they found that the primary mechanism of improvement in exercise capacity following training in older subjects was a large improvement in leg arterial blood flow.

## SUMMARY

Normal aging is accompanied by substantial alterations in anatomy and physiology of the heart and vasculature. There are declines in most aspects of cardiovascular function, including both cardiac output and blood flow distribution, and these create significantly reduced reserve capacity, which becomes more apparent during exercise and stress.

The age-related alterations in the anatomy and physiology of the heart and vasculature likely have varying degrees of significance. Some may not have functional significance and are essentially epiphenomena of aging. Others, such as aortic sclerosis, ventricular septal thickening, and attenuated cardiac function response during exercise, may simulate disease. Some findings, which are associated with age and are prevalent in elderly hearts, such as senile amyloid and calcified mitral annulus, are likely part of poorly understood disease processes rather than owing to aging. With currently available information, it is not always possible to distinguish the effects of aging from the effects of disease, particularly in very elderly hearts. However, it is reasonable to propose that many of the age-related changes discussed may lower the threshold for clinical disease and, thus, predispose to a variety of cardiovascular disorders in the elderly, including congestive heart failure, hypertensive hypertrophic cardiomyopathy, valvular stenosis and regurgitation, systolic hypertension, supraventricular arrhythmias, and conduction disturbances. Awareness of these age-related changes, as well as the principles of aging biology in general, will help investigators avoid potential errors in research study design or interpretation and help clinicians tailor intelligently treatments to the older patient.

Because these age-related declines in cardiovascular and exercise performance are modifiable and have been shown to be partially preventable and reversible with exercise training, maintaining regularly scheduled physical activity and conditioning is a potentially important strategy to mitigate the potential adverse effects of aging on cardiovascular function.

# Aging and Atherosclerosis

Susan Cheng ■ Susan M. Bell ■ Susan J. Zieman

Atherosclerosis confers an illness burden on the general population larger than that associated with any other disease process. With advancing age, the incidence and prevalence of coronary, cerebral, and peripheral arterial disease (PAD) and aneurysmal formation are higher and their severity is more pronounced. Thus, cardiovascular disease (CVD) outcomes are worse in older compared to younger adults. Although age is the most powerful independent risk factor for CVD, the mechanisms by which aging predisposes to atherogenesis are only now becoming elucidated, as are specific strategies to optimally prevent and treat atherosclerotic disease in older adults.

Research to date, spanning from basic science to epidemiology, suggests that aging potentiates atherosclerosis through a combination of factors (Figure 75-1). First, specific biological changes associated with aging increase vulnerability to atherosclerosis. Second, increasing age lengthens the time of exposure to known CV risk factors and modifies their effects. Finally, older individuals have increased comorbidities, which may contribute to or exacerbate the severity of atherosclerosis, particularly conditions that create or maintain a proinflammatory biologic milieu.

The clinical manifestations of atherosclerotic disease are more varied and severe in older compared to younger adults. Multiple etiologic factors have variable effects on the aging vasculature over a lifetime (Figure 75-2). Thus, vascular aging plays a primary and prominent role in predisposing older individuals to atherogenesis. This chapter highlights how vascular aging, in addition to both traditional and nontraditional risk factors, can enhance and accelerate the development of atherosclerosis in older adults.

## VASCULAR AGING

It is a common misconception that vascular aging is synonymous with the development of atherosclerosis. Although the majority of individuals older than 60 years have clinically significant (>75%) coronary stenoses on autopsy, at least 25% of this age group will

have only mild or no significant coronary plaque burden. Yet, age-associated vascular changes, and the cellular and molecular factors that underlie their development, do increase the vulnerability of older arteries to atherogenesis (Table 75-1).

The basic structure of the arterial blood vessel consists of three layers, each separated by a distinct elastic membrane. The intima is the innermost layer and consists of a monolayer of endothelial cells resting on a basement membrane made up of collagen and other extracellular matrix (ECM) molecules. The media consists primarily of smooth muscle cells (SMCs) on the background of an elastin-rich skeleton of ECM. Collagen, elastin, glycoproteins, and proteoglycans constitute the ECM. The outermost layer, the adventitia, contains a loose array of collagen fibrils as well as the vasa vasorum (blood vessels supplying the vasculature itself), nerve endings, fibroblasts, and mast cells.

Arterial structure changes with increasing age, but not in ways that necessitate atherogenesis. Morphologic changes associated with aging can include increased vessel diameter, intima-media thickening, SMC and collagen hypertrophy, fibrosis, and arterial wall calcification. In the absence of other predisposing factors, these progressive changes are age dependent but occur at varying rates in different individuals. Similar arterial alterations are seen prematurely in transplanted hearts and in a variety of vasculidities.

True atherosclerosis, by definition, requires the presence of an atheroma covered by a thin fibrous cap. An atheroma is a focal collection in the intima of foam cells (macrophages that have engulfed lipoproteins), proliferative SMCs (which have migrated from the media), and ECM. Postmortem studies of young Korean War soldier casualties revealed that the initial stages of atheroma formation can occur early in life.

Three major intertwining themes highlight how the biology of vascular aging predisposes to atherosclerosis (see Figure 75-1). First, *exposure* to various physical and metabolic stresses over time can alter normal pathways and processes. Second, progressive *accumulation* of metabolic byproducts can adversely affect arterial structure

**FIGURE 75-1.** Schematic view of the intersection and overlap between aging and atherosclerosis.

and function. Finally, time-dependent *attrition* of the basic arterial constituents and adaptive and reparative mechanisms of the arteries can lead to their dysfunction and, in turn, promote atherogenesis. This section details each of these themes.

### Exposure

Although biologic and chronologic ages are not necessarily equivalent, especially pertaining to vascular biology, the vector of time is inherent to the aging process (Figure 75-2). As such, chronic exposure to specific stresses over time contributes significantly to age-related pathology. These stresses include repeated exposure to both pulsatile and shear forces on a mechanical level and ongoing oxidative stress at the molecular level. Stress-induced vascular changes ensue and, in some individuals, accelerate atherosclerosis.

Shear stress over time provokes vascular injury, particularly at vessel bifurcations and curves, where atheromas tend to form. Endothelial cells subjected to chronic shear stress can physically deform and display altered intracellular activity. Specifically, laminar shear stress upregulates endothelial nitric oxide synthase (eNOS), the enzyme that produces nitric oxide (NO). Although shear stress increases with age, overall eNOS activity is lower in aged compared to younger rats and contributes to impaired endothelium-dependent vasorelaxation. Cytokine-stimulated inducible-NOS activity, which raises NO levels, may create more negative feedback effect on eNOS than on inducible NOS. Age-related endothelial dysfunction is characterized by the decreased ability of smaller arteries to dilate in response

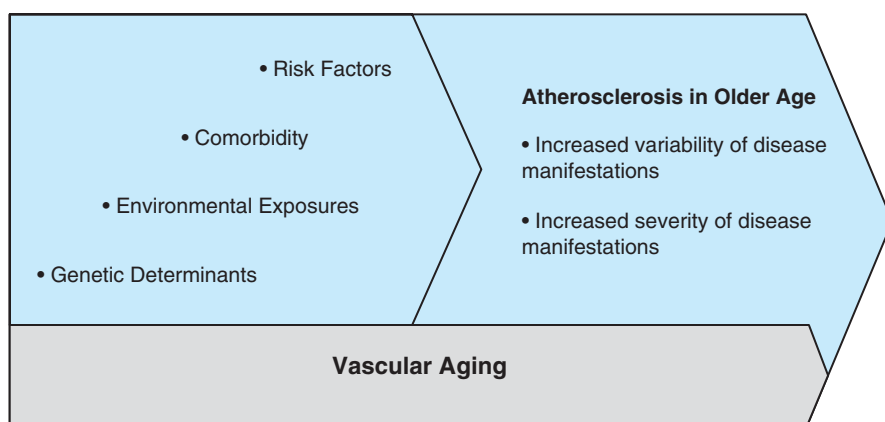

to increased blood flow. Endothelial dysfunction in healthy older adults improves with exogenous nitrate administration, suggesting impairment, in part, of endogenous NO production. Endothelial cells play a key role in nearly every step of the atherosclerosis process, including plaque formation, platelet adhesion and aggregation, cellular migration, and proliferation. Thus, their dysfunction plays a key role in atherosclerosis. In a vicious cycle, atherosclerosis further impairs endothelial cell function (Figure 75-3).

Similar to shear stress, chronic biomechanical stress can also affect endothelial function by activating mechanoreceptors, thereby converting physical stimuli to biochemical signals. In vitro, endothelial cells exposed to repeated pulsatile stress have diminished eNOS expression and Akt and NO signaling. Pulsatile stretch also stimulates vascular SMC hypertrophy and proliferation. Such exposed SMCs synthesize ECM components in a disorganized fashion. Mechanical stretch also activates matrix metalloproteinases (MMPs), some of which are proliferative while others are destructive. Imbalanced activation of MMP subtypes creates adverse vascular remodeling, including fibrosis, which increases arterial stiffness and decreases elasticity, further exacerbating sheer and pulsatile stresses (Figure 75-3).

At the molecular level, augmented oxidative stress, measured by reactive oxidant species (ROS), is a constituent of both vascular aging and atherogenesis. Since its conception in 1950s, the free radical theory of aging has contended that metabolic production of oxidants, especially ROS, results in a wide array of adverse reactions involving nucleic acids, proteins, and lipids. Cumulative exposure to toxic oxidative effects leads to progressive cellular and tissue dysfunction and eventual disease and death. ROS are implicated in every step of atherogenesis, and this relationship is magnified in older vessels owing to ROS augmentation (Figure 75-4). Lipid oxidation is also accelerated by ROS and, in turn, stimulates many atherogenic steps including inflammatory cell activation, SMC, monocyte and macrophage growth factor release, reduction of eNOS-regulated platelet activity, metalloproteinase formation, cytokine release, and renin–angiotensin activation. Accordingly, oxidized low-density lipoprotein (LDL) facilitates vulnerable plaque rupture. Conversely, oxidized LDL receptor blockade inhibits atherogenesis.

### Accumulation

With aging, the time vector permits accumulation of metabolic byproducts in the vascular wall, which creates adverse structural

**FIGURE 75-2.** Contributors to the development of atherosclerosis interact with vascular aging to increase the variability and severity of disease manifestation in older age.

TABLE 75-1

and metabolic sequelae. The prototypical example is accumulation of oxidized lipids in the bloodstream and their subsequent incorporation into atheromas. With time, the arterial wall also accrues increased amounts of normal and dysfunctional collagen, as well as broken and frayed elastin fibrils caused by elastase enzyme up-regulation. Additionally, recurrent inflammatory processes result in vascular fibrosis. These alterations decrease arterial compliance to

pulsatile flow, thicken the intima, and increase vascular permeability. Disruption in membrane permeability facilitates SMC proliferation and migration from the media to the intima as well as transit of immune and inflammatory cells that stimulate atherogenesis.

Progressive accumulation of advanced glycation end products (AGEs) also contribute significantly to CV structural and functional pathology over time. AGEs result from irreversible nonenzymatically formed bonds between glycated proteins. Time and high glucose concentration drive this reaction forward such in aging and diabetes. Long-lived proteins (collagen) are most susceptible to glycation over time and, once cross-linked, are less susceptible to routine hydrolysis and thus accumulate.

Structurally, AGE cross-linked arterial collagen is less compliant and contributes to age-associated central vascular stiffness. Similarly, AGE cross-linked myocardial collagen fibrils in the heart result in ventricular stiffness. In addition to their vascular structural impact, AGEs quench NO, stimulate ROS formation, facilitate inflammatory molecule and cell recruitment, and promote fibrosis. These alterations predispose the arterial wall to atherosclerosis. Receptors for AGE (RAGE) are located on endothelial cells, SMC,

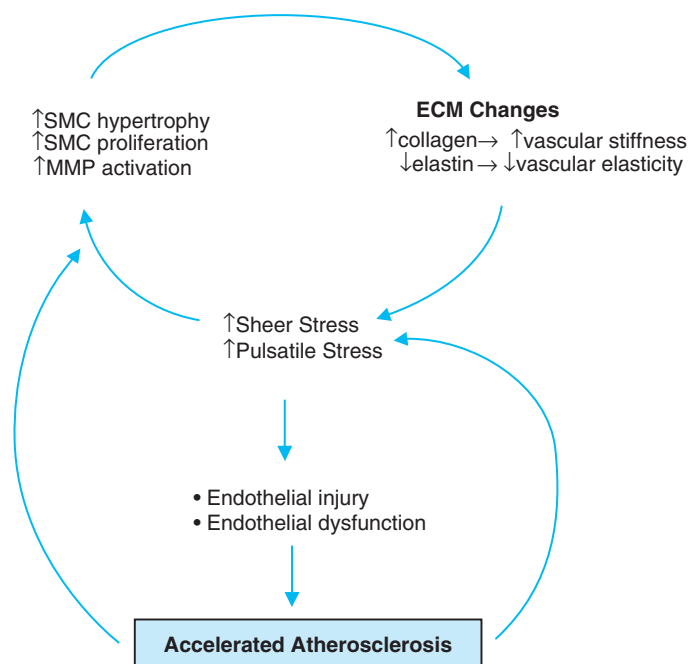

FIGURE 75-3. Chronic exposure of the arterial wall to shear and pulsatile stresses leads to both vascular aging and accelerated atherosclerosis.

FIGURE 75-4. Reactive oxygen species are involved in almost every step of atherosclerosis.

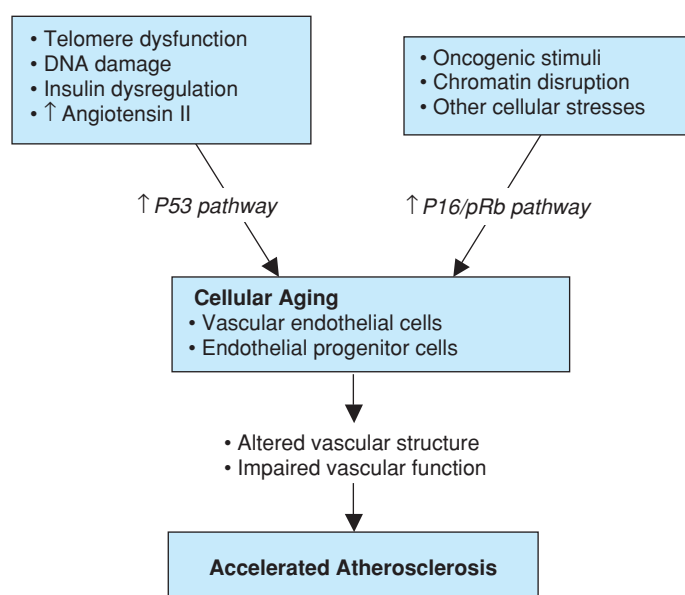

macrophages, and blood cells. AGE–RAGE attachment modulates a cascade of molecular events, resulting in vascular inflammation, fibrosis, vascular permeability, and altered NO signaling. Thus, time- and age-dependent accrual of AGEs, especially in diabetics, likely contributes significantly to age-associated increased endothelial dysfunction, vascular wall thickening, arterial stiffening, inflammation and fibrosis, restenosis, and atherogenesis. Clinical manifestations include isolated systolic hypertension (ISH), elevated pulse pressure (PP), left ventricular hypertrophy, delayed early diastolic relaxation, and atherosclerotic disease. LDL apoproteins are also a target of AGE, resulting in decreased LDL receptor uptake, more LDL oxidation, and increased susceptibility to macrophage engulfment, all leading to the formation of foam cells and atherosclerotic plaque.

### Attrition

The third age-related component predisposing to atherosclerosis is the reduced ability of reparative or compensatory biologic processes to appropriately adapt to the age-associated structural, dynamic, and molecular alterations. One hallmark of aging is cellular aging, also known as cellular senescence. Although the precise definition of cellular senescence is debated, it generally describes the irreversible arrest of the replicative cycle of a cell such that it no longer divides. The number of cell divisions in an organism is related to the organism's expected longevity. In addition to exhibiting a flattened and enlarged morphology, senescent cells express a specific set of genes, including negative regulators of the cell cycle such as p53 and p16. Cells with shorter life spans have been cultured from individuals with premature aging syndromes such as Werner syndrome and Hutchinson–Gilford progeria syndrome, both of which are characterized by very early-onset atherosclerosis. Recent studies suggest that cellular aging also plays an important role in the development of age-related diseases in general.

Senescent forms of endothelial progenitor cells and vascular endothelial cells, which have been found in atherosclerotic plaques, are likely facilitators of atherogenesis. Factors that predispose these vascular cells to premature aging are numerous and involve the attrition of basic cellular constituents and molecular mechanisms. These factors include telomere dysfunction, faulty DNA repair systems, dysregulation of the insulin/Akt pathway, and altered angiotensin II signaling (Figure 75-5). Telomere dysfunction is of particular interest, since telomeres act as protective caps at the ends of chromosomes and are involved in cellular replication pathways. Shorter telomere length, a marker of cell turnover, has been associated with endothelial dysfunction, elevated PP, and the presence of traditional CV risk factors as well as clinically significant atherosclerotic disease. There are now data from at least one large clinical trial (WOSCOPS) showing that shorter telomere length is a predictor of coronary heart disease, independent from the effect of chronologic age.

Whether owing to telomere shortening and/or other factors, aging of vascular cells is associated with processes that lead to altered vascular structure and function and, in turn, accelerated atherosclerosis. Senescent vascular endothelial cells are found to have upregulated adhesion molecules, proinflammatory cytokines, and decreased NO production. Senescence of endothelial progenitor cells is associated with decreased angiogenesis and impairment of the complex vascular repair system intended to attenuate the chronic vascular injury and inflammation that leads to atherosclerosis. Targeting the

**FIGURE 75-5.** Attrition of basic cellular constituents and mechanisms leads to cellular aging, which, in turn, predisposes to premature or accelerated atherosclerosis.

mechanisms underlying vascular cellular senescence could represent new approaches to treating atherosclerosis in the future.

### Summary

Vascular aging is characterized by specific structural and functional alterations that do not necessitate, but often potentiate, atherosclerosis (Table 75-1). Vascular aging changes result from ongoing exposure to physical and metabolic stresses, accumulation of metabolic byproducts, and attrition of basic cellular constituents and mechanisms that manifest as cellular senescence. Excess function or dysfunction of similar molecular pathways and cell types underlie vascular aging and atherosclerosis: endothelial cells, NO, ROS, SMC, AGE, and elements of the glucose metabolism pathway. Further elucidation of mechanisms that propagate vascular aging and its vulnerability to atherogenesis will facilitate development of interventions that could curtail both processes.

### RISK FACTORS FOR VASCULAR PATHOLOGY IN OLDER ADULTS

The age-related arterial structural and functional alterations that predispose older vessels to atherogenesis are heterogeneous across individuals and populations. This variability is influenced largely by the presence or absence of CV risk factors and comorbidities. Prolonged exposure to traditional CV risk factors over time impacts atherogenesis in older adults; diagnosing and modifying these risk factors early in life can reduce and prevent CV events in individuals up to 85 years of age. Since factors such as comorbidities, survivor bias, birth cohort effect, and long-term risk modification affect the potency of traditional and nontraditional risk factors in much older age, data regarding risk reduction in the very old are limited.

## Traditional Risk Factors

### Hypertension

Age-associated increased central arterial stiffness results in hypertension being the most prevalent traditional risk factor in older adults: the lifetime risk of a 50-year-old developing hypertension is 90%. More than 80% of women and 69% of men older than 75 years are classified as hypertensive, and yet they have the lowest rates of control. Unlike in younger patients, who predominately have elevated diastolic blood pressures (DBPs), more than 60% of patients with hypertension older than 65 years have ISH as defined by a systolic blood pressure (SBP)  $\geq 140$  mm Hg and a DBP  $< 90$  mm Hg. As individuals age, the CV risk index shifts from diastolic to systolic to pulse pressure (PP = SBP – DBP). This underscores the age-related difference in etiology (ISH is a manifestation of the vascular aging changes described in the previous section).

Although sphygmomanometry of the brachial artery is the most traditional noninvasive method to assess blood pressure, this technique does not fully characterize the age-related changes in central arterial stiffness. Brachial blood pressure measured this way represents an amalgamation of both small- and large-vessel properties. Accordingly, several noninvasive surrogate measures have been developed to assess central arterial pressure, including pulse wave velocity, carotid augmentation index, and estimated central pressures calculated by a generalized transfer function from applanation tonometry of a peripheral artery. These central artery stiffness surrogates are associated with increased CV risk, including myocardial infarction, stroke, renal disease, heart failure, and mortality. Ambulatory and nocturnal blood pressure results showing wide blood pressure variation also pose risk for adverse CV outcomes.

The importance of noninvasively determined central aortic pressure and its reduction was highlighted in The Conduit Artery Functional Endpoint (CAFÉ) study, which demonstrated discrepancies between two antihypertensive agents (amlodipine and atenolol) on CV outcomes despite similar brachial arterial cuff pressure changes. Improved CV outcomes associated with amlodipine compared with atenolol were coupled to an amlodipine-related reduction in estimated aortic stiffness.

Hypertension, itself, promotes vulnerability to atherosclerosis. This is especially true of the increased pulsatility associated with ISH. In response to increased perpendicular and parallel pressures on the arterials wall, vascular SMC hypertrophy and collagen accumulate. As discussed above, increased pulsatility on an endothelial cell with reduced capacity to stretch, such as in a stiff vessel, results in diminished NO signaling. Thus, hypertension exacerbates endothelial dysfunction and predisposes the endothelium to atherogenesis. As vascular collagen accrues in response to increased wall pressure so does AGE cross-linking, which, in turn, further thwarts vascular compliance in a viscous cycle. In this manner, hypertension and the excess forces it delivers to the older vascular wall accelerate vascular inflammation, AGE cross-linking, SMC hypertrophy, inflammatory cell migration, fibrosis, ROS production, apoptosis, and MMP stimulation, all of which predispose to atherogenesis.

### Dyslipidemia

Longitudinal studies report that total cholesterol (TC) and LDLs decrease with increasing age. The relationship of TC to CV risk is

additionally confounded by survival bias and the J-shaped correlation between TC and mortality. The CV risk of higher TC is offset by the increased total mortality associated with lower TC. However, TC remains predictive of incident CV events after controlling for levels of albumin, serum iron, and comorbidities. Observational studies show that a high TC/HDL ratio, high triglycerides (TG), and low HDL are all predictive of CV events in older women. Data from the Women's Health Study supports that high-sensitivity c-reactive protein (CRP) also adds predictive value to CV events in older women. In the Honolulu Heart Study, a longitudinal cohort study of adults older than 65 years, TC and LDL-C were only weakly associated with myocardial infarction, stroke, and all-cause mortality. In another large observational study, high HDL-C was associated with a decrease risk of ischemic stroke in men. Although it has not been formally studied, elevated TC, LDL, and triglycerides likely still increase the risk for further development of CVD in older adults with known CVD.

### Altered Glucose Metabolism

The most common form of diabetes in the elderly, type II, is manifested not only by a hyperglycemic environment but also by metabolic abnormalities, insulin resistance, and insulin deficiency. In addition to the toxic effects of hyperglycemia, other factors likely impact the vasculature, as demonstrated by the increased coronary disease found in prediabetic patients with insulin resistance. The exact mechanism behind the increased vulnerability of diabetics to atherosclerosis is difficult to elucidate because of an inability to produce small animal models without confounding risk factors and the intimate link with dyslipidemia.

Insulin resistance and deficiency lead to the continuous hyperglycemia that fuels the stepwise production of AGEs and consequent increased vascular stiffening. Hyperglycemia also fuels production of ROS, promotes endothelial dysfunction, and increases SMC and MMPs. A diabetic mouse model confirms that induction of diabetes leads to unstable atherosclerotic plaques that are reduced with insulin therapy.

### Smoking

The high incidence of atherosclerotic disease among smokers is well documented, contributing to 30% of attributable risk in strokes and 36% in first myocardial infarction. In fact, 11% of worldwide CV deaths are attributable to smoking. This risk is restricted not only to active smokers but also to second-hand smoke exposure. The prevalence of smoking decreases with age but remains a significant risk factor for atherosclerosis. Although continued smoking in patients older than 70 years has a higher relative risk for death or MI than each previous decade, older adults are far less likely to be given advice on smoking cessation. The exact contributing toxins are difficult to isolate in studies as more than 4000 chemicals exist in cigarette smoke, but the driving force appears to be via chronic vascular inflammation and oxidative stress. Chronic cigarette smokers display endothelial dysfunction leading to increased superoxide production through Nicotinamide Adenine Dinucleotide Phosphate (NADPH) oxidase and elevated xanthine oxidase transcription and activity. Despite upregulated NO production, NO levels are diminished because of ROS production and NO scavenging. Cigarette smoke promotes inflammation with elevated leukocyte counts, CRP, IL-6, and

increased expression of I-CAM1, E-Selectin, and P-Selectin. Monocytes of smokers show increased adherence to endothelial cells and increased oxidized LDL, as represented by high oxLDL antibodies that promote atherosclerotic plaque formation. In aged individuals, current smoking appears not to correlate with adverse CV events; however, pack/years and lifetime smoking exposure does appear to correlate and may be reflected by high CRP levels in healthy elderly individuals with lifetime exposure.

## Nontraditional Risk Factors

### Chronic Renal Disease

Accelerated atherosclerosis in chronic renal disease is likely multifactorial and self-perpetuating with renal artery stenosis (RAS) as an ideal model of an atherogenic consequence as well as an accelerator or further CVD. As renal insufficiency progresses, activation of the renin–angiotensin–aldosterone system results in vasoconstriction, and sodium retention and sympathetic activity exacerbate hypertension and end-organ damage. Interestingly, increased angiotensin II activity is seen within atherosclerotic lesions and via stimulating macrophages, and adhesion cell expression contributes to plaque formation and eventual rupture. Moreover, stimulation of vascular endothelial growth factor (VEGF) and Platelet derived growth factor (PDGF) at the RNA level leads to arterial wall remodeling, changes in ECM composition, and induction of a prothrombotic state. Elevated aldosterone, via stimulation of NADPH oxidase and ICAM-1, can increase oxidative products, a mechanism by which angiotensin converting enzyme (ACE)-I and angiotensin receptor blockers (ARBs) may counteract atherosclerosis.

Renal insufficiency is associated with a marked increase in CVD among individuals with end-stage renal disease. The risk is 10-fold that of individuals with a normal creatinine. All-cause CV morbidity and mortality is even increased in individuals with elevated creatinine, even at low levels or near normal levels. Serum creatinine as a measure of renal function is limited, especially in older adults. Cystatin C is a new serum test and a more robust and validated predictor of renal insufficiency in the elderly. Cystatin C levels identify those at an earlier preclinical state of renal dysfunction and are associated with increased myocardial infarction, stroke, and heart failure risk. Another potential link between end-stage renal disease and CVD is a low circulating endogenous secretory receptor for AGEs, which predicts CV mortality.

### Biomarkers Associated with Atherosclerosis

Interest has grown in novel markers as additive factors in atherosclerotic disease across the age spectrum. Whether these biochemical substances cause atherosclerosis or are simply markers of the overall inflammatory status of the host is difficult to separate. One such marker, CRP, has been investigated broadly as a predictor of outcomes. Prospective studies show increased events with elevated levels of high-sensitivity CRP. In men and women older than 65 years, regardless of other risk factors as assessed by Framingham scores, elevated CRP is associated with increased 10-year risk of coronary heart disease and augments the predictive value of those in high- and intermediate-risk groups. In patients aged 50 to 75 years, CRP levels were elevated in patients with ultrasound-confirmed carotid

atherosclerotic disease but not in those with cerebral small vessel disease by magnetic resonance imaging (MRI).

Serum homocysteine increases with age and is a strong independent risk factor for CVD, especially in younger individuals. As accelerated atherosclerosis involves enhanced collagen synthesis, smooth muscle proliferation, and increased lipoprotein oxidation, one mechanism is likely inflammation. Accordingly, high levels of acute-phase reactants correlate with homocysteine levels. In older subjects, IL-6 levels, but not other markers of inflammation, predict levels of homocysteine. Combined elevations of CRP and homocysteine are significantly associated with history of MI, heart failure, and CVD.

### Depression and Social Isolation

Social isolation and depression are more prevalent and may play a prominent role in CVD in older adults. Morbidity and mortality following myocardial infarction are higher in aged individuals with depression than in those who are not. Similarly, accelerated atherosclerosis has been linked to distrust and depression, yet the mechanism is not fully understood. In persons aged 45 to 84 years free of clinical CVD, those with higher measured scores of cynical distrust, major depression, and stress have higher inflammatory markers CRP, IL-6, and fibrinogen levels, which highlights a potential common mechanism between depression and CVD.

### Frailty

The phenotype of frailty encompasses low physical activity, weight loss, weakness, poor exercise tolerance, and slowness, and its severity is strongly associated with incident CVD. Patients meeting frailty criteria have a sixfold greater risk of death, and frailty is an independent mortality risk factor in persons without previous clinical atherosclerotic disease. Linking back to inflammatory mechanisms as a driver of atherosclerosis, frail individuals have increased hsCRP and IL-6 levels. Whether this relationship is cause or effect is unknown, as decreasing these markers in frail individuals does not appear to reduce adverse outcomes.

### Obesity

Obesity has been reclassified as a major modifiable CV risk factor by the American Heart Association, concomitant with evidence that the U.S. childhood obesity epidemic may underlie the first reduction in life expectancy in recent history. In the general population, obesity and increased BMI are associated with a higher incidence of CV events. However, isolated BMI measurements are less predictive of CV events in the elderly than are central obesity, measured by waist–hip circumference, the metabolic syndrome, and insulin resistance. With increasing obesity, the ability of adipose tissue to store deposited fat is exceeded and the excess is stored in abdominal viscera, which is not primarily designed for this function. In addition to fat storage, adipose tissue acts as an endocrine organ producing and regulating steroid hormones and their influence on lipid profiles. Additionally, adipose tissue is a source of immune modulators, cytokines, and adipocytokines, the levels of which are markedly augmented in obesity. Adipocytokines including leptin, resistin, and adiponectin, as well as classic inflammatory markers IL-6 and TNF, invoke a proinflammatory state. Mechanistically, the proinflammatory effects of leptin include enhancing angiogenesis,

impairing vascular distensibility, increasing platelet aggregation, and hence stimulating thrombus formation. Conversely, adiponectin appears to protect against atherogenesis and inflammation. Excessive obesity also predisposes the individual to hepatic steatosis, which along with insulin resistance alters glycogen pathways and lipid composition, which promotes atherogenesis. Levels of nonesterified fatty acids are increased with insulin resistance and contribute to endothelial dysfunction and oxidative stress, key steps in plaque formation.

### Autoimmune Disease

Atherosclerosis is multifactorial, but as chronic inflammation emerges as a core mechanism, the high incidence of atherosclerotic disease in those with chronic autoimmune disease is understandable. Accelerated atherosclerosis may accompany systemic lupus erythematosus (SLE), rheumatoid arthritis, antiphospholipid syndrome (APL), systemic sclerosis, and vasculitides such as Wegener's granulomatosis. Of these, rheumatoid arthritis, SLE, and APL are the most extensively investigated, and the correlation between CVD and these disorders contributes to the secondary later mortality peak, which is rising as more efficacious treatment has improved outcomes in the earlier active disease phase. The extent of increased attributable CV risk parallels the autoimmune disease duration, severity (measured by systemic inflammatory markers), extra-articular manifestations, and the long-term use of corticosteroids. Many of the activated components in autoimmune diseases, such as macrophages, T cells, cytokines, autoantibodies, and autoantigens, play a central role in atherogenesis. In the joints of patients with rheumatoid arthritis, damaged cartilage contains an abundance of adhesion cells, MMP, and cytokines. The relationship between SLE and premature CVD is highlighted in young women, who are otherwise unlikely to exhibit advanced atherosclerosis. Accordingly, patients with SLE with and without clinical CVD have evidence of central arterial stiffening, as evidenced by faster pulse wave velocities, than those without SLE. The vascular effects of autoimmune disorders are likely synergistic with vascular aging, as patients who are older at the time of SLE diagnosis have a higher risk of incident CVD.

Although not a chronic inflammatory condition by itself, APL is a prothrombotic state characterized by venous and arterial thrombus formation. The syndrome is characterized by high anticardiolipin antibody (aCL) levels and the autoantigen that aCL is most commonly directed to is B2GPI. Along with high oxLDL antibodies in APL, elevated aCL levels are associated with increased MI, cardiac death, and significant coronary artery stenosis compared with controls. The combination of aCL attracting monocytes into the arterial wall and the acceleration of oxLDL into macrophages promoted by B2GPI antibodies promotes atherosclerotic plaque formation. The impact of autoimmune diseases on atherosclerosis emphasizes their consideration as a CV risk equivalent.

### Impact of Other Aging Organs

Age-associated changes of other organ systems and hormones greatly influence the hemodynamics and functioning of the vasculature of an older adult. The reduced compliance of stiffer central arteries creates greater fluctuations in blood pressure in response to changes in blood volume. Thus, alterations in systems controlling intravascular volume contribute greatly to increased blood pressure lability with aging. These changes are often magnified by age-associated reduc-

tions in beta-adrenergically driven cardiac chronotropy and inotropy, as well as alterations in homeostatic-regulating systems such as thirst and baroreflexes.

### Volume-Regulating Hormones

Serum levels of aldosterone, angiotensin II, vasopressin, and renin diminish with increasing age. These changes manifest clinically as labile blood pressure to intravascular volume challenges. Salt sensitivity also increases with age, which may further challenge the reduced levels of volume-regulating hormones, creating an exaggerated hypertensive and edematous response to foods and medication or leading to salt and fluid retention.

### Renal Aging

Glomerular filtration rate declines by approximately 8 cc/minute/decade with normative aging. Additionally, the older kidney has less ability to reabsorb free water and sodium in the distal tubules. The aging kidney also declines in size and blood flow. Reductions in renin and aldosterone impact further on volume regulation. These alterations contribute to intravascular volume shifts in the older adult, which manifest as wide alterations in blood pressure of the noncompliant vascular system.

### Iatrogenic Contributors

#### Medications

Commonly used medications in older patients can inadvertently increase atherogenesis and CV risk. The impact of corticosteroids on the vasculature is multifactorial including weight gain, increased visceral adiposity, hypertension, dyslipidemia, hyperglycemic states, and predisposition to the metabolic syndrome. Additionally, hormone replacement therapy and COX-2 inhibitors, two classes widely used in older adults, are associated with increased CV risk. These medications are associated with thrombosis, fluid retention, and hypertension and thus, have been marked with warnings or removed from the market.

#### Radiation

As the detection and treatment of cancers improve, more cancer survivors treated with radiation are reaching advanced age. Anterior chest and neck radiations, especially for treatment of Hodgkin's lymphomas and local breast cancers, increase CV risk via radiation injury to arterial vessels in the treatment field. The incidence of coronary revascularization, carotid stenosis, and valve replacement is higher than expected in patients with a history of radiotherapy; the earlier in life the radiation, the more significant the CV risk. Common sites of radiation-related atherosclerotic disease included the left main, left anterior descending and right common coronaries and subclavian and carotid arteries. The mechanism of accelerated atherogenesis appears related to the acute inflammation following the radiation and subsequent neutrophil and cytokine infiltration. As the vessels, repair and remodel, fibrosis and scarring also enhance microvascular ischemia. Interestingly, increased CVD and events are also seen in atomic bomb survivors, the disease extent reflecting total radiation exposure. Techniques to reduce the dose and increase the focus of

radiation therapy have reduced the incidence of radiation-associated CVD over the past decade.

## Summary

Traditional CV risk factors continue to be important in older age and, in some cases, carry even higher risk than in younger age owing to their length of exposure. In addition, many nontraditional risk factors are increasingly important in older adults. Overall, CV risk factor profiling is more complex with older age as common risk profiling tools (Framingham Risk Score, European ProCam Risk Score, and Reynolds Risk Score) have limited ability to accurately predict CV risk beyond 80 years of age. Providers should be aware that these risk-profiling methods are generated using primarily middle-aged cohorts; although CV risk is most influenced by age, these do not account for the increasing variability of risk factors in older age groups. Risk-profiling models specific for older adults need to be developed.

## CLINICAL IMPLICATIONS OF VASCULAR AGING AND ATHEROSCLEROSIS

Atherosclerosis manifests clinically as coronary artery disease, cerebrovascular disease, aortic atheromatous as aneurysmal lesions and peripheral arterial disease. In older adults, the clinical presentation of these CV conditions can be nontraditional, and, especially in those accustomed to debility, the severity of the impairment is often underestimated or downplayed. Atherosclerotic disease may often be occult or insidious and not recognized by the patients, their family, or their provider. Clinical presentation may also be altered by cognitive abilities or lack of usual stressors such as exercise or immobility from musculoskeletal and/or neurological deficits. For these reasons and as CVD prevalence increases with age, the diagnosis should be considered even for vague symptoms such as confusion, atypical pain, lethargy, and shortness of breath.

The physiologic changes imparted by a stiff central vasculature (increased pulsatility, left ventricular hypertrophy, impaired early left ventricular diastolic filling, increased afterload, and diminished coronary perfusion) increase the vulnerability to atherosclerosis and worsen its consequences by reducing cardiac reserve. Thus, stressor such as blood pressure lability to alterations in intravascular volume or tachycardia (from dehydration, fever, hyperthyroidism, arrhythmias, or deconditioning) can easily provoke symptoms or events in older adults. The central-stiffness-induced coronary perfusion pressure reduction, in addition to left ventricular hypertrophy, diminishes myocardial perfusion, resulting in ischemia often in the absence of discrete coronary lesions. Further, increased left ventricular pressures from augmented afterload exacerbate left atrial and pulmonary pressures, which lower the dyspnea threshold.

## Isolated Systolic Hypertension

ISH is the clinical manifestation of both the vascular aging changes and/or the atherosclerosis of the older central arterial system. As previously noted, the vicious cycle of structural and dynamic arterial wall changes drives increased pulsatility and sheer stress, which further promotes vascular damage, inflammation, ROS accumulation, and endothelial dysfunction and vice versa. This pathology underly-

ing older hypertensive adults with ISH and their vasculature is often reflected in their inability to respond to traditional antihypertensives designed to reduce peripheral vascular tone, as compared to younger hypertensive, and highlights the need for novel therapeutics that target these age-associated alterations. There is now an abundance of data confirming that treatment of ISH results in reduction of CV events including MI, heart failure, strokes as well as renal failure, total mortality, and dementia.

## Heart Failure with Preserved Systolic Function

More than half of older heart failure patients presenting with symptomatic heart failure have a preserved ejection fraction, and the majority of these individuals are female. The pathogenesis of heart failure with preserved ejection fraction (HFPEF) is controversial but is likely based on long-standing hypertension, left ventricular hypertrophy (LVH) intrinsic ventricular stiffness, and impaired early diastolic relaxation. The myocardium of the left ventricle hypertrophies in response to increased ventricular afterload imposed by an increased aortic diameter, decreased aortic compliance, and the early reflected pulse wave. In addition to LVH, isovolumic relaxation of the ventricle is prolonged, encroaching on diastole. Thus, increased central arterial stiffness exacerbates impaired early diastolic relaxation and filling. At rest, the ventricular and central vascular functions of the older adult remain fairly energetically coupled. Normally, ventricular–vascular coupling implies that the heart is functioning at maximum metabolic efficiency and can maintain blood pressure and cardiac output in a physiologic range. However, in the older adult, as both the myocardium and the central vasculature stiffen, the CV reserve mechanisms are challenged by stressors, resulting in labile blood pressure at higher cardiac work. Characteristics associated with the clinical presentation of HFPEF include female sex, older age, relative obesity, anemia, and renal insufficiency. Factors that can trigger an exacerbation of HFPEF are similar to those that can trigger systolic heart failure. However, HFPEF may be more afterload and preload dependent, necessitating tight blood pressure control as a part of long-term management.

## Coronary Artery Disease (See Chapter 76)

On presentation with acute coronary syndrome, the age of a patient is one of the most powerful predictors of outcome, with more than 60% of myocardial deaths occurring in those older than 75 years, which may be attributed to confounding factors including the atypical presentation and absence of characteristic EKG changes often seen in this group. Aged individuals often present later, and in a more compromised state with shortness of breath. Additionally, comorbidities, frailty, and renal insufficiency worsen the outcome. Older patients are at higher risk of complications from antiplatelet, anticoagulant thrombolytic, and revascularization, therapies but clinical trials demonstrate that aggressive treatment in this cohort reduced morbidity and mortality. Management of acute atherosclerotic disease in older patients is not often addressed by evidence-based guidelines owing to the underrepresentation of older adults in clinical trials.

## Cerebrovascular Disease (See Chapter 64)

Atherosclerotic cerebrovascular disease is a significant cause of morbidity and mortality in aged individuals and of a major social cost

because of disability. Presenting complaints range from classical hemiplegic stroke to vascular dementia that is often silent until significant cognitive disease is reported. Clinically occult cerebrovascular disease is common in elderly individuals, especially in those with orthostatic hypotension and hypertension independent of other risk factors.

### Renovascular Disease

Approximately 90% renal artery stenosis (RAS) is caused by atherosclerosis, often characterized by plaque extending from the aorta into the renal artery lumen, creating an ostial lesion. The prevalence of RAS increases with age, especially in the setting of risk factors such as hypertension. Kidney atrophy and ischemic changes may result from progressive occlusion of renal blood flow or by microthromboembolism from unstable prothrombotic plaques. Progressive renal dysfunction, increased sympathetic nervous system activity by the ischemic kidney, and augmentation of the renin-angiotensin-aldosterone system can exacerbate preexisting essential hypertension, resulting in recurrent flash pulmonary edema in the absence of cardiac ischemia. This vicious hypertensive and shear stress cycle in unilateral RAS can also damage the contralateral kidney, resulting in rising creatinine, which signifies more than 60% reduction in nephron function. This risk of unilateral RAS evolving into bilateral renal disease is high and may progress to end-stage renal failure. Atherosclerotic RAS may account for up to 15% of elderly patients admitted to the hospital with ischemic nephropathy leading to end-stage renal disease.

### Aneurysms

Abdominal aortic aneurysms are most commonly found incidentally on examination or imaging. Determining the timing of surgery is extremely important in older patients, as the mortality associated with repair of ruptured aneurysms is significantly higher in patients older than 80 years compared with those younger than 80 years. Despite this, fact elective abdominal aortic aneurysm repair is often delayed or avoided in this cohort because of perceived elevated surgical risk. Accordingly, recommendations for repeat screening in patients with already diagnosed atherosclerotic disease are well established. Regarding the pathophysiology, increased MMP activity and decreased tissue inhibitor of MMPs are found in abdominal and thoracic atherosclerotic aneurysms compared with nonatherosclerotic lesions.

### Peripheral Arterial Disease

Prevalence of peripheral vascular disease in individuals older than 55 years is estimated at 16.9% in men and 20% in women (WHO) and is linked to symptomatic and asymptomatic CVD, smoking, and hypertension. Both objectively diagnosed PAD and symptomatic claudication increase with age. Interestingly, the trend to asymptomatic disease in the elderly is again found with the prevalence of PAD quite high but the corresponding prevalence of intermittent claudication at a much lower level. With chronic ischemia of the extremities, there may be evidence of dry skin changes, poor nail growth, and ischemic ulcers characteristically distal but may occur at the heel and ankle in immobile individuals. A large number of markers including homocysteine, TG, lipoprotein, and ApoA/B in patients up to 84

years of age have been investigated; however, CRP and HDL-C seem to have the strongest prognostic value in peripheral arterial disease.

### Reduced Exercise Capacity

Exercise capacity, reflected by maximum oxygen consumption, declines with increasing age even after adjustment for estimated total body muscle mass. Studies of healthy older volunteers in the Baltimore Longitudinal Study of Aging have confirmed this phenomenon and investigated possible etiologies. Impaired cardiac output is a significant contributor, in addition to decreased respiratory and peripheral muscle reserve possibly related to deconditioning. Cardiac output is the product of heart rate and stroke volume, and the expected increase in both of these indices with exercise is blunted in aging. The decreased heart rate response is primarily caused by decreased beta-adrenergic sensitivity. The decreased stroke volume response is likely caused by multiple factors, including reduced myocardial contractility, increased vascular afterload from arterial stiffening, and arterial-ventricular load mismatch. Not surprisingly, this blunted stroke volume response in aging is even further impaired in the setting of exercise-induced silent myocardial ischemia evidenced by electrocardiogram.

## DETECTION AND DIAGNOSIS

Advances in CV technology have enhanced our ability to detect and diagnose atherosclerosis at earlier stages of the disease process in adults of all ages. As the age-associated atherosclerotic burden continues to grow, diagnosing and managing CVD will consume a significant proportion of health care resources. Therefore, health-care providers should be aware that newer technologies currently add only incrementally to traditional approaches used to diagnose atherosclerosis in adults both young and old. This section provides a brief overview of currently available approaches and their utility in older populations.

### Stress Testing

The exercise treadmill test remains appropriate for diagnosing clinically important CAD in older adults who are not physically limited by noncardiac comorbidities and who have normal electrocardiograms. The ability to perform an adequate treadmill test declines with age; only a quarter of individuals older than 75 years achieve a maximal predicted effort. Causes may include reduced beta-adrenergic responsiveness, conduction disease, and decreased vascular compliance. Furthermore, the specificity of an ECG-positive treadmill stress is lower in older age as false positives from LVH increase. Despite these limitations, a good exercise tolerance in very old adults is associated with a favorable long-term prognosis, regardless of other findings.

Individuals who cannot exercise require the use of pharmacologic stress agents such as dobutamine, dipyridamole, or adenosine. Dobutamine, a beta-agonist, is often successful at inducing heart rate goals in older adults. Dipyridamole and adenosine, potent vasodilators, are used to assess distribution of vascular perfusion with stress. Both agents are as well tolerated in older adults as dobutamine. Dobutamine echocardiography may be more sensitive than adenosine echocardiography in assessing the presence and severity

of CAD, but a positive adenosine echo often represents more severe disease.

Single-photon nuclear imaging or echocardiographic imaging is often used in pharmacological stress tests and especially for individuals with baseline ECG abnormalities, which are frequent in older adults. The ability of a normal nuclear stress result to predict low event rates is time limited, requiring repeat evaluation in older patients with recurrent or changing symptoms. Nuclear imaging is also subject to false-negative results in “balanced three-vessel disease.” Likewise, the ability of echocardiography to image the lateral wall is limited and can produce false-negative results in this territory for individuals of any age.

### Computed Tomography

Two types of computed tomography (CT) scanning currently used to detect atherosclerosis are electron-beam CT (EBCT) and multi-detector CT (MDCT). The EBCT method uses relatively little radiation and can quickly assess coronary anatomy. EBCT is primarily used to quantify the presence of coronary artery calcium (CAC). High CAC scores correlate with histological plaque and to the number of stenosed vessels on invasive angiography. Furthermore, a high CAC score adds additional risk to the Framingham risk stratification, particularly in those with intermediate risk. However, CAC does not predict plaque stability, and EBCT cannot detect noncalcified plaques. Moreover, high CAC scores are widespread in older populations and do not correlate well with the clinical significance of the lesion. Thus, the use of EBCT to assist in differentiating between quiescent and clinically significant coronary disease in older adults is very limited.

The MDCT method uses more radiation than EBCT and images the heart in thinner slices to provide higher resolution and identify the presence of noncalcified as well as calcified plaques. Compared to invasive angiography, a 16-slice MDCT can detect hemodynamically relevant coronary stenoses with 90% sensitivity and specificity. However, 5% to 15% of the coronary circulation in a given study cannot be evaluated as a result of poor image quality. Factors that affect MDCT image quality include motion artifact of the heart, particularly at high heart rates, and the presence of severe CAC. Given the increased CAC in older adults, the ability of MDCT to evaluate for obstructive or hemodynamically significant lesions in older adults may be diminished compared to younger subjects. The combination of MDCT and single-photon nuclear imaging allows the process of acquiring anatomic and functional information in a single study. This technology has yet to be evaluated in large populations but may offer an important advantage over current modalities in the evaluation of older individuals who are more likely than their younger counterparts to have complex coronary anatomy.

### Magnetic Resonance Imaging

Using cardiac MRI to image atherosclerosis offers the advantage of avoiding contrast dye and ionizing radiation. In addition, MRI is capable of isolating atheroma and identifying specific components of the plaque, such as the fibrous cap, calcifications, the lipid-rich necrotic core, and intraplaque hemorrhage. MRI can identify disruptions of the plaque–lumen interface such as those associated with fibrous cap rupture or ulceration. However, current MRI technology suffers from extensive variability of image quality owing

to the time required to acquire images, the ability to account for cardiorespiratory motion, and limited spatial resolution. Limited penetration depth, in favor of better resolution, also affects the ability of MRI to evaluate plaques in larger vessels such as the aorta. For this reason, transesophageal MRI has been developed to optimize MRI of the aorta.

### Vascular Studies

In addition to CT and MRI, investigational modalities to detect atherosclerosis of the peripheral circulation include carotid ultrasonography, ankle–brachial index (ABI), and brachial reactivity testing. Detecting large or symptomatic atherosclerotic lesions, such as plaque or aneurysm, in the aorta or other large vessels is straightforward, whether by CT or MRI or ultrasound. However, smaller asymptomatic or subclinical atherosclerotic lesions may be more difficult to detect.

Carotid ultrasound remains the cornerstone to detect flow-limiting or obstructive plaques for evaluation of cerebrovascular disease. This technology also measures intima-media thickness (IMT) at various sites around the common carotid bifurcation point. Increased carotid IMT represents subclinical atherosclerosis and is associated with adverse CV events. Conversely, reduction in carotid IMT with statin therapy is associated with risk reduction. Advanced age is very strongly associated with increased carotid IMT, and the degree to which this relationship reflects vascular aging versus atherosclerosis is unknown. In addition, the measurement of carotid IMT can vary widely between imaging operators and is presently not widely used outside of clinical research studies.

Perhaps one of the most overlooked modalities for assessing the presence and severity of atherosclerosis is the ABI. Traditionally used in the diagnosis and evaluation of PAD, ABI is the ratio of Doppler-recorded SBP at the ankle divided by the SBP in the arm. Individuals without clinically significant PAD typically have an ABI greater than 1.00, while an ABI <0.90 is 90% sensitive and 95% specific for angiographically present PAD. Individuals with low-normal ABIs have a higher prevalence of CAC on CT and increased carotid IMT on ultrasound. Clinically diagnosed PAD carries higher risk for MI, stroke, and death, but even a low ABI alone is associated with increased CV morbidity and mortality. The ABI should be interpreted with caution, since its relationship with clinical atherosclerotic events is not linear. In fact, individuals with ABI >1.30 can also have increased CV risk. The degree to which higher ABIs represent upper extremity PAD (e.g., subclavian) out of proportion to lower extremity PAD (e.g., iliac, femoral, and popliteal) is unclear.

Another modality to identify the presence of atherosclerosis is brachial artery reactivity testing. Endothelial dysfunction may be one of the earliest detectable manifestations of atherosclerosis. Brachial artery reactivity testing detects endothelial dysfunction by measuring arterial vasodilatation in response to increased blood flow, or flow-mediated dilation. Changes in brachial artery blood flow and diameter are assessed before and immediately after blood vessel occlusion with a cuff using either high-resolution B-mode Doppler ultrasound or MRI. Endothelial dysfunction can predict CV events, even after adjusting for the presence and extent of morphologic atherosclerosis. Limitations to brachial artery reactivity testing include variations in flow-mediated dilation measurements and a lack of standardized approaches to interpreting measurements.

## STRATEGIES TO PREVENT, RETARD, AND REGRESS VASCULAR AGING AND ATHEROSCLEROSIS

### Novel Drug Targets

Elucidation of novel biochemical pathways, which contribute to vascular aging and atherosclerosis in older adults, has resulted in the design of novel targets for therapeutic intervention to reduce and ideally prevent the burden of atherosclerosis and its associated pathology. Pharmaceutical agents that block the formation of AGE have proved efficacious in decreasing vascular stiffness and nephrosclerosis, but clinical trials were halted owing to adverse drug effects. Preclinical studies with AGE cross-link breakers support their ability to reduce age-associated ventricular and vascular stiffness and reduce and prevent atherosclerotic plaques. Clinical trials with alagebrium chloride, an AGE cross-link breaker, demonstrate a significant reduction in total vascular compliance and left ventricular mass and improve endothelial dysfunction and early left ventricular diastolic filling. These strategies emphasize a shift in the focus of hypertension treatment from dynamic peripheral vasoconstriction to structural targets previously thought to be irreversible. Development of RAGE antagonist remains in the preclinical phase, but administration of these drugs are associated with significant reductions in endothelial-mediated vessel injury response and reduction in vascular inflammation and oxidative stress. Tetrahydrobiopterin, an agent that “recouples” NOS dimers to a functional molecule, shows promise in improving endothelial dysfunction and reducing age-associated vascular stiffness. Other potential drug targets, which exploit age-associated changes, include inhibitors of the elastase enzyme and strategies to augment no activity such as arginase blockade.

### Pleiotropic Effects of Available Therapies

#### ACE-I/ARB

Large clinical trials demonstrate the potential for ACE inhibitors to exhibit beneficial effects on morbidity and mortality beyond blood pressure lowering. Likewise, ARBs as well as ACE inhibitors specifically lower CV risk of type II diabetes. Both ARBs and ACE inhibitors also appear to increase insulin sensitivity through different mechanisms. ACE inhibitors do so via the bradykinin pathway. ARBs induce activity of peroxisome proliferator-activated receptor, a nuclear hormone receptor that plays an important role in regulating insulin sensitivity.

#### Statins

The pleiotropic effects of statins have beneficial effects on both vascular aging and atherosclerosis. Statins can improve endothelial function in individuals with hypercholesterolemia, atherosclerosis, smoking, and type II diabetes. These favorable endothelial effects are attributed to their ability to lower LDL cholesterol, downregulate eNOS, and exert antioxidant activity. With regard to atherosclerosis, statins contribute to plaque stability via fibrosis and MMP reduction and exhibit a powerful anti-inflammatory effect that can be reflected in lower CRP and adhesion molecule levels. Statins may even contribute to the differentiation and recruitment of endothelial

progenitor cells as well as modulate immune mechanisms involved in atherogenesis.

### Exercise

Despite the proven benefits of physical activity across all age groups, older adults are less likely than younger adults to be referred for exercise training. Although many older adults may be physically limited by non-CV comorbidities, older individuals can benefit significantly from any form of exercise program in which they can participate (e.g., aerobic, resistance, or flexibility training). In fact, exercise has a directly beneficial physiological impact on vascular changes associated with aging. Although these adaptations may be somewhat limited in areas of the vasculature affected by frank atherosclerosis, physical activity can both prevent and even reverse endothelial dysfunction in older adults. Subsequent improvements in vascular tone can manifest as significant lowering of blood pressure even beyond that achieved by antihypertensive medication alone. Indeed, the beneficial effects of exercise are likely pleiotropic. In addition to a lower blood pressure, older adults with coronary disease who participate in an exercise rehabilitation program can achieve improved lipid profiles, increased glucose tolerance, and also decreased measures of depression and anxiety.

## SUMMARY AND TAKE HOME POINTS

Aging is the most potent risk factor for atherosclerotic disease, and, in turn, atherosclerosis is responsible for a dominant portion of the chronic illness burden in older adults. Research to date reveals that the relationship between aging and atherosclerosis is complex and multifaceted. Nevertheless, it is apparent that vascular aging plays a central role and involves numerous biologic processes that greatly enhance the development of atherosclerosis. In concert with vascular aging, traditional and nontraditional risk factors manifest in increased number and with greater magnitude in older individuals. Furthermore, exposure to non-CV illness and iatrogenic contributors potentiate the development and progression of atherosclerotic disease through a variety of mechanisms over the course of a lifetime. As a result, the clinical presentations of atherosclerosis in older compared to younger individuals are more varied as well as more severe. Newer imaging modalities for detecting and diagnosing atherosclerosis are being refined for widespread use. Novel therapies to target vascular aging and atherosclerosis are being tested. Yet, the most powerful reduction in atherosclerotic disease results for early recognition and risk factor modification. Traditional and readily available therapies are vastly underused in older patients with CVD, and this should be emphasized to patients and providers, as evidence-based guidelines for older patients with CVD continue to be developed.

# Coronary Heart Disease

Eric D. Peterson ■ Shahyar M. Gharacholou

Data from the National Center for Health Statistics have noted that the life expectancy at birth in the United States reached a record high of 77.5 years in 2003, attributable, in part, to the decline in mortality from heart disease during the past three decades. Despite this, coronary heart disease (CHD) remains the leading killer of both men and women in the United States. More than 80% of CHD deaths occur in persons older than 65 years of age. In addition, 37% of recognized acute myocardial infarctions (MIs) occur in those older than 75 years of age, and, although these account for roughly 6% of the U.S. population, 60% of all MI-related deaths affect elderly patients 75 years of age or older.

The diagnosis, management, and posthospitalization care of elderly patients with CHD involve interplay of patient heterogeneity, comorbid conditions, functional status, drug pharmacology, and biological differences. This complexity is compounded by extrapolation of “evidence-based care” obtained from cardiovascular trials from which older patients were poorly represented. Given these characteristics, an adopted approach to cardiac care of elderly patients often requires developing a *patient-centered* plan of care and incorporating an individual’s own goals and health expectations in the care decision process. While the term “elderly” has been used in the literature, no specific guideline to the care of elderly patients with CHD attributes a particular level of evidence to specific age. This chapter will reference specific age groups reported in the medical literature as available, bearing in mind that one’s chronologic age may be a poor surrogate for one’s overall health status.

## PREVALENCE

The spectrum of CHD includes asymptomatic (or subclinical) CHD, chronic stable angina pectoris, unstable angina, and acute MI. Statistically, the first manifestation of CHD is an acute MI in 40% of cases and sudden death in 10% to 20% of cases. In the United States, the prevalence of overt CHD increases in a curvi-

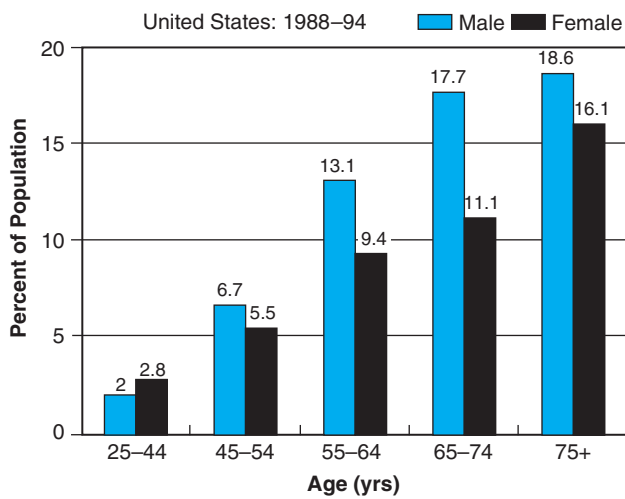

linear fashion with advancing age in both men and women (Figure 76-1). Similarly, the annual rate of first heart attack rises with age in all race and gender subgroups. Furthermore, despite the fact that women typically have a 10-year lag in developing CHD as compared to men, the majority of patients with CHD  $\geq 75$  years of age or older are women because they typically have a longer lifespan.

It should also be realized that overt CHD represents just the tip of the coronary disease iceberg and a great number of elderly patients have asymptomatic, subclinical disease. Researchers for the Cardiovascular Health Study examined the prevalence of both clinical and subclinical cardiovascular disease in a large community-dwelling Medicare population by using a composite measure of MI on electrocardiogram (ECG) or echocardiography and abnormal carotid artery wall thickness or ankle–brachial blood pressure index and found that disease frequency increased from 22% in women aged 65 to 70 years to 43% in those aged 85 years or older. Similarly, the frequency of subclinical vascular disease in men increased from 33% to 45% in these age groups, respectively.

## EFFECTS OF AGING ON THE CARDIOVASCULAR SYSTEM

The development of CHD is multifactorial and can be influenced by genetic predisposition and comorbid conditions such as diabetes, as well as environmental and lifestyle determinants such as diet, smoking, and physical exercise. Not surprisingly, as these factors vary among individuals, one’s likelihood for developing CHD also varies. While it is often believed that CHD is inevitable with advancing age, autopsy studies have found that 40% of those persons in their nineties will not have occlusive coronary disease.

With this patient-to-patient variability noted, certain cardiovascular changes are seen more commonly with advancing age, and the aging process confers important physiological considerations in elderly patients. Diastolic heart failure, “heart failure with preserved

**FIGURE 76-1.** Estimated prevalence of coronary heart disease by age and sex. (Adapted with permission from Vargas et al. *Cardiovascular Disease in the NHANES III. Ann Epidemiol* 1997;7:523.)

ejection fraction,” accounts for up to 50% of heart failure in patients older than 70 years of age and often coexists with vascular disease, contributing to significant morbidity and mortality. The exact mechanism of diastolic heart failure continues to remain controversial, but altered left ventricular end-diastolic pressures and increased pulmonary venous pressures can result in symptoms of dyspnea and signs of pulmonary edema. This disease process occurs with a higher prevalence in elderly patients with a history of hypertension and atrial fibrillation. Recent observational data suggest that rehospitalization or 1-year survival mirrors that of systolic heart failure, challenging earlier assumptions that diastolic heart failure might be a more benign condition. In parallel, arterial stiffening in elderly patients results in isolated systolic hypertension and widened pulse pressures, factors previously associated with increased cardiovascular events. The aging of the vasculature often heralds blunted responses to protective vasodilatory mediators and progressive endothelial dysfunction. This endotheliopathy results in increasing numbers and severity of atherosclerotic plaques (Figure 76-2). The composition of these lesions also changes with age, with reduction in the soft lipid core and an increase in calcification and fibrosis. While more

advanced calcified plaques are actually less likely to rupture, the sheer increase in lesion numbers leads to an increased overall likelihood for CHD events in the elderly patient.

## PRESENTATION

The elderly are much less likely than younger patients to present with “classic” exertional chest heaviness. Instead, older patients more often complain of a vague feeling of dyspnea, abdominal pain, fatigue, confusion, or malaise that may be misinterpreted as consequences of aging or other comorbid illness. Findings from the Global Registry of Acute Coronary Events, a large, prospective, multinational registry of acute coronary syndromes (ACSs), demonstrated that patients presenting with atypical symptoms were less likely to receive appropriate cardiac medications, undergo cardiac catheterization, and were at higher risk of in-hospital morbidity and mortality. The elderly can also have an impaired ischemia warning system, which delays their CHD presentation. In a series of patients with CHD undergoing treadmill testing, researchers found that patients aged >70 years took more than twice as long as their younger counterparts to report anginal symptoms after ECG-documented ischemia was noted. In the Worcester Heart Attack Study, patients 75 years of age and older had the longest prehospital delay of any age group, many outside the critical 6-hour window for fibrinolytic therapy. The Rapid Early Action for Coronary Treatment study quantified delay time as an additional 14 minutes for every 10-year increment in age, beginning with the age of 30 years. The significant prehospital delay among elderly patients is likely multifactorial and includes considerations such as atypical presentation, medical comorbidities, previous experiences within the health-care system, socioeconomic, access to care, and cognitive and functional impairments.

Difficulty in recognizing symptoms contributes to later presentation for acute CHD events in the elderly. In fact, studies show that more than two-thirds of patients with MI, >65 years of age, fail to reach an emergency department within 6 hours after the onset of their symptoms. Major predictors of a delay in MI presentation include advanced age, female sex, diabetes mellitus, and social isolation. Importantly, delays in MI presentation have strong prognostic implications and are closely associated with poorer outcomes in elderly patients. Thus, clinicians should proactively discuss with their

**FIGURE 76-2.** Atherosclerosis timeline.

patients that cardiac symptoms can vary widely and they should seek rapid medical attention if potential ischemic symptoms occur.

## DIAGNOSTIC EVALUATION

Given its prevalence and often atypical presentation in the elderly, clinicians must harbor a high index of suspicion for CHD in order to make the correct diagnosis. In taking a thorough clinical history, with emphasis on prior cardiovascular disease history, clinicians must pay close attention to assessing a patient's major cardiac risk factors (smoking, hypertension, diabetes mellitus, and lipid status), as well as any symptoms suggestive of CHD. Eliciting the temporal course of these symptoms is also important. Patients with new, progressive, or refractory symptoms typically require an expedited—and possibly inpatient—evaluation, in contrast to those patients with chronic stable symptoms. Physicians should also assess the impact of symptoms on the patient's functional status and overall quality of life, as these issues may alter preferences for invasive testing and/or need for coronary revascularization.

A systematic approach to the physical examination with awareness of age-related changes in the cardiovascular system may improve diagnostic accuracy and provide further clues to the presence of CHD. After evaluation of the patient's general appearance, blood pressure assessment with an appropriately fitting sphygmomanometer, one that encircles at least 80% of the arm, and examination of pulses in the extremities should be performed. Some older patients develop calcific vascular disease, and pseudohypertension may be observed. This becomes an important distinction when further titration of antihypertensive medications may predispose the patient to symptoms of cerebral hypoperfusion. Diminution of the femoral pulses or brachial–femoral delay may suggest the presence of atherosclerotic aortoiliac disease, and these findings may accompany observed dermatological changes with lower extremity hair loss. Performing ankle–brachial indices remains a useful and sensitive screening tool for identifying patients with peripheral vascular disease, a known risk factor for increased cardiovascular events. The cardiac examination may include signs of left- or right-sided heart failure (pulmonary edema, displaced point of maximal impulse, an  $S_3$ , or peripheral edema) or characteristic murmurs of valvular heart disease. Once a thorough history and physical has been completed, further diagnostic evaluation should be based on the patient's symptoms as outlined below.

### Asymptomatic Elderly Patients

For the asymptomatic elderly individual, risk factors, particularly blood pressure and lipid screening, should be measured as recommended for all aged patients in the Joint National Committee on Detection, Evaluation and Treatment of High Blood Pressure (JNC) VII and National Cholesterol Education Program (NCEP)—Adult Treatment Panel (ATP) III guidelines, as the elderly continue to remain the population with the lowest rates of blood pressure control. Obtaining a baseline ECG is also reasonable in the initial patient evaluation because of the high prevalence of “silent” MIs in the elderly population. This information should be summarized into a composite risk assessment using one of the multiple standardized indexes such as the Framingham Risk Score (<http://www.nhlbi.nih.gov/about/framingham/riskabs.htm>).

Patients with low CHD risk (10-year CHD risk <5%) can generally be reassured without further testing, with a plan for reevaluation of their risk factors in 5 years. In contrast, patients at high risk (10-year CHD risk >20%) should receive aggressive risk factor intervention to the same degree as if they had already experienced an overt CHD event. Patients with intermediate risk (10-year CHD risk, 5–20%) may benefit from further testing to clarify their CHD risk. In these intermediate patients, laboratory studies such as homocysteine, lipoprotein (a), B-type natriuretic peptide, and C-reactive protein have been proposed as means of identifying those at higher risk and in need of more aggressive risk-factor modification. Recently, this “multimarker” strategy was evaluated in a study of the Framingham Offspring cohort. The findings suggested that for outcomes of death or first major cardiovascular events, multimarker scoring added only a small increase to conventional risk factors in the ability to classify risk. Therefore, the role of biomarkers to aid in risk stratification of patients who are ambulatory remains an area of ongoing research, and its implications for clinical practice have yet to be clearly elucidated. Beyond the standard history, physical examination, and simple laboratory tests, further diagnostic testing (carotid ultrasound, treadmill testing, echocardiography, or electron-beam computed tomography) in the asymptomatic elderly patient to detect occult or subclinical CHD remains controversial and is not generally recommended.

### Chronic Stable Angina in the Elderly Patient

Elderly patients with symptoms suggestive of CHD should undergo a similar assessment of their likelihood for obstructive coronary disease based on algorithms that take into account symptom characteristics, including angina type (nonanginal, atypical, or typical), its course (stable, progressive, or unstable), and its duration. This initial assessment of a patient's “pretest probability of disease” should then guide further diagnostic testing. In particular, clinicians need to be cognizant that, according to Bayesian theory, the predictive value of a test is influenced by the disease prevalence in the population tested. For example, clinicians may interpret a negative stress test in a high-risk elderly woman (pretest probability of disease 80%) as “ruling-out” the presence of CHD, whereas this patient's post-test likelihood remains more than 60% (Table 76-1). For these reasons, elderly patients with high pretest likelihood for coronary disease should be considered for direct referral for cardiac catheterization (if revascularization is an appropriate option). At the other extreme, patients with a low pretest probability for CAD  $\leq$ 20% (i.e., no risk factors, normal ECG, and very atypical symptoms) can often be followed clinically and/or be assessed for other etiologies of their symptoms (gastrointestinal, pulmonary, musculoskeletal, etc.). Elderly patients with an intermediate pretest probability for CHD (between 20% and 70%) are those in whom stress testing tends to have its greatest impact on clinical decision making.

When a stress test is indicated, current guidelines still recommend standard exercise ECG as the test of choice for most patients. These tests provide very important prognostic information (including exercise duration and hemodynamic response), as well as electrocardiographic indications of ischemia (ST depression). Elderly patients, however, frequently experience difficulty with traditional stress testing because of deconditioning or comorbid illness or disability and may benefit from modified exercise protocols with lower starting levels and slower stage progression. Alternatively, for patients who

TABLE 76-1

## Influence of Age on Predictive Value of Stress Testing (Bayes Theorem)

HISTORY	AGE (yr)	PRETEST LIKELIHOOD OF SIGNIFICANT CAD* (%)	TREADMILL TEST <sup>†</sup>	POSTTEST LIKELIHOOD OF SIGNIFICANT CAD (%)

			Negative	3
	75	35	Positive	62
			Negative	18

CP, chest pain; RF, risk factors; CAD, coronary artery disease.

\*Based on CAD risk nomogram for predicting significant CAD.

<sup>†</sup>Sensitivity of treadmill test = 68%, specificity = 77%.

cannot exercise sufficiently, one can use a pharmacologic-based stress test (dobutamine, adenosine, or dipyridamole).

In elderly patients with baseline ECG abnormalities (resting ST depression, left bundle branch block, left ventricular hypertrophy with strain, or paced rhythms), imaging modalities, such as nuclear perfusion or stress echocardiography, are required. While these modalities significantly add to the cost of the test, these improve the diagnostic accuracy beyond stress ECG alone and provide information as to the location and extent of coronary disease. The published sensitivity and specificity for stress echocardiography and nuclear imaging (80–90% for each) are nearly identical in most series. Thus, the choice between the two should be based on local availability and expertise.

The use of cardiac catheterization in the elderly patient needs to be based on its potential risk–benefit ratio. While cardiac catheterization has become commonplace and relatively safe in contemporary practice, vascular injury, bleeding, MI, stroke, and even mortality can result, albeit rarely. Advanced age increases these risks slightly; however, the risk to life remains <0.2%, and the risk of other serious adverse events is <0.5%, even in those aged ≥75 years. Placing a patient even at minimal risk, however, is not worthwhile if the information obtained from a catheterization is unlikely to impact treatment decisions. For example, a cardiac catheterization may have limited impact on the management of an elderly patient who is not a candidate for coronary revascularization, based on medical comorbidity, cognitive decline, or personal preference.

## ACUTE CORONARY SYNDROMES

The pathophysiology of the ACS involves atherosclerotic plaque rupture, platelet activation/aggregation and embolization, endothelial dysfunction, inflammation, and thrombus formation. If the clot completely occludes the vessel, the patient suffers an acute MI, and an injury pattern (e.g., ST elevation) is often seen on the ECG. In contrast, patients with plaque rupture can also form a nonocclusive thrombus, resulting in subendocardial ischemia. These patients often have an acceleration of chest pain symptoms (unstable angina) and may have more subtle changes on the ECG (e.g., flipped T waves or ST depression). There is some evidence that plasma levels of procoagulation markers and coagulation factors are elevated in

elderly patients, but it remains unclear whether these findings alone are responsible for increased thrombotic tendencies in the elderly or alter risk when accompanied by other traditional risk factors for thrombotic events.

There are also significant proportions of elderly patients who develop ACS secondary to exacerbations of chronic comorbid conditions or acute medical illnesses. These include sepsis, acute blood loss or chronic anemia, pneumonia, pulmonary embolism, chronic obstructive pulmonary disease, congestive heart failure, dysrhythmias, or hypertensive urgencies. A recent retrospective study demonstrated that approximately 30% of patients present with an acute noncardiac condition concomitant with an MI, contributing to increased in-hospital mortality and variations in receipt of cardiac medications and invasive cardiac therapies. These “secondary” ACSs usually occur in the context of increased myocardial oxygen demand or hemodynamic stress in patients with underlying coronary artery disease and represent a substantial number of cases.

Elderly patients who present with ischemic-type symptoms, which are rapidly progressive, severe, and refractory or which occur at rest, should be immediately transferred to an emergency care setting for further evaluation. Initial testing for myocardial damage should consist of an ECG and cardiac biomarkers (troponin [I or T] and/or creatinine kinase isoforms [CK-MB]). Some patients will have clear ST elevation, making the diagnosis of ST-segment elevation MI (STE MI) straightforward. In others, however, the ECG may be nondiagnostic and the diagnosis often being confirmed by elevations and temporal trends of cardiac biomarkers, with or without accompanying EKG changes. These patients are classified as having non-ST-segment elevation ACS (NSTE ACS).

## PROGNOSIS

Multiple studies have shown that once CHD is manifested, the risk of morbidity and mortality increases steadily with age. In two very large randomized trials of patients having with ST elevation, age was the single strongest predictor of both short- and long-term mortality, with the risk of death increasing 6% with each year after 65 years of age. In another large registry population, patients aged 65 to 74 years admitted for an MI were four times more likely to die during the hospitalization than those aged 55 or younger. This risk rose

to greater than 10 times higher for patients aged  $\geq 85$  years. Elderly patients are also much more likely to suffer complications from their MI, including heart failure, cardiogenic shock, cardiac rupture, atrial fibrillation, stroke, acute renal insufficiency, and pneumonia. Finally, patients aged  $\geq 75$  years were three times more likely to be discharged to a nursing facility after an acute MI than those aged 65 to 69 years.

The reasons for increasing MI mortality and morbidity as a function of advancing age are multifold. Elderly patients have less cardiac reserve and more comorbid illness (e.g., pulmonary, renal, and cognitive impairments), limiting their ability to compensate for cardiac events. Also, as noted above, the elderly often present with “secondary” MIs where the cardiac event is a complication of another potential mortal primary process (i.e., sepsis), leading to high mortality. Finally, the elderly patients with MI present later, often receive less aggressive medical care, and undergo fewer potentially life-saving invasive procedures than younger patients.

## Acute Coronary Syndrome Therapies

### Fibrinolysis and Primary Angioplasty in Elderly Patients

The primary objective in the management of patients with STE MI is to provide early reperfusion therapy with either pharmacological means (i.e., fibrinolysis) or percutaneous intervention with balloon angioplasty. Numerous studies have confirmed that reperfusion therapy (fibrinolytic therapy or primary angioplasty) in patients presenting with acute STE MIs improves survival if performed in a timely fashion. An overview of the major thrombolytic trials from the Fibrinolytic Therapy Trialists’ Collaborative Group, a meta-analysis that included more than 58 000 patients, demonstrated a 15% relative risk reduction in death for patients 75 years of age or older with STE MI or bundle branch block treated with fibrinolytics. Despite elderly achieving a smaller relative reduction in death than younger patients, the trend toward absolute benefit in terms of lives saved with fibrinolytics was threefold greater in patients older than 75 years of age compared with those younger than 55 years.

In addition, an adjusted observational analysis from two studies using the Cooperative Cardiovascular Project database reported that patients aged  $\geq 75$  years actually had higher 30-day mortality with fibrinolysis than with standard medical therapy. Interestingly, in the one analysis that looked at 1-year outcomes, this early treatment risk in the very elderly reversed itself, and those treated with lysis actually had better survival rates after this interval (OR 0.84, 95% CI 0.79–0.89).

The possible therapeutic benefits of thrombolysis must be weighed carefully against the risks, especially in the elderly. Data from the Fibrinolytic Therapy Trialists’ meta-analysis showed that patients aged  $>70$  years had nearly a threefold higher relative risk of intracranial hemorrhage, the most feared complication in the post-lytic period, after fibrinolysis than those aged  $<60$  years. Bearing this in mind, clinicians should realize that intracranial hemorrhage is a rare event and the absolute risk of this complication after fibrinolysis in those  $>70$  years remains between 0.7% and 2.1% in major trials and nearing 3% in those older than 85 years of age. The risk factors for intracranial hemorrhage include low body weight, elevated blood pressures, facial or head trauma, and dementia. Dementia was found in one trial to significantly increase the risk for intracranial hemorrhage by threefold.

In contrast with these mixed results for fibrinolysis, reperfusion for STE MI with timely percutaneous transluminal coronary angioplasty (PTCA) is almost universally associated with improved outcomes in all age groups. For example, a recent randomized study of primary PTCA versus thrombolysis in patients with STE MI showed a 40% relative risk reduction for death, MI, and stroke in patients treated within 3 hours of presentation with PTCA. Primary PTCA in treatment of MI in the elderly is also supported by a series of observational analyses. In the Cooperative Cardiovascular Project analysis, acute PTCA was associated with lower 30-day and 1-year mortality when compared to no therapy or thrombolysis among elderly patients with acute MI.

The only caveat to the successes of primary PTCA in elderly patients was seen in a trial of patients with very-high-risk MI whose course was complicated by cardiogenic shock (i.e., hypotension and signs of poor tissue perfusion). In one trial, those randomized to primary PTCA had significantly higher survival rates; however, this effect was age dependent, and those  $>75$  years had actually had much higher mortality risk with PTCA.

### Antiplatelet Therapy

There is very strong evidence supporting the long-term benefits of aspirin in patients at risk of CHD. The Antithrombotic Trialists’ Collaboration, which performed a meta-analysis of aspirin trials and included more than 135 000 patients, identified a 25% risk reduction in cardiovascular events and noted that similar benefits were maintained in the older-aged patients. In the Physician’s Health Study of 44 000 men without known CHD, those randomized to aspirin had a 44% lower risk for subsequent MI versus those taking placebo. Observational data from the Nurse’s Health Study suggest similar benefits of aspirin for primary CHD prevention in women. These and other studies have led to the recommendation to treat all patients older than 40 years of age with one or more CHD risk factors with daily aspirin. Although the exact aspirin dose continues to be debated, evidence has suggested that efficacy of aspirin is not increased at doses greater than 150 mg/day, with higher doses increasing the risk for bleeding.

Clopidogrel, a thienopyridine that inhibits ADP-dependent platelet aggregation, was found to add incremental benefit to aspirin therapy in the setting on NSTEMI ACS by affording a 20% relative risk reduction in cardiovascular death, MI, or stroke in the Clopidogrel in Unstable Angina to prevent Recurrent Events trial. The study found similar benefits in elderly patients; nevertheless, registry data suggest that the in-hospital use of clopidogrel in elderly patients after MI remains low. The use of clopidogrel is recommended as an alternative to aspirin in the small subset of patients who are aspirin allergic. Patients who require long-term dual-antiplatelet therapy or oral anticoagulation with warfarin are advised to take a reduced aspirin dose of 81 mg daily.

Intravenous glycoprotein IIb/IIIa inhibitors have also been demonstrated to provide incremental value in patients with high-risk ACS (including ST-segment abnormalities and positive troponin) when used in combination with aspirin and heparin. For example, the Platelet Glycoprotein IIb/IIIa in Unstable Angina: Receptor Suppression Using Integrilin Therapy trial noted a significant overall reduction in death or nonfatal MI (14.2% vs. 15.7%;  $P = 0.04$ ) in patients who were treated with eptifibatid versus placebo. These benefits were also seen in patients aged 70 to 79 years. However,

among those aged 80 years or older, benefit was not observed and an associated increase in bleeding events was identified. These later findings suggest the importance of appropriate dosing of these agents in the elderly. In particular, the small molecule glycoprotein IIb/IIIa inhibitors (eptifibatid or tirofiban) are renally cleared; therefore, dosing reductions are often needed in elderly patients. Overall, glycoprotein IIb/IIIa inhibitors appear to have a role in appropriately selected elderly patients presenting with acute MI who are likely to undergo cardiac catheterization. Further research to identify dosing considerations specific to elderly patients and its safe and efficacious application to a heterogeneous elderly population will be needed.

### Antithrombin Therapy

Clinical trials of ACS have demonstrated reduction of cardiovascular events with the use of antithrombotic therapies, and these findings have been extended to the elderly population, making their use a class 1 recommendation by the ACC/AHA. Despite this, registry data reflect a decrease in use of antithrombotic therapy in elderly patients when compared to their younger counterparts. Unfractionated heparin, in conjunction with antiplatelet therapy, is associated with significant reduction in death or MI in patients with ACS, but important considerations involving their use are necessary as aged patients are more often susceptible to overdosing, reflected by an elevated partial thromboplastin time, and bleeding. The use of low-molecular-weight heparin for ACS has also been supported by evidence from clinical trials, with some suggestion of improved clinical outcomes, when compared with unfractionated heparin. Subgroup analyses of these studies have demonstrated a greater relative benefit in elderly patients treated with low-molecular-weight heparin, but concerns remain over the dosing of low-molecular-weight heparin in elderly patients, as these therapies are renally cleared and have been associated with excessive dosing and bleeding complications, which have translated to increased adverse events. There remains an ongoing need to further characterize and understand the efficacy and safety of antithrombotic therapies in elderly patients with ACS.

### Beta-blockers

Beta-blocker therapy has demonstrated benefit in reducing cardiovascular events and mortality in patients with post-MI. A meta-analysis of 25 randomized control trials showed a 25% reduction from beta-blockers in all-cause mortality and reinfarction in patients with prior MI. Data from an adjusted observational analysis demonstrated that elderly patients receiving beta-blockers following acute MI had a 33% reduction in 1-year mortality compared with those not treated. These long-term benefits are even more remarkable in patients having CHD with chronic heart failure and depressed left ventricular function. Beta-blockers decrease myocardial oxygen demand and improve coronary blood flow and are essential medications in the care of elderly patients with chronic angina.

While beneficial, elderly patients are often vulnerable to drugs with hypotensive actions and have altered responses to beta-blockers owing to conduction system deterioration and diminished adrenergic tone. Additionally, a recent trial found that early use of beta-blockers in patients with MI could worsen risks for congestive heart failure and result in poorer outcomes. Thus, medications should be

administered and titrated with caution in elderly patients along with a review of potential drug–drug interactions.

### Secondary Prevention Strategies

Medical therapy can play a key role in reducing the morbidity and mortality of CHD in all aged patients. In fact, as elderly patients with CHD face higher overall risk, the benefits of intervention in absolute terms actually tend to rise with age and the corresponding “number needed to treat” for these therapies fall. Secondary prevention therapies are aimed at reducing the recurrence of cardiovascular events in patients with prior MI. These therapies are targeted toward aggressive control of known traditional risk factors, such as hypertension, hyperlipidemia, and tobacco cessation.

Ongoing research has demonstrated that the renin–angiotensin–aldosterone system is a key determinant in hypertension, inflammation, atherosclerosis, and, ultimately, increased cardiovascular events. ACE inhibitors have strong support as safe and effective treatment of hypertension. They have also been shown to improve survival in patients having post-MI with depressed heart function, heart failure, and large anterior MIs. Most recently, the Heart Outcomes Prevention Evaluation study extended the benefits of ACE inhibitors to nearly all patients with either known CHD or who were at high risk of CHD. In Heart Outcomes Prevention Evaluation study, patients with CHD and other patients with high CHD risk (e.g., diabetes plus one or more cardiac risk factor) were randomized to 10 mg of ramipril daily versus placebo. After 5 years, treated patients had 26% lower risk of CHD death than those who were not treated. Rates of MI, congestive heart failure, stroke, renal dysfunction, and even development of diabetes were lower in the ACE-treated patient group. The treatment effects of ACE inhibition were greater in those patients aged  $\geq 65$  years than in younger patients. Current guidelines suggest consideration of ACE inhibitors in all patients having CHD with depressed ventricular function, diabetes, or hypertension. Some experts have suggested that these drugs be considered in all patients with known CHD regardless of other risk factors or left ventricular dysfunction, yet there remains conflicting evidence from clinical trials regarding this issue. Angiotensin receptor blockers (ARBs), similar to ACE inhibitors, are designed to produce antihypertensive and anti-inflammatory effects within the cardiovascular system, and recent studies demonstrate that these agents translate to decreased cardiovascular events. Several randomized control trials have shown that the ARBs can slow the progression of nephropathy in patients with diabetes and microalbuminuria in a fashion similar to ACE inhibitors. Overall, the data favor the use of established ACE inhibitors for primary and secondary prevention of cardiovascular events, with the consideration of ARB substitution in patients who are intolerant of ACE inhibitors (most commonly from troublesome cough). Patients who experience angioedema secondary to ACE inhibitor therapy should not be prescribed ARBs because of the risk of cross-reactivity. When used in elderly patients, however, one should carefully monitor serum electrolytes and creatinine, as these drugs can cause decreased renal function and hyperkalemia.

There are several classes of drugs marketed for lowering serum cholesterol. These include fibrates, bile acid sequestrants, niacin, fish oil, and the HMG-CoA (hydroxymethylglutaryl coenzyme A) reductase inhibitors (statins). Of these, statins have the most evidence supporting their efficacy in primary and secondary CHD prevention. A meta-analysis done with pooled data from five large statin

randomized control trials—two primary prevention and three secondary prevention studies—showed an average 31% relative risk reduction in coronary events and 29% relative risk reduction in coronary deaths. Unfortunately, of these five trials only one included patients aged  $\geq 65$  years and none included patients older than 75 years of age. Thus, the question of whether lipid lowering benefited the very elderly remained inconclusive until the recent Heart Protection Study.

The Heart Protection Study trial randomized more than 20 000 patients aged 40 to 80 years with known CHD or high-risk profiles to 40 mg of simvastatin daily or placebo. After 5 years, patients on simvastatin had a 16% relative risk reduction in cardiovascular deaths and 22% relative risk reduction in major cardiovascular events relative to placebo. Most importantly, the benefit of lipid-lowering therapy was independent of age and persisted among those in their middle eighties. Consistent with the results of this recent study, the NCEP guidelines for lipid-lowering therapy do not include age cutoffs or age-specific treatment recommendations. While lipid-lowering drugs are generally safe in elderly patients, routine monitoring of liver function studies are recommended.

Intensive lipid-lowering therapy in the post-MI period to prevent recurrent cardiovascular events has demonstrated benefit in elderly patients. In a post hoc analysis of the Pravastatin or Atorvastatin Evaluation and Infection Therapy-Thrombolysis in Myocardial Infarction (PROVE IT-TIMI 22) trial, elderly patients 70 years of age and older were found to derive greater benefit than younger counterparts in terms of reduction in cardiovascular events. In addition, the results suggested that if the NCEP optional LDL goal of less than 70 mg/dL were achieved, one could prevent four times as many events in the elderly as compared with the younger cohort. The benefits of statin therapy beyond lipid lowering alone—the so called pleiotropic effects—remain areas of ongoing investigation and suggest mechanisms of plaque stabilization, anti-inflammatory effects, and improvement in endothelial function as potential contributors to the overall cardiovascular benefit of these agents.

### Post-MI Testing

The post-MI period requires not only the initiation and continuation of the evidence-based medical therapies already reviewed but also further assessment of an individual's risk for future cardiovascular events. Care guidelines recommend that all those diagnosed with an MI should have an assessment of both left ventricular function (via echocardiography or other means) and coronary disease severity. In patients with NSTEMI ACS, the two options for assessment of post-MI risk are routine angiography with revascularization for all patients who have no contraindications or a conservative strategy

of medical therapy with patient selection for angiography based on symptoms or demonstrable ischemia on investigation (“ischemia-driven” approach). While in the past it had been suggested that “early invasive” (cardiac catheterization) and noninvasive (stress testing) approaches represented equivalent strategies, recent clinical trials suggest that the early invasive approach might be preferable for patients at increased risk of recurrent cardiovascular events. With the introduction of contemporary trials, the Treat Angina with Aggrastat and Determine Cost of Therapy with an Invasive or Conservative Strategy-Thrombolysis in Myocardial Ischemia/Infarction (TACTICS-TIMI)-18 trial randomized patients with unstable angina/NSTEMI ACS to one or the other of these strategies and found that those in the early invasive arm (within 48 hours) had nearly 20% lower rates of death, nonfatal MI, or rehospitalization at 6 months than conservatively treated patients. Interestingly, the successful enrollment of elderly patients (40% of patients were 65 years of age or older) allowed the identification of a 44% relative risk reduction in 30-day death or nonfatal MI among patients 65 years or older (invasive 5.7% vs. conservative 9.8%;  $P < 0.05$ ) and a 56% relative risk reduction in patients older than 75 years of age (invasive 10.8% vs. conservative 21.6%;  $P < 0.05$ ) with the early invasive strategy, findings consistent with a greater benefit in the elderly relative to younger patients.

## CORONARY REVASCULARIZATION

A major challenge in the care of elderly patients with CHD is related to who should be considered a candidate for coronary revascularization. In younger patients, randomized clinical trials have simplified this decision-making process by identifying subgroups in which PTCA or coronary artery bypass graft (CABG) surgery improves survival and/or quality of life beyond medical therapy. However, patients older than 75 years were generally not represented in these pivotal trials. Instead, clinicians and patients must rely on a careful comparison between the acute procedural risks and potential long-term benefits.

Procedural mortality rates following revascularization procedures rise dramatically and progressively with advancing age. Figure 76-3 displays the risks for in-hospital mortality following angioplasty and CABG from 123 991 patients in the National Cardiovascular Network Revascularization database. From these data, it is clear that age-associated risk in procedural mortality is not strictly linear but rises more rapidly beyond the age of 75 years. Additionally, at any age, patients with CABG face two- to threefold higher mortality risks than do patients receiving angioplasty. However, technological advances have led to improved procedural success rates and lower

**FIGURE 76-3.** In-hospital mortality following coronary artery bypass surgery and angioplasty by patient age (National Cardiovascular Network Registry 1994–1998).

risks for both procedures. Thus, despite the fact that procedures were performed on patients with higher risk, the risk of death after CABG in patients aged 65 years or older in the Society for Thoracic Surgery database declined nearly 20% between 1990 and 1999 and now rests at just above 4%. The Society for Thoracic Surgery has devised risk models that can be used to guide the impact of patient risk factors on operative morbidity and mortality and can be used in patient management. The web-based risk calculator can be found at <http://www.sts.org>.

Nonfatal procedural complications (stroke, MI, and renal failure) also rise in a curvilinear fashion with age and are higher in patients with CABG relative to those undergoing angioplasty. Of major importance to many elderly patients are the procedural risks of stroke and loss in mental acuity. Patients with CABG aged 75 years or older have a reported 3% to 6% incidence of permanent overt stroke as compared with a <1% incidence for angioplasty. Additionally, by using highly sensitive neurocognitive testing, Newman and colleagues found that up to 50% of patients of all ages undergoing CABG had measurable impairments in neurocognitive function at hospital discharge. Although half of patients with initial impairment recovered by 6 months, cognitive deficits reappeared in many of them during long-term follow-up and portended an impaired functional status. However, one recent study that compared cognitive ability after CABG to angioplasty and age-matched controls noted no meaningful clinical deterioration of cognitive performance between groups. Similarly, the initial enthusiasm of improving neurocognitive outcomes by performing off-pump CABG versus traditional on-pump CABG has been tempered by findings from a recent randomized trial, which demonstrated comparable cognitive outcomes between the two groups, although long-term follow-up has yet to occur. While increasing age is generally a major risk factor for procedural complications or mortality, it is not the only factor to consider. For example, by using published risk models, one can stratify an octogenarian's likelihood for mortality with CABG from 2% to 3% for a "healthy" patient without other comorbidities, to greater than 30% for the patient with multiple risk factors such as diabetes or preexisting cerebrovascular disease.

As with reperfusion therapy, the risks of revascularization must be balanced against the potential benefits in terms of prolonged survival, improved functional outcomes, or both. The Alberta Provincial Project for Outcomes Assessment in Coronary Heart Disease registry examined the care and outcomes of more than 6000 patients aged 70 to 79 years who underwent cardiac catheterization. Compared with medical therapy, those receiving CABG or PTCA had significantly higher adjusted 4-year survival rates (CABG 87%, PTCA 84%, medical therapy 79%,  $P < 0.001$ ). These survival benefits of revascularization also held for octogenarians and increased in all aged patients in proportion with the number of diseased vessels and the degree of left ventricular dysfunction. Results from the Alberta Provincial Project for Outcomes Assessment in Coronary Heart Disease registry have been confirmed in other observational analyses. Together, these studies strongly suggest that elderly patients with multivessel coronary disease have higher survival rates if treated with PTCA or CABG than if they are treated with medical therapy.

Beyond survival, there is also a growing body of literature to support the notion that PTCA and CABG also reduce angina symptoms and improve functional outcomes of elderly patients with CHD. Initially, these results were reported in observational studies that adjusted for treatment-selection issues, as well as other baseline clin-

ical factors. Most recently, similar results have been validated in the Trial of Invasive Versus Medical Therapy in Elderly Patients with Chronic Symptomatic Coronary Artery Disease trial. The Trial of Invasive Versus Medical Therapy in Elderly Patients with Chronic Symptomatic Coronary Artery Disease study randomized 305 patients with chronic angina, aged 75 years or older, to diagnostic catheterization (followed by coronary revascularization as appropriate) or optimized medical therapy with intervention only for those with refractory symptoms. Of those randomized to catheterization and intervention as appropriate, 74% underwent CABG or PTCA, while almost 33% of the conservative management arm crossed over to revascularization by 6 months. Patients in the early revascularization arm had significantly greater improvement in their symptoms and almost all aspects of functional status and quality of life when compared with medically treated patients. However, clinical end points in the trial were mixed, with a higher 6-month mortality rate but a lower incidence of nonfatal MI in the early invasive arm. While this randomized study was limited in sample size and presented several methodological challenges, its results do provide further support for the consideration of revascularization in the very elderly patient with CHD. While we await more representative randomized trials, the ACC/AHA guidelines stipulate that age should not be used as the sole criterion to rule out consideration of revascularization and that complex medical and surgical interventions have an adjunctive role in the care of elderly patients when in accordance with available scientific evidence and with the wishes of the patient.

## SPECIAL CONSIDERATIONS

### Underrepresentation in Clinical Trials

Clinical trials should closely approximate treated populations to increase applicability, yet almost all of the national treatment guidelines have been based on trials performed predominately in younger patients, and elderly patients have been routinely and greatly underrepresented. For example, up to 60% of cardiovascular clinical trials performed prior to 1990 explicitly excluded elderly patients. Even among recent studies (i.e., those published since 1995), fewer than 50% of studies enrolled a single patient aged 75 years or older. Patients older than 75 years comprise approximately 9% of the population enrolled in clinical trials of ACS therapies, but account for more than 37% of patients treated for ACS in the community. This age difference is reflected in the greater average age of patients treated for ACS in the community compared to trial populations, highlighting the known fact that patients treated for ACS in the community often have greater comorbidity and are at greater disease-related risk. This practice further complicates the interpretation of trial results when these are obtained with small samples of healthier, elderly patients. In addition, studies suggest that the elderly are often interested and willing to participate in clinical research and trial end points such as symptom burden, functional status, and quality of life, which can contribute meaningful information when applying results to the geriatric population. In order to improve the gap in care, which exists between the elderly and younger patients with ACSs, the current trend of limiting age exclusions and improving the enrollment of elderly patients is a first step toward understanding CHD in this heterogeneous population. Beyond the biologic

**TABLE 76-2****Key Differences in Elderly Patients**

## Cardiovascular

- Greater multivessel CHD
- Diastolic heart dysfunction
- Arterial stiffness, systolic hypertension, and endothelial dysfunction
- Increased conduction system disease

## General health

- Medical comorbidity
- Cognitive and functional impairment
- Atypical symptoms of disease

## Social

- More social isolation
- Hearing and visual impairments
- Limited or fixed financial resources
- Less formal education
- Different health-care expectations

## Drug related

- Polypharmacy
- Altered drug metabolism
- Different body composition
- Altered volume of distribution

## Biologic

- Anemia
- Altered coagulation and fibrinolytic proteins
- Elevated markers of inflammation

and cardiovascular changes observed with aging, fundamental ethical concerns are at the core of the patient–physician relationship, with particular emphasis on efforts to preserve individual autonomy and adhere to the doctrine of “do no harm.” The recognition of important differences between younger and older patients is at the foundations of providing patient-centered and effective care for the elderly (Table 76-2).

### Renal Function and Pharmacology

Consistently, an individual’s renal function remains a powerful predictor of cardiovascular morbidity and mortality. In the Cooperative Cardiovascular Project, renal dysfunction predicted adverse outcomes among an elderly post-MI population, such that 1-year mortality was 24% if serum creatinine was below 1.5 mg/dL and 66% if creatinine was above 2.5 mg/dL. The pitfalls attributed to using the serum creatinine as a surrogate for renal function are often compounded in the elderly. For example, most laboratories often report the result of a serum creatinine of 1.2 mg/dL as “normal.” However, when one considers that the sample is from an 85-year-old Caucasian female who weighs 125 pounds, using the Cockcroft–Gault formula, the estimated glomerular filtration rate is below 30 mL/min, consistent with severe renal impairment, and would necessitate dosing adjustments for many pharmacological agents. Consistent with recommendations from the Panel on Acute Coronary Care in the Elderly, the creatinine clearance should be calculated on all patients 75 years of age or older who present with an ACS. In addition, the clinician should remain cognizant of changes in the creatinine clearance during the index hospitalization and after discharge, as several medications prescribed may have an impact on renal function. From the Global Registry of Acute Coronary Events study, a

10 mL/minute decrease in creatinine clearance had the same impact on in-hospital mortality as a 10-year increase in age. The role of renal dysfunction in the management of elderly patients with ACSs cannot be overemphasized, as this entity plays a pivotal role at the interface of pharmacological management.

Cardiovascular drugs are among the most commonly prescribed therapies in elderly patients, and altered pharmacokinetics (i.e., drug distribution and metabolism) are frequently observed in elderly patients as a consequence of decreased lean body mass and volume of distribution. Combined, these factors lead to higher drug concentrations and prolonged half-lives. A drug’s pharmacodynamics (i.e., the effect of a drug on a target cell) can be considerably altered with age. For example, increased calcification of the cardiac conduction system can increase an elderly patient’s sensitivity to atrioventricular nodal blocking agents and lead to profound bradycardia. Comorbid illness and frailty can also influence drug selection and safety. For instance, a frail elderly person may have a higher risk of falling, which can markedly increase the likelihood of bleeding complications with anticoagulants. Finally, polypharmacy is often a serious issue in the elderly and can lead to life-threatening drug–drug interactions and poor compliance because of confusion over medications and/or prohibitive costs. It has been estimated that 25% of older patients have had at least one adverse drug reaction and that drug reactions are responsible for 3% to 10% of all hospital admissions in the elderly. Geriatricians have the adage, “start low, go slow,” in recognition of polypharmacy, altered drug distribution and clearance, and adverse drug reactions common among the elderly.

### Patient Preferences

Beyond physiological and pharmacological issues, cardiac treatment plans need to consider the patients’ overall health, as well as their health preferences and willingness to accept risk. While some elderly individuals engage in very active, independent lives well into their advanced years, others are frail and suffer from disabling physical and/or mental illnesses. Beyond this variability in health and functional status, there is great diversity in the health values of elderly patients. Some consider illness and disability to be inevitable and have no interest in extensive medical or surgical intervention. However, many elderly patients favor longevity if coupled with good cognitive ability and lack of neurological disability. In hospital settings, many elderly patients feel vulnerable and abdicate medical decision making to family or physicians, who are being entrusted to act in the patient’s best interest. It is incumbent on physicians caring for elderly individuals to attempt to directly elicit the elderly patient’s treatment goals, while providing the patient with the necessary information regarding potential risks and benefits of each treatment option.

### Social/Economic Issues

Finally, in devising a rational treatment plan for the elderly cardiac patients, physicians must consider the patient’s social and economic situation. Transportation issues, which are a major limitation for many elderly persons, can disrupt close office follow-up. Many elderly patients live on fixed incomes and may not realize or acknowledge that they cannot afford multiple cardiac medications. Hearing and visual deficits may impair health communication and comprehension. Prior negative experiences within the health-care

**FIGURE 76-4.** Evidence based care in elderly patients. Adherence to ACC/AHA guidelines improves outcomes. (Adapted from Alexander et al. *Evolution in Cardiovascular Case For Elderly Patients With Non-ST-Segment Elevation Acute Coronary Syndromes: Results From the CRUSADE National Quality Improvement Initiative.* *J Am Coll Cardiol.* 2005;46:1479, with permission.)

system may impact an elderly patient's willingness to receive care on subsequent occasions. The elderly population typically has fewer college graduates, and they are less likely to be connected to important sources of information and support. The health of an ailing spouse can also substantially impact on an elderly caregiver's personal health. Recently, one study found that the survival of a caregiving partner after hospitalization or death of a spouse was associated with an increased risk of death in the caregiver, particularly for the first 30 days. Although not thoroughly studied, clinicians must be aware of these fundamental issues and understand that additional time and attention are necessary to ensure proper communication during the physician–patient encounter.

## SUMMARY

Despite remarkable advances in prevention and treatment, CHD remains a major health problem for the elderly in terms of morbidity and mortality. As our population ages, the need for high-quality, well-informed cardiac care for patients aged  $\geq 75$  years will increase. Opportunities for improvement in care are highlighted by the fact that, given their greater age-related risks, older patients benefit as much, if not more, from existing therapies as do younger patients. However, the care of CHD in the elderly takes place within the context of their multidimensional health status and requires awareness of atypical presentations of ACS, altered pharmacokinetics of therapy, and underlying cognitive and functional status. Bearing this in mind, evidence continues to demonstrate that many treatment paradigms applied to younger patient groups are appropriate when treating very elderly patients, and adherence to ACC/AHA guidelines for ACS translates into better outcomes (Figure 76-4). Similarly, the durability of coronary artery revascularization over medical therapy for multivessel CHD in elderly patients has shown reduction in morbidity and mortality over time. The observation that cardiovascular trials have shifted to include broader enrollment of elderly patients and gather information beyond traditional endpoints will undoubtedly impact the evidence base of geriatric cardiology. The identification of physiological frailty through performance measures may offer additional risk assessment of elderly patients before complex medical therapy or revascularization is undertaken. This information could potentially identify a cohort of patients who may

benefit from a geriatric intervention program before or after hospitalization or revascularization. Finally, studies must focus on relative safety and efficacy in medical or procedural interventions when reporting results on elderly patients. There are significant challenges in this complex area of cardiovascular care, but redirecting efforts to a patient-centered model, while balancing risk versus benefit of selected strategies, may provide additional opportunity to both improve current care practices and limit harm and disability.

# Valvular Heart Disease

Nikhila Deo ■ Niloo M. Edwards

## AORTIC STENOSIS

### Etiology

Aortic stenosis is present in 2% to 9% of older patients and is the leading clinically significant valvular disorder in the elderly. The etiologies for aortic stenosis in this age group include calcification of a normal tricuspid aortic valve, calcification of a congenital bicuspid valve, and rheumatic valve disease.

Aortic stenosis in 90% of patients older than 65 years is caused by calcification of a tricuspid valve. The causes of aortic valvular calcification are unclear, although the process bears many similarities to atherosclerosis; both diseases are characterized by lipid deposition, inflammation, neoangiogenesis, and calcification. Even though the bicuspid aortic valve is the most common adult congenital cardiac anomaly and is present in approximately 2% of births, only one-third will progress to aortic stenosis with valve degeneration most frequently presenting in the fourth to sixth decade of life. Thus, it is not a major cause of aortic stenosis in the elderly. Similarly, rheumatic disease similarly presents earlier in life and often in association with mitral valve disease.

### Clinical Presentation and Diagnosis

Aortic stenosis has a long asymptomatic period of latency, when the only finding is a harsh, late-peaking, crescendo–decrescendo systolic murmur that radiates to the carotids and is best heard over the right, second interspace: The second heart sound ( $S_2$ ) may be paradoxically split. Characteristically, aortic stenosis is associated with “pulsus parvus et tardus”: meaning the patient has a weak and diminished pulse with a late upstroke that is most easily noted in the carotids. However, these characteristic physical findings may be less obvious both in the elderly, because of the ef-

fects of aging on the vascular bed, and when the ventricle starts to fail.

The American Heart Association recommends evaluation of early systolic, midsystolic grade 3 or greater, late systolic, or holosystolic murmurs with echocardiography. Older patients may present with ominous murmurs owing to aortic valve sclerosis without significant valvular stenosis. Aortic stenosis is graded as mild, moderate, or severe (Table 77-1).

On average, the rate of progression of disease has been estimated at an increase in jet velocity of 0.3 m/s/yr with an associated reduction in valve area of 0.1 cm<sup>2</sup>/yr. Despite these average rates of disease progression, the rate for any one individual is difficult to predict; therefore, asymptomatic patients with mild-to-moderate disease should be followed on a regular basis.

Aortic sclerosis is defined as aortic valve thickening without outflow tract obstruction. This pathology is present in 25% of patients older than 65 years and 48% of those older than 75 years; it is associated with male gender, hypertension, smoking, diabetes mellitus, and lipid abnormalities. The rate of progression to frank stenosis is not clear, but the Cardiovascular Health Study has identified an increased incidence of adverse cardiovascular outcomes in patients with sclerotic valve even when corrected for other cardiovascular risk factors. The mechanism for this association is unclear, and there are currently no guidelines for intervention.

Older patients slated for valve replacement should undergo preoperative coronary artery angiography. Measurement of the transvalvular gradient can aid in the diagnosis if there is a question about the severity of the stenosis; however, it is not recommended as a tool for assessment of the severity of disease in the asymptomatic patient, or if the noninvasive studies are consistent with the physical findings.

Impaired platelet function and decreased levels of Von Willebrand factor are also associated with severe aortic stenosis, and 20% of patients may present with epistaxis or ecchymoses; interestingly both abnormalities will resolve with valve replacement.

**TABLE 77-1****Echocardiographic Findings in Aortic Stenosis**

	MILD	MODERATE	SEVERE
Aortic valve area (cm <sup>2</sup> )	>1.5	1.0–1.5	<1.0
Velocity (m/s)	<3	3–4	>4
Mean gradient (mm Hg)	<25	25–40	>40

Patients with aortic valve stenosis also develop compensatory left ventricular hypertrophy, which can be seen both on echocardiogram and on electrocardiogram. The ventricular hypertrophy produces coronary malperfusion with subendocardial ischemia. These hypertrophied ventricles are also more sensitive to ischemic injury. Elderly females are prone to develop excessive ventricular hypertrophy, which may contribute to the higher perioperative morbidity and mortality in this cohort of patients.

Although aortic stenosis has a long latency, once symptoms develop the progression to death is rapid. The three classic symptoms are angina, syncope, and heart failure (Table 77-2). While sudden death occurs in 3% to 5% of patients with aortic stenosis and may be considered a fourth symptom group, this is rarely seen in asymptomatic patients. Unfortunately, the elderly often move into the symptomatic phase of aortic stenosis undetected because of the overlap of these major symptom constellations with other changes associated with aging.

Two-thirds of patients present with angina, which may be caused by concomitant coronary artery disease, although 40% of patients with severe aortic stenosis will present with angina without significant coronary artery disease. The most likely etiology for angina in the absence of coronary artery disease is subendocardial ischemia and the increased oxygen demands of the hypertrophied ventricle together with decreased coronary flow reserve. Untreated patients with aortic stenosis and angina have a 50% 5-year survival.

In the elderly, syncope is often caused by aortic stenosis. Syncope in this setting may be caused by inadequate cardiac output to meet demands, by dysfunctional left ventricular baroreceptor response, or by arrhythmias and is associated with a 50% 3-year mortality without valve replacement.

Aortic valve stenosis presenting with congestive heart failure carries the worst prognosis: 50% mortality at 2 years if not treated with valve replacement. The typical symptoms include paroxysmal nocturnal dyspnea, orthopnea, and dyspnea on exertion, which may be associated with signs of peripheral edema, pulmonary edema, and rales. Thickening of the left ventricle owing to aortic stenosis as well as the changes associated with aging both lead to diastolic dysfunction, consequently the older patient with aortic stenosis is more dependent on atrial contraction for ventricular filling. There-

fore, these patients often present with exacerbated or new onset of symptoms if they develop atrial fibrillation.

## Management

### Asymptomatic Patients

Survival of asymptomatic patients is the same as age-matched individuals without aortic stenosis; however, given the significant decline in survival once symptoms develop, it is essential to consider surgical intervention and to confirm the absence of symptoms in the patient who does not appear symptomatic. If a careful history fails to elicit symptoms and the patient has severe aortic stenosis, exercise testing may be considered. Exercise testing in symptomatic patients is not indicated and should not be performed because of the high risk of complications.

Patients who are asymptomatic by history but who on exercise testing develop symptoms or fail to generate a 20 mm Hg increase in blood pressure or develop ST-segment abnormalities have a 19% 2-year symptom-free survival compared with 85% 2-year symptom-free survival for patients who do not manifest these abnormalities on exercise testing. Exercise testing may elicit symptoms in as many as a third of patients thought to be asymptomatic by history alone. Close supervision and prompt termination of the study at any decline in blood pressure, significant ST-segment depression, or onset of arrhythmia are strongly advocated. On average, the probability of a patient with severe aortic stenosis remaining symptom free at 5 years is only 50%, which has prompted some to recommend earlier surgery while the patient is “younger” and in better health to undergo valve replacement.

If the patient is truly asymptomatic, continued frequent routine monitoring is reasonable, but patient should be instructed to report any development of chest pain, tightening, or pressure; syncope, lightheadedness, or dizziness; and any sign of congestive heart failure. Monitoring should include annual or biannual echocardiograms for patients with severe aortic stenosis, every 1 to 2 years for patients with moderate aortic stenosis and echocardiograms every 3 to 5 years if the stenosis is mild, although echocardiograms should be performed as needed if the patient develops symptoms. Patients who are demonstrated to be symptom free do not need to have their activity restricted and may participate in exercise.

### Medical Management

Once patients develop symptoms the patient should be considered for valve replacement. However, if the patient is asymptomatic or not a candidate for surgery, consideration should be given to medical management, even though there is no demonstrated survival advantage. Medical management includes antibiotic prophylaxis for endocarditis, antihypertensive management, and possibly statins. Although antihypertensive therapy with angiotensin-converting enzyme inhibitors and beta-blockers is warranted for the patient with hypertension, these should be initiated with caution in the elderly.

The American Heart Associate guidelines states that “patients who develop symptoms require surgery, not medical therapy”; nonetheless, every patient should be assessed based on their individual risks and benefits before advocating valve replacement. Given the similarities in histopathology between atherosclerosis and aortic stenosis, early retrospective studies suggested that statin therapy

**TABLE 77-2****Aortic Stenosis Symptoms**

SYMPTOM	50% MORTALITY (yr)
Angina	5
Syncope	3
Failure	2

might retard the rate of progression of aortic valvular stenosis; however, a more recent randomized prospective study has not demonstrated a benefit to statins over placebo. Currently, there is no documented medical treatment that will delay or reverse aortic valvular stenosis; therefore, any treatment other than surgery should be considered palliative care.

### Percutaneous Aortic Valvuloplasty

Balloon valvuloplasty is not a substitute for surgery but is a useful tool in the treatment armamentarium for temporary palliation of symptoms for nonsurgical candidates or as a bridge for patients with hemodynamically unstable aortic stenosis. The procedure uses transvalvular balloon inflations to crack the calcified aortic valve; unfortunately, the maximum enlargement rarely exceeds 1.0 cm<sup>2</sup> (severe-to-moderate aortic stenosis), carries a 10% risk of complications, and results in restenosis within 6 months to a year. One-year actuarial mortality is 35% to 50%, which is not better than untreated aortic stenosis, but it can result in significant relief of symptoms and improvement in quality of life.

On a more optimistic note, clinical studies are currently underway to explore deployment of percutaneously placed aortic valves. At this time, the data are too limited to determine the risks and durability of this procedure.

### Surgical Management

The development of symptoms is a clear indication for valve replacement. Current American Heart Association recommendations are listed in Table 77-3. Aortic valve replacement is recommended for all symptomatic patients because of the improvement in both symptoms and survival. Moreover, since there is an increased risk of sudden death, replacement should be performed as soon as feasible after the development of symptoms. Age alone is not a contraindication

to surgery, and to date numerous studies have demonstrated outcomes in elderly similar to those seen in younger patients. For example, as in younger patients, mortality in the elderly ranges from 3% to 4% to as high as 24%. On average, mortality for older patients in retrospective studies reportedly varies between 9% and 12%. The variability in published studies is the result of both patient selection and the definition of “older patient”—which varies from cohorts aged 65 to 80 years. Medicare outcomes data for 142 000 patients older than 65 years demonstrate a perioperative mortality of 8.8% and only 6.0% mortality in high-volume centers.

Predictors of mortality in this patient population include emergent surgery, right heart failure, severity of symptoms (NYHA class IV), renal insufficiency, female gender, depressed left ventricular function, associated coronary bypass, or mitral valve surgery. Consistent with most studies is the finding that emergent surgery increases the surgical risk substantially. This is often the result of a failure to refer the patient for elective surgery because it is “too risky,” but reconsidering the patient as a suitable surgical candidate when the patient is critically ill and the medical options have dwindled to none. Unfortunately the result is a self-fulfilling prophecy that older patients will not do well with surgery. A European study of older patients with aortic stenosis provocatively demonstrated that 41% of patients older than 70 years were not offered surgery despite severe valve stenosis and symptoms; these findings were corroborated in a second study of 1200 patients from 92 centers in 25 countries. In this study, 33% of patients older than 75 years with severe symptomatic aortic stenosis were denied valve replacement.

Although many studies have found that concomitant coronary artery bypass or mitral valve surgery increases the surgical risk, there is clear support for performing concomitant aortic valve replacement for any patient with severe aortic stenosis, who is undergoing any other cardiac surgical procedure, regardless of symptoms. Similarly, in patients with moderate stenosis, it is “accepted practice” to replace the aortic valve at the time of other cardiac surgery. Simultaneous valve replacement in patients with mild aortic stenosis undergoing heart surgery is more controversial, although an argument can be made for concomitant replacement in patients with mild stenosis but moderate-to-severe valve calcification.

**TABLE 77-3**

#### American Heart Association Recommendations for Valve Replacement in Aortic Stenosis

Indications for valve replacement in aortic stenosis

- Symptomatic patients with severe aortic stenosis
- Patients with severe aortic stenosis undergoing coronary artery bypass surgery (CABG)
- Patients with severe aortic stenosis undergoing other valvular or aortic surgery
- Patients with severe aortic stenosis and left ventricular dysfunction (ejection fraction less than 50%)

Considerations for valve replacement in aortic stenosis

- Patients with moderate aortic stenosis undergoing CABG
- Patients with moderate aortic stenosis undergoing other valvular or aortic surgery

Possible indications for valve replacement in aortic stenosis

- Asymptomatic patients with severe aortic valve stenosis with abnormal exercise testing
- Patients with mild aortic stenosis, with moderate-to-severe valve calcification who are undergoing coronary artery bypass surgery
- Severe asymptomatic stenosis in patients with a high likelihood of progression
- Critical aortic stenosis (valve area <0.6 cm<sup>2</sup>, mean gradient >60 mm Hg, jet velocity >5.0 m/s) if the operative mortality is less than 1.0%

## AORTIC INSUFFICIENCY

### Etiology

Aortic insufficiency is seen in 20% to 30% of individuals older than 65 years. Most often the valvular regurgitation is mild and is caused by aortic valve sclerosis or root dilatation as a result of hypertension or atherosclerosis. Other important causes of valvular insufficiency include ascending aortic dissection and endocarditis. Similar to aortic stenosis, there is a long latency period during which the patient is asymptomatic. However, even asymptomatic patients with normal left ventricular function have a 0.2% incidence of sudden death and will progress to symptomatic disease at a rate of approximately 3.5% per year and develop either left ventricular dysfunction or symptoms at a rate of approximately 6% per year. Once patients develop left ventricular dysfunction, more than 25% each year will progress to symptomatic disease and, once symptomatic, the mortality rate for aortic regurgitation is more than 10% per year.

**TABLE 77-4****Partial List of Eponymous Signs of Aortic Insufficiency**

EPONYM	PHYSICAL FINDING
Austin–Flint murmur	Low-pitched mid-diastolic rumble
Becker sign	Accentuated retinal artery pulsation
Corrigan pulses	Rapidly rising and falling pulse to palpation
de Musset sign	Bobbing of head
Duroziez sign	To-and-fro femoral artery murmur with compression
Gerhard sign	Pulsatile spleen
Hill sign	Higher BP in lower than upper extremity
Mayne sign	Decrease in blood pressure with arm elevated
Mueller sign	Pulsatile uvula
Quincke sign	Pulsatile nail beds
Rosenbach sign	Pulsatile liver
Traube sign	Double femoral artery pulse sound
Sherman sign	Dorsalis pedis pulse prominent in patients older than 75 yr
Watson's water hammer pulse	Bounding peripheral pulse

The five identified risk factors for the development of left ventricular dysfunction, symptoms, or death include age, left ventricular end-systolic dimension/volume, left ventricular end-diastolic dimension/volume, and left ventricular ejection fraction with exercise. Each year 19% of patients with end-systolic size greater than 50 mm develop left ventricular dysfunction and symptoms or die. The rate of development of these same end-points was 6% per year for patients with end-systolic size between 40 and 50 mm.

### Clinical Presentation and Diagnosis

The findings and eponyms associated with aortic insufficiency are a delight to lovers of medical trivia (Table 77-4); however, the most obvious physical findings are those of a diastolic murmur and a widened pulse pressure. Echocardiography provides both diagnostic confirmation and assessment of the severity of valve regurgitation; it also allows evaluation of both the valve and the aortic root as well as an assessment of left ventricular function and dimension. It is an excellent modality for monitoring left ventricular size and function, although these parameters can also be followed by cardiac magnetic resonance imaging or radionuclide angiography. Exercise testing may be reasonable for asymptomatic patients who wish to initiate an exercise regimen, but the results have not been consistently useful in predicting outcomes for asymptomatic patients with normal resting cardiac function.

Patients may present with angina or signs and symptoms of congestive heart failure. Surgery is indicated for patients who develop either angina or signs of congestive heart failure, since the mortality for patients with angina is more than 10% per year and for heart failure is more than 20% per year. Medical management in symptomatic patients results in poor outcomes even if the left ventricular function is normal. Patients older than 75 years are more likely to develop either symptoms or ventricular dysfunction at earlier stages of the disease and have a poorer prognosis once they develop ventricular dysfunction. Concomitant coronary artery disease should be ruled out by angiography in any older patient considered for valve replacement surgery.

## Management

### Medical Management

The medical management of aortic insufficiency is best achieved with vasodilators that reduce afterload and wall stress and, perhaps, ameliorate left ventricular dysfunction. Since symptomatic disease carries such a poor prognosis without surgery, medical management is primarily indicated for patients who are not surgical candidates because of comorbidities, to preoperatively optimize hemodynamics, or for asymptomatic hypertensive patients with normal ventricular function. Conflicting data exist as to the benefits of hydralazine, ACE inhibitors, and calcium channel-blockers, which suggests that vasodilator therapy is not indicated for asymptomatic, normotensive patients with normal ventricular function. However, once symptoms or ventricular dysfunction develops, the patient should be considered and evaluated for surgery.

The absence of data indicating that exercise contributes to the progression of aortic insufficiency would suggest that the asymptomatic patient with normal left ventricular function may participate in the full range of physical activities, with the exception of isometric exercises, which are contraindicated. However, it is prudent to exercise test patients to the anticipated level of activity to assess tolerance prior to initiating an exercise regimen.

Patients with aortic regurgitation should have regularly scheduled follow-up. Mild regurgitation with normal ventricular function can be followed clinically on an annual basis with biennial or triennial echocardiograms; more severe valvular regurgitation should be followed with annual or even biannual echocardiograms depending on the presence of ventricular dilatation (60 mm). Asymptomatic patients with more severe dilatation (>70 mm) should be followed with echocardiograms every 4 to 6 months because the likelihood of developing symptoms or ventricular dysfunction is as high as 20% per year.

### Surgical Management

Surgery is not indicated for asymptomatic patients with normal ventricular function and minimal ventricular dilatation regardless of the severity of valvular regurgitation; however, once symptoms or left ventricular dysfunction develops in patients with severe aortic regurgitation, the patient should be considered for surgery (Table 77-5). Although significantly better than medical management, patients with severe left ventricular dysfunction have a high operative mortality (at least 10%) and a lower postoperative survival; therefore, asymptomatic patients should be closely followed for the development of left ventricular dysfunction.

In older patients with severe compensated aortic insufficiency, the onset of symptoms can be hard to ascertain, since mild dyspnea on exertion and fatigue often mimic the effects of aging. However, once ventricular dysfunction develops, the older patient is more likely to have continued postoperative ventricular dysfunction and symptoms, as well as decreased postsurgical survival. Therefore, in patients without comorbidities that contraindicate surgery, an earlier commitment to surgery carries a better overall prognosis.

If the patient is asymptomatic but the left ventricular end-diastolic dimension exceeds 75 mm, surgery should be considered because of the high risk of sudden death. Although the surgical treatment of asymptomatic patients with severe aortic regurgitation and left ventricular dilatation is controversial, if surgery is planned based

**TABLE 77-5****Recommendations for Surgery in Aortic Insufficiency**

Indications for valve replacement in aortic insufficiency

- Symptomatic patients with severe aortic regurgitation
- Asymptomatic patients with severe aortic regurgitation and left ventricular ejection fraction less than 50%
- Patients with severe aortic regurgitation undergoing other cardiac surgical procedures

Considerations for valve replacement in aortic insufficiency

- Asymptomatic patients with severe aortic insufficiency, normal left ventricular function and dilated ventricles—LVEDD >75 mm

Possible indications for valve replacement in aortic insufficiency

- Patients with moderate aortic insufficiency undergoing other cardiac surgical procedures
- Asymptomatic patients with severe aortic regurgitation, normal cardiac function, and left ventricular dilatation greater than 70 mm, in conjunction with progressive dilatation and decreased exercise capacity

on ventricular size or function, two consecutive studies should confirm the findings. Certainly consideration for surgery in the asymptomatic elderly patient should be carefully considered, if not avoided until symptoms develop.

## MITRAL STENOSIS

### Etiology

The overwhelming majority of mitral stenosis is caused by rheumatic heart disease; other etiologies are rare and include left atrial thrombus, left atrial myxomas, and other tumors. Therefore, this valvular disease tends to occur in the younger patient and is rarely seen in the elderly, although the number may be increasing. In developed countries, most patients present in their forties and fifties, although some studies note that a third of their patients are older than 65 years. Only 60% of patients presenting with mitral stenosis recall a history of rheumatic fever, which causes thickening and calcification of the leaflets and cordae as well as shortening of the cordae and fusion of the commissures. This results in a decrease of the mitral valve orifice, which normally measures 4.0 to 5.0 cm<sup>2</sup>. The disease progresses very slowly, and it is estimated that the mitral valve area decreases by 0.09 to 0.32 cm<sup>2</sup> per year. When the valve area is reduced to 2.5 to 1.5 cm<sup>2</sup>, patients start to develop symptoms. Significant valvular disease lags the development of rheumatic fever by 20 to 40 years; however, once symptoms start, the 10-year survival is only 50% to 60%. Patients who are asymptomatic or with minimal symptoms have an 80% survival for 10 years, with as many as 60% of patients having no progression of symptoms. However, once significant symptoms develop, the 10-year survival is as low as 0% to 15%. Patients with severe pulmonary hypertension usually live less than 3 years, and most patients will die from progressive pulmonary hypertension, congestive heart failure, systemic embolic, pulmonary emboli, or infection.

### Clinical Presentation and Diagnosis

Most often, mitral stenosis presents with new-onset atrial fibrillation or an embolic event, sometimes patients come to medical attention

because of fatigue or dyspnea and rarely because of hemoptysis or hoarseness. The onset of atrial fibrillation can result in pulmonary edema and death. On physical examination, an opening snap may be noted to the first heart sound associated with a diastolic rumble.

Evaluation of patients with suspected mitral stenosis includes an echocardiogram, both to confirm the diagnosis and assess the severity of the disease as well as to assess therapeutic options. Patients are deemed to have mild mitral stenosis if the valve area is greater than 1.5 cm<sup>2</sup>, moderate if the valve area is 1.0 to 1.5 cm<sup>2</sup>, and severe if the mitral valve area is less than 1.0 cm<sup>2</sup>. Additionally, pulmonary pressures should be assessed, since these are helpful in grading the severity of the disease.

## Management

### Medical Management

It should be emphasized that medical management cannot reduce a mechanical narrowing like mitral stenosis; however, increasing diastolic filling time by slowing heart rate may be helpful in patients in sinus rhythm and exertional symptoms. Often, medical regimens include a beta-blocker or calcium channel blocker to reduce heart rate and increase diastolic fill time, as well as sodium restriction and a diuretic to ameliorate pulmonary edema. Additionally, patients with mitral stenosis should receive antibiotic prophylaxis for endocarditis for high-risk procedures (Tables 77-6 and 77-7). Asymptomatic patients should be followed closely for the development of symptoms, at which time they should be assessed by echocardiogram.

A substantial number of patients (30–40%) will present with atrial fibrillation, especially the older patient. Both age and left atrial size are predictive of the development of atrial fibrillation. Unfortunately, the development of atrial fibrillation carries a more guarded prognosis, since only 25% of patients with atrial fibrillation will survive 10 years compared to 46% of those who remain in sinus rhythm. Treatment for atrial fibrillation includes anticoagulation,

**TABLE 77-6****Endocarditis Prophylaxis Procedures**

	<b>ENDOCARDITIS PROPHYLAXIS IS RECOMMENDED</b>	<b>ENDOCARDITIS PROPHYLAXIS IS NOT REQUIRED</b>
Respiratory procedures	<ul style="list-style-type: none"> <li>• Oral surgery including tonsillectomy and adenoidectomy</li> <li>• Respiratory tract surgery involving mucosal surfaces</li> <li>• Rigid bronchoscopy</li> </ul>	<ul style="list-style-type: none"> <li>• Intubation</li> <li>• Flexible bronchoscopy</li> </ul>

TABLE 77-7

## Prophylactic Antibiotic Recommendations

	ANTIBIOTIC	DOSAGE
Standard	Amoxicillin	2.0 g PO 1 h before procedure
Penicillin	Clindamycin	600 mg PO 1 h before procedure
allergic	Cephalexin	2.0 g PO 1 h before procedure
Unable to take oral medicines and Penicillin allergic	Ampicillin	2.0 g IV or IM 30 minute before procedure
	Clindamycin	600 mg IV 30 minute before procedure
	Cefazolin	1.0 g IV or IM 30 minute before procedure

rate control, and electrical or chemical cardioversion, especially if associated with hemodynamic instability. Patients who remain in atrial fibrillation for more than 24 to 48 hours are at increased risk of embolic complications and should be promptly anticoagulated. Electrical cardioversion may be used but only after confirming the absence of a left atrial thrombus by echocardiogram; if a thrombus is present, treatment may include 3 weeks of anticoagulation, followed by confirmation of the absence of thrombus by repeat echocardiography and subsequent defibrillation. In this setting, transesophageal echocardiography is often the diagnostic tool of choice.

Atrial fibrillation often becomes refractory to treatment; should the patient develop paroxysmal or permanent atrial fibrillation, long-term anticoagulation is warranted. Certainly patients with either prior emboli or left atrial thrombus should be anticoagulated regardless of rhythm. Systemic emboli may occur in as many as 20% of patients; again age (and atrial fibrillation) is predictive of embolization. Paroxysmal and persistent atrial fibrillations as well as prior embolic events increase the risk of recurrent embolization; therefore, anticoagulation is indicated.

Older patients, patients with atrial fibrillation, and patients with prior history of emboli are at high risk for systemic embolization, which is as high as 20% in patients with mitral stenosis. Therefore, anticoagulation is recommended for mitral stenosis patients with atrial fibrillation, previous emboli, or left atrial thrombus. Additionally, warfarin may be appropriate for mitral stenosis patients with large left atria (greater than 55 mm), especially in conjunction with “smoke” or spontaneous contrast on echocardiogram.

Exercise is not contraindicated in asymptomatic patients with mild mitral stenosis. In patients with more severe stenosis, exercise is often limited by symptoms; therefore, exercise regimens for patients with more symptomatic or severe disease should be individually tailored.

### Percutaneous Mitral Valvuloplasty

Percutaneous mitral valvuloplasty is successful in selected patients and often doubles the valve area with a substantial decrease in valve gradient. The selection of patients best suited for this treatment option is determined by echocardiographic assessment of the valve, which is based on leaflet mobility, subvalvular apparatus, leaflet thickening, and the presence of calcium. The lowest scores are assigned to valves with the greatest leaflet mobility, the least subvalvular thickening, the most normal leaflet thickness, and the least calcium

TABLE 77-8

## Risk of Percutaneous Mitral Valvuloplasty

COMPLICATION	PERCENT RISK
Left ventricular perforation	0.5–4.0
Systemic embolization	0.5–3.0
Myocardial infarction	0.3–0.5
Death	1.0–2.0

deposition; patients with these valve characteristics (lowest scores) are predicted to have the best response to balloon valvuloplasty. The majority of patients (90%) will see symptomatic relief, with a freedom from valve-related complications or death of between 50% and 65% at 7 years and as high as 80% to 90% in patients with favorable (low) pre-procedural echocardiographic scores.

Symptomatic patients or patients with pulmonary hypertension, those with favorable echocardiographic mitral valve scores and without atrial thrombi, should be referred for mitral valvuloplasty. The risks for percutaneous mitral valvuloplasty are low (Table 77-8); therefore, even patients with less favorable echocardiographic scores who are at high surgical risks may be considered candidates for this percutaneous approach. However, this approach is contraindicated in patients with moderate-to-severe mitral regurgitation and/or the presence of left atrial clot. Unfortunately, older patients (older than 65 years) have a lower success rate, higher incidence of complications, and shorter duration of symptom relief with this approach.

### Surgical Management

As a result of the success of balloon valvuloplasty in patient with favorable valve morphology, surgery is usually indicated only if the patient has failed percutaneous intervention or if the valve characteristics make it unfavorable for balloon valvuloplasty. Patients with mitral stenosis in conjunction with moderate or severe mitral regurgitation are best treated surgically, as are patients with left atrial thrombus, which has not resolved despite an appropriate period of anticoagulation. Since balloon valvuloplasty requires a significant level of expertise and the outcomes are related to experience, the American Heart Association recommends surgery if this experience is not available.

Patients with mild symptoms, severe pulmonary hypertension, and moderate-to-severe mitral stenosis may also benefit from surgery if balloon valvuloplasty is not appropriate or available; similarly, patients with recurrent systemic emboli despite therapeutic anticoagulation may benefit from surgical intervention if ineligible for percutaneous treatment (Table 77-9). Notably, surgery is not recommended for patients with isolated mild mitral stenosis.

The surgical options include open repair with commissurotomy or valve replacement with either a mechanical or a bioprosthetic valve. The surgical risk increases with decreased preoperative functional status, age, cardiac function, pulmonary hypertension, and the presence of coronary artery disease. Operative mortality can be as high as 20% in the older patient with significant comorbidities and pulmonary hypertension; nonetheless, it is not recommended to wait until the patient becomes severely symptomatic (NYHA IV), since this results in a substantial increase in the surgical risk. Conversely, surgery should be considered despite severe symptoms, since

**TABLE 77-9****Surgical Recommendations for Mitral Stenosis**

Indications for valve replacement in mitral stenosis

- Symptomatic patients who are unable to undergo balloon valvuloplasty (owing to unavailability, contraindications, or unfavorable valve score)
- Symptomatic patients with moderate or severe stenosis and moderate or severe mitral regurgitation

Considerations for valve replacement in mitral stenosis

- Mildly symptomatic patients with severe mitral stenosis and severe pulmonary hypertension if ineligible for balloon valvuloplasty

Possible indications for valve replacement in mitral stenosis

- Patients with recurrent emboli despite anticoagulation

both quality of life and survival are exceedingly poor without surgical intervention.

## MITRAL REGURGITATION

### Etiology

The causes of mitral valve regurgitation can be divided into two broad categories: functional or organic. Organic regurgitation is caused by problems with the valve leaflets, the cordae, the papillary muscles, or the mitral annulus. The most common cause of organic valvular regurgitation include mitral valve prolapse, rheumatic heart disease, endocarditis, and coronary artery disease.

Mitral valve prolapse is present in 1% to 2.5% of the population and can occur either spontaneously or as a familial disorder; the latter is associated with a low but significant incidence of sudden death, presumably owing to ventricular arrhythmias. Acute mitral regurgitation, which can occur as a consequence of endocarditis or ruptured cordae or owing to a ruptured papillary muscle, is poorly tolerated because of the sudden volume overload and will present with shock and/or respiratory distress because of pulmonary edema. Chronic mitral regurgitation is better tolerated but, when severe, especially in association with a flail leaflet, is associated with a 7% per year mortality. A common cause of chronic mitral regurgitation in the elderly is myxomatous mitral valve disease. Patients with severe mitral valve regurgitation and a low ejection fraction have a poor prognosis; patients with ejection fractions less than 50% have a 32% 10-year survival, compared to 70% 10-year survival for patients with ejection fractions greater than 60%; even patients with borderline normal ejection fractions between 50% and 60% have decreased 10-year survival of only 53% if not corrected.

### Clinical Presentation and Diagnosis

Patients with mitral valve prolapse may present with palpitations, atypical chest pain, dyspnea, easy fatigue, or panic attacks. Cessation of caffeine, tobacco, alcohol, and other stimulants may help control the anxiety in some patients. Acute mitral regurgitation presents either with shock or with respiratory distress, while more chronic regurgitation presents with dyspnea on exertion, pedal edema, and other signs of chronic volume overload and congestive heart failure.

Physical examination reveals a systolic ejection murmur, which is best heard at the apex of the heart with radiation to the axilla. As with other cardiac valvular problems, the diagnosis is best confirmed and quantified by echocardiogram. This study allows assessment of severity of regurgitation, putative cause of the valve dysfunction, as well as assessment of left ventricular ejection fraction. Patients without organic causes for mitral regurgitation should be assessed, based on patient history, for other etiologies such as coronary artery disease.

## Management

### Medical Management

Asymptomatic patients with organic moderate mitral regurgitation may be followed with annual echocardiograms; however, asymptomatic patients with organic severe regurgitation should probably undergo exercise testing to confirm the absence of symptoms or limitations and if truly asymptomatic should undergo restudy by echocardiogram every 6 to 12 months. The asymptomatic patient with organic mitral regurgitation, a normal ejection fraction without pulmonary hypertension, or left ventricular dilation may exercise without restriction.

Medical management consists mostly of control of hypertension, with vasodilators and diuretics. Once symptoms develop, either from atrial fibrillation or from volume overload, if the patient is not a surgical candidate, treatment is focused on the treatment of the symptoms as well as preload reduction. Endocarditis prophylaxis is recommended for all patients with mitral valve prolapse and patients with moderate or severe organic mitral regurgitation.

### Surgical Management

The surgical options consist of either repair or replacement (Table 77-10). All patients should be considered with an eye to repairing the valve because of the marked improvement in survival, left ventricular function, and the avoidance of long-term anticoagulation with valve repair compared to valve replacement. Although

**TABLE 77-10****Surgical Recommendations for Mitral Regurgitation**

Indications for valve repair or replacement in mitral regurgitation

- Patients with mild-to-severe symptoms and severe mitral regurgitation and normal left ventricular size and function
- Asymptomatic patients with severe regurgitation and decrease left ventricular function (<60%) or ventricular dilatation (>40 mm)
- Acute mitral regurgitation

Considerations for valve repair or replacement in mitral regurgitation

- Asymptomatic patients with severe regurgitation and normal left ventricular size and function IF the valve can be repaired with a high degree of certainty
- New-onset atrial fibrillation in asymptomatic patients with severe regurgitation with normal left ventricular size and function
- Pulmonary artery hypertension in asymptomatic patients with severe regurgitation with normal left ventricular size and function

Not indicated for valve repair or replacement in mitral regurgitation

- Asymptomatic patients with severe regurgitation with normal left ventricular size and function when repair is unlikely
- Mild or moderate mitral regurgitation

durability of repair is excellent with freedom from reoperation equaling that of valve replacement (7%–10% at 10 years), the freedom from reoperation is dependent on the adequacy of the repair, whether the repair involved the anterior or the posterior valve leaflets, and whether cordal replacement was necessary. Patients with isolated posterior leaflet pathology are more likely to have long-term success compared to patients with anterior or bileaflet repairs.

Mitral replacement when necessary should strive to retain as much of the mitral valve apparatus as possible. Preservation of these structures results in improved left ventricular function, exercise tolerance, and survival. The choices for mitral valve replacement include bioprosthetic or mechanical valves. Bioprosthetic valves in the mitral position are not as durable as a bioprosthetic valve in the aortic position; however, this family of valves avoids the risks of lifelong anticoagulation. Conversely, a mechanical valve has the advantage of durability but requires a commitment to lifetime anticoagulation.

Mitral valve repair or replacement is indicated for all patients with symptoms (NYHA Class II–IV) and severe regurgitation even in the face of normal cardiac size and function. Asymptomatic patients benefit from surgical intervention if they develop atrial fibrillation, pulmonary hypertension, left ventricular dysfunction (ejection fraction <60%), or dilation (>40 mm). In patients with atrial fibrillation, an intraoperative maze or modified maze procedure combined with suture closure of the left atrial appendage should be considered, in order to reestablish sinus rhythm and possibly reduce the risk of systemic embolization, respectively. Once left ventricular dysfunction develops, patient survival even after repair or replacement is compromised; therefore, patients who are asymptomatic, with normal left ventricular size and function, should be followed closely, and, if necessary, exercise testing should be considered to confirm the absence of symptoms. Surgical intervention may be warranted for asymptomatic patients with severe mitral regurgitation with none of the noted indications for surgery if and only if the mitral valve can be repaired.

Operative mortality varies based on procedure. Mitral valve repair is associated with a 2% perioperative mortality compared to 6% for valve replacement. Patients with ischemic and functional mitral regurgitation do much worse than the patients with organic regurgitation. A study of 292 patients older than 70 years demonstrated an in-hospital mortality of 0.7% for mitral repair compared to 13.9% for replacement. Operative mortality is higher for the elderly, with the risk of mortality for valve replacement being as high as 14%, although repair carries a lower mortality. A recent paper comparing cohorts of patients older than 75 years, between 65 and 75 years and younger than 65 years, demonstrated an increased operative risk for the older patients, but restoration of life expectancy following surgery is the same for older as for younger patients. Although current data would suggest no improvement in survival by performing a concomitant mitral repair with coronary artery bypass, nonetheless there may be an improvement in postoperative symptoms.

## GENERAL CONSIDERATIONS

### Endocarditis Prophylaxis

Although there is surprising dearth of data supporting or refuting the use of antibiotic prophylaxis for patients with valvular disease,

**TABLE 77-11**

#### Anticoagulation for Prosthetic Valves

	MECHANICAL VALVE	BIOPROSTHETIC VALVE
Aortic	INR 2.0–3.0 Aspirin 75–325 mg daily	INR 2.0–3.0 for 3 months Aspirin 75–100 mg daily
Aortic with risk factors*	INR 2.5–3.5 Aspirin 75–325 mg daily	INR 2.0–3.0 Aspirin 75–100 mg daily
Mitral	INR 2.5–3.5 Aspirin 75–325 mg daily	INR 2.0–3.0 for 3 months Aspirin 75–100 mg daily
Mitral with risk factors*	INR 2.5–3.5 Aspirin 75–325 mg daily	INR 2.5–3.5 Aspirin 75–100 mg daily

\*Risk factors: Atrial fibrillation, prior thromboembolism, LV dysfunction (ejection fraction <30%), and hypercoagulable condition.

the American Heart Association recommends antibiotic coverage for a variety of dental and surgical procedures.

Prophylactic antibiotics are recommended for patients with any valve replacement or repair and for patients with native valve abnormalities (Table 77-12). Patients at risk of endocarditis should be covered for all dental procedures and for other contaminated invasive procedures (a partial list is provided in Table 77-6).

Standard antibiotic prophylaxis is orally administered, penicillin based, and given 1 hour before the procedure (see Table 77-7).

### Anticoagulation

Anticoagulation has a significant associated morbidity—particularly in the older patient. Consequently, the need for anticoagulation plays a pivotal role in the choice of valve. Patients with mechanical valves require lifelong anticoagulation, while patients with bioprosthetic valves are often anticoagulated for only 3 months (Table 77-11). If there is no contraindication to antiplatelet therapy, aspirin is also recommended for all patients with valve replacement.

Recommended INR for patients with mechanical aortic valves is between 2.0 and 3.0; however, if the patient has a history of prior thromboembolism, LV dysfunction, atrial fibrillation, or hypercoagulability, the INR should be maintained between 2.5 and 3.5. Patients with mechanical mitral valves should have their INR

**TABLE 77-12**

#### Indications for Endocarditis Prophylaxis

Patients for whom endocarditis prophylaxis is recommended

- Patients with any prosthetic valve—either mechanical or bioprosthetic
- Patients who have had valve repair procedures
- Patients with abnormal native valves—e.g., bicuspid aortic valve
- Mitral valve prolapse with clinical findings of regurgitation or leaflet abnormalities by echocardiogram

Endocarditis prophylaxis is not required

- Mitral valve prolapse without regurgitation or abnormal leaflets
- Aortic valve sclerosis if jet velocity <2.0 m/s
- Physiological mitral regurgitation with normal valve leaflets
- Physiological tricuspid regurgitation with normal valvular apparatus
- Physiological pulmonary valve regurgitation with normal valvular apparatus

maintained between 2.5 and 3.5. Patients with bioprosthetic valves are often anticoagulated (INR 2.0–3.0) for the first 3 months following implantation.

The risk of thromboembolism for anticoagulated patients with mechanical valves is approximately 1% to 2% per year. The risk is lower in bioprosthetic valves (0.7%) compared to mechanical valves, and lower in patients with aortic prosthetic valves compared to mitral valves, regardless of the type of prosthetic valve implanted.

Hemorrhagic complications are more likely if the INR is greater than 5.0. Patients with an INR between 5 and 10 can be treated by holding warfarin and administration of 1 to 2.5 mg of oral vitamin K. However, the INR should be monitored daily until the INR is below 5, at which time warfarin can be reinitiated at adjusted doses. Of note, it is often harder to manage anticoagulation in the older patient as a result of the numerous other medications that these patients are often taking and the high incidence of warfarin cross-reactivity with other medications. An acute reduction in the INR for patients who are suffering from bleeding complications may be achieved by administering intravenous fresh frozen plasma. Vitamin K can also help reduce a dangerously high INR, but it will make reanticoagulation difficult.

Sometimes temporary cessation of anticoagulation in patients with mechanical valves is medically necessary. Patients with mechanical aortic valves (without risk factors) can have warfarin held 48 to 72 hours preoperatively and restarted within 24 hours following surgery without the need for bridging heparin anticoagulation. However, patients with mechanical mitral or mechanical aortic valves and high-risk factors should be bridged with heparin when the INR falls below 2.0. The heparin may be held 4 to 6 hours before surgery and restarted as soon as possible when the immediate postoperative risk of bleeding allows. For emergent procedures, it is preferable to administer fresh frozen plasma to reverse the effects of warfarin, since the administration of vitamin K will make reanticoagulation difficult and increases the risk of a hypercoagulable state.

## Prosthetic Valve Choices

All prosthetic valves fall into two broad groups: biologic and mechanical valves. Mechanical valves have the advantage of durability but the disadvantage of requiring lifelong anticoagulation. Bioprosthetic valves do not require anticoagulation; however, these are limited by a finite durability. Both the risk of embolism and the durability are determined, in part, by valve location. Biological aortic valve prostheses are more durable than the same valve in the mitral position, and mechanical valves in the aortic position have a lower risk of thromboembolism than in the mitral position.

Within each class of valve, mechanical and bioprosthetic, there are numerous types of prostheses; each type of valve is available in different forms (e.g., porcine vs. bovine pericardial or bileaflet vs. tilting disc).

### Mechanical Valves

The original design mechanical valve was the ball-caged valve, which while durable has inefficient flow characteristics and requires higher levels of anticoagulation than the current generation of valves. The bileaflet mechanical valve is the most commonly used valve in the aortic position; while single leaflet tilting disc valves are available,

these are less frequently implanted. The risk of thromboembolism with anticoagulation is approximately 1% to 2% per year.

### Bioprosthetic Valves

Stented and nonstented porcine valves are available, as well as stented valves fashioned from bovine pericardium. Like homografts, these valves do not require immunosuppression or anticoagulation. The risk of embolism for these types of valves is approximately 0.7% per year without anticoagulation; however, all the biological valves are prone to structural deterioration. The rate of deterioration is slower in older patients; consequently, the freedom from reoperation is 90% to 95% for patients who were older than 75 years at the time of implantation. Stentless valves do not have the valve mounting and are, therefore, more hemodynamically efficient for the same valve size; although initial data suggested regression of left ventricular hypertrophy, this has not been consistently noted in the literature, nor has the promise of improved survival, as a result of the reduction in ventricular hypertrophy, been realized.

### Aortic Homografts

Cadaver valves that have been treated and cryopreserved unfortunately do not provide improved durability. Most data suggest either more rapid failure or at best comparable failure rates to other types of bioprosthetic valves. These valves can be more challenging to implant but are particularly useful in patients with endocarditis and tissue loss; additionally, the rate of thromboembolism is low, and, like the stentless porcine valves, these are very hemodynamically efficient especially at small sizes. Although there is no need for anti-rejection medications, the valve has a propensity to become heavily calcified, making replacement much more challenging.

### Pulmonary Valve Autotransplants (Ross Procedure)

Mr. Donald Ross devised an operation to excise the patient's own pulmonary valve, which is used to replace the aortic valve, and then to replace the pulmonary valve with a homograft or bioprosthetic valve. Conceptually, the lower-pressure pulmonary circuit will allow for longer durability of the homograft or bioprosthetic valve in this circuit, and the aortic valve, which is now an autologous valve, would, therefore, also have increased durability. The operative morbidity and mortality for this procedure, especially in unfamiliar hands, are higher than bioprosthetic replacement. Although the ability of this procedure to accommodate growth makes it useful in pediatric patients, the increased procedural risk and limited benefit in the older patient rarely make it indicated in this population. A variation of this operation is also available for mitral replacement, but it is currently investigational and has the same limitations for use in the older patient.

### Valve Repair

Repair of the aortic or mitral valves is the ideal. The ability to maintain ventricular geometry and to accommodate natural annular motion and durability makes mitral valve repair the best option for suitable patients; these advantages translate to lower operative mortality for mitral repair compared to replacement—1% to 2% versus 5.4% to 6.4%, respectively. Aortic valve repair for calcific disease is

less durable and is rarely indicated; however, in the setting of normal leaflets, the aortic valve is repairable with excellent results (85% freedom from reoperation at 10 years).

The choice of replacement valve is sometimes determined by the contraindication to anticoagulation (which would necessitate the implantation of a bioprosthetic valve); otherwise, the choice resides with the patient. There are some data to suggest that the rate of bioprosthetic valve deteriorating slows down in older patients, prompting many surgeons to recommend bioprosthetic aortic valves for patients older than 65 years and bioprosthetic mitral valves for patients older than 70 years.

Other indirect factors may weigh the choice of valve in one direction or another: atrial fibrillation, multiple valve replacement, prior mechanical valve, prior cardiac surgery, annulus size—which might weigh the argument in favor of a mechanical valve rather than face the possibility of the third operation, etc. Essentially, the risk of the mechanical valve is the continuous low-level risk of anticoagulation and embolization, and the risk of the bioprosthetic valve is that of valve failure and reoperation. In the end, the choice of valve—unless there are contraindications to anticoagulation—belongs to the patient, since ultimately they must live with the perils of anticoagulation or the threat of reoperation.

# Heart Failure

*Michael W. Rich*

Heart failure may be defined as an inability of the heart to pump sufficient blood to meet the metabolic needs of the body's tissues or the ability to do so only at the expense of elevated intracardiac pressures. Heart failure represents a clinical syndrome rather than a specific diagnosis, and, to a large extent, it is a geriatric syndrome in much the same way that dementia and incontinence are geriatric syndromes. Indeed, heart failure may be viewed as the quintessential disorder of cardiovascular aging since, as discussed later in this chapter, extensive age-related changes in cardiovascular structure and function, in conjunction with the rising prevalence of cardiovascular diseases with advancing age and the recent decline in premature cardiovascular deaths, all contribute to an exponential rise in the prevalence of heart failure with advancing age. Thus, although the clinical syndrome of heart failure has been recognized by physicians for more than 2000 years, it has only been within the past two decades that it has been identified as a major public health concern, a development that is largely attributable to the aging of the population.

## EPIDEMIOLOGY AND ECONOMIC IMPACT

Despite progressive declines in age-adjusted mortality rates from coronary heart disease and hypertensive cardiovascular disease, both the incidence and the prevalence of heart failure are increasing, and it is projected that these trends will continue for the next several decades. As shown in [Table 78-1](#), several factors have contributed to the progressive rise in heart failure. Foremost among these is the increasing number of older adults who, by virtue of advanced age and the high prevalence of hypertension, coronary heart disease, and cardiac valvular disorders in older individuals, are predisposed to the development of heart failure. In addition, advances in the treatment of other acute and chronic cardiac and noncardiac conditions, most notably atherosclerotic heart disease, hypertension, renal failure, cancer, and infectious diseases, have paradoxically contributed to the increasing burden of heart failure. Thus, individuals who 20

years ago might have died in middle age from acute myocardial infarction are now surviving to older age only to develop heart failure in their later years. Similarly, improved blood pressure control has led to a 60% decline in stroke mortality over the last 30 years, yet these same patients remain at risk of the subsequent development of heart failure as a complication of hypertension and left ventricular hypertrophy.

Heart failure affects approximately 5.2 million Americans, and 550 000 new cases are diagnosed each year. Moreover, both the incidence and the prevalence of heart failure are strikingly age dependent ([Figures 78-1 and 78-2](#)). Thus, heart failure is relatively uncommon in individuals younger than 40 years, but the prevalence doubles for each decade thereafter and exceeds 10% in adults older than 80 years. Similarly, heart failure mortality rates increase exponentially with advancing age in all major demographic subgroups of the U.S. population ([Figure 78-3](#)).

Heart failure is also a major source of chronic disability and impaired quality of life in older adults, and it is currently the leading indication for hospitalization in individuals older than 65 years. Moreover, the number of hospital discharges for heart failure increased by more than twofold from 1979 to 2004, primarily owing to the aging of the population ([Figure 78-4](#)). In 2004, there were 1.1 million hospital admissions in the United States with a primary diagnosis of heart failure ([Table 78-2](#)). Of these, 75% were in patients older than 65 years and more than 50% occurred in patients 75 years of age or older. The majority of heart failure patients younger than 65 years are males, but women comprise nearly 60% of heart failure admissions after the age of 65 years, and the proportion of females continues to rise with advancing age. The prevalence of heart failure in older Caucasians and African-Americans is similar, but hospital admission rates are lower in Hispanics and Asians. Whether this represents a true difference in population prevalence or a cultural difference in the likelihood that affected individuals will seek medical attention is unknown. Heart failure is also a common reason for outpatient physician office visits, with estimates ranging from

**TABLE 78-1****Factors Contributing to the Rising Incidence and Prevalence of Heart Failure**

Aging of the population
• Age-related cardiovascular changes
• High prevalence of cardiovascular disease
Improved therapy for coronary heart disease and hypertension
• Decline in coronary mortality
○ Thrombolytic therapy
○ Coronary angioplasty and bypass surgery
○ Aspirin, beta-blockers, and converting-enzyme inhibitors
○ Hypocholesterolemic agents
• Decline in stroke mortality
○ More widespread use of antihypertensive agents
○ Beneficial effects of treating diastolic and isolated systolic hypertension
Improved therapy for other disorders
• End-stage renal disease
• Cancer
• Pneumonia and other infections

3 to 12 million office visits annually. In this regard, heart failure ranks second only to hypertension among cardiovascular causes for outpatient physician visits.

As a result of its high prevalence and the need for intensive resource use in both the inpatient and the outpatient settings, it is not surprising that the economic burden of heart failure is staggering. Heart failure is currently the most costly diagnosis-related group in the United States, with estimated total annual expenditures in excess of \$33 billion. Indeed, inpatient expenditures for heart failure exceed those for all cancers combined by a factor of 2.4 and for all myocardial infarctions combined by a factor of 1.7.

## PATHOPHYSIOLOGY

Heart failure represents the prototypical disorder of cardiovascular aging in that age-related changes in the cardiovascular system in concert with an increasing prevalence of cardiovascular diseases at older age conspire to produce an exponential rise in heart failure prevalence with advancing age.

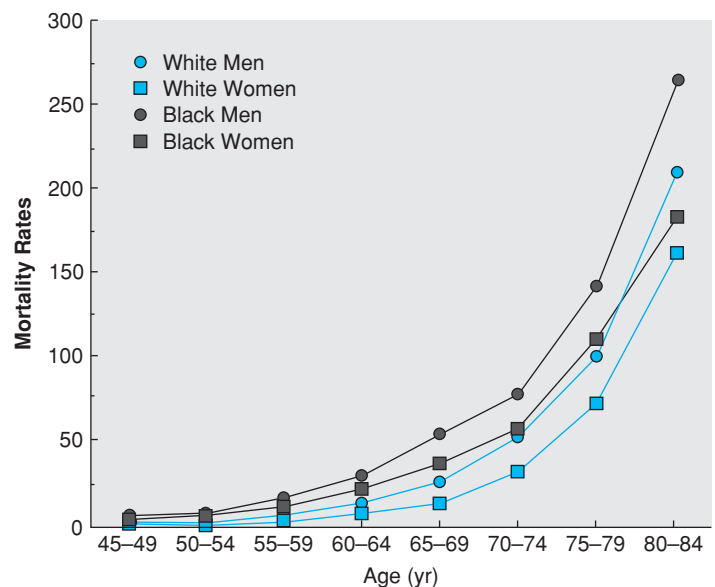

Aging is associated with extensive changes in cardiovascular structure and function (see Chapter 74). However, in the absence of co-existent cardiovascular disease, resting cardiac function is well pre-

**FIGURE 78-2.** Prevalence of heart failure by age and sex in the United States. (Source: National Health and Nutrition Examination Survey: 1999–2004.)

served even at very elderly age. Thus, the resting left ventricular ejection fraction, an index of left ventricular systolic performance, is unaffected by age in healthy individuals. Similarly, most studies indicate that resting cardiac output is either maintained or declines minimally with normal aging.

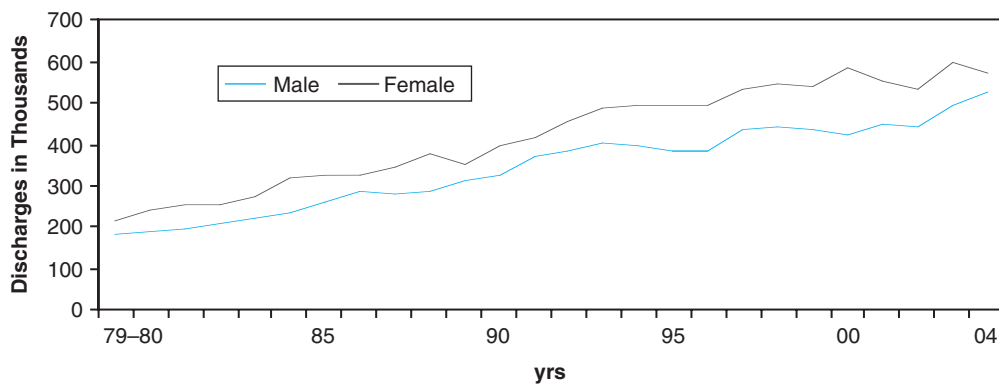

From the clinical perspective, the changes associated with cardiovascular aging result in an impaired ability of the heart to respond to stress, whether that stress is physiologic (e.g., exercise) or pathologic (e.g., hypertension or myocardial ischemia). Four principal changes in the cardiovascular system contribute directly to the heart's attenuated capacity to augment cardiac output in response to stress. First, aging is associated with reduced responsiveness to  $\beta$ -adrenergic stimulation. The mechanism underlying this change has not been fully elucidated, but it is not caused by reduced circulating catecholamine levels, decreased  $\beta$ -receptor density on cardiac myocytes, or altered responsiveness to intracellular calcium. In any case, the diminished response to  $\beta$ -adrenergic stimulation limits the heart's capacity to maximally increase heart rate and contractility in response to stress, and  $\beta_2$ -mediated peripheral vasodilatation is also compromised.

**FIGURE 78-3.** Mortality rates for congestive heart failure in the U.S. by age, sex, and race: 1990. (Adapted with permission from Gillum RF. Epidemiology of heart failure in the United States. *Am Heart J.* 1993;126:1042–1047.)

**FIGURE 78-1.** Incidence of heart failure in the United States by age and sex: 1980–2003. (Source: Framingham Heart Study 1980–2003; National Heart, Lung, and Blood Institute.)

**FIGURE 78-4.** Hospital discharges for heart failure by sex: 1979–2004. (Source: National Hospital Discharge Survey, National Center for Health Statistics.)

A second major effect of aging is increased vascular stiffness, primarily because of increased collagen deposition and cross-linking and degeneration of elastin fibers in the media and adventitia of the large- and medium-sized arteries. Increased vascular stiffness results in increased impedance to left ventricular ejection (i.e., increased afterload), and it also contributes to the increased propensity of older individuals to develop isolated systolic hypertension.

A third major effect of aging is altered left ventricular diastolic filling. Diastole is characterized by four phases: isovolumic relaxation, early rapid filling, passive filling during mid-diastole, and late filling owing to atrial systole. The first two phases, isovolumic relaxation and early rapid filling, are largely dependent on myocardial relaxation, an active, energy-requiring process, whereas filling during the latter two phases is governed principally by intrinsic myocardial “stiffness,” or compliance. Aging is associated with impaired calcium release from the contractile proteins and reuptake by the sarcoplasmic reticulum at the end of systole, leaving the heart in a state of “partial contraction” at the onset of diastole and inhibiting early diastolic relaxation. In addition, increased interstitial connective tissue content and collagen cross-linking reduce ventricular compliance. Compensatory myocyte hypertrophy in response to increased ventricular afterload and myocyte loss because of apoptosis further compromise left ventricular compliance. Thus, normal aging is associated with important changes that impair both relaxation and

compliance, adversely impacting all four phases of diastole and substantially altering the pattern of left ventricular diastolic filling.

Age-related changes in diastolic filling and atrial function can be evaluated noninvasively using Doppler echocardiographic techniques to examine diastolic inflow across the mitral valve (Figure 78-5). In healthy young persons, the transmitral inflow pattern is characterized by a large E-wave, with a rapid upstroke representing rapid filling of the ventricle immediately following the opening of the mitral valve and corresponding to active ventricular relaxation (Figure 78-5A). This is followed by a period in which the rate of filling slows (the downslope of the E-wave), mid-diastolic diastasis (in which left atrial and left ventricular pressures are essentially equal), and a second burst of flow at the end of diastole corresponding to atrial contraction (the A-wave, or atrial “kick”). Importantly, the majority of ventricular filling occurs in the first half of diastole in young individuals, with a relatively small contribution from atrial contraction.

In older persons, alterations in cardiac relaxation and compliance result in characteristic changes in the pattern of diastolic filling (Figure 78-5B). Early filling is impaired, and the upstroke of the E-wave is delayed. Similarly, the downslope of the E-wave is less steep, as it takes a longer time to achieve diastasis. In order to compensate for increased resistance to emptying, the left atrium enlarges and hypertrophies. This results in a more forceful left atrial contraction

**TABLE 78-2**

**Epidemiology of Heart Failure in the United States**

POPULATION GROUP	PREVALENCE*	INCIDENCE	MORTALITY*	HOSPITAL DISCHARGES	COST†
Both sexes	5.2 million (2.5%)	550 000	57 700	1.099 million	\$33.2

Philadelphia: Lea & Febiger; 1994:152.)

and an augmented A-wave. As a result of these changes, a greater proportion of filling occurs in the second half of diastole in older individuals, and as much as 30% to 40% of left ventricular end-diastolic volume may be attributable to atrial contraction. Thus, older individuals become increasingly reliant on the atrial “kick” to maximize left ventricular filling.

A third pattern of diastolic filling, referred to as the restrictive pattern, occurs when the left ventricle’s ability to accept blood becomes severely compromised. In this situation (Figure 78-5C), very little flow occurs after the rapid filling phase in early diastole. This pattern is characterized by a tall, narrow E-wave with a rapid downslope, as diastasis is achieved early in diastole. Little additional flow occurs during mid-diastole, and the A-wave is typically small, with an amplitude that is less than 50% of the E-wave. A restrictive pattern generally indicates marked elevation of the left ventricular diastolic pressure, and it is generally associated with a poor prognosis, particularly in patients with concomitant systolic dysfunction. However, the restrictive pattern generally occurs in patients with advanced cardiac disease, and it rarely results from aging alone.

Age-related changes in diastolic filling have several important clinical implications. First, inability to distend the cardiac myocytes to an optimal fiber length results in a failure of the Frank–Starling mechanism, one of the cardinal adaptive responses (along with sympathetic activation) for acutely increasing cardiac output. Second, impaired diastolic filling results in a shift to the left in the normal ventricular pressure–volume relationship; i.e., a small increase in diastolic volume is associated with a greater increase in diastolic pressure in older compared to younger individuals. This increase in diastolic pressure is transmitted back to the left atrium, and left atrial myocytes become “stretched.” This, in turn, increases the likelihood of atrial ectopic beats and atrial arrhythmias, especially atrial fibrillation. This accounts, in part, for the fact that atrial fibrillation, like heart failure, increases in prevalence with advancing age. In addition, atrial fibrillation itself is a common precipitant of heart failure in older adults for two reasons. First, the absence of a coordinated atrial contraction substantially compromises late diastolic filling as a result of loss of the atrial “kick.” Second, the rapid, irregular ventricular rate associated with acute atrial fibrillation shortens the diastolic filling period, which further attenuates ventricular filling.

A third effect of altered diastolic filling is an increased propensity for older adults to develop diastolic heart failure (i.e., heart failure

with normal left ventricular systolic function). Because of the altered left ventricular pressure–volume relation, increases in left ventricular pressure owing to ischemia or uncontrolled hypertension may lead to pulmonary congestion and edema. Moreover, individuals with impaired diastolic function are often “volume sensitive”; i.e., small increments in intravascular volume, as may occur with a dietary salt load or intravenous fluid administration, are poorly accommodated by the noncompliant ventricle. As a result, intraventricular pressure rises abruptly and heart failure ensues. Conversely, intravascular volume contraction, which may arise from poor oral intake or overdiuresis, can cause a marked fall in intraventricular volume, which in turn leads to a fall in stroke volume and cardiac output.

The fourth major effect of cardiovascular aging is altered myocardial energy metabolism at the level of the mitochondria. Under resting conditions, older cardiac mitochondria are able to generate sufficient quantities of adenosine triphosphate to meet the heart’s energy requirements. However, when stress causes an increase in adenosine triphosphate demands, the mitochondria are often unable to respond appropriately. Although the precise mechanism underlying this mitochondrial failure is unclear, the defect adds to the heart’s inability to maintain normal metabolic function under stress.

To summarize, four major age-related changes in cardiovascular structure, function, and physiology combine to reduce cardiovascular reserve and greatly increase the risk of heart failure in older adults. Recalling that cardiac output is determined by four primary factors (heart rate, preload, afterload, and contractile state), and recognizing that each of these factors is adversely affected by one or more of the four major effects of aging on the heart, and that superimposed upon these changes is the high prevalence of cardiac disease in older adults, it is indeed not surprising that the incidence and prevalence of heart failure rise exponentially with advancing age.

It is also important to note that aging is associated with significant changes in other organ systems, which impact directly or indirectly on the development and/or management of heart failure. Aging is accompanied by a decline in glomerular filtration rate, and the aging kidney is less able to maintain intravascular volume and electrolyte homeostasis (see Chapter 85). The reduced capacity of the kidneys to respond to intravascular volume overload or dietary sodium excess further increases the risk of heart failure in older individuals. In addition, older patients are less responsive to diuretics and more likely to develop diuretic-induced electrolyte abnormalities than younger patients, factors that may complicate the management of heart failure in the older age group.

Aging is also associated with numerous changes in respiratory function, which serve to diminish respiratory reserve (see Chapter 82). Some of these effects, such as  $V/Q$  mismatching and sleep-related breathing disorders, may contribute directly to the development of heart failure by producing hypoxemia or pulmonary hypertension. Other changes reduce the capacity of the lungs to compensate for the failing heart by increasing tidal volume and minute ventilation, thereby contributing to the patient’s sensation of dyspnea. In more severe cases of cardiac failure, such as pulmonary edema, acute respiratory failure may ensue, partly as a consequence of the inability of the lungs to maintain oxygenation and effective ventilation.

Age-related changes in nervous system function include an impaired thirst mechanism, which may contribute to dehydration and intravascular volume contraction in patients treated with diuretics, and reduced capacity of the central nervous system’s autoregulatory mechanisms to maintain cerebral perfusion in the face of changes

in systemic arterial blood pressure. The latter effect may contribute to subtle changes in mental function in older heart failure patients treated with vasodilators. Aging is also associated with widespread changes in reflex responsiveness. For example, impaired responsiveness of the carotid baroreceptors to acute changes in blood pressure may cause orthostatic hypotension or syncope, and these effects may further be aggravated by many of the drugs used to treat heart failure.

Finally, as is well recognized, aging is associated with significant changes in the pharmacokinetics and pharmacodynamics of almost all drugs. In addition, older patients tend to be at increased risk of both drug–drug and drug–disease interactions as a result of the high prevalence of comorbid conditions and the use of multiple pharmacological agents. These factors often lead to alterations in drug efficacy and an increased side-effect profile, and these effects must be taken into consideration when designing therapy for older heart failure patients (see Chapters 8 and 24).

## ETIOLOGY AND PRECIPITATING FACTORS

In general, the etiology of heart failure is similar in older and younger patients (Table 78-3), but heart failure in older individuals is more often multifactorial. As in younger patients, hypertension and coronary heart disease are the most common causes of heart failure, accounting for more than 70% of cases. Hypertensive hypertrophic cardiomyopathy represents a more severe form of hypertensive heart disease most commonly seen in older women and often accom-

panied by calcification of the mitral valve annulus. These patients often manifest severe diastolic dysfunction and may exhibit dynamic left ventricular outflow tract obstruction indistinguishable from that seen in classical hypertrophic cardiomyopathy.

Valvular heart disease is an increasingly common cause of heart failure at older age. Calcific aortic stenosis is now the most common form of valvular heart disease requiring surgical intervention, and aortic valve replacement is the second most common open heart procedure performed in patients older than 70 years (after coronary bypass grafting). Mitral regurgitation in older individuals may be caused by myxomatous degeneration of the mitral valve leaflets and chordae tendineae (mitral valve prolapse), mitral annular calcification, valvular vegetations, ischemic papillary muscle dysfunction, or altered ventricular geometry owing to ischemic or nonischemic dilated cardiomyopathy. Importantly, mitral regurgitation may be acute (e.g., following acute myocardial infarction), subacute (e.g., endocarditis), or chronic (e.g., myxomatous degeneration), and the clinical manifestations may vary widely in each of these settings. In the United States, rheumatic mitral stenosis is a less common cause of heart failure in older adults, but it is still occasionally seen. Functional mitral stenosis owing to severe mitral valve annulus calcification with encroachment on the mitral valve orifice is an uncommon cause of heart failure, but it is associated with a poor prognosis. Aortic insufficiency may be either acute (e.g., because of endocarditis or type A aortic dissection) or chronic (e.g., annuloaortic ectasia or syphilitic aortitis), but it is a relatively infrequent cause of heart failure in older adults. Finally, prosthetic valve dysfunction should be considered as a potential cause of heart failure in any patient who has undergone previous valve repair or replacement.

Cardiomyopathies are classified into three categories: dilated, hypertrophic, and restrictive. In older adults, ischemic heart disease with one or more prior myocardial infarctions is the most common cause of dilated cardiomyopathy. Nonischemic dilated cardiomyopathy is less common in older than in younger individuals; when present, it is most often either idiopathic in origin or attributable to chronic ethanol abuse. Less frequently, dilated cardiomyopathy may be caused by cancer chemotherapy (e.g., anthracyclines and trastuzumab) or other causes. Classical hypertrophic cardiomyopathy, once thought to be rare in the geriatric age group, has been increasingly recognized in older adults since the advent of echocardiography. Similarly, restrictive cardiomyopathy, most commonly owing to amyloid deposition (so-called senile cardiac amyloid), is an occasional cause of heart failure. In one autopsy series, cardiac amyloid deposition was thought to be clinically important in approximately 10% of individuals 90 years of age or older.

Infective endocarditis is an uncommon but important cause of heart failure in older patients because it is one of the few etiologies for which curative pharmacological therapy is available. Endocarditis should be strongly suspected in any patient with persistent fever and either a prosthetic heart valve or a preexisting valvular lesion. It should also be considered in any patient with fever, recent dental work or other procedure, and a new or worsening heart murmur. It is important to recognize, however, that the clinical manifestations of endocarditis are often protean, and the absence of fever or a heart murmur does not exclude this diagnosis in older individuals.

Myocarditis is a relatively rare cause of heart failure in older adults. It may be infectious (e.g., postviral) or noninfectious (e.g., owing to sarcoid or collagen vascular disease). Pericardial effusions, for which there are numerous etiologies, occasionally present with heart

Age-related diastolic dysfunction

failure symptomatology, including fatigue, exertional dyspnea, and edema. Constrictive pericarditis may be infectious (e.g., tuberculous) or noninfectious (e.g., postradiation), but it is a rare cause of heart failure in older patients.

High-output failure is an uncommon cause of heart failure in older adults, but when present the diagnosis is frequently overlooked. Potential causes of high-output failure include chronic anemia, hyperthyroidism, thiamine deficiency, and arteriovenous shunting (e.g., owing to a dialysis fistula or arteriovenous malformations).

Finally, in a small percentage of older heart failure patients, detailed investigation may fail to identify any primary cardiovascular pathology. In cases with normal left ventricular systolic function, heart failure may be attributed to age-related diastolic dysfunction.

## Precipitating Factors

In addition to determining the etiology of heart failure, it is important to identify coexisting factors that may have contributed to the acute or subacute exacerbation (Table 78-4). The most common precipitant in patients with preexisting heart failure is noncompliance with medications and/or diet. Indeed, noncompliance may contribute to as many as two-thirds of heart failure exacerbations. In hospitalized patients, iatrogenic volume overload is also an important precipitant of heart failure.

Among cardiac factors, myocardial ischemia or infarction and new-onset atrial fibrillation or flutter are the most common causes of an acute episode of heart failure. Other cardiac causes include

ventricular arrhythmias, especially ventricular tachycardia, and bradyarrhythmias, such as marked sinus bradycardia or advanced atrioventricular block. Sick sinus syndrome, which is common in older adults, is a frequent cause of bradyarrhythmias in this population.

As previously discussed, older patients have limited cardiovascular reserve and they are less able to compensate in response to increased demands. As a result, heart failure in older adults is often precipitated by acute or worsening noncardiac conditions. Patients with acute respiratory disorders, such as pneumonia, pulmonary embolism, or an exacerbation of chronic obstructive lung disease, are particularly prone to exhibit deterioration in cardiac function. Other serious infections, such as sepsis or pyelonephritis, may also lead to heart failure exacerbations. In patients with hypertension, inadequate blood pressure control is a common cause of worsening heart failure. Thyroid disease, anemia (e.g., owing to gastrointestinal bleeding), and declining renal function may also contribute directly or indirectly to the development of heart failure.

Finally, numerous drugs and medications may contribute to heart failure exacerbations. Alcohol is a cardiac depressant, and it may also precipitate arrhythmias, especially atrial fibrillation. Beta-blockers (including ophthalmologic agents) and calcium antagonists are widely used in older individuals with cardiovascular disease, but both classes of agents are negatively inotropic and may exacerbate heart failure. Class Ia (e.g., quinidine, procainamide, and disopyramide) and Ic (e.g., flecainide and propafenone) antiarrhythmic agents have important myocardial depressant effects that may worsen cardiac function. Nonsteroidal anti-inflammatory drugs (NSAIDs), which are widely used by older adults, impair renal sodium and water excretion and may, therefore, contribute to intravascular volume overload. In addition, NSAIDs antagonize the effects of angiotensin-converting enzyme (ACE) inhibitors, thereby limiting the efficacy of these agents. Corticosteroids and estrogen preparations may cause fluid retention and an increase in total body water. Fluid retention is the most important side effect of the insulin-sensitizing thiazolidinediones (rosiglitazone and pioglitazone), and worsening heart failure may occur with these agents. The antihypertensive agent minoxidil also promotes fluid retention, and several other antihypertensive drugs (e.g., clonidine and guanethidine) may have unfavorable hemodynamic effects.

**TABLE 78-4**

### Common Precipitants of Heart Failure in Older Adults

Myocardial ischemia or infarction
Dietary sodium excess
Excess fluid intake
Medication noncompliance
Iatrogenic volume overload
Arrhythmias
• Atrial fibrillation or flutter
• Ventricular arrhythmias
• Bradyarrhythmias, especially sick sinus syndrome
Associated medical conditions
• Fever
• Infections, especially pneumonia or sepsis
• Hyperthyroidism or hypothyroidism
• Anemia
• Renal insufficiency
• Thiamine deficiency
• Pulmonary embolism
• Hypoxemia from chronic lung disease
• Uncontrolled hypertension
Drugs and medications
• Alcohol
• Beta-blockers (including ophthalmologic agents)
• Calcium channel-blockers
• Antiarrhythmic agents
• Nonsteroidal anti-inflammatory drugs
• Corticosteroids
• Estrogen preparations
• Antihypertensive agents (e.g., clonidine and minoxidil)

## CLINICAL FEATURES

### Symptoms

As in younger patients, the most common symptoms of heart failure in older adults are exertional shortness of breath, orthopnea, dependent edema, fatigue, and exercise intolerance. However, there is an increased prevalence of atypical symptomatology in older patients, particularly those older than 80 years (Table 78-5). As a result, heart failure in older adults is paradoxically both over- and underdiagnosed. Thus, shortness of breath and orthopnea in an older individual may be attributed to heart failure when the underlying cause is chronic lung disease, pneumonia, or pulmonary embolism. Similarly, fatigue and reduced exercise tolerance may be caused by anemia, hypothyroidism, depression, or poor physical conditioning. On the other hand, sedentary individuals and those limited by arthritis or neuromuscular conditions may not report exertional dyspnea

**TABLE 78-5****Atypical Manifestations of Heart Failure in Older Persons**

• Anorexia
• Abdominal discomfort
• Nausea
• Diarrhea

or fatigue, and atypical symptoms such as those listed in [Table 78-5](#) may be the first and only clinical manifestations of heart failure. In such cases, the physician must maintain a high index of suspicion, or the diagnosis of heart failure may be readily overlooked.

**Signs**

As with symptoms, the physical findings in older heart failure patients may be nonspecific or atypical. The classic signs of heart failure include moist pulmonary rales, an elevated jugular venous pressure, abdominojugular reflux, an S<sub>3</sub> gallop, and pitting edema of the lower extremities. However, pulmonary rales in older individuals may be due to chronic lung disease, pneumonia, or atelectasis, and peripheral edema may be caused by venous insufficiency, renal disease, or medication (e.g., calcium channel-blockers). Conversely, older patients may have an essentially normal physical examination despite markedly reduced cardiac performance. Alternatively, impaired sensorium or Cheyne–Stokes respirations may be the only findings to suggest the presence of heart failure.

**Systolic versus Diastolic Heart Failure**

The clinical manifestations of systolic and diastolic heart failure are similar, and no single clinical feature can reliably distinguish heart failure patients with intact left ventricular systolic function from those with impaired contractility. Nonetheless, certain features tend to favor one form or the other ([Table 78-6](#)). Based on the presence or absence of specific features, the probability of normal or reduced systolic function can be estimated, and there have been several attempts to develop algorithms for distinguishing these syndromes. Unfortunately, the predictive accuracy of these algorithms has been modest, and additional testing is essential in order to reliably differentiate systolic from diastolic heart failure.

**DIAGNOSTIC EVALUATION**

Heart failure may be difficult to diagnose in older patients with multiple comorbid conditions and either vague or nonspecific symptoms and signs. Thus, the first task facing the physician is to establish whether or not heart failure is present. This begins with a careful history and physical examination, giving due consideration to potential alternative etiologies for the patient's findings. As discussed in the previous section, physical signs may be unreliable in older patients. Nonetheless, certain findings, including pulsus alternans, an S<sub>3</sub> gallop, and the presence of jugular venous distension at rest or in response to the abdominojugular reflux maneuver, are highly specific signs of heart failure in older patients. In the absence of these findings, the diagnosis often remains in doubt, and additional laboratory studies are required.

To differentiate shortness of breath attributable to heart failure from that owing to other causes, the level of B-type natriuretic peptide (BNP—a 32 amino acid hormone released by the cardiac ventricles in response to increased wall tension) or its precursor N-terminal pro-BNP (NT-pro-BNP) is the single most useful test. However, BNP levels increase with age, especially in women ([Figure 78-6](#)), and with declining renal function. Therefore, the specificity

of an elevated BNP level for clinical heart failure declines with age. BNP levels in excess of 500 pg/mL in the appropriate clinical context are highly suggestive of active heart failure, whereas a normal value (<100 pg/mL) in an older adult makes the diagnosis of heart failure much less likely. In addition to the BNP level, the chest radiograph remains useful for establishing the presence of active pulmonary congestion. In patients with moderate or severe heart failure, the chest film will usually demonstrate typical findings of cardiomegaly, pulmonary vascular engorgement, parenchymal edema, and pleural effusions. However, in patients with mild heart failure or coexisting pulmonary disease, the chest radiograph may be nondiagnostic.

Once the presence of heart failure has been established, the physician must address two crucial questions, the answers to which will serve as the basis for selecting appropriate therapy:

1. What is the underlying etiology and pathophysiology of heart failure (see Table 78-3)?
2. What additional factors, if any, contributed to or precipitated the development of heart failure (see Table 78-4)? Often, one or more precipitating factors can be identified, and alleviating these factors may significantly improve symptoms and reduce the likelihood of subsequent heart failure exacerbations.

In 2005, the American College of Cardiology and American Heart Association Task Force on Practice Guidelines published revised guidelines for the diagnosis and management of heart failure. Table 78-7 outlines an appropriate initial diagnostic assessment for patients with new-onset heart failure. Class I studies are defined as those that are indicated in most patients, Class II procedures are acceptable in some patients but are of unproven efficacy and may be controversial, and Class III studies are not routinely indicated and in some cases may be harmful. Briefly, basic laboratory studies, a thyroid function test, a chest radiograph, an electrocardiogram, and an echocardiogram with Doppler are recommended in all patients. Cardiac catheterization and coronary angiography are appropriate in patients with angina or significant ischemia on noninvasive testing, and in those who require surgical correction of a noncoronary car-

**TABLE 78-7**

### Diagnostic Evaluation of Patients with Heart Failure

Class I (indicated in most patients)

- Complete blood count
- Blood chemistries: electrolytes, creatinine, blood urea nitrogen, fasting glucose, magnesium, calcium, liver function tests, and lipid profile
- Thyroid stimulating hormone (TSH)
- Urinalysis
- Chest radiograph and electrocardiogram (ECG)
- Echocardiogram: two-dimensional with Doppler
- Cardiac catheterization and coronary angiography in patients with angina or significant ischemia unless the patient is not eligible for revascularization

Class II (acceptable in selected patients; see text)

- Serum iron and ferritin
- Antinuclear antibody and rheumatoid factor
- If suspected, assessment for human immunodeficiency virus, amyloidosis, or pheochromocytoma
- Screening for sleep-disordered breathing
- Stress test to evaluate for ischemia in patients with unexplained heart failure who are potential candidates for revascularization
- Coronary angiography in all patients with possible or probable ischemia who are potential candidates for revascularization
- Endomyocardial biopsy when a specific diagnosis is suspected that would influence therapy

Class III (not routinely indicated, possibly harmful)

- Routine measurement of circulating neurohormone levels (e.g., norepinephrine)
- Routine signal-averaged electrocardiography
- Endomyocardial biopsy as a routine procedure in the evaluation of patients with heart failure

Data from Hunt SA, et al. ACC/AHA 2005 guideline update for the diagnosis and management of chronic heart failure in the adult – summary article. *J Am Coll Cardiol.* 2005;46:1116–1143.

diac lesion (e.g., aortic stenosis), unless the patient is not a suitable candidate for coronary revascularization.

The recommendations outlined in Table 78-7 are targeted toward a broad range of adult heart failure patients, and most are applicable in patients at an advanced age. Nonetheless, in older patients it is appropriate to consider the potential risks and benefits of each diagnostic procedure on an individualized basis, taking into account comorbid conditions, the extent of cardiac and non-cardiac disability, and the wishes of the patient. For example, in a frail 85-year-old individual with diabetic nephropathy, the risk of precipitating dialysis-dependent end-stage renal disease as a complication of coronary angiography must be carefully weighed against the potential benefits to be derived from a successful revascularization procedure. Similarly, patient autonomy must be respected in all cases, and it is inappropriate to exert pressure on an older patient to undergo a procedure that the patient clearly does not desire. In this regard, it is imperative to discuss the therapeutic implications of specific procedures (especially invasive procedures) with respect to the patient's subsequent care (e.g., need for coronary bypass surgery) prior to performing the diagnostic assessment.

### Systolic versus Diastolic Heart Failure

An important goal of the diagnostic evaluation, apart from determining the etiology of heart failure, is differentiating systolic from diastolic dysfunction, since the management of these two syndromes

differs. As noted above, it is difficult to make this distinction on clinical grounds alone, and it is therefore essential to evaluate left ventricular function directly by echocardiography, radionuclide angiography, magnetic resonance imaging, or contrast ventriculography. In general, transthoracic echocardiography is the most useful technique because it is noninvasive, relatively inexpensive, and, in addition to providing information about systolic and diastolic function, it is helpful in evaluating chamber size, wall thickness and motion, valve function, and pericardial disease. Thus, transthoracic echocardiography is appropriate in virtually all older patients with newly diagnosed heart failure and in those with an unexplained change in symptom severity. The principal limitation of echocardiography is that adequate visualization of the heart may be unobtainable in a small percentage of patients, although the availability of echo-contrast agents has minimized this problem. Alternatively, radionuclide angiography can provide an accurate assessment of left ventricular function, as well as information about cavity size and regurgitant valvular lesions. Magnetic resonance imaging provides much the same information as echocardiography and radionuclide angiography but is less readily available and more expensive. For those patients who require cardiac catheterization, contrast left ventriculography is an excellent method for evaluating ventricular function.

Based on the results of echocardiography, radionuclide angiography, magnetic resonance imaging, or contrast ventriculography, heart failure may be classified as being primarily due to systolic dysfunction, as defined by a left ventricular ejection fraction of less than 40%; primarily due to diastolic dysfunction, as suggested by an ejection fraction of 50% or greater; or mixed, as indicated by an ejection fraction of 40% to 49%. However, it must be emphasized that systolic and diastolic dysfunction are not mutually exclusive. Indeed, almost all patients with significant systolic dysfunction also have concomitant diastolic dysfunction. Conversely, systolic dysfunction may play a role in the development of heart failure even when the ejection fraction under resting conditions is normal or near normal. Despite these limitations, the classification of heart failure as systolic or diastolic is useful in guiding therapy.

## MANAGEMENT

The primary goals of heart failure therapy are to improve quality of life, reduce the frequency of heart failure exacerbations, and extend survival. Secondary goals include maximizing independence and exercise capacity, enhancing emotional well-being and reducing resource use and the associated costs of care.

To achieve these goals, optimal therapy in older patients comprises three principal components: correction of the underlying etiology whenever possible (e.g., aortic valve replacement for aortic stenosis or coronary revascularization for severe ischemia), attention to the nonpharmacological and rehabilitative aspects of treatment, and the judicious use of medications.

As discussed in the section on prognosis, the outlook for patients with established heart failure is poor. Therefore, the importance of effectively treating the primary etiology and all comorbid conditions predisposing to heart failure cannot be overemphasized. Since coronary heart disease and hypertension are the most common causes of heart failure in older adults, primary and secondary prevention of these conditions are critical if the development of heart failure is to be forestalled. Indeed, it has now been shown in multiple clinical trials

that effective treatment of both systolic and diastolic hypertension can reduce the incidence of heart failure by up to 50%. Similarly, appropriate management of other coronary risk factors, particularly hyperlipidemia and cigarette smoking, will undoubtedly further reduce the burden of heart failure through the primary prevention of coronary heart disease.

## Nonpharmacological Therapy

Despite recent advances in the pharmacotherapy of heart failure, repetitive heart failure exacerbations are common and are more often precipitated by behavioral and social factors than by either new cardiac events (e.g., ischemia or an arrhythmia) or progressive deterioration in ventricular function. In one study, lack of adherence to prescribed medications and/or diet contributed to 64% of heart failure exacerbations among urban blacks, while emotional and environmental factors contributed to 26% of hospital readmissions. In another study involving 140 patients 70 years of age or older hospitalized with heart failure, 47% were readmitted at least once during a 90-day follow-up period. Behavioral and social factors contributing to readmission included medication and dietary noncompliance (15% and 18%, respectively), inadequate social support (21%), inadequate discharge planning (15%), inadequate follow-up (20%), and failure of the patient to seek medical attention promptly when symptoms recurred (20%). The findings suggest that interventions directed at behavioral and social factors could potentially reduce readmissions and improve quality of life in patients with heart failure, and this hypothesis has now been confirmed in numerous prospective randomized trials. In a recent meta-analytic review of 33 such trials, heart failure readmissions were reduced by 42%, all-cause readmissions were reduced by 24%, and mortality was reduced by 20% in patients with heart failure enrolled in a “disease management” program relative to conventional care.

Components of a comprehensive nonpharmacological treatment program are listed in [Table 78-8](#). As with other aspects of geriatric care, it is important to structure the treatment program in order to accommodate the needs of each individual patient. Clearly, not every patient will require all of the components listed in the table. Similarly, the optimal intensity of any given component, e.g., patient education or follow-up care, will vary substantially. For these reasons, it is desirable to designate a single individual, such as a nurse case manager, to coordinate all aspects of the patient’s care.

## Physical Activity and Exercise

Traditionally, patients with heart failure have been advised to restrict physical activity on the grounds that rest is beneficial for the heart and that exercise could potentially worsen cardiac function or precipitate arrhythmias. However, it is now recognized that although some degree of activity restriction may be appropriate, excessive limitation of physical activity may contribute to a progressive decline in functional capacity as a result of cardiovascular and muscular deconditioning. In addition, several small studies have demonstrated that participation in an appropriately structured exercise program may result in significant improvements in functional capacity and quality of life in patients with heart failure. As a result, current guidelines recommend regular exercise for the majority of patients with heart failure.

Data from nine randomized trials on the effects of exercise training in patients with heart failure involving 801 patients have been

summarized. Most of the studies excluded patients with preserved left ventricular systolic function, and none of the studies specifically targeted older patients. The average duration of training ranged from 8 to 60 weeks, with a mean follow-up of almost 2 years. The mode of exercise consisted primarily of walking and/or cycling. Exercise capacity consistently improved with training, primarily as a result of adaptations in the oxidative capacity of skeletal muscle without evidence for a beneficial effect on central cardiac hemodynamics. In addition, mortality was reduced by 35% and the combined end point of death or hospitalization was reduced by 28% in patients participating in an exercise program.

A more recent randomized trial of cardiac rehabilitation in 200 patients 60 to 89 years of age (mean 72 years, 66% male) with New York Heart Association Class II–III heart failure evaluated the effects of exercise prescription, education, occupational therapy, and psychosocial counseling. At 24 weeks follow-up, intervention group patients experienced significant improvements in New York Heart

**TABLE 78-9****Contraindications to Exercise in Older Patients**

Recent myocardial infarction or unstable angina (within 2 weeks)
Severe, decompensated heart failure (New York Heart Association Class IV)
Life-threatening arrhythmias not adequately treated
Severe aortic stenosis or hypertrophic cardiomyopathy
Any acute serious illness (e.g., pneumonia)
Any condition precluding safe participation in an exercise program

Association class, 6-minute walk distance, and quality of life, whereas control-group patients demonstrated no change from baseline in any of these parameters. In addition, patients receiving the intervention had significantly fewer hospital admissions relative to the control group. These data provide further support for a beneficial effect of exercise and cardiac rehabilitation in older patients with mild-to-moderate heart failure. Despite these findings, additional studies are needed to evaluate the safety and efficacy of regular exercise in older heart failure patients, especially those older than 75 years and patients with diastolic heart failure.

**Exercise Prescription**

A comprehensive exercise and conditioning program is appropriate for most older patients with mild-to-moderate heart failure symptoms and no contraindications to exercise (Table 78-9). Table 78-10 outlines the basic components of such a program. In general, patients should try to exercise every day. A typical session should include some gentle stretching exercises as well as strengthening exercises using elastic bands or light weights and targeting all of the major muscle groups. Suitable forms of aerobic exercise for older patients include walking, stationary cycling, and swimming. The choice of aerobic exercise should be tailored to the patient's wishes and abilities. When initiating an exercise program, the duration and intensity of the aerobic activity should be well within the patient's comfort range. The activity should be enjoyable, not stressful, and after completing the activity the patient should feel "positive" about the experience and not unduly fatigued. For many older patients with heart failure, this may mean starting with as little as 2 to 5 minutes of slow-paced walking. Once the patient feels comfortable exercising, the duration of exercise can be gradually increased over a period of several weeks. Weekly increases of 1 to 2 minutes per session are appropriate for most patients. Once the patient can exercise

**TABLE 78-10****Exercise Prescription for Older Patients with Heart Failure**

Components of conditioning program
<ul style="list-style-type: none"> <li>• Flexibility exercises</li> <li>• Strengthening exercises</li> <li>• Aerobic conditioning</li> </ul>
Frequency of exercise: daily, if possible
Duration of exercise: individualized; start low, go slow
Intensity of exercise: low to moderate (see text for details)
Rate of progression: gradual over weeks to months
Monitoring: heart rate, perceived exertion (see text)

continuously and comfortably for 20 to 30 minutes, the intensity of exercise may be increased, if desired. For example, if the patient is walking a half-mile in 30 minutes, he or she may gradually reduce the half-mile time to 20 minutes, while maintaining a total exercise duration of 30 minutes.

The two most common techniques for monitoring exercise intensity are the target heart rate method and the patient's subjective assessment of perceived exertion. For patients not taking medications that lower heart rate (e.g., beta-blockers), the maximum attainable heart rate in beats per minute (bpm) can be estimated from the following formula:  $220 - \text{age}$ . The patient's resting heart rate is then subtracted from this figure to determine the *heart rate reserve*. A suitable target heart rate for low-intensity exercise can be calculated as the resting heart rate plus 30% to 50% of the heart rate reserve. For moderate-intensity exercise, the target range is the resting heart rate plus 50% to 70% of the heart rate reserve. For example, an 80-year-old individual has a predicted maximum heart rate of  $220 - 80 = 140$  bpm. If the resting heart rate is 80, the heart rate reserve is 60 (i.e.,  $140 - 80$ ). For low-intensity exercise, 30% to 50% of the heart rate reserve would be 18 to 30 bpm. Adding this to the resting heart rate of 80 would yield a range for the target heart rate of 98 to 110 bpm.

For many older patients, calculating the target heart rate may be difficult. In addition, it may not be possible to accurately determine heart rate during exercise (unless a heart rate monitor is used). For these reasons, the patient's subjective assessment of perceived exertion is often the most practical method for monitoring exercise intensity. In addition, perceived exertion correlates reasonably well with exercise heart rate. A simple perceived exertion scale comprises five levels: very light, light, moderate, somewhat heavy, and heavy. Older patients with heart failure should begin with very light exercise, progressing to the light range as tolerated. After several weeks, some patients may wish to increase their perceived exertion level into the moderate range, but more strenuous exercise is not recommended for patients with heart failure.

### Cessation of Exercise

All patients participating in an exercise program should be advised to discontinue exercise if they experience persistent chest discomfort, undue dyspnea or fatigue, dizziness, rapid or irregular heart beats, excessive sweating, or any other symptom suggesting that continuation of exercise may be unsafe. If the above symptoms do not resolve promptly with termination of exercise or if they occur repeatedly, the physician should be notified prior to continuing the exercise program.

### Treatment of Systolic Heart Failure

From the therapeutic perspective, patients with heart failure and a left ventricular ejection fraction of less than 45% may be considered as having predominantly systolic heart failure, while those with an ejection fraction of 45% or greater may be considered as having predominantly diastolic heart failure. Although there is considerable overlap between these syndromes, their distinction is useful in designing therapy.

In general, the treatment of systolic heart failure in older patients does not differ substantially from that in younger patients. [Table 78-11](#) lists currently available therapeutic options for systolic heart failure, and these are discussed in detail below.

**TABLE 78-11**

#### Treatment Options for Systolic Heart Failure

Angiotensin-converting enzyme inhibitors
Angiotensin II receptor blockers
Other vasodilators
Beta-adrenergic blocking agents
Diuretics
• Aldosterone antagonists
Digoxin
Calcium channel-blockers
Antithrombotic agents
• Aspirin
• Warfarin

### ACE Inhibitors

Numerous prospective randomized clinical trials using multiple different ACE inhibitors in a variety of clinical settings have conclusively demonstrated that these agents significantly reduce mortality and hospitalization rates and improve exercise tolerance and quality of life in patients with impaired left ventricular systolic function, even in the absence of clinical heart failure. Although none of these studies included patients older than 80 years, available evidence indicates that ACE inhibitors are as effective in older patients as in younger ones. Based on these findings, ACE inhibitors are now considered first-line therapy for all patients, regardless of age, with left ventricular systolic dysfunction with or without overt heart failure. However, despite these recommendations, ACE inhibitors remain underused, particularly in older patients.

ACE inhibitors approved for use in the United States for the treatment of heart failure include captopril, enalapril, lisinopril, ramipril, trandolapril, quinapril, and fosinopril. In older patients, therapy should be initiated with a low dose (e.g., captopril 6.25–12.5 mg tid–qid or enalapril 2.5–5 mg bid), and the dose should be gradually increased as tolerated. In hospitalized patients who are hemodynamically stable, the dose may be increased daily; in outpatients, the dose should be increased weekly or biweekly. Throughout the titration period, blood pressure, renal function, and serum potassium levels should be monitored.

For maintenance therapy, ACE inhibitor dosages should be commensurate with those used in the clinical trials. Recommended “target” doses for selected ACE inhibitors are as follows: captopril 50 mg tid, enalapril 10 to 20 mg bid, lisinopril 20 to 40 mg daily, ramipril 10 mg daily, trandolapril 4 mg daily, quinapril 40 mg bid, and fosinopril 40 mg daily. In patients unable to tolerate full therapeutic doses of ACE inhibitors, lower doses may be used; however, it must be recognized that clinical benefits may be attenuated. In addition, although captopril is an excellent agent for use during the titration phase, once the maintenance dose has been reached, it may be desirable to change to a once-daily ACE inhibitor at equivalent dosage for reasons of convenience, compliance, and cost.

The most common side effect from ACE inhibitors is a dry, hacking cough, which may be severe enough to require discontinuation of therapy in 5% to 10% of patients during long-term use. Less common but more serious side effects include hypotension, a decline in renal function, and hyperkalemia. These side effects tend to occur

shortly after initiation of therapy and may be aggravated by intravascular volume contraction as a result of overdiuresis. Indications for downward titration or discontinuation of an ACE inhibitor include symptomatic hypotension, persistent increase in serum creatinine of 1 mg/dL or greater, or a rise in the serum potassium level above 5.5 meq/L. Note that asymptomatic low blood pressure does not mandate dosage reduction.

Although ACE inhibitors are generally well tolerated and can be taken safely in combination with most other medications, it is important to recognize that NSAIDs, which are widely used by older adults (both by prescription and over the counter), are potent ACE inhibitor antagonists. In addition, NSAIDs promote sodium and water retention and may adversely affect renal function. Therefore, NSAIDs should be avoided whenever possible in patients with heart failure. The use of aspirin in combination with an ACE inhibitor is controversial, as there is some evidence suggesting that aspirin may attenuate the effects of ACE inhibitors. However, recent studies indicate that aspirin does not adversely affect clinical outcomes in patients with heart failure treated with ACE inhibitors. Therefore, patients with a clear indication for aspirin therapy, such as coronary artery disease, peripheral arterial disease, cerebrovascular disease, or diabetes mellitus, should receive aspirin according to current treatment guidelines for these conditions. The value of prophylactic aspirin in older patients with heart failure without known vascular disease or diabetes is unknown, and additional study of this issue is needed.

### Angiotensin II Receptor Blockers

Angiotensin II receptor blockers (ARBs) bind directly to angiotensin II receptors on the cell membrane. Unlike ACE inhibitors, ARBs do not inhibit the breakdown of bradykinins, thus eliminating bradykinin-mediated side effects, including cough.

The use of ARBs for the treatment of heart failure, either alone or in combination with an ACE inhibitor, has been evaluated in several studies. In the second Evaluation of Losartan in the Elderly trial (ELITE-II), losartan 50 mg once daily was compared to captopril 50 mg TID in 3152 patients 60 years of age or older (mean age 71 years) with moderate heart failure and an ejection fraction of 40% or less. After a mean follow-up of 18 months, there was no statistically significant difference in mortality between the two treatments, although there were 12% more deaths in the losartan group (280 vs. 250). As in the smaller ELITE-I trial, losartan was better tolerated than the ACE inhibitor captopril.

In the Valsartan Heart Failure trial (Val-HEFT), 5010 patients with heart failure and an ejection fraction of less than 40% were randomized to valsartan or placebo in addition to standard care, which included an ACE inhibitor in 93% of patients and a beta-blocker in 35%. During a 2-year follow-up period, mortality did not differ between patients treated with valsartan or placebo, but there was a significant 24% reduction in rehospitalizations for heart failure in the valsartan group, with similar effects in younger and older patients. However, patients receiving both an ACE inhibitor and a beta-blocker as background therapy experienced an unexplained increase in mortality when valsartan was added.

In the Valsartan in Acute Myocardial Infarction trial, 14 703 patients with clinical heart failure and/or an ejection fraction less than 35% within 10 days of experiencing an acute myocardial infarction were randomly assigned to receive valsartan, captopril, or both drugs. More than 70% of patients were also receiving beta-blockers. Dur-

ing a median follow-up of 24.7 months, there were no differences between groups with respect to all-cause mortality or the composite end point of fatal or nonfatal cardiovascular events. Median age was 65 years, and results were similar in older and younger patients. Hypotension and renal dysfunction were more common with valsartan, whereas cough, rash, and taste disturbances were more common with captopril. Limiting side effects were more common in patients receiving both drugs than in those receiving either drug alone.

The use of candesartan for the treatment of patients with heart failure and an ejection fraction of 40% or less has been evaluated in two large trials. In the Candesartan in Heart Failure: Assessment of Reduction in Mortality and Morbidity (CHARM)—Alternative study, 2028 patients intolerant to ACE inhibitors were randomized to candesartan or placebo and followed for a median of 33.7 months. Compared to patients in the placebo group, patients randomized to candesartan experienced a significant 30% reduction in the composite end point of cardiovascular death or hospitalization for heart failure. All-cause mortality was reduced by 17%, which was of borderline statistical significance. Hypotension, worsening renal function, and hyperkalemia, but not cough or angioedema, were more common in the candesartan group. The mean age of patients in the CHARM-Alternative study was approximately 66.5 years, and nearly one-fourth of patients were 75 years of age or older; however, subgroup analysis by age has not been reported.

In the CHARM-Added trial, 2548 symptomatic patients with heart failure and an ejection fraction of 40% or less who were receiving an ACE inhibitor were randomized to candesartan or placebo and followed for a median of 41 months. Compared to the placebo group, there was a significant 15% reduction in the composite end point of cardiovascular death or hospitalization for heart failure in patients randomized to candesartan. All-cause mortality was 11% lower in the candesartan group, but the difference was not significant. The mean age of patients in the CHARM-Added trial was 64 years, 19% of patients were 75 years of age or older, and similar results were reported in older and younger patients.

Based on these studies, ARBs are indicated for treatment of symptomatic heart failure in patients intolerant to ACE inhibitors and in patients with heart failure or left ventricular systolic dysfunction following acute myocardial infarction. In the United States, valsartan and candesartan are approved for the treatment of heart failure. The recommended starting dose of valsartan is 20 to 40 mg bid, and the dose should be titrated to 160 mg bid as tolerated. The starting dose of candesartan is 4 to 8 mg once daily, with titration to 32 mg once daily as tolerated. The major side effects of ARBs include hypotension, renal insufficiency, and hyperkalemia.

### Other Vasodilators

In patients who are unable to tolerate an ACE inhibitor or ARB, the combination of hydralazine with oral or topical nitrates provides an acceptable alternative. In the first Veteran's Administration Heart Failure trial (V-HeFT-I), the hydralazine/nitrate combination was associated with a 36% mortality reduction compared to prazosin and placebo in patients with chronic heart failure and impaired systolic function. In a follow-up study (V-HeFT-II), patients with systolic heart failure were randomized to receive hydralazine/nitrates or enalapril. Although hydralazine/nitrates and enalapril had similar effects on exercise tolerance and quality of life, mortality was lower in the enalapril group.

More recently, the African-American Heart Failure trial (A-HeFT) randomized 1050 black patients with New York Heart Association Class III or IV heart failure to a fixed-dose combination of isosorbide dinitrate plus hydralazine or to placebo in addition to standard heart failure therapy. The study was stopped after an average follow-up of 10 months because of a significantly higher mortality rate in patients randomized to placebo. Heart failure hospitalizations were also lower and quality of life was improved in patients randomized to hydralazine-nitrates relative to placebo. Based on the results of A-HeFT, the fixed-dose combination of isosorbide dinitrate and hydralazine has been approved for treatment of heart failure in black patients in the United States. Although there was no upper-age restriction for the A-HeFT study, the average age of patients enrolled in the trial was only 57 years, so the efficacy of this therapy in elderly blacks remains unknown.

The dose of hydralazine used in the V-HeFT trials was 75 mg QID, and nitrates were administered as isosorbide dinitrate 40 mg QID. In A-HeFT, the total daily dose of hydralazine was 225 mg and of isosorbide dinitrate 120 mg. For older patients, treatment should begin with lower dosages (e.g., hydralazine 12.5–25 mg TID–QID; isosorbide dinitrate 10 mg TID–QID), followed by gradual upward titration to achieve the doses used in the trials. The most common side effects associated with hydralazine/nitrates in the V-HeFT and A-HeFT studies included headache and dizziness. A small percentage of patients in V-HeFT developed arthralgias or other symptoms suggestive of hydralazine-induced lupus.

### Beta-Blockers

Traditionally, beta-adrenergic blocking agents have been considered contraindicated in patients with heart failure owing to their negative inotropic and chronotropic effects, both of which serve to diminish cardiac output. However, it is now recognized that persistent activation of the sympathetic nervous system is detrimental in patients with heart failure because it exacerbates ischemia, aids in arrhythmogenesis, promotes  $\beta$ -receptor down-regulation, and contributes to a progressive decline in ventricular function. These considerations led to the hypothesis that long-term treatment with  $\beta$ -blockers might be beneficial in patients with heart failure, and several large prospective randomized clinical trials have now confirmed that long-term beta-blockade improves left ventricular function and reduces both total mortality and sudden cardiac death in a broad range of patients with heart failure and impaired left ventricular systolic function.

These findings were recently confirmed in the Study of the Effects of Nebivolol Intervention on Outcomes and Rehospitalization in Seniors with Heart Failure trial, which randomized 2128 patients 70 years of age or older (mean age 76 years, 37% women) to nebivolol or placebo. During a mean follow-up of 21 months, the primary composite outcome of death or cardiovascular hospitalization was significantly lower in patients randomized to nebivolol, with similar results in younger and older patients, including those older than 85 years. Based on these studies, beta-blockers are now recommended as a standard therapy, along with ACE inhibitors, in almost all patients with symptomatic heart failure in the absence of contraindications.

In the United States, carvedilol and metoprolol have been approved for the treatment of heart failure. Starting dosages are carvedilol 3.125 mg bid and metoprolol 12.5 mg bid (or extended release metoprolol 25 mg once daily). The dose should be gradually increased at approximately 2 week intervals as tolerated, to achieve

maintenance dosages of carvedilol 25 to 50 mg bid or metoprolol 100 to 200 mg daily.

Contraindications to the use of beta-blockers include severe decompensated heart failure, significant bronchospastic lung disease, marked bradycardia (resting heart rate less than 50/min), systolic blood pressure less than 90 to 100 mm Hg, advanced heart block (greater than first degree), and known intolerance to beta-blockade. In addition, as a result of the potential for significant adverse effects, it is important to monitor heart rate, blood pressure, clinical symptoms, and the cardiorespiratory examination during initiation and titration of therapy. Patients should be advised that they may experience a modest deterioration in heart failure symptoms during the first few weeks of beta-blocker therapy, but that in most cases these symptoms resolve and the long-term tolerability of beta-blockers is excellent. However, if severe adverse effects occur, dosage reduction or discontinuation of treatment may be necessary.

### Diuretics

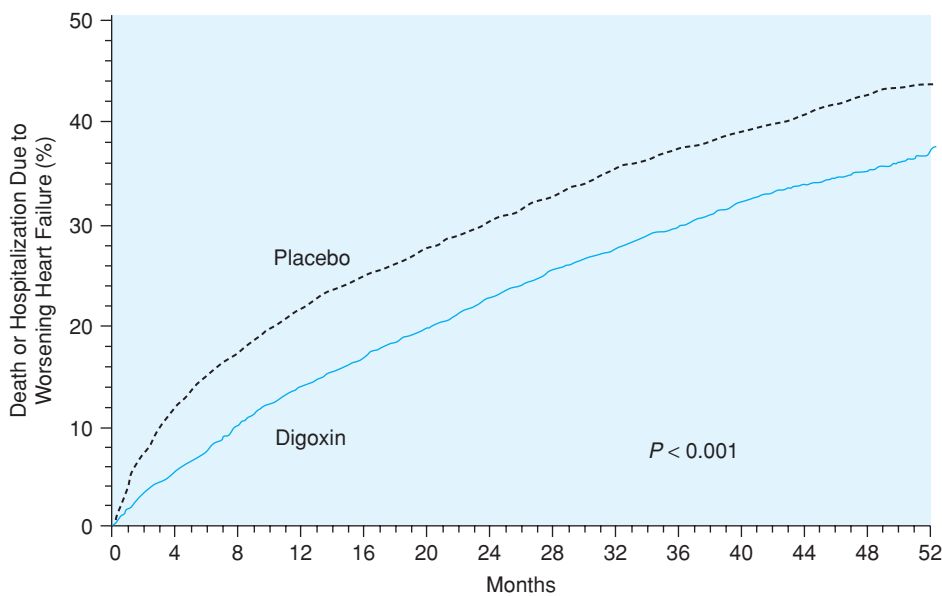

Diuretics are the most effective agents for relieving pulmonary congestion and edema, and for this reason they remain a key component of heart failure management. However, neither thiazide nor loop diuretics have been shown to alter the natural history of heart failure, and their beneficial effects are primarily palliative.

In patients with mild chronic heart failure, a thiazide diuretic (e.g., hydrochlorothiazide 12.5–50 mg daily) may be sufficient for relieving congestive symptoms and maintaining fluid homeostasis. However, most patients will require a more potent agent, and the “loop” diuretics, including furosemide, bumetanide, and torsemide, are the drugs most widely used. For optimal effectiveness, patients should be instructed to maintain a low sodium diet (1.5–2.0 g/d) and to avoid excessive fluid intake. Typical daily doses of “loop” diuretics range from 20 to 160 mg for furosemide, 0.5 to 5 mg for bumetanide, and 5 to 100 mg for torsemide. In patients hospitalized with an acute episode of heart failure, intravenous administration is more effective than the oral route in promoting diuresis, and continuous intravenous infusion is more effective than bolus dosing. In patients who fail to respond adequately to a loop diuretic, the addition of metolazone 2.5 to 10 mg daily often leads to a brisk diuresis.

The most common and important side effects of diuretics are electrolyte disturbances, including hypokalemia, hyponatremia, hypomagnesemia, and increased bicarbonate levels indicative of metabolic alkalosis. Owing to age-related changes in renal function as well as a higher prevalence of comorbid illnesses such as diabetes, older patients are at increased risk of serious diuretic-induced electrolyte abnormalities. For this reason, electrolytes should be monitored closely when diuretic therapy is being adjusted. This is particularly true when using metolazone, which can cause life-threatening hyponatremia after relatively short-term use.

### Aldosterone Antagonists

The aldosterone antagonists spironolactone and eplerenone are relatively weak potassium-sparing diuretics that interfere with the effect of the neurohormone aldosterone. In the Randomized Aldactone Evaluation of Survival trial, spironolactone 12.5 to 50 mg once daily reduced mortality by 30% and heart failure hospitalizations by 35% in patients with New York Heart Association Class III or IV heart failure and a left ventricular ejection fraction  $\leq 35\%$ , despite therapy with an ACE inhibitor, digoxin, and loop diuretic. Moreover, the

**FIGURE 78-7.** Incidence of death or hospitalization due to worsening heart failure in patients treated with digoxin versus placebo. The risk for the combined end point was 25% lower in the digoxin group. (Adapted with permission from The Digitalis Investigation Group. The effect of digoxin on mortality and morbidity in patients with heart failure. *N Engl J Med.* 1997;336:525–533.)

beneficial effects of spironolactone were at least as great in older as in younger patients. In the Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival study, eplerenone 25 to 50 mg once daily significantly reduced mortality by 15% over a mean follow-up period of 16 months in patients with clinical evidence for heart failure and an ejection fraction of 40% or less within 3 to 16 days following acute myocardial infarction. Sudden death from cardiac causes and cardiovascular hospitalizations were also reduced in the eplerenone group. Compared to placebo, hyperkalemia occurred more commonly but hypokalemia occurred less frequently with eplerenone. The average age of patients in the Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival study was 64 years, and although the relative benefit of eplerenone was somewhat less in older compared to younger patients, the difference was not statistically significant.

Based on the results of these studies, an aldosterone antagonist is recommended in patients with advanced heart failure symptoms and severe left ventricular systolic dysfunction, and in patients with heart failure and an ejection fraction of 40% or less following myocardial infarction. These agents are contraindicated in patients with significant renal dysfunction (creatinine  $\geq 2.5$  mg/dL) or preexisting hyperkalemia. Older patients may be at increased risk of adverse effects, and renal function as well as serum potassium levels should be monitored closely during initiation and titration of therapy. In addition, up to 10% of patients receiving long-term treatment with spironolactone may experience painful gynecomastia requiring discontinuation of the drug; this side effect occurs less frequently with eplerenone.

### Digoxin

Digoxin inhibits the sodium–potassium exchange pump located within the myocyte membrane, producing a rise in intracellular sodium concentration. This facilitates sodium–calcium exchange, leading to an increase in intracellular calcium. Calcium binds with troponin C, which initiates the process of contraction by allowing myosin to bind with actin. By increasing calcium availability, digoxin induces a modest increase in the force of myocardial contraction (positive inotropic effect). This effect occurs whether or

not heart failure is present, and it does not appear to be affected by advancing age.

In 1997, the Digitalis Investigation Group (DIG) reported the results of a prospective randomized trial involving 6800 patients with heart failure and ejection fractions less than 45%. Patients were randomized to receive digoxin or placebo in addition to diuretics and an ACE inhibitor, and the average duration of follow-up was 37 months. Overall mortality did not differ between digoxin and placebo (34.8% vs. 35.1%), but there were 28% fewer hospitalizations for heart failure in the digoxin group, and the combined end point of death or hospitalization for heart failure was significantly reduced (Figure 78-7). In addition, the beneficial effects of digoxin were similar in younger and older patients, including octogenarians. Subsequent analyses based on data from the DIG trial suggest that digoxin administered at low dosages to achieve serum concentrations in the range of 0.5 to 0.9 ng/mL may be associated with improved survival as well as a reduction in all-cause hospitalizations. These findings confirm that digoxin is beneficial in controlling heart failure symptoms and support the use of low-dose digoxin in patients who remain symptomatic despite appropriate dosages of an ACE inhibitor, beta-blocker, and diuretic.

Side effects from digoxin fall into three major categories: cardiac, neurological, and gastrointestinal. In the DIG study, side effects that occurred more frequently in patients receiving digoxin included nausea and vomiting, diarrhea, visual disturbances, supraventricular and ventricular arrhythmias, and advanced atrioventricular heart block. Although not reported in the DIG trial, older patients may be at increased risk of digoxin toxicity, especially cardiac toxicity, in part owing to a decreased volume of drug distribution. Patients with chronic lung disease, amyloid heart disease, and other conditions may also be at increased risk of digoxin toxicity.

In most older patients with relatively normal renal function, a digoxin dose of 0.125 mg daily is usually sufficient to achieve a therapeutic effect. Patients with renal impairment or small body habitus may require a lower dose. Serum digoxin concentration should be measured 2 to 4 weeks after initiating therapy, and periodically thereafter, to ensure that the level is in the therapeutic range of 0.5 to 0.9 ng/mL. It is also appropriate to measure the digoxin level

whenever digitalis intoxication is suspected. In addition, since diuretic-induced hypokalemia and hypomagnesia potentiate digoxin's cardiotoxic effects, including proarrhythmia, it is important to maintain normal serum concentrations of these electrolytes in all patients receiving digoxin.

### Calcium Channel-Blockers

First-generation short-acting calcium channel-blockers, including nifedipine, diltiazem, and verapamil, are contraindicated in patients with systolic heart failure because each of these agents has been associated with adverse clinical outcomes. In addition, although long-acting formulations of these agents may ultimately prove to be safe and effective, there is currently insufficient information to recommend their use.

The third-generation calcium channel-blockers amlodipine and felodipine have each been studied in prospective randomized trials involving heart failure patients with impaired systolic function. Although the initial Prospective Randomized Amlodipine Survival Evaluation (PRAISE) suggested that amlodipine might be beneficial in patients with nonischemic systolic heart failure, this was not confirmed in PRAISE-2. Similarly, the V-HeFT-3 trial failed to demonstrate a significant benefit in patients with heart failure treated with felodipine. In light of these findings, there are no currently approved indications for the use of calcium channel-blockers in patients with systolic heart failure, and their use in this condition is not recommended. However, in patients with heart failure and active anginal symptoms not controlled with beta-blockers and nitrates, the addition of amlodipine or felodipine is reasonable.

### Antithrombotic Therapy

Patients with left ventricular systolic dysfunction are at increased risk of thromboembolic events, including stroke. However, in the absence of atrial fibrillation, rheumatic mitral valve disease, or a history of prior embolization, the value of antithrombotic treatment for the prevention of embolic events is unknown. In the Warfarin and Antiplatelet Therapy in Chronic Heart Failure trial, 1587 patients with New York Heart Association class II or III heart failure were randomized to receive aspirin 162 mg/day, clopidogrel 75 mg/day, or warfarin to maintain an international normalized ratio (INR) of 2.5 to 3.0. After a mean follow-up of 23 months, there were no differences between the three groups in the primary composite end point of death, myocardial infarction, or stroke. Hospitalizations for heart failure occurred more frequently in the aspirin group than with either clopidogrel or warfarin, whereas bleeding complications were more common with warfarin. The mean age of patients in the Warfarin and Antiplatelet Therapy in Chronic Heart Failure trial was 63 years; subgroup analysis by age has not been reported. Based on currently available data, anticoagulation with warfarin to achieve an INR of 2.0 to 3.0 is recommended in high-risk patients without major contraindications. Such patients include those with chronic or intermittent atrial fibrillation or atrial flutter, rheumatic mitral valve disease with left atrial enlargement, prior stroke or unexplained arterial embolus, a mobile left ventricular thrombus (as demonstrated by echocardiography or other imaging modality), or a left atrial appendage thrombus identified by transesophageal echocardiography. Routine use of warfarin in other circumstances is not recommended.

Aspirin is justified in patients with known coronary heart disease, particularly those with recent myocardial infarction, unstable angina,

coronary angioplasty, or bypass surgery. Aspirin is also recommended for patients with peripheral arterial disease or diabetes. In addition, aspirin is appropriate in high-risk patients (as listed above) who are not suitable candidates for warfarin. As noted previously, additional study is needed to determine the value of aspirin in older patients with heart failure without established vascular disease or diabetes.

### Statins

Statins have been shown to reduce mortality and nonfatal cardiovascular events in patients up to age 80 with coronary artery disease, peripheral arterial disease, or diabetes. In addition, several studies have suggested that statins may be beneficial in patients with heart failure. However, the recently reported rosuvastatin in older patients with systolic heart failure trial, in which 5011 patients 60 years of age or older (mean age 73 years, 24% female) with ischemic cardiomyopathy and an ejection fraction of 40% or less were randomized to rosuvastatin or placebo and followed for an average of 33 months, failed to show a significant benefit of rosuvastatin on either the primary outcome of death from cardiovascular causes, nonfatal myocardial infarction, or nonfatal stroke, or on total mortality. Hospitalizations for cardiovascular causes occurred less frequently in patients randomized to rosuvastatin. Based on these findings, rosuvastatin is not recommended for older patients with systolic heart failure. The role of other statins in this population requires further investigation.

### Treatment of Diastolic Heart Failure

Despite the fact that approximately 50% of older patients with heart failure have preserved left ventricular systolic function, few large-scale clinical trials have evaluated specific pharmacologic agents for the treatment of this condition. As a result, therapy for diastolic heart failure remains largely empiric.

At least 70% to 80% of older persons with diastolic heart failure have hypertension, and coronary and valvular heart diseases are also highly prevalent in this population. Optimal therapy for diastolic heart failure begins with aggressive treatment of hypertension to target levels, as established by Joint National Committee guidelines. Myocardial ischemia should be treated with antianginal medications and/or coronary revascularization as indicated. Resting and exercise heart rate should be well controlled in patients with atrial fibrillation. Patients with severe valvular heart disease should be considered for valve repair or replacement, and less severe regurgitant valvular lesions should be treated with unloading agents, such as ACE inhibitors. As with systolic heart failure, nonpharmacologic aspects of therapy should be appropriately addressed.

### Diuretics

Diuretics are an essential component of therapy for the relief of pulmonary and systemic venous congestion in patients with diastolic heart failure. However, such patients are often "volume sensitive." As a result, overly zealous diuresis can lead to a reduction in left ventricular diastolic volume, with a resultant decline in stroke volume and cardiac output, often manifested by increased fatigue, relative hypotension, and worsening prerenal azotemia. Thus, diuretics must be prescribed judiciously in order to relieve congestion while avoiding overdiuresis.

### Beta-Blockers

Beta-blockers have little or no direct effect on diastolic function, but they may improve symptoms in patients with diastolic heart failure by slowing heart rate and lengthening the diastolic filling period. In patients with left ventricular hypertrophy, long-term beta-blockade and effective blood pressure control may aid in the regression of left ventricular hypertrophy, which in turn may be associated with improved diastolic function. In addition, in the Study of the Effects of Nebivolol Intervention on Outcomes and Rehospitalization in Seniors with Heart Failure trial, more than 20% of patients had relatively preserved left ventricular systolic function (ejection fraction  $\geq 40\%$ ), and the benefits of nebivolol were similar in this group compared to those with ejection fractions  $< 40\%$ . These data support the use of beta-blocker therapy in all patients with heart failure, independent of whether left ventricular systolic function is preserved or impaired.

The goal of beta-blocker therapy in diastolic heart failure is to reduce the resting heart rate to less than 65 beats/min. The initial beta-blocker dose should be low and titration should be gradual. In the event that symptoms and exercise tolerance do not improve, alternative therapy should be considered.

### ACE Inhibitors

ACE inhibitors may improve symptoms in diastolic heart failure both directly (by improving diastolic function) and indirectly (by promoting regression of left ventricular hypertrophy). The use of ACE inhibitors for the treatment of diastolic heart failure in patients of advanced age is supported by recently reported findings from the Perindopril in Elderly People with Chronic Heart Failure study, in which 850 patients  $\geq 70$  years of age (mean age 76 years, 55% women) with heart failure and relatively preserved left ventricular systolic function (estimated ejection fraction  $\geq 40\%$ ) were randomized to perindopril 4 mg once daily or placebo and followed for an average of 2.1 years. Overall, there was no significant difference between groups with respect to the primary outcome of death or unplanned hospitalization for heart failure. However, heart failure hospitalizations were significantly reduced by 78% during the first 12 months of follow-up in patients randomized to perindopril. Relative to placebo, perindopril-treated patients also experienced significant improvements in New York Heart Association class and exercise tolerance during the first year of therapy. Perindopril is not currently approved for the treatment of heart failure in the United States, and the efficacy of other ACE inhibitors for the treatment of diastolic heart failure is unknown.

### Angiotensin II Receptor Blockers

ARBs lower blood pressure and may have salutary effects on diastolic function similar to those observed with ACE inhibitors. In the CHARM-Preserved Trial, 3024 patients with New York Heart Association Class II–IV heart failure and an ejection fraction  $> 40\%$  were randomized to candesartan or placebo and followed for a median of 36.6 months. The mean age was 67 years, 27% were 75 years of age or older, and 40% were women. Mortality did not differ between groups, but patients randomized to candesartan experienced a significant 16% reduction in the risk of hospitalization for heart failure and 29% fewer total heart failure admissions. Subgroup analysis by age was not reported. Hypotension, hyperkalemia, and worsening renal function occurred more frequently in the candesartan group.

Taken together, the findings of Perindopril in Elderly People with Chronic Heart Failure and CHARM-Preserve indicate that ACE inhibitors and ARBs reduce hospitalizations and improve symptoms in patients with diastolic heart failure but have little or no effect on mortality. The ongoing Irbesartan in Heart Failure with Preserved Systolic Function (I-PRESERVE) trial, the largest study to date in patients with diastolic heart failure, should provide additional insight into the value of ARBs in the treatment of this condition. In the meantime, the favorable effects of ACE inhibitors and ARBs on quality of life and resource use imply that these agents should play an important role in the management of patients with diastolic heart failure, at least until more effective treatments have been established.

### Aldosterone Antagonists

The aldosterone antagonists spironolactone and eplerenone reduce myocardial hypertrophy and fibrosis in laboratory animals and may have a favorable effect on left ventricular diastolic function. In addition, as discussed previously, both of these agents have been shown to improve mortality and other outcomes in patients with heart failure with reduced ejection fractions. Based on these considerations, the effects of spironolactone on clinical outcomes in patients with diastolic heart failure are now being evaluated in a large prospective randomized trial, sponsored by the National Heart, Lung, and Blood Institute.

### Calcium Channel-Blockers

Calcium channel-blockers decrease intracellular calcium and may have a modest beneficial effect on diastolic function. Verapamil has also been shown to improve symptoms and exercise tolerance in selected patients with hypertrophic cardiomyopathy and normal systolic function. In addition, in 20 older patients with heart failure with an ejection fraction above 45%, it was found that, in comparison with placebo, verapamil at dosages of up to 120 mg tid improved symptoms, exercise capacity, and indices of diastolic function. On the other hand, some patients with diastolic heart failure may experience marked clinical deterioration when treated with verapamil. Moreover, the lack of benefit from calcium channel-blockers for the treatment of systolic heart failure tempers enthusiasm for their use in diastolic heart failure. There are also no ongoing clinical trials evaluating calcium channel-blockers for the treatment of diastolic heart failure. In light of these factors, calcium channel antagonists are not considered first-line agents for the treatment of this condition.

### Nitrates

In addition to relieving ischemia, nitrates are effective venodilators and these lower pulmonary capillary wedge pressure. For these reasons, nitrates may serve as a useful adjunct to diuretics in relieving symptoms of pulmonary congestion, particularly orthopnea. However, nitrates have the potential for decreasing venous return to the heart, thereby reducing left ventricular diastolic volume and stroke volume. In addition, tolerance to the hemodynamic effects of nitrates occurs in the majority of patients. As a result, the value of nitrates in the long-term management of diastolic heart failure is uncertain.

### Digoxin

Traditionally, digoxin has been considered contraindicated in patients with heart failure and normal systolic function. However, digoxin, as well as other inotropic agents, may exert a favorable

effect on diastolic function by accelerating calcium reuptake by the sarcoplasmic reticulum at the onset of diastole. In the original DIG trial, 988 patients with heart failure and an ejection fraction of more than 45% were randomized to digoxin or placebo in an ancillary study. As in the main trial, digoxin had no effect on mortality. However, the combined end point of death or hospitalization for heart failure was reduced by 18% in patients receiving digoxin. In addition, all-cause mortality tended to be lower in patients with a serum digoxin concentration of 0.5 to 0.9 ng/mL. Although none of these differences were statistically significant, the findings suggest that digoxin may be beneficial in some patients with heart failure and preserved systolic function. Nonetheless, additional study is needed before digoxin can be recommended as routine therapy for patients with diastolic heart failure.

### Summary

Studies published to date indicate that ACE inhibitors, ARBs, and beta-blockers have favorable effects on hospital admission rates and symptom severity in patients with diastolic heart failure, but none of these agents have been shown to reduce mortality and none are recommended as standard therapy in current practice guidelines. Management of diastolic heart failure should include aggressive treatment of the underlying cardiac disease, and a diuretic should be administered at low-to-moderate doses to relieve congestion and edema. The addition of an ACE inhibitor, ARB, or beta-blocker to improve symptoms and reduce the risk of hospitalization seems prudent. However, if the patient fails to respond to initial therapy, alternative treatment should be considered. Such therapy might include the use of nitrates, digoxin, a calcium channel blocker, or a combination of agents.

### Refractory Heart Failure

Refractory heart failure may be defined as heart failure not amenable to primary corrective measures (e.g., valve replacement or revascularization) and not responsive to aggressive nonpharmacologic and pharmacologic therapy as described above. However, before designating heart failure as refractory, it is important to perform a careful search for potentially treatable causes, to carefully review the patient's medication regimen to ensure that therapy is optimal, and to discuss the patient's diet and medication habits in detail with the patient and family to ensure that an appropriate level of compliance is being maintained. The latter issue is of particular importance, since many cases of refractory heart failure can be traced to nonadherence to dietary restrictions, medications, or both.

In most cases, refractory heart failure simply represents the final common pathway of end-stage heart disease. Under these circumstances, the value of highly aggressive treatment is questionable, and decisions regarding the appropriateness of specific therapeutic interventions must be made on an individualized basis (see also Chapters 31 and 34).

Table 78-12 lists treatment options for refractory heart failure. In patients with systolic heart failure, intensifying the vasodilator regimen by using high doses of ACE inhibitors (e.g., up to 400 mg/day of captopril or 80 mg/day of enalapril), either alone or in combination with hydralazine/nitrates or an angiotensin II receptor blocker, may result in significant symptomatic improvement. This can often be accomplished in the outpatient setting, but titration must be very gradual, with frequent follow-up contacts to avoid adverse events. In patients who fail to respond to these measures,

**TABLE 78-12**

#### Treatment Options for Refractory Heart Failure

##### *Systolic heart failure*

Intensive vasodilator therapy

- High-dose ACE inhibitors
- Combination therapy
  - ACE inhibitor plus hydralazine/nitrates
  - ACE inhibitor plus angiotensin II receptor blocker
- Intravenous agents (e.g., nitroglycerin, nitroprusside, and niseritide)

Intensive diuretic therapy

- High-dose oral agents, especially in combination
- Continuous intravenous infusion

Chronic or intermittent inotropic therapy

- Dobutamine
- Milrinone

Pacemaker therapy

Dialysis

- Short-term or chronic dialysis
- Dry ultrafiltration

Investigational agents

Surgical options

- Myocardial resection
- Cardiomyoplasty
- Ventricular assist device

##### *Diastolic heart failure*

Intensive diuretic therapy (see above)

Empiric trial of inotropic therapy

Dialysis (see above)

A-V sequential pacemaker

ACE, angiotensin-converting enzyme.

intravenous vasodilator therapy with nitroglycerin, nitroprusside, or niseritide (recombinant B-type natriuretic peptide, BNP) may lead to significant clinical and hemodynamic improvements.

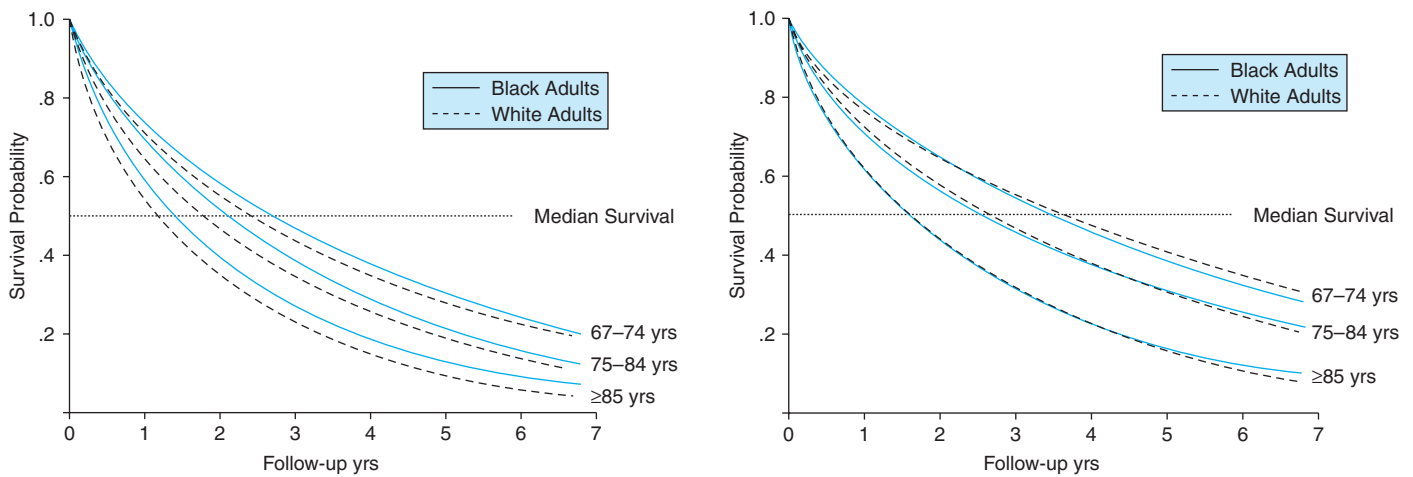

In patients with persistent pulmonary congestion or peripheral edema, high-dose oral diuretics (e.g., furosemide 200 mg bid or bumetanide 10 mg daily), alone or in combination with metolazone, may be effective. Alternatively, a continuous intravenous infusion of furosemide 5 to 40 mg/h or bumetanide 0.5 to 1 mg/h will often facilitate diuresis.

The use of intravenous inotropic agents in the management of chronic heart failure is somewhat controversial, since these agents have not been shown to improve outcomes and they may increase the risk of life-threatening arrhythmias. Nonetheless, extensive clinical experience indicates that intermittent or continuous outpatient infusions of dobutamine or milrinone may significantly reduce symptoms and improve quality of life in selected patients with refractory heart failure.

Recently, biventricular pacing has been shown to improve symptoms, quality of life, and survival in patients with advanced heart failure and left bundle branch block or marked intraventricular conduction delay on the 12-lead electrocardiogram. This procedure should, therefore, be considered in appropriately selected patients with persistent Class III or IV heart failure symptoms.

If the above interventions fail, patients with significant renal dysfunction may benefit from short-term dialysis or dry ultrafiltration to remove excess fluid and stabilize electrolyte homeostasis. If the patient responds to short-term treatment, chronic dialysis may be considered. Finally, in highly selected patients, referral to a tertiary or quaternary facility for investigational medical or surgical treatment may be appropriate.

**FIGURE 78-8.** Probability of survival by age and race after first hospitalization for heart failure among older men (left panel) and women (right panel). (Adapted with permission from Croft JB, Giles WH, Pollard RA, et al. Heart failure survival among older adults in the United States: a poor prognosis for an emerging epidemic in the Medicare population. *Arch Intern Med.* 1999;159:505–510.)

For patients with refractory heart failure because of diastolic dysfunction, therapeutic options are limited (see [Table 78-12](#)). Intensive diuretic therapy may be attempted, but efficacy is often limited by the development of progressive prerenal azotemia. Similarly, a trial of inotropic therapy or dialysis may be considered, but the clinical response to these interventions is variable. Finally, although preliminary reports have suggested that some patients with diastolic heart failure may benefit from permanent dual-chamber pacing, this procedure remains investigational.

## PROGNOSIS

The overall prognosis in patients with established heart failure is poor, and the 5-year survival rate is less than 50%. In elderly patients, the prognosis is even worse, and fewer than 20% of patients with heart failure older than 80 years survive more than 5 years ([Figure 78-8](#)). In general, the prognosis is worse in men than in women, in patients with systolic rather than diastolic dysfunction, and in patients with an ischemic rather than nonischemic etiology. Patients with more severe symptoms or exercise intolerance, as defined by the New York Heart Association functional class or as assessed by a 6-minute walk test, also have a less favorable outlook. Other markers of an adverse prognosis include elevated plasma norepinephrine, B-type natriuretic peptide, tumor necrosis factor- $\alpha$ , and endothelin-1 levels; low systolic blood pressure; hyponatremia; renal insufficiency; anemia; peripheral arterial disease; cognitive dysfunction; reduced heart rate variability; and the presence of atrial fibrillation or high-grade ventricular arrhythmias. In patients with chronic heart failure, 40% to 50% die from progressive heart failure, 40% die from arrhythmias, and 10% to 20% die from other causes (e.g., myocardial infarction or noncardiac conditions).

## ETHICAL ISSUES AND END-OF-LIFE DECISIONS

As noted above, the prognosis for patients with heart failure is extremely poor, and 5-year survival rates are lower than for most forms of cancer. In addition, once heart failure symptoms have reached

an advanced stage (e.g., New York Heart Association Class III or IV), quality of life is often severely compromised and therapeutic options are limited. Moreover, even patients with relatively mild or well-compensated heart failure are continually at risk of experiencing sudden cardiac arrest, and, if initial resuscitative efforts are successful, questions regarding life support and related issues may arise.

For these reasons, it is incumbent upon the physician to discuss the patient's wishes regarding the intensity of treatment and end-of-life care at a time when the patient is still capable of understanding the issues and making informed choices. In addition, since the patient's views may evolve over the course of illness, these issues should be readdressed at periodic intervals. The development of an advance directive and appointment of durable power of attorney should also be encouraged (see [Chapter 51](#) and [34](#)).

A related concern is the extent to which the physician should offer aggressive or investigational therapeutic options that are unlikely to substantially alter the natural history of disease or significantly improve quality of life. This concern applies not only to many of the treatment modalities discussed in the refractory heart failure section above, but also to such procedures as endotracheal intubation and intra-aortic balloon counterpulsation. In many cases, these interventions not only fail to modify the clinical course but actually contribute to the patient's pain and suffering in the terminal stages of disease. Moreover, the suggestion that a given intervention may help stabilize the patient and slow disease progression may create false hopes in the minds of the patient and family, and subsequent failure of the intervention may compound the emotional suffering that both the patient and the family are forced to endure. For these reasons, it is essential that the physician realistically appraise the potential benefits and attendant risks, both physical and emotional, prior to offering aggressive therapeutic options, which may provide little or no hope of improving the patient's quality of life over a clinically important period of time.

Finally, as the patient approaches the terminal stages of disease, there should be discussions with the patient and family regarding where the patient would like to spend his or her final days. For many patients, the idea of dying at home surrounded by close family is comforting, and this desire should be honored whenever possible. For some patients, a hospice that provides compassionate end-of-life

care may be a suitable alternative. For others, the hospital may be the most desirable environment, but an attempt should be made to secure a private room with open visitation hours. The intensive care unit, with its austere, “high-tech” facade, is the least desirable place to die, and this should be avoided whenever possible.

## PREVENTION

In view of the exceptionally poor prognosis associated with established heart failure in older adults, it is essential to develop and implement preventive strategies. Appropriate treatment of hypertension has been repeatedly shown to reduce the incidence of heart failure by up to 50% (Table 78-13). Moreover, in the Systolic Hypertension in the Elderly Program, the greatest benefit was seen in patients older than 80 years (Figure 78-9). Treatment of hyperlipidemia has also been shown to reduce the incidence of heart failure, most likely through prevention of myocardial infarction and other ischemic events. Likewise, smoking cessation reduces the risk of myocardial infarction and stroke in older adults and likely has a similar effect on the development of heart failure. Unfortunately, despite abundant evidence that heart failure prevention is feasible through risk factor modification, such strategies are underused, especially in persons older than 80 years.

## SUMMARY

Heart failure is an exceedingly common and important clinical problem in older adults, owing, in large part, to the complex interplay between age-related changes in the cardiovascular system, the high prevalence of cardiovascular and noncardiovascular diseases in the older population, and the widespread use of certain drugs and other therapies that may adversely affect cardiovascular physiology. As the population of the United States continues to age, heart failure will exact a progressively greater toll on our health-care delivery system. In addition, the impact of heart failure on quality of life and independence in the large number of older adults with this disorder is incalculable. Clearly, there is an urgent need to develop more effective

# Cardiac Arrhythmias

*Xiao-Ke Liu* ■ *Arshad Jahangir* ■ *Win-Kuang Shen*

## OVERVIEW OF THE EFFECT OF AGING ON CARDIAC ELECTROPHYSIOLOGY AND EVALUATION OF ARRHYTHMIAS

### Electrophysiology and Arrhythmias in the Elderly

In older patients without apparent cardiovascular disease, the number of cardiac myocytes declines, while residual myocytes enlarge. Concurrently, there is an increase in elastic and collagenous tissue in all parts of the interstitial matrix and conduction system with advancing age. Around the sinoatrial node, adipose tissue accumulates with age, producing a partial or complete separation of the sinoatrial node from the surrounding musculature. The number of pacemaker cells steadily decreases with age, such that by the age of 75 years, less than 10% of pacemaker cells remain functional. Calcification of the cardiac skeleton, which includes the aortic and mitral annuli, the central fibrous body, and the summit of the atrioventricular (AV) septum, also increases with age. Because of their proximity to these structures, the AV node (AVN), His-Purkinje bundle, and right and left bundle branches are frequently affected by aging. Prolongation of action potential duration and diminished autonomic response are also integral components of the aging process. Taken together, these changes provide the substrate for the age-related increase in propensity for chronotropic and dromotropic incompetence and for the development of atrial and ventricular arrhythmias.

The Baltimore Longitudinal Study on Aging demonstrated that basal heart rates in the supine position do not differ significantly among younger and older healthy subjects. Heart rate response to orthostatic challenge decreases slightly in older men and women. Heart rate variability during respiration diminishes with advancing age, reflecting changes in autonomic regulation. The PR interval increases slightly with aging, most likely owing to a delay in AVN conduction.

The prevalence of atrial premature beats on ambulatory monitoring increases with age, exceeding 80% in healthy volunteers and asymptomatic elderly subjects, particularly those older than 80 years. Brief salvos of supraventricular tachycardia occur in up to 50% of older subjects, and the prevalence doubles between the seventh and ninth decades of life. These arrhythmias have not been shown to have adverse prognostic significance. Atrial fibrillation (AF) and tachycardia–bradycardia syndrome are predominant conditions of the elderly.

Ventricular arrhythmias also increase with age. In longitudinal studies, the prevalence of ventricular arrhythmias on ambulatory monitoring is as high as 60% to 90% in asymptomatic elderly subjects. Complex forms such as pairs and triplets occur in up to 10% of such individuals. Exercise testing may induce ventricular arrhythmias in up to 60% of subjects in the ninth decade of life. The prognostic significance of these arrhythmias is dependent in large part on the presence of underlying cardiovascular disease. In patients with cardiovascular disease, frequent ventricular ectopy may adversely affect quality of life, may contribute to deterioration in myocardial function increasing susceptibility to heart failure, and may be a harbinger of symptomatic and sustained ventricular arrhythmias and cardiac arrest. Conversely, the prognostic impact of rest or exercise-induced ventricular arrhythmias is limited in the absence of cardiovascular disease. Reduced heart rate variability by fractal analysis has also been linked to the occurrence of sudden cardiac death (SCD) and non-sudden cardiac death in an unselected population of elderly subjects.

### Clinical Testing

Several clinical tools are available for identification of patients at risk of cardiac arrhythmias or its consequences that may benefit from interventions to reduce morbidity and risk of sudden death. These include noninvasive tests, such as a standard 12 lead electrocardiogram

(ECG), exercise test or imaging to determine the severity of left ventricular systolic dysfunction, presence of late potentials on signal-average electrocardiography, severity of ventricular arrhythmias by ambulatory cardiac monitoring (Holter monitor or external or implantable event monitor), detection of repolarization instability by measurement of QT interval, QT dispersion and microvolt T-wave alternans, autonomic balance by heart rate variability or baroreflex sensitivity, or invasive tests to determine inducibility of sustained ventricular arrhythmias by programmed electrical stimulation. The effect of advanced age on predictability of these tests for risk stratification, however, has not been fully assessed.

A standard 12-lead ECG allows identification of underlying structural disease, such as conduction system abnormalities with heart block, bundle-branch block, ventricular hypertrophy, or prior infarction, as well as primary electrical disorders, such as the long-QT syndrome, short-QT syndrome, Brugada syndrome, or arrhythmogenic right ventricular cardiomyopathy. A prolonged QRS duration >120 milliseconds in patients with a severely depressed ventricular function or a prolonged QTc interval in the elderly predict higher risk of SCD. Absence of a slowly conducting zone, the electrophysiologic substrate for reentrant ventricular arrhythmias that is otherwise detected as late potentials on signal-average electrocardiography may be useful with its high negative predictive value to exclude a wide-complex tachycardia as a cause of unexplained syncope in the elderly patient with coronary artery disease.

The indications for ambulatory ECG recordings are similar between the younger and elderly populations. To detect a suspected arrhythmic event occurring frequently (e.g., greater than once every 48 hours or reproducible by outpatient activities), detect a precise count of ectopy, evaluate daily ventricular rate control in AF, or detect asymptomatic nonsustained ventricular tachycardia, a continuous ECG recorder such as a Holter is useful. Less frequent arrhythmias (e.g.,  $\geq 1$  event per month but not occurring daily) can be investigated using an event recorder. A pre-event loop recorder is needed for patients with syncope or symptoms of brief duration. Even less frequent events or in patients who are unable to activate the event recorder, an implantable loop recorder such as the Reveal device, which may record either automatically or by patient activation, can be very helpful in correlating symptoms to arrhythmias. Exercise ECG with or without cardiac imaging with echocardiogram or nuclear scan may also provide useful diagnostic and prognostic information in the evaluation of patients with known or suspected coronary artery disease or exercise-induced arrhythmias triggered by ischemia or catecholamine. Assessment of left ventricular systolic function and other structural and functional information about myocardial dimensions, wall thickness, and valvular and congenital heart disorders with imaging technique, such as echocardiogram, is an essential part of risk stratification of patients with ventricular arrhythmias at risk of SCD.

In most cases, the indications for invasive electrophysiologic study (EPS) in elderly patients are also the same as in younger patients (Table 79-1) and vary with the type and severity of heart disease. It is useful for arrhythmia assessment and risk stratification for SCD in elderly patients with ischemic heart disease and left ventricular dysfunction or syncope but plays only a minor role in the evaluation of patients with nonischemic cardiomyopathy or inherited arrhythmia syndromes, such as the long- or short-QT syndrome. It should be noted that Table 79-1 is based on the AHA/ACC guidelines from 1995, and there has been no recent update on indications

for EPS. Some of the recommendations have changed as more data become available through multiple recent device trials, e.g., as discussed later in the chapter, EPS is no longer considered necessary for recommending device implantation in many patients with ischemic or nonischemic cardiomyopathy or in patients with documented out-of-hospital cardiac arrest. This section provides a brief overview of criteria for the selection of elderly patients for EPS, as well as a discussion of procedural risks.

Indications for EPS can be divided broadly into diagnostic and therapeutic purposes. In any patient, but especially in the elderly, the use of an intervention such as EPS, whether for diagnosis or therapy, should be determined from the clinical presentation and the specific goals of the study. Therefore, two key questions should be addressed before proceeding with EPS. First, is information obtained from the history and noninvasive evaluation sufficient to explain the clinical presentation, or is invasive EPS necessary to ensure an accurate diagnosis? Second, will the results of invasive EPS help guide therapy, or is catheter ablation being considered as a therapeutic option? Importantly, the decision to proceed with EPS remains a clinical judgment based on the history and physical findings, the probability of a cardiac cause of symptoms, and the likelihood that the results of EPS will substantially improve patient care and outcomes.

In general, procedural complications in the elderly are similar to those in younger patients. These include complications related to the procedure itself, such as (1) vascular damage, pneumothorax, or myocardial perforation leading to pericardial effusion and tamponade, and (2) exacerbation of preexisting medical conditions (e.g., chronic obstructive pulmonary disease and chronic heart failure). Exacerbation of preexisting conditions is most common with prolonged procedures, such as complicated ablation, and is rarely a problem during diagnostic EPS or straightforward catheter ablation. A widely held belief is that morbidity and mortality associated with invasive EPS are higher in elderly patients. Although this is not borne out by available data, which suggest similar rates of complications even in very elderly patients, one must be cognizant that patient selection bias is inevitably present in these observational studies. Thus, the potential risks and benefits of invasive EPS should be weighed on an individual basis and not merely by age.

## BRADYARRHYTHMIA AND CARDIAC PACEMAKER THERAPY IN THE ELDERLY

Aging is associated with progressive fibrosis of the sinoatrial node and AV conduction system, resulting in bradycardia, which may be further exacerbated by disease and medications, resulting in symptoms requiring permanent pacemaker implantation. More than 80% of pacemaker recipients in the United States are older than 65 years, and the median age is 75 years. As the population ages, it is anticipated that the number of older persons requiring permanent pacemakers, as well as the associated costs, will continue to rise.

### Standard Indications

Current guidelines for pacemaker implantation are updated regularly by the American College of Cardiology, American Heart Association, and North American Society of Pacing and Electrophysiology (now the Heart Rhythm Society). This section provides a synopsis of

TABLE 79-1

## Indications for Invasive Electrophysiologic Study Based on AHA/ACC Guidelines (1995)

CLINICAL CONDITION OR INDICATION	CLASS I (APPROPRIATE)*	CLASS II (EQUIVOCAL)†	CLASS III (INAPPROPRIATE)‡
Recurrent syncope	Patients with recurrent syncope that remains unexplained after appropriate evaluation	Patients with recurrent unexplained syncope without structural heart disease and negative tilt	Patients with a known cause of syncope in whom treatment will not be guided by invasive EPS
Sinus node dysfunction	To establish association between symptoms and arrhythmia	Patients with documented sinus node dysfunction in whom other arrhythmias are suspected	Patients in whom an association has already been established or who are asymptomatic
Atrioventricular block	Symptomatic patients in whom atrioventricular block is suspected	Patients in whom knowledge of the site of block would help guide therapy	Patients in whom an association has already been established or who are asymptomatic or have pauses only during sleep
Intraventricular conduction delay	Symptomatic patients in whom the cause is unknown	Asymptomatic patients in whom pharmacologic therapy is planned	Symptomatic patients in whom an association has already been established or asymptomatic patients
Narrow complex tachycardia (QRS <120 ms)	Frequent or poorly tolerated tachycardia; patient preference	Intolerance of antiarrhythmic or atrioventricular nodal blocking drugs	Patients with few episodes of tachycardia or in whom ablation is not appropriate
Wide-complex tachycardia	Mechanism unclear or to help guide appropriate management	None	Patients in whom knowledge of the mechanism is clear from ECG or in whom knowledge is unnecessary
Out-of-hospital cardiac arrest	Survivors of cardiac arrest without obvious reversible cause	Cardiac arrest caused by documented bradycardia; patients in whom the results of EPS may be nondiagnostic or equivocal	Cardiac arrest within 48 h of AMI Cardiac arrest owing to clearly definable cause
Risk stratification for patients who may be candidates for implantable cardioverter defibrillator	Primary prevention in patients with MI, impaired LV function and nonsustained VT, or out-of-hospital cardiac arrest§	Patients with syncope and structural heart disease	Patients who are not candidates for implantable cardioverter defibrillator
Indications for catheter ablation procedures	Patients with symptomatic supraventricular arrhythmias owing to AVNRT or AVRT in whom ablation is preferred	Patients found to have a tachycardia substrate that is different from that suspected clinically	Patients with well-tolerated PSVT and who prefer conservative treatment to ablation
	Patients with symptomatic atrial tachyarrhythmias, such as typical atrial flutter, that may be amenable to catheter ablation therapy	Patients with atrial tachyarrhythmias in which catheter ablation may be successful in some cases	Patients with atrial tachyarrhythmias that are well tolerated or in whom catheter ablation is not preferred
	Patients with some forms of ventricular tachycardia that are amenable to catheter ablation therapy	Selected patients with VT because of reentry around a scar after (remote) myocardial infarction	Patients with well-tolerated ventricular arrhythmias or patients with multiple VT morphologic findings

AMI, acute myocardial infarction; AV, atrioventricular; AVNRT, atrioventricular nodal reentrant tachycardia; AVRT, atrioventricular reentrant tachycardia; ECG, electrocardiography; EPS, electrophysiologic study; LV, left ventricular; MI, myocardial infarction; PSVT, paroxysmal supraventricular tachycardia; VT, ventricular tachycardia.

\*Class I: conditions for which there is general agreement that the form of therapy is appropriate.

†Class II: conditions for which there is divergence of opinion with respect to the necessity of the procedure.

‡Class III: conditions for which there is general agreement that the therapy is unnecessary or inappropriate.

§See text for comments.

current indications for pacemaker implantation and outcomes from recent clinical trials relevant to pacemaker selection in older adults.

### Acquired Advanced AV Block

Class I indications for permanent pacemaker implantation include third-degree AV block and advanced second-degree AV block in symptomatic patients. Pacing therapy is also recommended in patients with neuromuscular diseases and third-degree AV block

whether or not they are symptomatic, because progression of AV conduction slowing is not predictable in such patients.

### AV Conduction Disease

Symptomatic patients (syncope and presyncope) with conduction system disease manifesting as bifascicular or trifascicular block on ECG in the absence of an alternative explanation for their symptoms are candidates for an EPS and/or permanent pacing. Prolongation of

the HV interval beyond 80 milliseconds may be an index of potential high-degree AV block, and some clinicians recommend prophylactic permanent pacing in this setting. Other experts consider HV prolongation a marker of underlying heart disease and increased risk for sudden death but do not recommend pacemaker therapy unless the patient is symptomatic. According to the current guidelines, in the absence of syncope or presyncope, an HV interval of 100 milliseconds or more and/or nonphysiological infra-His block demonstrated during EPS are class IIa indications for pacemaker insertion.

### Sinus Node Dysfunction

Pacemaker therapy is indicated in patients with symptomatic bradycardia (syncope, presyncope, dyspnea, and exercise intolerance) correlated to sinus node dysfunction (pauses, persistent bradycardia, or chronotropic incompetence). In elderly patients, sinus node dysfunction is often associated with atrial tachyarrhythmias, including AF. Because of the frequent association of sinus node dysfunction with AF, VVI and VVIR pacing were once considered the preferred pacing modes. Recent studies suggest that atrial-based pacing in patients with sinus node dysfunction is beneficial for preventing progression of AF. Current pacemaker technology allows mode switching from DDD to VVI or DDI in case of paroxysmal AF, thus avoiding ventricular tracking of fast atrial rates. These considerations have led to a progressive increase in the use of dual-chamber pacemakers in elderly patients. Some clinicians advocate AAI or AAIR pacing as the best pacing mode because these modes provide more physiological ventricular activation and are technically less complex. This approach has not been widely adopted in clinical practice because progression to AV block during long-term follow-up has been reported in up to 10% of elderly patients with sinus node dysfunction. Although maintaining AV synchrony during AV block and the availability of mode switch to reduce or eliminate inappropriate tracking during atrial tachyarrhythmia support the rationale for dual-chamber pacing in patients with sinus node dysfunction, recent data raised concerns whether excessive ventricular pacing from the right ventricular apex may cause increased incidence of heart failure and heart failure-mediated hospital admission. The clinical advantages of programmable features such as “AV delay hysteresis” or “managing ventricular pacing” to minimize ventricular pacing in the presence of AV conduction are currently under investigation.

## Pacemaker Therapy

### Prospective Trials of Ventricular (VVI) and Physiological (AAI or DDD) Pacing

In 1998, the results of the Pacemaker Selection in the Elderly trial were published. This randomized comparison of ventricular and dual-chamber pacing included 407 patients 65 years or older followed for 30 months. Patients with sinus node dysfunction, but not those with AV block, had a moderately better quality of life and cardiovascular functional status with dual-chamber pacing. One-fourth of all patients assigned to the VVI mode crossed over to dual-chamber operation because of symptoms suggesting “pacemaker syndrome.” In the same year, Mattioli et al. reported a randomized trial involving 210 patients, which showed a higher incidence of AF and stroke in patients randomized to ventricular pacing.

Although the above trials were too small to assess the effect of pacemaker mode on mortality, three large mortality trials have now been completed (Table 79-2). The Canadian Trial of Physiologic Pacing enrolled 2568 patients who were scheduled for an initial implantation of a pacemaker to correct symptomatic bradycardia, did not have chronic AF, and were at least 18 years old. These patients were then randomized to ventricular pacing (VVIR) or a physiologic mode (AAIR or DDDR). At 4 years follow-up, there were no differences between the two groups in the primary study end point, the combination of cardiovascular death or stroke. In addition, all-cause mortality, stroke or arterial thromboembolism, hospitalization for heart failure, and performance on a 6-minute walk test did not differ between groups. Physiologic pacing had a modest benefit in association with less new onset of AF, but there were also more perioperative complications, such as lead dislodgment or inadequate atrial pacing or sensing, in patients receiving physiological pacemakers.

The Mode Selection Trial randomized 2010 patients with sinus node dysfunction to single- or dual-chamber pacing. After a mean follow-up of 2.7 years, there was no difference between groups in the primary end point, death, or stroke. However, progression to chronic AF and heart failure symptoms were less frequent, and quality of life was better in the dual-chamber pacing arm.

In the prospective U.K. Pacing and Cardiovascular Events trial that enrolled 2021 patients older than 70 years with AV block,

**TABLE 79-2**

morbidity and mortality were similar with VVI and DDD pacing, and there was also no difference in the incidence of AF between groups.

The main findings of these prospective randomized trials assessing the effect of pacing mode on long-term clinical outcomes are summarized in Table 79-2. The three largest trials conducted in three countries (United Kingdom, United States, and Canada), enrolling more than 6500 patients, did not find a beneficial effect of dual-chamber pacing for the prevention of stroke or improvement in survival when compared with ventricular pacing. However, the incidence and progression to chronic AF were reduced moderately in two of these studies. In addition, heart failure symptoms were reduced slightly and quality of life was better in patients receiving dual-chamber pacemakers for sinus node dysfunction, most likely because of the prevention of pacemaker syndrome.

## SYNCOPE IN THE ELDERLY

### Hypersensitive Carotid Sinus Syndrome

Carotid sinus hypersensitivity ( $\geq 3$ -second pause or a decrease in systolic blood pressure  $\geq 50$  mm Hg during carotid sinus massage) predominantly affects elderly patients, although the prevalence in the general population has not been precisely defined. In elderly patients with recurrent syncope, carotid sinus hypersensitivity has been reported in up to 35% of cases. Permanent pacing in patients with carotid sinus syndrome (carotid sinus hypersensitivity associated with syncope) is indicated. Observational and randomized studies have shown that recurrent symptoms are significantly reduced after permanent pacemaker implantation in patients with carotid sinus syndrome. Dual-chamber pacing is considered the best choice for these patients, although data are lacking from randomized trials. Newer algorithms, such as the “rate-drop response” or “sudden-brady response,” which accelerates the pacing rate when bradycardia is detected, are now available. However, the clinical utility of pacemakers with these newer algorithms compared with conventional pacemakers has not been determined in patients with carotid sinus syndrome.

### Neurocardiogenic (“Vasovagal”) Syncope

Vasovagal syncope is more common in younger patients but also should be considered in elderly patients with unexplained syncope. Although the triggering mechanisms are complex and may differ among young and elderly patients, the efferent responses generally can be categorized as cardioinhibitory (pauses of  $\geq 3$  seconds or heart rate  $< 40$  beats per minute for more than 10 seconds), vasodepressor (systolic blood pressure falls by 50 mm Hg or more without symptoms or 30 to 50 mm Hg with symptoms of syncope or presyncope, and the heart rate does not decrease by more than 10%), or mixed (heart rate decreases but the ventricular rate does not fall below 40 beats per minute for more than 10 seconds, and there are no pauses  $> 3$  seconds; blood pressure usually decreases before the heart rate drop). Of note, the vasodepressor component is frequently present in patients with vasovagal syncope, and pacing therapy does not necessarily eliminate or significantly reduce vasodepressor-mediated symptoms.

In three recent unblinded randomized trials (Vasovagal Pacemaker Study, Vasovagal International Study, and Syncope Diagnosis and Treatment) comparing pacing with conventional therapy (conservative or drug), recurrent symptoms were significantly reduced with pacemaker therapy. As a result, pacing for “significantly symptomatic and recurrent neurocardiogenic syncope associated with bradycardia documented spontaneously or at the time of tilt-table testing” is considered a class IIa indication for pacemaker implantation. However, following publication of these guidelines in 2002, the Vasovagal Pacemaker Study II trial, in which patients and investigators were blinded to pacing mode, failed to confirm a beneficial effect from pacing therapy in patients with vasovagal syncope.

In general, outcomes from pacing and drugs for treating vasovagal syncope reflect the heterogeneous patient population, complex underlying mechanisms, and sporadic nature of the neurocardiogenic reflex. On the basis of available evidence, it is reasonable to consider pacing as a class II indication in elderly patients who have recurrent syncope with documented bradycardia during a vasovagal response. Current data are insufficient to determine whether pacemakers with rate-drop or sudden-brady response features provide additional benefit.

### Elderly Patients with Syncope of Uncertain Cause

Syncope is a common cause of falls, injuries, and hospitalizations in older adults. Normal age-related physiological changes often combine with pathological mechanisms to impair cerebral perfusion and induce syncope. Elderly community-dwelling patients have an average of 3.5 chronic illnesses, many of which predispose to syncope. In addition, elderly patients receive three times as many medications as the general population, further increasing their vulnerability to syncope. Numerous age-related autonomic and humoral changes also predispose older patients to syncope. Decreased heart rate responsiveness to postural changes and diminished baroreceptor sensitivity impair the ability to adapt to orthostatic stress. Reduced concentrations of plasma aldosterone, coupled with impaired thirst, place elderly patients at risk of volume depletion. These age-dependent changes, in combination with comorbid medical illnesses, increase the propensity for multiple potential etiologies of syncope in elderly patients. In turn, multiple-cause syncope is an independent predictor of poor clinical outcome.

The diagnostic approach to syncope is similar in older and younger patients and begins with a careful history and physical examination, recognizing that cardiogenic causes of syncope are more common in the elderly. Factors associated with an increased risk of cardiogenic syncope include a history of coronary artery disease, prior myocardial infarction, chronic heart failure, abrupt onset of symptoms (no prodrome), event occurring in the supine position, older age, abnormal cardiovascular examination (aortic stenosis murmur and  $S_3$  gallop), abnormal ECG (Q waves, bundle branch block, or sinus bradycardia), and an abnormal echocardiogram (structural abnormality or reduced ejection fraction). Carotid sinus massage should be a routine part of examination in elderly patients presenting with syncope, unless there is a carotid bruit or prior history of stroke. In elderly patients with unexplained syncope and an increased risk of a cardiogenic cause, EPS should be considered. In patients at low risk of cardiogenic syncope, noninvasive cardiac monitoring or tilt-table testing may be appropriate. An implantable loop recorder should be considered in elderly patients with recurrent syncope of

unknown cause, especially if structural heart disease is present. Once a cause of syncope has been established, treatment is similar in older and younger patients.

Despite advances in diagnostic technology for syncope evaluation, the cause of syncope remains undetermined in approximately 20% of patients after medical evaluation; many are elderly with an increased tendency for multiple etiologies. Current guidelines do not recommend “empirical” pacemaker therapy in elderly patients with recurrent syncope if carotid sinus massage, tilt-table testing, and EPS are all nondiagnostic. In such cases, an implantable loop recorder may be helpful in establishing a diagnosis. Data from implantable loop recorders for unexplained syncope have shown a predominance of bradycardic events among patients with recurrent symptoms during follow-up.

## TACHYARRHYTHMIAS AND CARDIAC IMPLANTABLE DEFIBRILLATOR THERAPY IN THE ELDERLY

### Atrial Fibrillation

Atrial Fibrillation affects approximately 2.3 million people in the United States and is the most common rhythm disorder among U.S. patients hospitalized with a primary diagnosis of an arrhythmia. The median age of AF patients is 75 years; 84% are older than 65 years. Pooled data from studies of chronic AF in North America, Britain, and Iceland suggest a prevalence of 0.5% to 1% in the general population. In two separate studies restricted to patients older than 60 years, the incidence was 5% to 9% after 5 to 15 years of follow-up. In the United States, hospitalization for AF has increased two- to threefold in the past 15 years and the size of the AF population is projected to triple by 2050. The genesis of this AF “epidemic” is strongly linked to the expanding elderly population.

AF has a substantial impact on both morbidity and mortality. It is a strong independent risk factor for stroke, responsible for an estimated 75 000 cerebrovascular accidents annually. AF is also associated with a more than twofold increase in all-cause mortality. Although AF frequently coexists with other medical conditions, especially cardiovascular and pulmonary disorders, mortality remains higher after adjusting for these and other conditions. (For a comprehensive review of AF, see: ACC/AHA/ESC Guidelines for the Management of Patients with Atrial Fibrillation; [http://www.cardiosource.com/guidelines/guidelines/atrial\\_fib/pdfs/AF\\_final.pdf](http://www.cardiosource.com/guidelines/guidelines/atrial_fib/pdfs/AF_final.pdf).)

### Stroke Prevention in Atrial Fibrillation

Data supporting the use of anticoagulation for primary and secondary stroke prevention are more compelling than those for any other pharmacologic intervention in AF. The annual incidence of stroke in elderly patients with nonvalvular, chronic, or paroxysmal AF is approximately 5% in the absence of anticoagulation, compared with approximately 1% for comparable populations in sinus rhythm. Clinical risk factors for stroke in patients with AF include prior cerebrovascular accident, history of hypertension, diabetes mellitus, heart failure, and advanced age. Echocardiographic risk factors include increased left atrial size and decreased left ventricular systolic function.

Data from a pooled analysis of primary prevention studies indicate that the annual risk of stroke in patients with one or more

clinical risk factors varies from 4% to 12% and that warfarin therapy reduces the risk by 60% to 70% (i.e., down to 1.2–4%). In patients older than 75 years, the beneficial effect of warfarin in embolic stroke prevention is offset by increased serious bleeding complications, especially in women. In the Stroke Prevention in Atrial Fibrillation (SPAF) II trial, combined embolic and hemorrhagic stroke rates were approximately 2% in patients less than 75 years of age and 5% in patients older than 75 years. From these data, current guidelines recommend maintaining the international normalized ratio (INR) near 2.0 in patients older than 75 years, particularly women.

Aspirin is substantially less effective than warfarin for preventing thromboembolic events, especially in elderly patients with risk factors for stroke, but aspirin is also associated with a lower risk of bleeding complications, including hemorrhagic stroke. In the Atrial Fibrillation, Aspirin, and Anticoagulation study, aspirin 75 mg daily was not significantly better than placebo for stroke prevention. However, aspirin 325 mg daily significantly decreased the risk of stroke in the SPAF trial, which enrolled younger patients than Atrial Fibrillation, Aspirin, and Anticoagulation study (mean age 67 vs. 75 years). Warfarin and aspirin were directly compared in the SPAF II trial, which failed to show a significant advantage of warfarin over aspirin in either of two age groups (60–75 years and >75 years). In SPAF II, patients 60 to 75 years old had a remarkably low event rate with either regimen, whereas in the older patients a reduction in the incidence of ischemic stroke was offset by a higher rate of intracranial bleeding in the warfarin arm. In contrast, the SPAF III study, which recruited patients with at least one risk factor for stroke in addition to AF, showed a clear advantage of warfarin adjusted to maintain an INR of 2 to 3 compared with a combination of aspirin 325 mg/day and a low, fixed-dose of warfarin (0.5–3.0 mg/day; INR, 1.2–1.5). Similarly, for secondary stroke prevention, the European Atrial Fibrillation trial demonstrated a 40% lower event rate with warfarin compared to aspirin.

The role of newer antiplatelet agents, such as clopidogrel, and antithrombotic agents, such as ximelagatran, for the prevention of thromboembolic events in elderly patients with AF is being determined. From the recent “clopidogrel plus aspirin versus oral anticoagulation for atrial fibrillation in Atrial fibrillation Clopidogrel Trial with Irbesartan for prevention of Vascular Events (ACTIVE W): a randomized controlled trial,” the study was stopped early because warfarin was superior to clopidogrel plus aspirin for prevention of vascular events in patients (primarily elderly) with AF at higher risk of stroke. In the Stroke Prevention using an Oral Thrombin Inhibitor in Atrial Fibrillation III and V trials, ximelagatran, a new oral antithrombin, was not inferior to warfarin for the prevention of stroke in patients with AF. Major adverse effects, including bleeding, occurred less frequently in patients treated with ximelagatran than in those who received warfarin. Transient increases in liver enzymes were reported in approximately 6% of patients. Ximelagatran was not approved for clinical use primarily owing to the side effect of liver toxicity. Other oral antithrombin agents are currently under development and clinical investigation.

Current recommendations for stroke prevention in patients with AF are summarized in Table 79-3. More detailed discussion and models of stroke risk estimation including the CHADS2 score system are described in the 2006 AHA/ACC guidelines for management of AF. In elderly patients, the decision to initiate anticoagulation with warfarin must be balanced against the increased risk of intracerebral bleeding and bleeding related to injuries from falls.

TABLE 79-3

## Risk-Based Approach to Antithrombotic Therapy in Patients with Atrial Fibrillation

PATIENT CHARACTERISTICS	ANTITHROMBOTIC THERAPY	GRADE OF RECOMMENDATION
Age <60 yr, no heart disease (lone AF)	Aspirin (81–325 mg/day) or no therapy	I
Age <60 yr, heart disease but no risk factors*	Aspirin (81–325 mg/day)	I
Age 60–74 yr, no risk factors*	Aspirin (81–325 mg/day)	I
Age 65–74 yr with DM or CAD	Oral anticoagulation (INR, 2.0–3.0)	I
Age ≥75 yr, women	Oral anticoagulation (INR, 2.0–3.0)	I
Age ≥75 yr, men, no other risk factors	Oral anticoagulation (INR, ≈2.0) or ASA (81–325 mg/day)	I
Age 65 yr or older, heart failure	Oral anticoagulation (INR, 2.0–3.0)	I
LV ejection fraction less than 35% or fractional shortening less than 25%, and hypertension	Oral anticoagulation (INR, 2.0–3.0)	I
Rheumatic heart disease (mitral stenosis)	Oral anticoagulation (INR, 2.0–3.0)	I
Prosthetic heart valves	Oral anticoagulation (INR, 2.0–3.0 or higher)	I
Prior thromboembolism		
Persistent atrial thrombus on TEE	Oral anticoagulation (INR, 2.0–3.0 or higher)	IIa

AF, atrial fibrillation; CAD, coronary artery disease; DM, diabetes mellitus; INR, international normalized ratio; LVEF, left ventricular ejection fraction; TEE, transesophageal echocardiography.

\*Risk factors for thromboembolism include heart failure, left ventricular ejection fraction less than 35%, and history of hypertension.

From Fuster V, Rydén LE, Asinger RW, et al. ACC/AHA/ESC guidelines for the management of patients with atrial fibrillation: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines and the European Society of Cardiology Committee for Practice Guidelines and Policy Conferences (Committee to Develop Guidelines for the Management of Patients With Atrial Fibrillation). *J Am Coll Cardiol.* 2006;114:e257–e354. By permission of the American College of Cardiology, the American Heart Association, Inc, and the European Society of Cardiology.

Careful monitoring of warfarin dosing with frequent evaluation of the level of anticoagulation is warranted.

The risk of thromboembolism with acute cardioversion in patients with AF, which has been present for fewer than 48 hours, is low (0.8%). In patients with AF for longer than 48 hours or of unknown duration, warfarin therapy is recommended for 4 weeks before attempting cardioversion (either electrical or chemical). Recent data suggest that transesophageal echocardiography is effective for excluding atrial thrombi and allows earlier cardioversion in patients with AF of unknown duration. However, anticoagulation must be continued for at least 4 weeks after cardioversion because mechanical atrial stunning increases the risk of atrial thrombus formation.

### Pharmacologic Therapy for Atrial Fibrillation

**Rate Control** Although urgent cardioversion is required for patients with AF associated with hemodynamic instability, persistent angina, or critical aortic stenosis, most acute-phase symptoms can be controlled by prompt reduction of the ventricular rate. Digitalis glycosides decrease ventricular rate in AF by augmenting cardiac vagal tone and increasing the level of block at the AVN. However, in both acute and chronic settings, digoxin is generally less effective at controlling rate than either  $\beta$ -adrenergic blockers or calcium channel-blockers (i.e., diltiazem or verapamil), especially during exercise or parasympathetic withdrawal. There are also no data to support the use of digoxin for chemical cardioversion or for the maintenance of sinus rhythm; in fact, digoxin theoretically may facilitate AF by shortening the atrial refractory period and increasing atrial automaticity.

$\beta$ -Blockers and calcium channel-blockers reduce the ventricular rate in AF by slowing conduction through the AVN. The choice between these two groups of drugs primarily depends on the clinical context. For example,  $\beta$ -blockers are preferable for rate control of AF paroxysms precipitated by acute coronary ischemia, whereas calcium channel-blockers are chosen in the setting of asthma. Clonidine, a

central  $\alpha$ 2-receptor agonist, can be moderately effective for reducing ventricular rate by decreasing central nervous system sympathetic outflow. In elderly patients, optimizing rate control with drugs may be difficult because of presence of comorbidities and susceptibility to adverse effects. Clinical conditions such as sinus node dysfunction, AV conduction delay, and ventricular dysfunction may result in significant bradyarrhythmia or worsening heart failure when rate-controlling agents are administered. In addition, rate control alone may be insufficient to alleviate symptoms in some patients, such as those with hypertrophic cardiomyopathy, in whom restoration of sinus rhythm may be beneficial.

**Rhythm Control** In the acute setting, rhythm control can be established by pharmacological or nonpharmacological cardioversion. The efficacy of intravenous and oral antiarrhythmic drugs for cardioversion of AF is highly variable, ranging from 30% to 75%. Efficacy also varies with the age of the patient, duration of the arrhythmia, presence of atrial flutter, underlying left ventricular function, and left atrial size. Ibutilide, a class III drug, is more effective in restoring sinus rhythm in atrial flutter than AF. Dofetilide, another class III agent, is effective for oral prophylaxis and safe in patients with left ventricular dysfunction. Single-dose oral propafenone has also been evaluated for AF cardioversion and has an excellent efficacy and safety profile. In general, higher cardioversion efficacy rates are reported for paroxysmal than for persistent AF. Elderly patients may be at increased risk of proarrhythmia with all of these agents, thus necessitating careful monitoring during and after cardioversion. The efficacy of intravenous amiodarone for termination of recent-onset AF is disputed. Although some studies suggest a high efficacy comparable to direct-current cardioversion, intravenous amiodarone was not more effective after 24 hours than placebo in a randomized trial of 100 patients with recent AF. This may be explained by the delayed onset of amiodarone's antiarrhythmic effects. Current data do not support the use of amiodarone for acute cardioversion.

TABLE 79-4

## Atrial Fibrillation Clinical Trials: Rate versus Rhythm Control

TRIAL,* YEAR REPORTED	NO. ENROLLED	MEAN AGE (yr)	TYPE OF AF	PRIMARY END POINT	PRIMARY END POINT OUTCOME	COMMENTS		
						QOL	Hospitalization	Stroke
PIAF, 2000	252	61	Persistent	Symptoms	NS	NS	↑	Not stated
AFFIRM, 2002	4060	70	Mostly persistent Paroxysmal <30%	All-cause mortality	NS (trend toward higher mortality in rhythm control)	NS	↑	(↑)
RACE, 2002	522	68	Persistent	Composite: cardiovascular death, hospitalized for heart failure, thromboembolic events, severe bleeding, drug side effects, and PM implantation	NS	NS	↑	(↑)

AF, atrial fibrillation; NS, no significant difference; PM, pacemaker; QOL, quality of life; TIA, transient ischemic attack; ↑, significantly higher in rhythm control; (↑), higher, but not significantly, in rhythm control.

\*AFFIRM, Atrial Fibrillation Follow-up Investigation of Rhythm Management; PIAF, Pharmacological Intervention in Atrial Fibrillation; RACE, Rate Control Versus Electrical Cardioversion for Persistent Atrial Fibrillation Study; STAF, Strategies of Treatment of Atrial Fibrillation.

External direct-current cardioversion can restore sinus rhythm in 75% to 90% of patients with AF. Catheter- or device-delivered internal cardioversion has a reported efficacy rate of close to 100%, even in patients in whom external cardioversion has failed. Internal cardioversion is indicated in patients who are refractory to external techniques and when restoration of sinus rhythm is deemed obligatory. Failure of external cardioversion is becoming uncommon because cardioverters with biphasic current waveforms, with improved efficacy in restoring sinus rhythm, are now used in routine clinical practice.

For maintenance of sinus rhythm in patients with recurrent AF, consideration is given to chronic antiarrhythmic therapy. Class Ia antiarrhythmic drugs such as quinidine, disopyramide, and procainamide; class Ic agents such as flecainide and propafenone; and class III agents such as sotalol, amiodarone, and dofetilide have all been used to prevent recurrent AF, with efficacy rates ranging from 30% to 80% during the first year of follow-up. Amiodarone is more efficacious and safer during short- and intermediate-term follow-up than class I agents, for which the risk of ventricular proarrhythmia must be carefully considered. The presence of structural heart disease, which is common in the elderly, increases the risk of proarrhythmia with class I agents. However, amiodarone is associated with considerable noncardiac side effects during long-term use, resulting in drug discontinuation rates of up to 20% at 1 year. In general, drugs with substantial negative inotropic effects, including procainamide, disopyramide, and flecainide, are contraindicated in patients with left ventricular systolic dysfunction. Class IC drugs should not be used in patients with underlying coronary artery disease. Class Ia and III agents prolong ventricular repolarization and the QT interval owing to potassium channel blockade. Propafenone, sotalol, and amiodarone have a  $\beta$ -blocking effect that could be clinically significant in elderly patients with sinus node or AVN conduction disease. In patients with His-Purkinje disease (e.g., bifascicular or trifascicular block on electrocardiography), class I agents should be used with caution because of their potential to slow infranodal conduction.

Dofetilide, sotalol, and active metabolite of procainamide are predominantly excreted by the kidney and should be used with extreme caution in elderly patients with concomitant renal dysfunction.

**Rate versus Rhythm Control** Ideally, the goals of treating AF are to restore and maintain sinus rhythm, but all currently available therapeutic options are also associated with significant risks. Four randomized trials (Table 79-4) recently compared the effectiveness of rate control (i.e., controlling ventricular rate in AF) versus rhythm control (attempting to maintain sinus rhythm).

The largest of these studies was the Atrial Fibrillation Follow-up Investigation of Rhythm Management trial, which enrolled more than 4000 elderly patients with AF and at least one risk factor for stroke. After a mean follow-up of 3.5 years, there was a trend toward increased mortality in the rhythm control arm, but there was no difference between groups in a composite secondary end point that included stroke and other cardiovascular events. The Rate Control versus Electrical Cardioversion for Persistent Atrial Fibrillation study and the Strategies of Treatment of Atrial Fibrillation trial also found that rate control was not inferior to rhythm control for the prevention of death and cardiovascular morbidity. Functional outcomes were addressed in the Rhythm or Rate Control in Atrial Fibrillation—Pharmacological Intervention in Atrial Fibrillation study, in which patients were randomized to amiodarone for rhythm control or diltiazem for rate control. During a follow-up of 12 months, the proportion of patients who reported improvement in symptoms was similar in both groups. Exercise tolerance was better with rhythm control, although hospital admissions were significantly more frequent in the amiodarone-treated group.

Outcomes of the Atrial Fibrillation Follow-up Investigation of Rhythm Management, Rate Control versus Electrical Cardioversion for Persistent Atrial Fibrillation Study, Strategies of Treatment of Atrial Fibrillation, and Rhythm or Rate Control in Atrial Fibrillation—Pharmacological Intervention in Atrial Fibrillation trials suggest that medical therapy for rate control and chronic

anticoagulation are the preferred approaches in asymptomatic or minimally symptomatic patients with persistent AF. These studies clearly show that an optimal drug therapy regimen for AF is not currently available; as a result, the most efficacious therapeutic strategy for the large population of patients with *symptomatic* AF, who are predominantly elderly (estimated to be at least 40% of the entire AF population), remains to be resolved.

### Nonpharmacologic Therapy for Atrial Fibrillation

In the absence of a simple and effective drug-based treatment strategy, major efforts are being undertaken to develop and evaluate nonpharmacologic methods for treating recurrent AF. Before wide application of these approaches can be recommended in the elderly, clinically relevant end points, such as survival, stroke, major cardiovascular events, symptoms, and functional capacity, must be evaluated. General guidelines on catheter ablation, including ablation for AF, were updated in 2006: ACC/AHA/ESC 2006 guidelines for the management of patients with AF and 2007 (Heart Rhythm Society guidelines for AF ablation).

**Rate Control** In patients with severe symptoms and in whom drug therapy fails, ablation of the AVN and permanent pacing are effective for controlling ventricular rate. Although ablation of the AVN does not eliminate AF or the need for anticoagulation, it relieves symptoms and improves health-related quality of life, exercise tolerance, and left ventricular function. In addition, recent data from the Left Ventricular-Based Cardiac Stimulation Post AV Nodal Ablation Evaluation study suggest that biventricular pacing after AVN ablation is associated with improved 6-minute walk distance compared with conventional right ventricular apex pacing in patients with preexisting heart failure symptoms. Despite the efficacy of AVN ablation and pacemaker implantation for controlling symptoms in patients with AF, there is concern that the creation of complete AV block and the associated requirement for permanent pacing may have an adverse effect on long-term survival. However, in a large observational study, survival among patients who underwent ablation of the AVN to control ventricular rate for AF was similar to that among patients who received drug therapy.

Although ablation of the AVN plus pacemaker therapy seems to be a logical solution in the elderly with recurrent and symptomatic AF because the procedures are relatively straightforward with a high success rate (near 100%) and subsequent clinical improvement, most of the data accumulated thus far are from observational studies with a highly selected patient population. Large-scale randomized trials are needed to determine whether AVN ablation is beneficial to patients compared to pharmacologic rate control in the AF elderly population at large. In addition, large-scale randomized trials are needed to determine whether patients who have undergone AVN ablation should receive conventional pacemakers versus cardiac resynchronization therapy (CRT) pacemakers.

**Rhythm Control** Despite antiarrhythmic drug therapy, recurrent and refractory symptomatic AF is common in patients of all ages. Nonpharmacologic treatment options are increasingly being used to maintain sinus rhythm in these patients. However, the projected benefits must be weighed carefully against the potential risk of invasive procedures, especially in older patients with other comorbid conditions. The surgical maze procedure is highly effective in the treatment of refractory AF and has become an important adjunctive

procedure for patients with AF undergoing cardiac surgery for other reasons. The long-term success rate has been reported to be as high as 90% during 4- to 5-year follow-up. The surgical experience has also provided impetus to develop catheter-based ablative techniques for the treatment of AF.

Currently, there are two general catheter approaches to target the arrhythmogenic AF substrate. Isolation of pulmonary veins, the first approach, is based on the premise that most AF is initiated or “triggered” from foci at the pulmonary vein and left atrial junction. This approach appears to be most suited for patients with paroxysmal AF and no significant preexisting heart disease; usually these patients are younger and likely to have a predominantly triggered mechanism initiating AF. The second approach is based on the concept that AF is usually sustained by a diffuse arrhythmogenic atrial substrate in patients with persistent AF and preexisting heart disease; usually these patients are older. The second approach requires a wider area of ablation involving the pulmonary vein orifices, the left atrium, and the right atrium. The success rate of catheter-based ablation for AF reported in the literature has been highly variable. Some explanations include, but not limited to, differences in patient selection, operator’s experience, ablation techniques, procedural endpoints, follow-up, and definition of “success.” In a recent survey from multiple centers around the globe, the success rate for catheter ablation has been estimated in the range of 60% to 70% in patients with paroxysmal AF and 40% to 60% in patients with persistent or permanent AF during an average follow-up of 2 years. One should also be aware that the mean age of patients undergoing primary AF ablation in most studies has been in the range of 50 to 65 years of age. Whether similar outcomes can be obtained in the majority of the AF patients, >80% older than 65 years, remain to be determined.

Major complications of AF ablation include death, stroke, tamponade, esophageal perforation or fistula, and pulmonary vein stenosis. The impact of AF ablation on stroke is also unknown; therefore, continuation of anticoagulation is recommended.

An alternative approach to the treatment of infrequent episodes of paroxysmal AF is the implantable atrial defibrillator. This device is safe and effective for terminating AF. However, its clinical application is limited because of discomfort experienced by conscious patients and the lack of evidence of a beneficial effect on long-term clinical outcomes.

### Supraventricular Tachyarrhythmia

The principles of drug and nondrug management of supraventricular tachyarrhythmia (SVT) are similar to those outlined for AF. However, for most SVTs, the arrhythmogenic substrate is isolated and well defined. AV nodal reentrant tachycardia (localized to the region of AVN) and AV reentrant tachycardia (with use of an accessory pathway) are the two most common types of SVT. Atrial tachycardia can be reentrant or non-reentrant in mechanism, can be right or left atrial in origin, and can occur more frequently in the elderly population than in younger patients.

$\beta$ -Blockers and calcium channel-blockers are effective for treating SVTs originating or using the sinoatrial node or AVN as a component of the tachycardia and for treating SVTs mediated by catecholamines. Class I and III antiarrhythmic agents are effective for treating SVTs involving conduction through an accessory pathway or atrial tissue. Ablative therapy is also highly effective for the treatment of SVTs (see Supraventricular Arrhythmias: ACC/AHA/ESC Guidelines for the Management of Patients with Supraventricular Tachyarrhythmias;

<http://www.cardiosource.com/guidelines/guidelines/arrhythmias/sva-index.pdf>).

Class I indications for catheter ablation are (1) symptomatic AV nodal reentrant tachycardia, (2) recurrent atrial flutter, (3) SVTs associated with preexcitation if the tachyarrhythmia is drug resistant or if the patient is drug intolerant or does not want long-term drug therapy, and (4) atrial tachyarrhythmias with rapid ventricular response as a result of conduction over an accessory pathway. Indications for catheter ablation in elderly and very elderly patients have not been separately defined and are the same as those for the general population. Success rates for catheter ablation of SVT range from 75% to more than 95%, depending primarily on the nature of the arrhythmia and the experience of the operator; notably, age is not predictive of procedural success.

The incidence of major complications associated with SVT ablation is approximately 3%, and the risk of minor complications is approximately 8%. Major complications include death, stroke, myocardial infarction, and complete heart block requiring permanent pacemaker implantation. The overall risk of thromboembolic complications is approximately 0.6%, but the risk is higher when ablation is performed in the left heart (1.8%–2%). Independent predictors of major complications include increasing age, the presence of heart disease, and multiple ablation targets.

## Ventricular Tachyarrhythmia

Advancing age is associated with a progressive increase in the incidence of ventricular premature beats and nonsustained ventricular tachycardia in patients with or without manifest cardiac disease. These trends have been attributed to undetected cardiac disease, increased left ventricular mass, higher serum catecholamine levels, and intrinsic age-related changes in the cardiac myocyte and the extracellular matrix.

The management of ventricular arrhythmias in elderly patients is similar to that in the general population. In patients with asymptomatic nonsustained ventricular tachyarrhythmia, a careful evaluation for the presence of cardiac disease, including occult coronary artery disease, structural heart disease, and left ventricular dysfunction, is required. Premature ventricular contractions and nonsustained ventricular tachyarrhythmia are associated with a benign prognosis in the absence of any significant heart disease. The risk of SCD is increased in patients with compromised left ventricular ejection fraction, whether because of ischemic or nonischemic heart disease. Prevention of SCD entails optimization of therapy directed at the underlying disease and the use of implantable cardioverter-defibrillator (ICD) therapy in selected patients (ACC/AHA guidelines for implantation of cardiac pacemakers and antiarrhythmia devices). Note that although none of the indications for ICDs exclude or allude to special considerations in elderly patients, individual assessment and determination of primary therapeutic objectives are particularly pertinent in this population because comorbid medical illnesses are frequently present and life expectancy is shorter in the very elderly.

## Secondary Prevention of Sudden Cardiac Death

Indications for implantation of a cardioverter defibrillator for secondary prevention of SCD include (1) cardiac arrest owing to ventricular tachycardia or ventricular fibrillation not related to a transient

or reversible cause (e.g., acute myocardial infarction), (2) spontaneous sustained ventricular tachycardia in association with structural heart disease, and (3) syncope of undetermined origin with clinically relevant, hemodynamically significant sustained ventricular tachycardia or ventricular fibrillation induced at EPS when drug therapy is ineffective, not tolerated, or not preferred. Randomized, prospective clinical trials comparing antiarrhythmic drug therapy to ICD have demonstrated the usefulness of ICD in reducing the risk of SCD as a result of cardiac arrhythmias in those at risk of or resuscitated from cardiac arrest or life-threatening ventricular arrhythmias. However, none of these trials have focused specifically on the efficacy of ICD in the older-elderly. Overall, the average age of patients in the clinical trials of ICD has been in the sixties, ranging from the fifties into the high seventies. Data on octogenarian and nonagenarian patients are scant; however, using pooled data from the three major randomized ICD secondary prevention trials of SCD, a recent study by Healey et al. found no statistically significant reduction in all-cause mortality or arrhythmic death among patients aged 75 years, randomized to ICD therapy versus amiodarone. This highlights the importance of individualization when making decisions on ICD implantation in the older-elderly, taking into account the current guidelines, patient's preference, biological age, functional capacity, and underlying comorbidities.

## Primary Prevention of Sudden Cardiac Death

Results from several recently completed trials have important implications for the primary prevention of SCD (Table 79-5). In patients with coronary artery disease, prior myocardial infarction, and ejection fraction of 30% or less, a survival benefit was found with prophylactic implantation of a cardioverter defibrillator compared with medical therapy (MADIT-II). In the MADIT-II trial, benefits in patients with preexisting left bundle branch block were more pronounced. In the Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT), an ICD was associated with improved survival compared with amiodarone or medical therapy in patients with class II or III heart failure symptoms and an ejection fraction of 35% or less, and the benefit was evident in patients with or without ischemia (48%). Although not significant, the Defibrillators in Non-ischemic Cardiomyopathy Treatment Evaluation trial also noted a trend toward improved survival in patients with nonischemic cardiomyopathy, nonsustained ventricular tachycardia, and an ejection fraction of 35% or less treated with an ICD compared with medical therapy.

Indications for the implantation of a cardioverter defibrillator for primary prevention of SCD were recently updated in 2006: ACC/AHA/ESC 2006 guidelines for management of patients with ventricular arrhythmias and prevention of sudden cardiac death (<http://www.cardiosource.com/guidelines/guidelines/arrhythmias/va-scd.pdf>). An ICD is currently approved by Medicare for use in patients with ischemic or nonischemic cardiomyopathy, ejection fraction of 35% or less, and class II or class III heart failure symptoms based on the MADIT-II and SCD-HeFT trial results. Patients who had history of MI (greater than 40 days after the event) and ejection fraction of 30% or less also qualify regardless of their functional status. In patients with ejection fractions between 35% and 40%, an ICD is indicated if a sustained ventricular tachyarrhythmia is inducible during EPS evaluation. As shown in Table 79-5, the mean age of patients in the primary prevention

TABLE 79-5

## Primary Prevention of Sudden Cardiac Death: Major Trials of Implantable Cardioverter Defibrillators Since 2002\*

TRIAL, <sup>†</sup> YEAR REPORTED	NO. ENROLLED	MEAN AGE (yr)	CONDITION	STUDY DESIGN	PRIMARY END POINT	PRIMARY END POINT OUTCOME	COMMENTS
CAT, 2002	104	52	Nonischemic EF ≤30% NYHA II, III	ICD versus medical therapy	Total mortality	NS	Low total mortality
MADIT-II, 2002	1232	64	CAD EF ≤30%	ICD versus medical therapy (control)	Total mortality	↓	Increased hospitalization for heart failure with ICD
AMIOVIRT, 2003	103	59	Nonischemic EF ≤35%	ICD versus amiodarone	Total mortality	NS	QOL not different Trend in favor of amiodarone in arrhythmia-free survival and cost
DEFINITE, 2004	558	58	Nonischemic EF ≤35% Nonsustained VT	ICD versus medical therapy	Total mortality	(↓) P = 0.066	Final numbers remain to be confirmed; pending publication
SCD-HeFT, 2005	1676	60	EF ≤35% NYHA II, III CAD = 52% Nonischemic = 48%	ICD versus medical versus amiodarone	Total mortality	↓	No difference between amiodarone and controls in mortality Survival benefit in CAD and non-CAD after ICD therapy
COMPANION, 2004	1520	67	EF ≤35% NYHA III, IV CAD = 55% Nonischemic = 45%	Medical versus CRT versus ICD/CRT	Mortality or hospitalization	↓	Survival benefit in CAD and non-CAD with ICD/CRT
DINAMIT, 2004	674	62	MI 6–40 d previously EF ≤35%	Medical versus ICD	Total mortality	No difference	Patients with recent MI do not benefit from prophylactic ICD

CAD, coronary artery disease; EF, ejection fraction; ICD, implantable cardioverter defibrillator; NS, no significant difference; NYHA, New York Heart Association; QOL, quality of life; ↓, significantly lower mortality in group that received an implantable cardioverter defibrillator.

Zipes DP, CA, Borggreffe M, et al. ACC/AHA/ESC 2006 guidelines for management of patients with ventricular arrhythmias and the prevention of sudden cardiac death: a report of the American College of Cardiology/American Heart Association Task Force and the European Society of Cardiology Committee for Practice Guidelines (Writing Committee to Develop Guidelines for Management of Patients With Ventricular Arrhythmias and the Prevention of Sudden Cardiac Death). *J Am Coll Cardiol*. 2006;48:e247–e346.

trials ranged from 52 to 64 years. Data for primary prevention of SCD in very elderly patients, octogenarians and older, are not available.

### Cardiac Resynchronization Therapy and Implantable Cardioverter Defibrillator

CRT improves functional capacity and quality of life in patients with persistent class III and IV heart failure despite optimal medical therapy, and there is also evidence that CRT may reverse structural remodeling in selected patients. Although individual trials of CRT were underpowered to assess survival, a meta-analysis of outcomes from four randomized trials involving more than 800 patients found that CRT reduces mortality from heart failure. More recently, the Comparison of Medical Therapy, Pacing, and Defibrillation in Chronic Heart Failure trial found that CRT reduces hospitalizations and that CRT with an ICD reduces mortality in chronic heart failure. These benefits from CRT were further confirmed in the CARE-HF trial in which CRT was shown to significantly reduce all cause mortality. However, it must be recognized that very limited data are

available on the use of these devices in the very elderly. Therefore, recommendations for the use of CRT and ICDs in this age group must be individualized, taking into consideration the patient's life expectancy, concomitant medical illnesses, and therapeutic objectives.

## AGING AND DRUG-INDUCED PROARRHYTHMIA

### Changes in Pharmacokinetics Associated with Aging

There are several important changes in pharmacokinetics associated with aging that predispose the elderly to increased risk of drug-induced side effects including arrhythmia.

First, advanced age is accompanied by a decrease in overall body weight, total body water, lean body mass, and intravascular volume, resulting in a greater volume of distribution ( $V_d$ ), which is defined by the drug dose divided by drug plasma concentration ( $V_d = \text{dose}/\text{concentration}$ ). The reduced distribution volume will, therefore, lead to a higher drug concentration after a given dose in

the elderly compared to the younger population. This effect will become more pronounced when elderly patients receive intravenous boluses of pharmacological agents, especially drugs that have a narrow therapeutic index.

The other significant change occurring in the elderly patients is decreased drug clearance secondary to either decreased hepatic metabolism or renal elimination. It is well known that liver and renal diseases are more common in the elderly, resulting in higher chances of drug-induced side effects. Even with normal aging, there is a trend toward decreased hepatic metabolizing capacity, which can affect the body's ability to clear therapeutic drugs and environmental chemicals. It was shown recently that the half-life of drugs processed by hepatic cytochrome P450 enzymes is typically 50% to 75% longer in those older than 65 years than in young adults. In addition to decreased hepatic clearance, renal clearance also decreased with age and is lower in women compared to men. It has been estimated that the glomerular filtration rate decreases by 10% per decade, which can result in significant increase in plasma concentration of these drugs eliminated by the kidneys.

Finally, polypharmacy in the elderly and the resulting potential drug interactions may also contribute significantly to their increased risk of adverse reactions. In a recently published survey conducted from 1998 to 1999 among ambulatory adults in the United States, it was found that women 65 years or older had the highest prevalence of medication use: 94% took at least one, 57% took five or more, and 12% took 10 or more. Men 65 years or older also reported a high prevalence of medication use, although not quite as high as among older women. As the number of medication used increases, the potential for drug interaction also increases exponentially.

## Drug-Induced Arrhythmias

As discussed earlier in this chapter, there are intrinsic changes in the cardiac pacemaker cells and the cardiac conduction system associated with aging, which increase the propensity of the elderly population to develop chronotropic incompetence, conduction block, and bradycardia overall. Moreover, the already-at-risk elderly population is more likely to receive and is more sensitive to a variety of cardiovascular agents that may cause further bradycardia through suppression of the pacemaker activity or AV block.

In addition to bradyarrhythmias, the elderly are also at risk of drug-induced tachyarrhythmias. Acquired long-QT syndrome or drug-induced torsades de pointes is a form of ventricular tachyarrhythmia that can potentially degenerate into ventricular fibrillation and is an often overlooked cause of syncope and SCD. The underlying mechanism of drug-induced torsades de pointes has been attributed to the ability of multiple clinically used drugs to increase cardiac action potential duration and QT interval, leading to increased intracellular calcium loading and the generation of early afterdepolarization activity. Although data on the exact prevalence of drug-induced torsades de pointes in the elderly are lacking, the increased exposure of the elderly population to drugs that are capable of lengthening the QT interval, from reasons described above, may increase their likelihood of developing this life-threatening arrhythmia. Normal aging itself has also been reported to be associated with increased action potential duration as well as the propensity to develop calcium overload, which may lead to early afterdepolarization activities and, therefore, trigger torsades de pointes.

## NOVEL, EMERGING THERAPIES FOR CARDIAC ARRHYTHMIAS

### Biological Pacemakers for Bradyarrhythmias

Pacemaker implantation is the mainstay for treating bradyarrhythmias currently; however, this form of therapy does not cure the fundamental changes in cardiac electrophysiology that led to the arrhythmia and is associated with significant risks and complications. These include potential risk of bleeding, hematoma, pneumothorax, cardiac perforation, lead dislodgement, infection, need for battery replacement, inadequate rate response, and the potential to cause dyssynchrony and worsening heart failure.

In an effort to avoid the multiple potentially serious complications associated with pacemaker implantation, a number of innovative gene and cell therapy approaches have recently emerged as potential means to develop future biological alternatives of implantable electronic devices. These approaches are designed to reverse or modify the underlying electrophysiologic process accompanying aging and, therefore, may provide real "cure," rather than just palliative treatment using external pacemaker, for aging-related bradyarrhythmias.

The intrinsic cardiac pacemaker activity is based on spontaneous phase 4 depolarization of the cell membrane in the conduction system, as a result of the intricate balance of inward and outward currents that ultimately generates a net depolarization current triggering a new action potential. One of the key players in the generation of pacemaker activity is the inward pacemaker current called the "funny current,"  $I_f$ , encoded by the hyperpolarization-activated cyclic-nucleotide-modulated (HCN) channel gene family. Any intervention that increases inward current such as the  $I_f$  or the calcium currents and/or decreases outward current such as potassium current will increase the pacemaker rate. Catecholamine binding to  $\beta$ -adrenergic receptors results in cyclic AMP generation, which in turn leads to faster membrane depolarization and increased rate by enhancing current through  $I_f$  and calcium channel.

One of the early genetic approaches in an attempt to develop alternative to extrinsic pacing involved enhancing the expression of  $\beta$ -2 adrenergic receptor in the atria of pigs through injection of plasmids encoding for the receptor. Injection of the  $\beta$ -2 adrenergic receptor construct significantly enhanced automaticity compared with control injections using saline. An increase in heart rate of  $\geq 50\%$  was achieved. The problem with this approach was the potential arrhythmogenicity of  $\beta$ -adrenergic agonists. Another early approach that was tested was the use of adenoviral vector that harbors a genetic construct capable of suppressing one of the voltage-gated potassium channels, the inward rectifier,  $I_{K1}$ . When such viral vectors were injected into the guinea pig ventricles, these were able to "convert" normally quiescent ventricular myocytes into pacemaker cells with spontaneous, rhythmic activity. These transfected cells also responded to  $\beta$ -adrenergic stimulation (by isoproterenol) just as nodal cells do, by increasing their pacing rate. However, by prolonging cardiac repolarization, this approach may result in an increased risk of developing ventricular arrhythmia similar to the congenital long-QT syndrome. The third approach focused on the enhancement of the pacemaker current  $I_f$ , through viral vectors carrying potassium channel genes mutated to mimic certain characteristics of the HCN

family. These are inserted via catheter injection into ventricles or atria of experimental animals to generate a variation on the pacemaker current  $I_f$  and, therefore, produce spontaneous pacemaker activity.

The methods described above all require use of a viral vector, typically an adenovirus. Although these vectors are deficient adenoviruses that have little infectious potential, there is always the possibility of only a transient improvement in pacemaker function and potential inflammatory responses. The use of retroviruses and other vectors carries a risk of carcinogenicity and infectivity that is unjustified, given the current success of electronic pacemakers. A possible alternative to the gene therapy that does not require the use of a viral vector is the use of cell therapy. Two major forms of this type of biological pacing strategy have been evaluated. The first form involves a combined cell and gene therapy approach in which cells can initially be modified *ex vivo* to express the required ionic channels and then injected into the myocardium. Proof of concept for this strategy was performed by using mesenchymal stem cells overexpressing the HCN-encoded pacemaker current ( $I_f$ ). By means of electroporation, investigators were able to transfect the human mesenchymal stem cells with the HCN2 (mHCN2) gene. The HCN2 expressed in human mesenchymal stem cells was able to change the beating rate of cocultured neonatal rat ventricular myocytes and, when injected into the canine left ventricle, able to generate a spontaneous rhythm.

The second form of cell therapy involves the administration of fetal/neonatal cardiomyocytes or human embryonic stem cells developing into a cardiac lineage. The proof-of-concept experiment of using human embryonic stem cell has been successfully conducted recently. Investigators established an animal model of slow heart rate in pigs, mimicking the clinical scenario of patients having complete AV block, requiring the implantation of an electronic pacemaker. Following creation of AV block in these animals, spontaneously contracting embryonic bodies were injected into the posterolateral left ventricular wall and ECGs were monitored. Following cell grafting a few days later, episodes of a new ectopic ventricular rhythm could be observed and was confirmed to come from the transplanted cells.

Finally, in addition to the research to develop biological pacemaker for treatment of sick sinus syndrome, there has been other innovative, cell-based approaches designed to treat heart block. Recently, engineered tissue constructs in rat hearts harboring myoblasts were implanted into the AV groove and were shown to survive for the duration of the animal's natural life and there is evidence of permanent AV conduction through the implant in one-third of recipient animals using optical mapping and electrophysiological analyses.

### Genetic and Cell Therapy for Tachyarrhythmias

The same genetic and cell approaches used for treatment of bradyarrhythmia can potentially be modified to treat tachyarrhythmias. Arrhythmogenesis typically results from increased automaticity, triggered activity, or reentry. Different genetic approaches can, therefore, be designed based on the individual mechanism.

For tachyarrhythmias caused by enhanced or abnormal automaticity, approaches opposite to that used for bradyarrhythmia for generating biological pacemaker may be used theoretically to reduce automaticity. Studies have demonstrated that overexpression of different potassium channels can be used to alter the action potential

properties in cardiomyocytes *in vitro* and even to suppress cardiac hyperexcitability in rabbit ventricular myocytes.

Arrhythmias secondary to early afterdepolarization and triggered activity can also be treated via genetic modification of the balance between inward and outward current, with an aim at reducing the action potential duration. Gene delivery of different potassium channels was suggested as a method to accelerate cardiac repolarization and abbreviate the QT interval for the treatment of the long-QT syndrome and was also proposed as a way to reverse the down-regulation of potassium channels in cardiomyocytes isolated from failing hearts.

Finally, arrhythmias resulting from reentry could potentially be treated by genetic production of local conduction blocks to interrupt the reentry circuits. Genetically engineered fibroblasts, transfected to express the voltage-gated potassium channel Kv1.3, have been demonstrated to significantly alter the electrophysiological properties of the cardiomyocyte cultures. These changes were manifested by a significant reduction in the local extracellular signal amplitude and by the appearance of multiple local conduction blocks. The ability of these cells to cause conduction block may be used to facilitate ablations in the EP laboratory, reducing or even eliminating the need for cauterization and extensive tissue injury, thereby reducing procedure-related complications.

Modification of the AVN through gene or cell therapy is another innovative way to treat AF with rapid ventricular response. A study used viral gene transfer through catheter injection in the AV nodal artery to overexpress  $G\alpha_i2$  in swine AVN and was able to suppress baseline AV conduction and slow the heart rate during AF without producing complete heart block in the animals. This approach represents a novel strategy for ventricular rate control for AF, mimicking the effects of beta-adrenergic antagonists. Another study using direct injection of fibroblast into the slow and fast pathways of the AVN have been successfully shown to modify the electrophysiologic activities of the AVN. In this study, dogs injected with fibroblasts, especially those treated with TGF- $\beta1$ , was able to significantly delay conduction over the AVN without causing AV block when compared to saline controls. This may suggest an alternative cell-based strategy to treat AF with rapid ventricular response.

### SUMMARY

Guidelines on the treatment of cardiac arrhythmias continue to evolve and being updated regularly. Although many well-designed clinical trials have provided solid evidences for our clinical practice, the small number of very elderly patients (octogenarians and nonagenarians) participating in clinical trials poses significant limitations on a more specific practice recommendation in the elderly population. Live expectancy is finite; survival is expected to be less in the elderly. Clinical outcomes such as symptoms, quality of life, functional capacity, independent living, and hospitalization should be critically addressed when treating arrhythmias in this fastest growing segment of our population. Genetic and cell-based regenerative therapy for cardiac arrhythmia is evolving as experimental strategy for treatment of bradyarrhythmias through enhancement of pacemaker activity and facilitation of AV conduction or treatment of tachyarrhythmias through suppression of automaticity and/or creation of local conduction block. Multiple proof-of-concept experiments

have been successfully conducted in several laboratories and have generated encouraging results. Although no human trials have been conducted to test the efficacy of these experimental therapies, safety and efficacy of cardiac cell therapy overall have already been evaluated in patients with heart failure and myocardial infarction in several clinical trials with overall promising results. Research in this area may provide ultimate cure for aging-associated arrhythmias through genetic reprogramming of the aging process or via cardiac regenerative therapy.

## KEY POINTS

- Aging is associated with diffuse changes throughout the heart and conduction system, which predispose older individuals to the development of bradyarrhythmias, conduction disturbances, and supraventricular and ventricular tachyarrhythmias, all of which increase in incidence and prevalence with advancing age.
- The indications for invasive electrophysiological testing are generally similar in younger and older patients.
- The indications for permanent pacing for treatment of bradyarrhythmia are similar in older and younger patients, and more than 80% of permanent pacemakers are placed in patients 65 years of age or older, with sinoatrial dysfunction being the leading indication for pacemaker implantation in this age group.
- Compared with single-chamber ventricular pacing, dual-chamber pacing reduces the risk of AF but does not affect mortality or the risk of stroke.
- The median age for patients with AF is 75 years, and 84% of patients with AF are 65 years or older.
- Age of 75 years or older is a well-recognized risk factor for thromboembolism in patients with AF.
- In asymptomatic or minimally symptomatic patients with AF, a strategy of rate control and anticoagulation is associated with equivalent or better outcomes than a strategy of rhythm control during long-term follow-up.
- In patients with symptomatic AF refractory to pharmacological treatment, various catheter-based ablation procedures, as well as the surgical maze procedure, provide effective control of rate and/or arrhythmia in a high proportion of patients. Ablation of the AVN and permanent pacing for rate control are effective in reducing symptoms in selected elderly patients. Primary AF ablation for rhythm control has shown encouraging short-term outcomes predominantly in younger patients. Randomized trials with sufficient sample size for meaningful clinical outcomes comparing ablative therapy to the gold standard drug therapy are needed for the fast growing elderly population.
- The indications for ICDs and CRT are similar in older and younger patients, as are the benefits in terms of reducing mortality and improving symptoms; however, few data are available on the use of these devices in patients older than 80 years.
- Syncope is a common cause of falls and hospitalizations in older adults, and cardiovascular causes of syncope are more common in elderly than in younger patients; therefore, an evaluation for possible cardiovascular causes is warranted in older patients with unexplained syncope.
- Elderly patients are more prone to polypharmacy, drug interactions, and drug-induced brady- and tachyarrhythmias.
- Emerging research may provide novel gene- and cell-based therapies for arrhythmias in the elderly and ultimately lead to cardiac “rejuvenation.”

# Peripheral Vascular Disease

Andrew W. Gardner ■ John D. Sorkin ■ Azhar Afaq

## DEFINITION

Atherosclerotic cardiovascular disease is the most significant health problem in the United States, as heart and cerebrovascular diseases are leading causes of mortality and peripheral vascular disease is a leading cause of morbidity in elderly people. Peripheral arterial disease (PAD) is the most typical form of peripheral vascular disease. PAD is characterized by a partial or complete failure of the arterial system to deliver oxygenated blood to peripheral tissue. Atherosclerosis is, by far, the most common etiology of PAD. However, several other processes can lead to the clinical syndrome (Table 80-1). Although lesions (and symptoms) of PAD can occur in both the upper and the lower extremities, these are much more common in the lower extremity, which is the focus of this chapter.

## EPIDEMIOLOGY

The ankle-brachial blood pressure index (ABI), defined as the systolic blood pressure measured at the ankle divided by the systolic blood pressure measured in the arm during supine rest, is the most widely used quantitative measure to identify subjects with PAD and to determine PAD severity. The ABI varies widely in the general population and is generally normally distributed with a long tail of low values (Figure 80-1). The prevalence of PAD is highly dependent on the exact ABI cutpoint used to detect inadequate peripheral circulation. The definition of an abnormal ABI has ranged between  $<0.80$  and  $<0.97$ , with a value of  $\leq 0.90$  generally considered to be the best reference standard.

The prevalence of PAD is 16% in the general population older than 55 years of age when an ABI value of  $\leq 0.90$  and symptoms of intermittent claudication and rest pain are used as criteria of PAD. In the Edinburgh Artery Study, approximately 20% of the men and women aged 55 to 74 years were noted to have an ABI

$\leq 0.90$  and, thus, were diagnosed as having PAD. The prevalence of PAD increases with age and at all ages is higher in men than in women. At ages 65 to 69 years, the prevalence of PAD in men from the Cardiovascular Health Study was approximately 7%, and approximately 5% in women. In subjects aged 85 years and older, the prevalence was 23% in men and 21% in women.

PAD and coronary artery disease (CAD) share risk factors. In addition to age and male sex, risk factors for PAD include smoking, hypercholesterolemia, diabetes, hypertension, hyperhomocystinemia, elevated fibrinogen concentration, having a family history of premature atherosclerosis (suggesting that genetic factors may influence the development of PAD), and being nonwhite. Although PAD can be seen in the absence of clinical CAD, asymptomatic CAD is frequently present in patients with PAD. Every patient presenting with PAD should be considered to have CAD until proven otherwise. Evaluation and treatment for PAD should include evaluation and control of CAD risk factors.

PAD has important implications for function. PAD severity (assessed by ABI) is directly related to 6-minute walk distance, free-living energy expenditure, and steps taken per day. Of particular interest to geriatricians, patients with PAD are more likely to fall than are subjects without PAD.

PAD is not a static disease. Progression from intermittent claudication to rest pain or gangrene can occur in anywhere from 2% to 7% of patients per year. Furthermore, PAD is associated with increased risk for mortality, and this risk becomes greater as the severity of PAD increases (Figure 80-2).

Patients with PAD are at increased risk of coronary heart disease, coronary vascular disease, and all-cause mortality. This risk is independent of traditional risk factors, including age, sex, smoking, systolic blood pressure, plasma lipids, fasting glucose, body mass index, and preexisting clinical cardiovascular disease. Risk for mortality as a consequence of coronary heart disease and cardiovascular disease is three to six times higher in subjects with PAD than in subjects without PAD, even after accounting for traditional risk factors.

**TABLE 80-1**

**Causes of Peripheral Arterial Disease**

Atherosclerosis	Arterial entrapment
Thrombus	Adventitial cyst
Embolism	Fibromuscular dysplasia
Dissection	Trauma
Vasculitis	Vasospasm

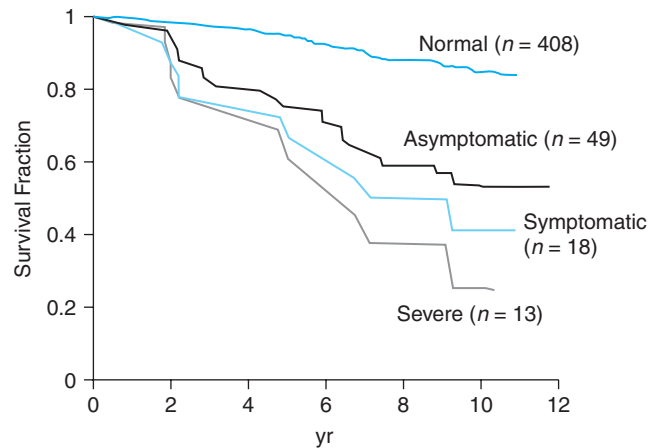

**PATHOPHYSIOLOGY**

The atherosclerotic lesions that lead to PAD tend to form in a few well-defined locations in the vascular tree, and patients often will have lesions in more than one location. Thirty percent of the patients have lesions in the abdominal aorta, 80% to 90% have lesions in the femoral and popliteal arteries, and 40% to 50% have lesions in the tibial and peroneal arteries. The location of the arterial lesion will determine the clinical presentation. For example, aortoiliac disease (Leriche syndrome) leads to buttock, hip, and thigh pain along with erectile dysfunction; the more common femoral–popliteal disease leads to symptoms in the calf. The atherosclerotic process is similar to that in other major arteriostenoses and is discussed in Chapter 75.

**PRESENTATION**

Clinical PAD was recognized as early as 1831, when Jean-Francois Bouley Jeune observed a horse that, when pulling a cabriolet, limped with the hind legs. At autopsy, the horse was noted to have a partially thrombosed aneurysm of the abdominal aorta and occlusion of both femoral arteries.

Two schemes, both based on symptoms and clinical measures, are commonly used to classify the severity of PAD (Tables 80-2 and 80-3). In the early stages of PAD, the reduction in blood flow

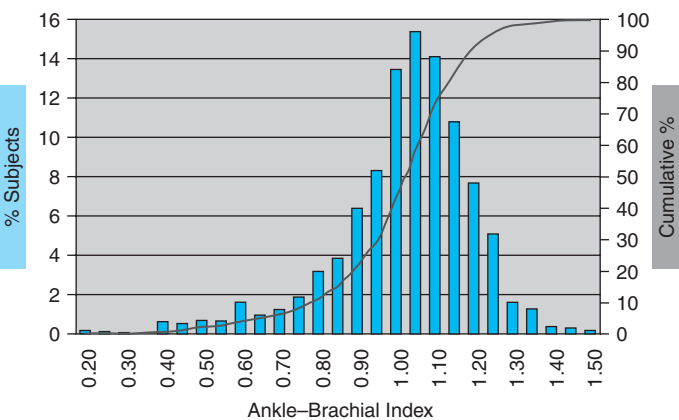

**FIGURE 80-2.** Relation of peripheral arterial disease (PAD) severity to mortality in subjects from Rancho Bernardo. (Adapted from Criqui MH, et al. Mortality over a period of 10 years in patients with peripheral arterial disease. *N Engl J Med.* 1992;326:381.)

and ABI does not result in any noticeable symptoms (asymptomatic PAD) and is defined as stage I according to the Fontaine classification system and grade I, category 0 according to the more widely accepted Rutherford classification system. As PAD progresses, ischemic pain in the leg musculature occurs when patients walk (intermittent claudication) and is classified as either Fontaine stage II-a or II-b, or Rutherford grade I, category 1, 2, or 3, depending on the walking distance and the change in ABI following walking. In more advanced stages of disease, ABI is reduced to such an extent that pain is experienced even while at rest, classified as either Fontaine stage III or Rutherford grade II, category 4. Further progression of the disease leads to ischemic ulcerations on the lower extremities, gangrene, and tissue loss, classified as either Fontaine stage IV or Rutherford grade II, category 5, or grade III, category 6. Patients in these categories have critical limb-threatening ischemia in which the ischemia endangers part or all of the lower extremity. These patients are candidates for aggressive limb salvage interventions such as percutaneous transluminal angioplasty or bypass surgery.

The presentation of PAD varies widely among patients. PAD can be present without any clinical signs, in which case diagnosis of PAD can only be made with laboratory tests. With mild disease, the peripheral pulses can be decreased. With more advanced disease, there may be an audible bruit or the distal pulses may be absent. The extremity may be pale or cyanotic at rest, upon raising the leg, or with exercise. The skin of the extremity can be cool, smooth and shiny with hair loss, and thickened nails. Dangling the legs following elevating the extremity can lead to delayed return of color to the skin (usual time approximately 10 seconds), delayed filling of the veins of the feet and ankles (normal approximately 15 seconds), and the development of a dusky rubor in the legs. Patients with the most severe disease will present with ulcers on their extremity or frank gangrene.

The patient may complain of a sensation of cold or numbness in the foot or toes. Patients with more severe disease will often complain of pain when the extremity is at rest. This pain will often occur at night and will be relieved by dangling the leg over the edge of the bed.

**FIGURE 80-1.** Ankle-brachial blood pressure index (ABI) in men and women in the Edinburgh Artery study. The bars and left-hand scale represent the percentage of subjects having a given ABI. The solid line and right-hand scale represent the cumulative percentage of subjects having an ABI at or below the ABIs listed on the abscissa. **TABLE 80-2****Fontaine Classification of Peripheral Arterial Disease**

STAGE	SYMPTOMS
I	Asymptomatic
II	Intermittent claudication
IIa	Pain free, claudication walking >200 m
IIb	Pain free, claudication walking <200 m
III	Rest/nocturnal pain
IV	Necrosis/gangrene

Adapted from Pentecost MJ, et al. Guidelines for peripheral percutaneous transluminal angioplasty of the abdominal aorta and lower extremity vessels. A statement for health professionals from a special writing group of the Councils on Cardiovascular Radiology, Arteriosclerosis, Cardio-Thoracic and Vascular Surgery, Clinical Cardiology, and Epidemiology and Prevention, The American Heart Association, *Circulation* 89(1):511–531, 1994.

**EVALUATION****Pulse Palpation and San Diego Claudication Questionnaire**

A number of noninvasive tests have been used to screen for and to evaluate the extent of a patient's PAD. The most basic clinical test is palpation and auscultation of the peripheral pulses. Little is known about the sensitivity of pulse palpation for the diagnosis of PAD. In situations in which direct examination of subjects is not feasible, such as epidemiological studies, the San Diego Claudication Questionnaire, which is a version of the Rose Questionnaire, is often used to screen subjects for PAD. Using these questionnaires, PAD is defined as leg pain associated with walking that goes away with rest. The sensitivity of the Rose Questionnaire has been reported as being anywhere from 10% to 50%.

**Noninvasive Vascular Tests**

The most common measure to assess the presence and severity of PAD is the ABI. PAD is typically defined by an ABI value  $\leq 0.90$ . The sensitivity of using this cutpoint of ABI is >90%. Generally, a

patient whose ABI is  $<0.8$  will be symptomatic with intermittent claudication during exercise, and a patient whose ABI is  $<0.30$  will generally complain of pain at rest. Very high ABIs, for example  $>1.3$ , are considered invalid because these do not reflect the true ankle blood pressure caused by arteries that have become calcified or noncompressible, termed calcific medial sclerosis, which is observed in patients with diabetes.

Segmental systolic blood pressure measures in the brachial, upper thigh, lower thigh, and ankle locations have been used to access the extent of PAD. Additional noninvasive tests for PAD include Doppler ultrasonography (i.e., measurement of blood flow velocity), plethysmography (pressure-wave tracing), and measurement of postocclusive reactive hyperemia. Postocclusive reactive hyperemia is performed by occluding arterial flow by inflating a blood pressure cuff above systolic pressure at the level of the upper thigh or knee for 3 minutes, followed by measurement of the systolic blood pressure at the ankle or calf blood flow 15 to 30 seconds after releasing the occlusion. When compared to patients without vascular disease, patients with PAD will demonstrate a lower postocclusive ABI and a delayed return to preocclusion pressures. The sensitivity of the postocclusive ABI is  $>95\%$ . For individuals who present with classic claudication and who have ABI values in the borderline-to-normal range (0.91–1.30), or who have ABI values above normal (greater than 1.30), alternative diagnostic strategies should be used to confirm the diagnosis of lower extremity PAD. These alternative methods include the toe-brachial index, ABI after treadmill exercise, segmental systolic blood pressures, or duplex ultrasound.

**Treadmill Testing**

The main effect that PAD has on acute exercise is the development of claudication pain in the leg musculature as a result of insufficient blood flow. As a result, claudication and peripheral hemodynamic measurements obtained from a treadmill test are the primary criteria to assess the effectiveness of an exercise program. The specific claudication variables that are measured to assess the functional severity of PAD include the distances (or times) to onset and to maximal claudication pain. ABI measurements obtained before and after the treadmill test, in addition to claudication measurements, provide a more objective assessment of disease severity.

The primary objective of a treadmill test for patients with PAD is to obtain reliable measures of (1) the rate of claudication pain development, (2) the ABI response to exercise, and (3) the presence of coexisting coronary heart disease. The test should be a progressive test with gradual increments in grade. By having a test with small increases in exercise intensity, claudication distances of patients can be stratified according to disease severity. A highly reliable treadmill tests for patients with PAD uses a constant walking speed of 2 mph and gradual increases in grade of 2% every 2 minutes beginning at 0% grade. By using this treadmill protocol, typical distances to onset of pain and to maximal pain are approximately 170 m (3 minutes) and 360 m (6.5 minutes), respectively. Measurement of the ABI immediately after a treadmill exercise stress test can help diagnose PAD in difficult cases as well as determine the extent of impairment of the peripheral circulation. Exercise increases systemic blood pressure (i.e., the brachial pressure), while pressure distal to an arterial lesion in the lower extremity falls with exercise as a consequence of dilation of secondary arterioles. As a result, ABI typically drops from a resting value of 0.6 to approximately 0.2 immediately following

**TABLE 80-3****Rutherford Classification of Peripheral Arterial Disease**

GRADE	CATEGORY	CLINICAL DESCRIPTION
I	0	Asymptomatic; not hemodynamically correct
	1	Mild claudication
	2	Moderate claudication
	3	Severe claudication
II	4	Ischemic rest pain
	5	Minor tissue loss; nonhealing ulcer, focal gangrene with diffuse pedal ischemia
III	6	Major tissue loss extending above transmetatarsal level; foot no longer salvageable

Adapted from Rutherford RB. Standards for evaluating results of interventional therapy for peripheral vascular disease. *Circulation*. 1991;83(suppl 2):16.

the treadmill test. The sensitivity of ABI measured after treadmill walking is >95%.

Gas-exchange measures during the treadmill test show that PAD patients with intermittent claudication have peak oxygen consumption values in the range of 12 to 15 mL/kg/min, which is approximately 50% of age-matched controls. Favorable changes following a program of exercise rehabilitation should include greater walking distances covered before the occurrence of the onset and maximal claudication pain, an increase in peak oxygen consumption, and possibly a blunted drop in ABI and a faster rate of recovery in ABI to the resting baseline value.

## Physical Function

Claudication distance and ABI are the most common measurements obtained in patients with claudication, because previous studies have been done from a vascular surgery perspective. However, a more gerontologic perspective would focus on the improvement in function of PAD, for example, in patients following exercise rehabilitation. Because the typical profile of a PAD patient is that of an elderly person with chronic ambulatory disability, the decline in physical functioning with aging may be accelerated in this population because of the extreme deconditioning brought about from the disease process. Consequently, performance on a 6-minute walk test, as well as measures of gait, walking economy (i.e., efficiency), balance, flexibility, lower extremity strength, and health-related quality of life, may be expected to be worse in PAD patients than in age-matched controls, but should improve after a program of exercise rehabilitation. However, little information is available on these measures in the PAD population.

## MANAGEMENT

### Risk Factor Modification

All patients with PAD need aggressive risk factor modification including cessation of cigarette smoking, control of diabetes, hypertension, and hypercholesterolemia along with dietary restrictions aimed at reducing cholesterol and obesity.

### Smoking Cessation

Smoking is strongly associated with development of PAD. Smokers do worse in exercise performance compared to PAD patients who are nonsmokers. Similarly, walking distance has shown to be improved after smoking cessation. Smoking cessation slows the progression to more serious critical limb ischemia, reduces the need for revascularization, and improves graft patency in case of revascularization. As a result of these benefits, it is imperative that these patients should be referred to a smoking cessation program coupled with nicotine replacement therapy.

### Hypercholesterolemia

Statins should be prescribed to all patients with PAD irrespective of whether CAD is also present or not. In a meta-analysis of more than 90,000 individuals, statin therapy reduced the 5-year incidence of major vascular events by approximately one-fifth per 1 mmol/L

reduction in low-density lipoprotein concentration. This was irrespective of initial lipid profile or other characteristics, such as age, sex, or existing disease. Current PAD guidelines recommend target low-density lipoprotein concentration to be <100 mg/dL in all PAD patients, with an additional target of <70 mg/dL in patients with very high risk of ischemic events.

## Hypertension

Control of hypertension is critical for prevention of stroke, myocardial infarction, and congestive heart failure. Antihypertensive therapy may decrease limb perfusion pressure and potentially exacerbate symptoms of claudication or chronic limb ischemia. However, most patients are able to tolerate therapy without worsening of symptoms. Furthermore, contrary to prior belief,  $\beta$ -blockers do not worsen intermittent claudication in PAD patients. Current PAD guidelines recommend using ACE inhibitors in symptomatic PAD patients based on the Heart Outcomes Prevention Evaluation study, where ramipril reduced the risk of myocardial infarction, stroke, or vascular death in patients with PAD by approximately 25%.

## Diabetes

Diabetes is a strong risk factor for the development of PAD and is present in up to 20% of patients with PAD. Diabetic patients are prone to complications from severe PAD including critical limb ischemia, foot ulceration, and amputation. Thus, an annual comprehensive foot examination that includes palpation of pedal pulses and the use of a monofilament at specific sites to detect loss of sensation in the foot is recommended to identify risk factors predictive of ulcers and amputation. It is also recommended to control blood sugars with target HbA1C level <7% to reduce microvascular complications and potentially improve cardiovascular outcomes. Standard treatment in a diabetic patient who has PAD includes antithrombotic medication like aspirin, a statin, and an ACE inhibitor along with the usual oral hypoglycemic medications.

## Antiplatelet and Anticoagulation Therapy

Aspirin is effective in preventing secondary events in patients with PAD, including delaying the rate of progression and decreasing the need of peripheral arterial procedures. Aspirin therapy does not improve walking distance or symptoms and, therefore, is not currently recommended for symptoms of patients with PAD. Clopidogrel is a useful alternative among patients intolerant of aspirin or can also be considered as the initial choice for patients with PAD. To date, there is no evidence to support the efficacy of combined aspirin and clopidogrel treatment versus a single antiplatelet agent in patients with lower extremity PAD. This combination is being used in patients who had endovascular intervention with a resultant stent placement in lower extremity vasculature.

Oral anticoagulation therapy with warfarin is not indicated to reduce the risk of adverse cardiovascular ischemic events in individuals with atherosclerotic lower extremity PAD.

## Vasodilators

In addition to exercise rehabilitation, pharmacological intervention is another medical option to treat intermittent claudication. Pharmacological therapy for intermittent claudication in the United States

is limited to pentoxifylline and cilostazol. Pentoxifylline, which has a hemorrheologic effect by improving the flexibility of red blood cell membranes and by reducing platelet aggregation, was first studied in the United States in 1982. It was found to increase the distance to onset of claudication pain by 45% and the distance to maximal pain by 32% following 24 weeks of treatment, compared to 23% and 20% increases with placebo. Although this initial study demonstrated the efficacy of pentoxifylline, its usefulness in treating intermittent claudication has been questioned. Cilostazol is a newer medication with more potent vasodilatory and antiplatelet activity than aspirin. Cilostazol was found to increase the distances to onset and to maximal claudication pain by 40% and 42%, respectively, compared to 1% and -14% with placebo treatment. These studies suggest that pharmacological intervention may be used to treat intermittent claudication in some patients. However, exercise rehabilitation results in greater increases in walking distances in patients who are capable and motivated to walk on a regular basis.

### Revascularization Therapy

Patients with lifestyle limiting claudication can be considered for revascularization with endovascular or surgical therapy. Endovascular intervention is recommended in case of failure of pharmacological or exercise therapy and or favorable risk–benefit ratio per 2005 ACC/AHA PAD guidelines. Endovascular interventions include percutaneous transluminal angioplasty, stenting, stent grafting, atherectomy, and cryotherapy. Initially percutaneous transluminal angioplasty and stenting were thought to be procedures of choice for shorter, more focal stenosis, whereas longer occlusions were thought to require surgical therapy. However, with improvement in endovascular techniques and experience, more complex procedures involving longer infrainguinal lesions are now being treated by endovascular intervention.

The indications for surgical treatment are the same as those for endovascular treatment. Comparable efficacy can often be achieved, with less risk imposed by endovascular intervention when both procedures are feasible. Choosing between endovascular versus surgical therapy depends on several factors including age, comorbidities, and type of the lesion (TransAtlantic Inter-Society Consensus [TASC] lesion classification). Surgery is usually reserved for individuals who have limb arterial anatomy that is favorable to obtaining a durable clinical result, and in whom the cardiovascular risk of surgical revascularization is low.

### Effects of Exercise Rehabilitation

In contrast to either drug treatment or surgical procedures, the clinical management of intermittent claudication in patients with PAD can be significantly improved with little cost, morbidity, and mortality through physical conditioning. Significant improvements in claudication pain have occurred following exercise rehabilitation. For example, meta-analysis demonstrated that, in 21 exercise rehabilitation studies conducted between 1966 and 1993, the average distance walked on a treadmill to onset of claudication pain increased 179%, from a mean of 126 to 351 m following rehabilitation, and the average distance walked to maximal claudication pain increased 122%, from 326 to 723 m.

Numerous mechanisms have been proposed to explain the improvement in walking distances to the onset and to maximal

claudication pain following exercise rehabilitation. The mechanisms primarily center on hemodynamic and enzymatic adaptations within the exercising musculature of the symptomatic leg(s). These mechanisms include an increase in blood flow to the exercising leg musculature, a more favorable redistribution of blood flow, greater use of oxygen because of a higher concentration of oxidative enzymes, improvement in hemorrheologic properties of the blood, a decrease in the reliance upon anaerobic metabolism, and an improvement in the efficiency of walking. It is likely that a combination of changes in these factors contribute to the improved walking distances. Improvements in psychosocial attitude owing to accomplishments that are achieved during exercise rehabilitation may further enhance this effect.

Although substantial increases in the average distances to onset and to maximal claudication pain during treadmill walking have been noted following exercise, considerable variability among the studies exists; for example, the increased distance to onset of pain ranges between 73% and 746%, and the increased distance to maximal pain ranges between 61% and 765%. Differences in the components of exercise programs (e.g., intensity, duration, and frequency of exercise sessions) may largely account for these widely divergent responses.

To examine the contributions of the components of an exercise rehabilitation program, a meta-analysis was carried out. As displayed in [Table 80-4](#), six components were examined: (1) duration of exercise (minutes per session), (2) frequency of exercise (sessions per week), (3) length of the program (weeks), (4) claudication pain end point used in the program (onset vs. near maximal pain), (5) mode of exercise (walking vs. a combination of exercises), and (6) level of supervision. All of the exercise rehabilitation components had a significant effect on the magnitude of change in the claudication distances except for the level of supervision. For example, programs that exercised patients to near-maximal claudication pain were more effective than programs that exercised patients to only the onset of pain. Additionally, programs consisting of higher exercise duration, higher frequency, greater program length, and walking as the only mode of exercise were more effective than programs consisting of lower exercise duration, lower frequency, and shorter program length, and having patients train by a variety of exercise modes. The addition of home exercise to supplement the amount of exercise performed in a supervised setting did not result in additional ambulatory benefit. Of the five components that had an effect on the change in the claudication distances, only three were found to have an independent effect through multivariate analyses. These components were the claudication pain end point used in the program, the length of the program, and the mode of exercise. The combination of these components explained nearly 90% of the variance in the increase in the walking distances following exercise rehabilitation.

### Recommended Exercise Program for Treating Intermittent Claudication

Optimal improvements in claudication symptoms are elicited by having patients walk intermittently beyond the onset of pain for as long as they can safely tolerate and perform this exercise program for a minimum of 6 months. Although the duration and frequency of the exercise sessions are not independent predictors of the change in claudication pain times, patients should walk for at least 30 minutes per session and for at least three sessions per week, as these amounts

**TABLE 80-4****The Effects of Exercise Program Components on Changes in Claudication Pain Distances from 21 Studies**

COMPONENTS OF EXERCISE PROGRAMS	CHANGE IN THE DISTANCE TO ONSET OF PAIN (m)*	CHANGE IN THE DISTANCE TO MAXIMAL PAIN (m)*
Exercise duration		
≤30 minute/session (n = 8)	143 ± 163 <sup>†</sup>	144 ± 419 <sup>‡</sup>
>30 minute/session (n = 6)	314 ± 172 <sup>†</sup>	653 ± 364 <sup>‡</sup>
Exercise frequency		
<3 sessions/week (n = 7)	178 ± 130 <sup>†</sup>	249 ± 349 <sup>†</sup>
≥3 sessions/week (n = 11)	271 ± 221 <sup>†</sup>	541 ± 263 <sup>†</sup>
Length of program		
<26 weeks (n = 10)	132 ± 159 <sup>‡</sup>	275 ± 228 <sup>‡</sup>
≥26 weeks (n = 11)	346 ± 162 <sup>‡</sup>	518 ± 409 <sup>‡</sup>
Claudication pain end point used during training sessions		
Onset of pain (n = 15)	105 ± 91 <sup>‡</sup>	195 ± 78 <sup>‡</sup>
Near-maximal pain (n = 6)	350 ± 246 <sup>‡</sup>	607 ± 427 <sup>‡</sup>
Mode of exercise		
Walking (n = 6)	294 ± 290 <sup>†</sup>	512 ± 483 <sup>†</sup>
Combination of exercises (n = 15)	152 ± 158 <sup>†</sup>	287 ± 127 <sup>†</sup>
Level of supervision		
Supervised (n = 11)	238 ± 120	449 ± 292
Combination of home and supervised (n = 8)	208 ± 198	339 ± 472

\*Values for each component are adjusted means ± standard deviations of the change in the distances to onset and to maximal claudication pain after statistically controlling for the other five exercise programs components.

<sup>†</sup>Significant difference between groups ( $P \leq 0.05$ ).

are more beneficial than programs using a lower exercise duration and frequency. Table 80-5 summarizes recommendations for an exercise program for patients with PAD.

## PREVENTION

Risk factors for PAD are typical of those for CAD, including cigarette smoking, race (nonwhite), diabetes, age, systolic blood pressure,

**TABLE 80-5****Recommended Exercise Program for Patients with Peripheral Arterial Disease**

EXERCISE COMPONENT	COMMENT
Frequency	Three exercise sessions per week
Intensity	Initially, 50% of peak exercise capacity, with gradual progression to 80% by the end of the program
Duration	Initially 15 minute of exercise per session, with gradual progression to 40–50 minute by the end of the program
Mode	Weight bearing (e.g., walking and stair climbing); Non-weight-bearing tasks (e.g., bicycling) may be used for warming up and cooling down
Type of exercise	Intermittent walking to a claudication pain score of 3 using a four-point pain scale
Program length	Approximately 6 months

Data from Gardner AW. Guidelines for developing an exercise program for elderly patients with peripheral arterial occlusive disease. *Clin Geriatr*. 1995;3:41.

body mass index, low-density lipoprotein cholesterol, total cholesterol, creatinine, and forced vital capacity. Thus, efforts at risk factor reduction make sense in trying to prevent PAD or its progression.

In addition, properties of blood rheology and coagulation also play a role in the development of arterial occlusive disease. Increased blood viscosity and red cell aggregation is associated with an increased risk of PAD. Fibrinogen is an independent risk factor for heart disease and stroke, and disorders of fibrinolysis such as increased plasminogen activator inhibitor are associated with ischemic heart disease. Consequently, fibrinogen and plasminogen activator inhibitor may be independent risk factors for PAD. An emerging body of evidence shows a beneficial effect of exercise training in reducing blood viscosity, red cell aggregation, fibrinogen, and increasing fibrinolytic activity both in healthy subjects and in PAD patients.

Thus, exercise training may improve the more traditionally accepted PAD risk factors (e.g., blood lipids, blood pressure, and obesity) as well as measures of blood rheology and coagulation. Finally, because physical activity level is associated with ABI, increasing the activity level may have a preventative role in the development of PAD.

## SUMMARY

PAD is a significant health concern in the elderly population, and it will continue to increase in future years. Conservative management of patients with asymptomatic PAD and patients with intermittent claudication is recommended to modify risk factors and improve ambulatory ability, while patients with more severe PAD

typically require revascularization of the lower extremities. Exercise rehabilitation is a highly effective, conservative treatment to improve ambulation in patients with intermittent claudication. To date, the primary focus of attention on the benefits of exercise rehabilitation has centered on the increase in walking distances to onset and to maximal claudication pain during a treadmill test. Future research should focus on the improvement in other functional outcomes, which may be more representative of everyday activities such as submaximal exercise performance, walking economy, balance, flexibility, and lower extremity strength. Until these measures are obtained, the full benefit of exercise rehabilitation for PAD patients remains undefined.

# Hypertension

*Mark A. Supiano*

## INTRODUCTION

High blood pressure has the greatest impact on global attributable mortality of any other risk factor and accounts for the third leading cause of global burden of disease—64 million disability adjusted life years lost. The age-associated increase in blood pressure combined with the worldwide demographic increase in the aging population translates to an enormous emerging public health problem. In addition to the well-ascribed hypertension risk factors of cardiovascular disease and stroke, it is also a significant risk for chronic kidney disease, atrial fibrillation, congestive heart failure (CHF, including diastolic dysfunction), and cognitive impairment—each with a relative risk between 2.0 and 4.0. Lowering blood pressure by 10 mm Hg systolic and 5 mm Hg diastolic at age 65 years is associated with a reduction of up to 25% in myocardial infarction, 40% in stroke, 50% in CHF, and 10% to 20% overall decrease in mortality. Despite this knowledge, current rates of hypertension control are extremely low, especially among older women. In addition to illustrating the clinical importance of hypertension, these data are compelling in a call to improve both our knowledge concerning the mechanisms that underlie the age-associated increase in blood pressure to aid in its prevention as well as to make changes in the systems of care necessary to improve blood pressure control among those with hypertension.

## EPIDEMIOLOGY

Although high blood pressure should not be construed to be a normal aspect of aging, there is clearly an age-associated increase in blood pressure and in the prevalence of hypertension. The National Health and Nutrition epidemiological surveys have documented that hypertension is a very prevalent condition among older Americans. Based on this study's definition of hypertension—the average of three readings  $\geq 140$  mm Hg systolic and/or  $\geq 90$  mm Hg diastolic or those

receiving an antihypertensive medication—the overall prevalence for hypertension among those aged 65 years or older ranges between 50% and 75%. For women aged 75 years and older, the prevalence exceeds 75%. Of note, there is an age-gender interaction in hypertension prevalence across age. At younger ages, prevalence rates are higher among men while above the age of menopause, there is a crossover when the prevalence in women surpasses that of men.

Another viewpoint on epidemiology is to examine the lifetime risk of developing hypertension as has been done in participants in the Framingham Heart Study. This study identified that among men and women participants who had normal blood pressure readings at age 55 years, nearly 85% developed Stage 1 or higher hypertension over 20 to 25 years of follow-up, their residual lifetime risk.

## CLASSIFICATION

The current scheme to classify various levels of hypertension published by the Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure, JNC 7 makes no adjustment for age. This classification scheme incorporates recent evidence that the cardiovascular risks associated with high blood pressure are continuous beginning at a level of 115/75 mm Hg and includes a prehypertension category (systolic from 120 to 139 mm Hg or diastolic 80–89 mm Hg). A former category known as isolated systolic hypertension was deleted from the current classification system. Instead, the conjunction that links the systolic and diastolic blood pressure columns in the classification table that defines each stage of hypertension was changed from “and” to “or.” Consequently, since isolated diastolic hypertension is so uncommon among older patients, one may correctly classify an older patient's hypertension based entirely on the level of their systolic blood pressure (i.e. Stage 1, between 140 and 159 mm Hg systolic, and Stage 2,  $\geq 160$  mm Hg systolic).

**TABLE 81-1****Age-Related Physiological Changes that Contribute to Elevated Blood Pressure**

- Arterial stiffness
- Decreased baroreceptor sensitivity
- Increased sympathetic nervous system activity
- Decreased alpha- and beta-adrenergic receptor responsiveness
- Endothelial dysfunction
- Decreased ability to excrete sodium load (sodium sensitivity)
- Low plasma renin activity
- Resistance to insulin's effect on carbohydrate metabolism
- Central adiposity

**PATHOPHYSIOLOGICAL CHARACTERISTICS**

A single factor is unlikely to explain the cause of essential hypertension regardless of its age of onset. However, a number of age-related changes in physiology have been identified and summarized in [Table 81-1](#) that likely contribute to the age-associated increase in blood pressure and in the prevalence of hypertension. Lifestyle factors such as obesity, especially central adiposity, being sedentary, and eating a diet high in sodium content are also contributors commonly identified among older individuals.

Homeostatic regulation of blood pressure within its normal range while continuously maintaining adequate cerebral perfusion requires intricate and dynamic coordination of several complex interacting physiological systems. Under resting conditions, despite age-related physiological changes that occur in these systems, older individuals experience little difficulty maintaining their blood pressure and cerebral perfusion. However, when this balance is placed at risk by perturbations imposed by the intravascular volume shifts that occur with upright posture or following a meal, or the stimulus of exposure to one or more vasodilating medications, the older patient is less able to adapt and significant declines in blood pressure and inadequate cerebral perfusion may ensue.

Arterial stiffness, especially in the large arteries, is the pathophysiological characteristic that best exemplifies geriatric hypertension. It is directly related to the increase in peripheral vascular resistance, a pathognomonic characteristic of hypertension in the elderly population. In addition to age and body mass index, insulin resistance also appears to be independently related to increased arterial stiffness. The connection between arterial stiffness and the type of hypertension most commonly encountered in older patients, namely, systolic hypertension with high pulse pressure.

Beyond this structural change in the arteries, the regulation of vascular resistance is also affected by age-related changes in the autonomic nervous system and in the vascular endothelium. There is an age-associated decline in the sensitivity of the arterial baroreceptor. This effects the regulation of vascular resistance in two important ways. First, a larger change in blood pressure is required to stimulate the baroreceptor to invoke the appropriate compensatory response in heart rate. This also contributes to the age-related increase in blood pressure variability. Second, the decrease in baroreceptor sensitivity leads to relatively greater activation of sympathetic nervous system outflow for a given level of blood pressure. An age-associated increase in sympathetic nervous system activity has been demonstrated by higher plasma norepinephrine levels, rates of norepinephrine re-

lease derived from tracer kinetic studies, and muscle sympathetic nerve activity. If the increased activity of the sympathetic nervous system did not result in a corresponding decrease in adrenergic receptor responsiveness, one would expect a net increase in cardiovascular adrenergic responses. However, many studies have demonstrated age-associated declines in beta-adrenergic receptor chronotropic, inotropic, and vascular responses as well as alpha-adrenergic vasoconstrictor responses. Consequently, in normotensive older individuals, the increase in sympathetic nervous system activity does not lead to an overall increase in vascular tone and appears not to explain an age-related increase in blood pressure. In contrast, in older hypertensive subjects, arterial alpha-adrenergic receptor responsiveness has been shown to be elevated in relation to their high level of sympathetic nervous system activity possibly contributing to their higher blood pressure.

Regulation of vascular resistance by the vascular endothelium is also changed in relation to age. Endothelial dysfunction demonstrated by a decrease in the production of endothelial-derived nitric oxide has been identified to accompany aging as well as hypertension. Impaired nitric oxide-mediated vasodilation is a potential contributor to the age-related increase in peripheral vascular resistance.

Age-related changes in renal function and in particular in renal regulation of sodium balance may also contribute to an increase in blood pressure. Decreased renal blood flow and glomerular filtration rate impair the aging kidney's ability to excrete a sodium load. These renal changes in the regulation of sodium balance create a tendency for sodium retention. This likely plays a part in the finding that a high proportion of older hypertensive individuals, perhaps as high as two-thirds, are characterized as having salt sensitivity. Salt sensitivity is operationally defined as an increase in mean arterial blood pressure, commonly 5 mm Hg or more, during a high compared to a low dietary sodium intake.

Aging also alters the renin-angiotensin-aldosterone system in ways that may contribute both to elevated blood pressure as well as sodium sensitivity. In general, older hypertensive subjects are characterized by having low levels of plasma renin activity. The role of aldosterone as a contributor to elevated blood pressure, aside from overt primary hyperaldosteronism as a secondary cause of hypertension, in the age-related increase in blood pressure is being actively investigated. A direct relationship between plasma aldosterone levels within the physiologic range of normal and the future development of hypertension has been shown in normotensive individuals. Since higher levels of aldosterone have also been linked with central obesity, vascular stiffness, blunting of baroreceptor sensitivity, impaired endothelial function, insulin resistance, and sodium sensitivity, it seems very possible that aldosterone may prove to be a unifying factor that accounts for many of the age-related changes in these physiological features that also contribute to elevated blood pressure.

Abnormalities in glucose homeostasis and, in particular, resistance to insulin's effects on carbohydrate metabolism are evident with aging as well as in hypertension. Insulin resistance has been grouped together with a constellation of other characteristics—obesity, central adiposity (commonly measured as increased waist circumference), hyperlipidemia, and hypertension—referred to as the metabolic syndrome. Studies that have been careful to control for the confounding factors of obesity, central adiposity, physical inactivity, and hypertension demonstrate that age is not independently associated with insulin resistance. Therefore, although many

older hypertensive individuals will be insulin resistant, and many may have impaired glucose tolerance if not meet criteria for type 2 diabetes, an isolated age-related change in insulin resistance appears not to directly contribute to elevated blood pressure in aging.

## DIAGNOSTIC EVALUATION

### Measurement Considerations

The first and most critical step in the diagnostic evaluation of hypertension among older individuals is the accurate measurement of blood pressure. In addition to the standard measurement instructions dictating cuff size and type of instrument, several factors regarding appropriate blood pressure measurement deserve emphasis. First, as a result of the observation that blood pressure is more variable in older people, the dictum that “hypertension should never be diagnosed on the basis of a single blood pressure measurement” is especially true. Studies have documented that there is considerable misdiagnosis of hypertension among older people. For example, up to one-third of subjects who were receiving antihypertensive therapy when they enrolled in the Systolic Hypertension in the Elderly Program failed to meet entry blood pressure criteria for the study after their medications had been withdrawn. The diagnosis of hypertension should be based on the average of a minimum of nine blood pressure readings that have been obtained on three separate visits.

Second, there is a strong association between arterial stiffness and the presence of an auscultatory gap. For this reason, if the blood pressure cuff is initially not inflated to a pressure above the true systolic pressure but falls within the range of the individual’s auscultatory gap, the systolic pressure will be underestimated. One may palpate the systolic pressure by recording the pressure at which the radial artery pulse is first appreciated as the cuff is deflated to ensure that the true systolic pressure is obtained.

Third, while not directly related to the diagnostic classification of hypertension, another important factor in blood pressure measurement is to always obtain supine and upright standing readings to determine if there is evidence for an orthostatic or postural decrease in blood pressure. The commonly used definition of postural hypotension is a decrease in systolic blood pressure of 20 mm Hg or more from supine to upright positions within the first several minutes of standing. Elevated supine systolic blood pressure is one of the strongest predictors of postural hypotension. The presence of postural hypotension is an important risk factor for falls and may be exacerbated by almost all antihypertensive medications. Therefore, identifying those patients with postural hypotension at the outset and during therapy is of critical importance.

Fourth, some individuals may have in-office blood pressure readings that are markedly elevated compared with their in-home, self-taken readings, commonly referred to as white coat hypertension. For these individuals, it is worth considering further evaluation with carefully taken home readings using an appropriately calibrated instrument or obtaining 24-hour ambulatory monitoring. The 24-hour blood pressure monitor approach has an added advantage of defining both the daytime and the nocturnal as well as the overall average blood pressure values. The 24-hour average provides a good measure of the blood pressure load and correlates with indicators of target organ damage. The circadian blood pressure pattern may also

be informative in that individuals who fail to decrease their nocturnal blood pressure by at least 10% relative to their daytime blood pressure, referred to as nondippers, have been shown to have greater cardiovascular disease risk compared to those with the normal, dipper pattern.

A final point concerning blood pressure measurement is to emphasize the primacy of systolic over diastolic blood pressure as the pressure that confers the most significance with respect to cardiovascular risk. Moreover, the pulse pressure, the difference between systolic and diastolic pressure, appears to outweigh either systolic or diastolic blood pressure as a cardiovascular risk factor. Based on the pathophysiology of vascular stiffness discussed above, elevations in both systolic and pulse pressure are the expected correlates of increased vascular stiffness.

### Evaluation

Similar to younger patients, more than 90% of older hypertensive patients have essential hypertension. A diagnostic evaluation for secondary and potentially reversible causes of hypertension should be completed following the standard guidelines that have been developed for younger patients. There are several factors that deserve special attention in an older patient population. First, since the majority of hypertension among this population is systolic hypertension, older patients who present with primarily diastolic hypertension merit a careful evaluation with a focus on a renovascular cause. This is especially true for those who present with relatively abrupt onset of diastolic hypertension. Second, older patients are apt to be receiving a number of medications, some of which could be contributing to elevated blood pressure. A complete medication review is warranted to search for medications that may be implicated, e.g., corticosteroids and nonsteroidal anti-inflammatory drugs including COX-2 inhibitors. Third, the prevalence of sleep apnea among older patients with hypertension is high and may be an important pathophysiological explanation for their elevated blood pressure. Fourth, although the incidence of pheochromocytoma is rare, there is a suggestion from an autopsy study that the incidence of this condition increases with increasing age.

### Target Organ Damage and Risk Factor Assessment

The evaluation should also include a determination of target organ damage and a cardiovascular risk factor assessment and identification of comorbid conditions that may impact antihypertensive drug selection. Determining the extent of hypertension-related target organ damage may be complicated by the confounding effects of concurrent age- or disease-related changes. It is important to assess whether the patient has evidence of renal impairment, proteinuria, hypertensive retinopathy, electrocardiographic abnormalities or left ventricular hypertrophy. An assessment of overall cardiovascular risk—smoking history, alcohol intake, dietary salt and fat intake, and level of physical activity—should also be completed. Older patients presenting with hypertension are likely to have other conditions included among a group of abnormalities described collectively as the metabolic syndrome. Therefore, it is important to consider the coexistence of abdominal obesity; insulin resistance, impaired glucose tolerance, or overt type 2 diabetes mellitus; and hyperlipidemia and incorporate screening for these conditions into the diagnostic evaluation.

## APPROACH TO TREATMENT

### Treatment Effectiveness

Results from meta-analyses of numerous placebo-controlled randomized clinical trials that have been conducted in older hypertensive patients have confirmed that significant reductions in cardiovascular and cerebrovascular morbidity and mortality occur with antihypertensive therapy and that the treatments are also safe. Active treatment leads on average to a 12% to 25% decrease in the rate of death, a 35% reduction in stroke, and a 25% reduction in myocardial infarction in addition to significant decreases in the development of chronic kidney disease and congestive heart failure. Treatment may also be associated with a decreased rate in the development of dementia. Depending on the individual group's additional cardiovascular risk factors and assuming a 12 mm Hg decrease in systolic blood pressure for 10 years, between 9 (the highest risk group) and 81 (lowest risk group) patients would need to be treated to prevent one death. For these reasons, there is a clear consensus that treating hypertension in older patients is safe and effective.

### Therapeutic Goals and Monitoring

In accordance with general geriatric principles, it is important to consider establishing individualized patient treatment goals. The general recommended target (for patients without diabetes or chronic kidney disease) is to decrease systolic blood pressure below 140 mm Hg and diastolic blood pressure below 90 mm Hg utilizing therapies that are least likely to produce adverse side effects or have a negative impact on quality of life. The goal for patients with diabetes or chronic kidney disease is a systolic blood pressure level below 130 mm Hg. Since the major risk factor, along with elevated pulse pressure, is the level of systolic pressure, lowering the systolic blood pressure to these goals without excessively lowering diastolic blood pressure (e.g., below 70 mm Hg) should be the primary therapeutic target.

The most common treatment-related adverse side effect, shared by all antihypertensive medications, is the development of postural hypotension. Patients may present with atypical symptoms such as generalized weakness or fatigue rather than noting postural lightheadedness or dizziness. For this reason, it is important not to treat blood pressure too aggressively and also to always determine supine and upright blood pressure measurements during monitoring of all older patients. If a patient's seated systolic blood pressure cannot be lowered to below 140 mm Hg without the development of postural hypotension, it is prudent to consider modifying that patient's target blood pressure goal to instead focus on their standing blood pressure. This may be more important from an overall perspective to minimize the patient's fall risk.

When patients present with markedly elevated blood pressures in the absence of a true hypertensive emergency (e.g., signs of target organ damage, hypertensive encephalopathy, intracranial hemorrhage, acute heart failure with pulmonary edema, dissecting aortic aneurysm, or unstable angina), it is not necessary and may in fact be harmful to reduce blood pressure to normal values too rapidly. Setting an intermediate treatment goal of 160 mm Hg may be appropriate for these patients. Dosage adjustments or additions of new

therapies should be made gradually over time to avoid overtreatment. Similarly, once patients have reached their therapeutic target and have been maintained on stable therapy, their need for continued treatment should be periodically reassessed. Many patients will tolerate a dosage reduction or medication discontinuation, especially if they have been successful in making lifestyle modifications, achieved during a carefully monitored withdrawal period.

### Lifestyle Modifications

Based on the physiological profile of the typical older hypertensive patient described in the preceding section—overweight, sedentary, and salt-sensitive—lifestyle modifications directed toward these characteristics would be predicted to be especially efficacious. Additional reasons to focus attention on lifestyle modification are that they will be adjunctive if medications are also needed, will lead to improvements in other cardiovascular risk factors (e.g., lipids), are associated with other salutary outcomes (notably exercise), and are associated with minimal adverse effects. For patients with Stage 1 hypertension (systolic levels between 140 and 160 mm Hg) who do not have diabetes mellitus, a 6-month treatment intervention with appropriate lifestyle modifications is the recommended first step in the treatment algorithm. Randomized controlled trials of multifactorial lifestyle interventions have been conducted and demonstrate the benefit in blood pressure reduction that is achieved as well as sustained in the intervention groups. A meta-analysis of 105 such trials (although few were directed solely to older subjects), demonstrated the overall benefits of weight reduction, aerobic exercise, and decreased intake of sodium and alcohol. Each of these modifications was associated on average with a 5 mm Hg reduction in systolic blood pressure, comparable to the level achieved with a single antihypertensive medication.

The Trial of Nonpharmacologic Intervention in the Elderly (TONE) targeted the effect of dietary sodium restriction and weight loss in older hypertensive patients. In this study, the intervention led to fairly modest declines in dietary sodium intake (average of 40 mmol/day) and body weight (average 4 kg), but there was a 30% decrease in the need to reinstitute antihypertensive therapy among the intervention group.

## Pharmacological Therapies

### Overview

Currently available evidence supports two general principles with respect to antihypertensive medication selection: one, that the level of blood pressure reduction achieved is more important than which drug is used, and two, that all classes of antihypertensive medications have been demonstrated to be efficacious in older patients. Following these principles, the initial antihypertensive drug selection should be based on patient-specific factors. For example, drug selection will depend on whether the patient's hypertension is simple or complicated by another coexisting condition. The presence of a coexisting condition will often dictate the optimal medication (e.g., an angiotensin converting enzyme [ACE] inhibitor for patients with type 2 diabetes or CHF). Beyond these factors, medications that are least likely to produce adverse effects should receive first priority. For this reason, as a general statement, centrally acting antihypertensive medications and direct vasodilators are best avoided in older

**TABLE 81-2****General Treatment Recommendations for Stage 1 Hypertension**

- Begin with nonpharmacological lifestyle modifications—weight loss, exercise, salt restriction for 6-month period.
- Focus treatment goal on systolic blood pressure reduction to below 140 mm Hg.
- If target blood pressure is not met, consider low dose thiazide-type diuretic as initial drug selection.
- Base alternative drug selection on individual patient characteristics.
- Consider combination of low doses of one or more agents if goal blood pressure not met with a single drug.
- When initiating drug therapy, begin at half of the usual dose, increase dose slowly, and continue nonpharmacological therapies.
- Aggressive therapy is not appropriate if adverse side effects (e.g., postural hypotension) cannot be avoided.

hypertensive patients due respectively to concerns regarding central nervous system sedating effects and association with marked postural hypotension. In addition, attention should be paid to selecting a once-daily medication to promote adherence and to avoiding any medication interactions with the patient's other medications.

An algorithmic approach to treating hypertension is provided in the JNC 7 report. As noted in the preceding discussion regarding hypertension classification, the category of prehypertension merits emphasis as this category calls attention to its importance as a risk factor and a determinant of future hypertension. Therapeutic recommendations are then stratified on the presence or absence of "compelling indications" such as diabetes, heart failure, and chronic kidney disease. In the absence of these conditions, there are some general recommendations for initial therapy based on the stage or severity of the patient's hypertension. For patients with Stage 1 hypertension in whom a 6-month lifestyle modification intervention strategy has failed to lower blood pressure to the goal level, a thiazide-type diuretic is the most commonly recommended initial medication. General treatment recommendations for Stage 1 hypertension are summarized in [Table 81-2](#). Patients who present with Stage 2 hypertension will almost certainly require at least two drugs to control their blood pressure. Most often one of these two is a thiazide-type diuretic with the second agent selected either on compelling indications or on the basis of synergy with the initial agent (e.g. a thiazide diuretic combined with ACE inhibitor). It should be noted that regardless of the drug choice, the starting dose should be reduced and dosage titration be carried out gradually.

There are three additional general considerations to be made before a brief review of each of the major antihypertensive classes. (1) Beta-receptor antagonists are no longer recommended as an appropriate choice for the initial antihypertensive drug, especially among older patients. In part because of the age-related changes in sympathetic nervous system function discussed previously, older individuals are less responsive to beta-agonist stimulation. Beyond this physiological explanation, results from a meta-analysis concluded that unless there is a compelling indication for their use, beta-blockers should not be considered as a first-line antihypertensive agent in older (60 years and older) patients. Whereas beta-blockers were found to be equally efficacious in younger patient populations, this was not the case among the older population in whom compared with other agents, beta-blocker therapy was associated with an

creased risk of a composite outcome of death, stroke, or myocardial infarction. (2) Although the algorithm provides overall recommendations, patient-specific factors that directly impact adherence also need to be taken into account. For example, thiazide diuretics are considered to be first-line agents, but persistence rates with their continued use are lower than with angiotensin receptor blockers. As with any prescription, cost, simplicity of the regimen, and absence of side effects are important factors impacting rates of adherence. (3) Especially for Stage 2 patients, currently available data are suggesting that prescribing a fixed and especially low-dose combination capsules may be associated with improved outcomes. Although the concept of a single multiple-medication capsule seems to contradict the general geriatric principle of avoiding polypharmacy, there appear to be benefits to this approach both with respect to improved efficacy and lower rates of side effects. For example, a fixed dose preparation of four antihypertensives (a thiazide diuretic, calcium antagonist, ACE inhibitor, and beta-blocker) each at one-quarter of their usual monotherapy starting dose was superior in blood pressure control to each of the agents administered individually when given at the usual monotherapy dosage. This evidence suggests that it may be preferable to add a second agent in lower dose rather than titrating up the dosage of the first medication if a patient is not at target blood pressure in response to the starting dose of the first agent.

### Thiazide-type Diuretics

[Table 81-3](#) summarizes the advantages and disadvantages for each of the major drug classes from the geriatric patient perspective. There are several reasons why thiazide-type diuretics have become the preferred initial antihypertensive agent for most older patients. The primary pathophysiological explanation is that diuretic therapy has been noted to reduce systolic blood pressure to a greater extent than diastolic blood pressure, and also achieves greater reductions in systolic pressure relative to other antihypertensive agents. Moreover, the majority of large-scale randomized controlled trials have utilized a thiazide-type diuretic in the treatment arm and there exist an abundance of outcome data demonstrating their therapeutic effectiveness in older hypertensive populations. Additional benefits include low cost, once daily dosing, and a favorable side effect profile. The most common adverse drug events are metabolic abnormalities, especially hypokalemia, as well as hyperuricemia and impaired glucose intolerance; and urinary frequency or incontinence. These side effects are quite uncommon at lower doses. Thus, 12.5 mg of hydrochlorothiazide or its equivalent is the recommended initial starting dose and since the blood pressure lowering effect plateaus at doses higher than 50 mg, 50 mg is considered to be the maximal dose. Finally, there is good synergy with most of the other commonly used medications, such that adding a second drug if needed to a thiazide-type diuretic is a reasonable approach.

Nonthiazide-type diuretics have been less well studied. Given that hypokalemia is a common side effect of thiazide-type diuretics, and that maintaining normal potassium levels aid in blood pressure control, combination drugs with a thiazide together with a potassium-sparing diuretic (e.g., amiloride or triamterene) have been developed. Owing to the similarities observed between the physiological effects of aldosterone and the age-related contributors to elevated blood pressure listed in [Table 81-1](#), aldosterone receptor blockers (spironolactone or eplerenone) are other alternatives to consider.

TABLE 81-3

## Advantages and Disadvantages of Antihypertensive Medication Classes Specific to Older Patients

ANTIHYPERTENSIVE CLASS	POTENTIAL ADVANTAGES	POTENTIAL DISADVANTAGES	CLINICAL SITUATIONS TO RECOMMEND USE	CLINICAL SITUATIONS TO RECOMMEND AGAINST USE, OR WHICH REQUIRE MONITORING
Thiazide-type diuretics	<ul style="list-style-type: none"> <li>• Documented benefit in clinical trials</li> <li>• Produce greater reduction in systolic than diastolic blood pressure</li> <li>• Improve bone mineral density</li> <li>• Inexpensive</li> </ul>	<ul style="list-style-type: none"> <li>• Metabolic abnormalities (e.g., hypokalemia)</li> <li>• Urinary frequency</li> </ul>	<ul style="list-style-type: none"> <li>• Systolic hypertension</li> </ul>	<ul style="list-style-type: none"> <li>• Hyponatremia</li> <li>• Gout</li> </ul>

ACE, angiotensin converting enzyme; COPD, chronic obstructive pulmonary disease; CHF, congestive heart failure; CNS, central nervous system; BPH, benign prostatic hypertrophy.

### Angiotensin Converting Enzyme Inhibitors and Angiotensin Receptor Antagonists

ACE inhibitor agents and angiotensin receptor antagonists are good alternative choices for initial therapy or as second agents in combination with a thiazide-type diuretic. Their advantages include the absence of central nervous system or metabolic side effects and overall favorable side effect profile. They are also often used owing to the recommendations for their use in the setting of coexisting type 2 diabetes or systolic dysfunction. Another consideration favoring the use of these agents is the evidence that their use is associated with preservation of renal function and decreases in proteinuria in several clinical conditions.

### Calcium Channel Antagonists

All three chemical classes of calcium channel antagonists have been shown to be effective in treating older hypertensive patients. Their mechanism of action—decreased peripheral vascular resistance—and lack of significant central nervous system or metabolic side effects provide a good match with the characteristics of the geriatric patient. Age-related changes in the pharmacokinetics of these drugs (decreased clearance and increased plasma levels) mean that lower doses need to be used in older patients. The longer acting agents in the dihydropyridine class of calcium channel antagonists have been the most widely studied in randomized controlled trials where their effectiveness in treating older patient populations has been demonstrated.

### Adrenergic Receptor Antagonists

As discussed previously, beta-receptor antagonists are not an appropriate choice for monotherapy for older patients with uncomplicated hypertension. Beta-receptor antagonists should be reserved for patients with a compelling indication for their use, namely, as secondary prevention for those patients who have had prior myocardial infarction or in some patients with systolic dysfunction.

Several observations have limited the adoption of alpha<sub>1</sub>-receptor antagonists as first-line treatment for older hypertensive patients. In addition to their predilection to produce postural hypotension, subjects who received an alpha<sub>1</sub>-receptor antagonist as monotherapy in the Antihypertensive and Lipid Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) were found to have a twofold higher risk of being hospitalized for CHF relative to the subjects randomized to the diuretic arm of the study. Based on these observations, alpha<sub>1</sub>-receptor antagonist therapy should be considered for use as monotherapy, only in men in whom their use may be beneficial for symptoms related to benign prostatic hypertrophy, or in combination with another antihypertensive agent.

### Barriers to Improving Blood Pressure Control

Since there is no cure for this chronic condition, effective treatment of hypertension requires a lifelong commitment to its management. For this reason, an approach that engages and sustains the patient's motivation and adherence over time is needed. Several methods may be recommended to promote the patient's efforts such as providing

patient education materials, clear instructions for diet and exercise lifestyle recommendations, and prescribing once-daily medications to facilitate adherence. Some patients may benefit from the feedback and engagement that accompany home or self-taken blood pressure monitoring, although the effectiveness of this approach has not been proven. Another patient factor is the likelihood that the older hypertensive patient will have two or more additional chronic conditions. The complexity imposed by concurrently managing these comorbid conditions becomes extremely challenging. This is especially the case when treating a frail older individual when it is not clear how to best prioritize which of several guidelines should take precedence or for that matter if the guideline is still applicable to the patient's clinical situation.

In addition to these patient-specific factors, a number of barriers have been identified in the health care system that may impede progress in achieving better success in blood pressure control rates in the older population. The underdetection, undertreatment, and inadequate control of hypertension, especially among older patients, are well documented. Some of these system factors are limited access, lack of a team approach to care, constraints imposed by limited patient visit times, and the reimbursement system. Physician factors—the failure to modify treatment when the patient's target blood pressure goal has not been achieved—also contribute to this situation. Inadequate knowledge of the current guidelines and recommended goals outlined in the JNC 7 is one potential explanation for the failure of physicians to respond appropriately. Results from the TONE study demonstrated for example that there is systematic underutilization of the recommended thiazide-type diuretic among hypertensive patient populations. Moreover, many physicians overestimate their compliance with these standards as well as the proportion of their patient populations who have blood pressure levels below their target. However, solely providing education appears not to be an effective solution to changing physician behavior in this regard. The Assessing Care in the Older Vulnerable Elders (ACOVE) project has demonstrated that hypertension is one of many conditions for which quality indicators are not being met in this patient population. However, some quality improvement strategies have been demonstrated to be effective in improving hypertension management. The most effective strategies in this regard have involved a multidisciplinary team approach (assigning a nonphysician member of the team to assume responsibility for management), home blood pressure monitoring, and patient education. Thus, it appears that incorporating a geriatrics approach to hypertension management in the context of a quality improvement program is one effective way to eliminate some of the barriers to improving hypertension control in older patient populations.

## UNANSWERED QUESTIONS AND FUTURE RESEARCH DIRECTIONS

Prior to the completion of the Hypertension in the Very Elderly Trial (HYVET) in 2007, very few subjects aged 80 years or older had been included in the controlled clinical trials of hypertension treatment. The HYVET study recruited 3,845 hypertensive individuals aged 80 years and older and randomized them to receive either active treatment (a diuretic plus an angiotensin-converting enzyme inhibitor if needed) or a placebo and followed outcomes (stroke and mortality rates were the primary outcomes) for 5 years. The HYVET study's Data Safety Monitoring Board ended the study early when an unexpected significant, 21%, reduction in overall mortality in

the active treatment group was identified. In the intention-to-treat analysis, the treatment group also had a 30% reduction in fatal and non-fatal stroke, and a 64% decrease in the rate of congestive heart failure. Moreover, active treatment was associated with fewer adverse events than placebo. While this trial's results clearly demonstrate the beneficial effects of antihypertensive therapy in patients 80 years of age and older, it is important to emphasize that its results cannot be generalized to frail older patients who would not have met the study's entry criteria. For example, the trial excluded those with dementia, who had an inability to walk or who had dementia.

Future research directions should increase our understanding of the mechanisms underlying the age-associated increase in blood pressure, with important implications for prevention and management. For example, it seems clear that understanding the predictors and modifiers of vascular stiffness is of critical importance in preventing the age-associated development of hypertension. Similarly, although none of the currently available antihypertensive agents specifically targets vascular stiffness, future advances in drug development aimed at preventing hypertension will likely address decreasing vascular stiffness as a mechanism of action.

Additional new approaches in antihypertensive therapy may derive from advances in understanding the genetic contributions to hypertension. In addition, improvements in the ability to genetically profile an individual patient based on the unique characteristics of their specific genes related to hypertension may be used in the future to better inform the selection of an appropriate antihypertensive medication. Pharmacogenetics or personalized medicine holds great promise for tailoring drug therapy to the individual patient and also may help to explain some of the racial/ethnic and perhaps age-related differences observed in response to therapy.

Research advances to define the physiological mechanisms for the nondipper effect, i.e., the absence of a nocturnal decrease in blood pressure, may help improve our understanding about this pattern, its implications, and how it may be treated. One intriguing prospect is the extent to which altered sleep patterns, especially sleep apnea, may be linked to the nondipper pattern of blood pressure.

Finally, additional investigation will aim to elucidate why hypertension is a significant risk factor for mixed dementia, the overlap of Alzheimer's and vascular dementia. Based on the results from several studies suggesting that antihypertensive therapy may help to prevent cognitive decline and decrease the incidence rate for dementia, controlling blood pressure may also confer beneficial effects in preserving cognitive function with aging. The interactions between elevated blood pressure, insulin resistance, and other aspects of the metabolic syndrome and cognitive function will be another area for productive future investigation.

## SUMMARY

Key points for clinical practice highlighted in this chapter include:

1. Hypertension is not a normal aspect of aging, but its prevalence increases steadily with age. Hypertension is emerging as an extremely important global public health problem. The increasing prevalence of hypertension and its associated morbidity and mortality warrant increased attention to strategies to prevent the age-associated increase in blood pressure.
2. Older people primarily develop systolic hypertension most likely related to an age-related increase in arterial stiffness. Systolic

blood pressure and pulse pressure, both closely associated with arterial stiffness, confer the greatest significance as cardiovascular and cerebrovascular risk factors.

3. Age-related changes in systems that regulate blood pressure result in greater blood pressure variability. This dictates careful attention to accurate measurement and diagnosis of hypertension.
4. Older hypertensive individuals have physiological characteristics that are well suited to respond effectively to lifestyle modifications.
5. The focus of therapy should be on lowering the systolic blood pressure to the patient's target goal. Since the major antihypertensive drug classes have all been demonstrated to be effective in older patient populations, drug selection itself is less important and should take into consideration comorbidities and other patient-specific factors.
6. Thiazide-type diuretic drugs are preferred as the initial drug in most patients. Combination therapy with low doses of one or more agents should be considered if needed to control blood pressure below the target level.
7. Patients should be monitored for adverse drug events, especially postural hypotension, throughout treatment.
8. Current blood pressure control rates are inadequate, especially among the older patient population. Systems approaches that incorporate geriatric approaches to team care combined with quality improvement strategies need to be adopted to improve treatment outcomes.

# Aging of the Respiratory System

*Paul L. Enright*

## INTRODUCTION

This chapter first reviews the changes in lung function with aging that are known to occur in healthy persons (normal, never smokers). Included are the major categories of pulmonary function tests: static lung volumes, maximal expiratory flow, lung mechanics, and gas exchange, plus bronchodilator (BD) response and nonspecific airway reactivity. [Table 82-1](#) summarizes these changes. The chapter then adds a discussion of how lung function tests may be used by a clinician to assist in the differential diagnosis of asthma and chronic obstructive pulmonary disease (COPD) in an elderly patient, and to objectively measure the efficacy of asthma and COPD therapy (see Chapter 83 for additional information on this topic).

## LUNG VOLUMES

Total lung capacity (TLC) is the volume of air within the respiratory system when a subject makes a maximal voluntary inspiratory effort (and the air seen in the lungs on a chest x-ray). It is determined by the balance of forces between the maximally activated inspiratory muscles and the elastic recoil of the lung and chest wall. A decrease in TLC and other static lung volumes is called restriction.

The elastic recoil of lung tissue decreases with aging (just as the skin becomes less elastic), making the lungs easier to expand during a deep breath toward TLC. This reduction of elastic recoil tends to increase TLC; however, the chest wall (rib cage) becomes stiffer with aging, so that a maximal inspiratory effort is not able to achieve a higher lung volume even though the lungs themselves have become easier to expand. Thus, TLC normally remains stable throughout the aging process.

The volume of air remaining in the lungs when subjects have exhaled as much air as possible is called residual volume (RV). Because lung elastic recoil decreases as a consequence of normal aging, the RV and RV/TLC increase from young adulthood to older age. An

abnormally high RV/TLC is called hyperinflation, can often be seen on a chest x-ray, and occurs with both asthma and COPD.

Vital capacity (VC) is the difference between the absolute lung volume at TLC and at RV, and the amount of air that a person can slowly exhale after inhaling maximally. Because TLC is relatively constant while RV increases with age, the VC decreases with age. Hutchinson coined the term vital capacity over 150 years ago because it predicted the vigor and length of life of his patients. Many modern epidemiologic studies have verified his observation.

## MAXIMAL EXPIRATORY FLOW

Maximal expiratory flow, as seen during spirometry tests, varies as a function of lung volume because higher flows are possible at a higher lung volume. For forced exhalation beginning from a deep inhalation (the first phase of a spirometry maneuver), the initial (peak) flow (phase 2) is determined by the recoil of the lung and chest wall and the degree of effort expended by the patient, as well as by the speed with which the patient's respiratory muscles can generate positive pleural pressure. Once maximal flow is achieved, maximal flow throughout the remainder of the VC (phase 3) is determined by the intrinsic properties of the lung.

## SPIROMETRY

Spirometry is the most common test of lung function, and is easily performed by 9 of 10 elderly patients. Modern office spirometers use a flow sensor, connected to a microprocessor that determines the forced expiratory volume in one second (FEV<sub>1</sub>), forced vital capacity (FVC), and FEV<sub>1</sub>/FVC from the best maneuver, as well as the predicted values. FEV<sub>1</sub> is the most important value, representing the volume of air (in liters) exhaled during the first second. Guidelines for spirometry methods and instrument accuracy are available from the American Thoracic Society.

**TABLE 82-1**

**Effects of Aging on Lung Function**

Lower maximal expiratory flows: FEV <sub>1</sub> , FEV <sub>1</sub> /FVC, FEF 75%
Increased FRC and RV, lower VC, but stable TLC
Lower diffusing capacity (oxygen uptake)
Lower PO <sub>2</sub> and SpO <sub>2</sub> as a consequence of V/Q mismatch (but no change in PCO <sub>2</sub> )
Lower respiratory muscle strength and endurance
Stiffer chest wall (less compliant)
Increased lung tissue compliance (loss of lung recoil)
Reduced respiratory drive (for hypoxia, hypercarbia, and resistive loads)
Increased airway reactivity (but no change in bronchodilator responsiveness)

FEF, forced expiratory flow; FEV<sub>1</sub>, forced expiratory volume in one second; FRC, functional residual capacity; FVC, forced vital capacity; PCO<sub>2</sub>, partial pressure of carbon dioxide; PO<sub>2</sub>, partial pressure of oxygen; RV, residual volume; SpO<sub>2</sub>, arterial oxyhemoglobin saturation; TLC, total lung capacity; VC, vital capacity; V/Q, ventilation/perfusion.

The presence of airways obstruction is determined by a low FEV<sub>1</sub>/FVC ratio and visualized on the flow–volume (*F–V*) curve as concavity toward the volume axis or tail at the end of the maneuver (Figure 82-1). The descending limb of the *F–V* curve of healthy young adults is a straight line of about 45 degrees until the end of the maneuver (shaped like a sail), corresponding to exponential emptying of the lungs. The shape of the *F–V* curve becomes progressively more curvilinear as a healthy adult becomes older, corresponding to decreases in expiratory flows at low lung volumes. The reduced flow at low lung volumes, even in healthy elderly persons, is a result of a decrease in the mean diameter of small airways.

Adults normally experience a loss in FEV<sub>1</sub> of about one-third liter per decade (Figure 82-2). The decline in FEV<sub>1</sub> with aging is greater than the decline in FVC, so that the FEV<sub>1</sub>/FVC also declines with age. Values below 0.65 usually indicate airway obstruction in patients aged 65 years and older.

Many nonpulmonary factors contribute to the decline in the FEV<sub>1</sub> in elderly persons (see Table 82-2 for a list). The strongest

**FIGURE 82-1.** Flow–volume curves with increasing degrees of obstruction. Bo, borderline obstruction (85% predicted); Mi, mild obstruction (70% predicted); Mo, moderate obstruction (60% predicted); N, normal (100% predicted FEV<sub>1</sub>); Se, severe obstruction (35% predicted).

**FIGURE 82-2.** The FEV<sub>1</sub> normally declines about 30 mL per year with aging, even in healthy men and women without lung disease.

factors are cigarette smoking; a diagnosis of COPD or asthma; and wheezing symptoms—all of which are known to cause airway obstruction (a low FEV<sub>1</sub>/FVC ratio). The inability to take a deep breath (restriction) also reduces the FEV<sub>1</sub>, as with obesity, malnutrition, heart disease, and chest wall abnormalities. For a given height, gender, and age, the FVC and FEV<sub>1</sub> of healthy elderly African-Americans is approximately 12% lower than that of healthy elderly white persons, thus spirometry reference equations, which are race/ethnicity-specific (as from the NHANES III study), are used to calculate predicted values. Since spirometry tests require athletic-type breathing maneuvers, poorly trained technologists in outpatient settings often do not obtain maximal patient effort during one or more of the three phases of the maneuver, causing misclassification of the results.

**RESPIRATORY MUSCLE STRENGTH**

Another vital component of respiratory function is respiratory muscle strength and endurance. Diaphragm strength is approximately 25% lower in healthy elderly persons as compared to young adults. The VC is reduced when the diaphragm is weak and when the expiratory muscles of the abdominal and thoracic wall cannot empty the

**TABLE 82-2**

**Factors Associated with a Lower FEV<sub>1</sub> in Elderly Individuals**

Important factors associated with airway obstruction
Cigarette smoking (current, former, and pack-yrs)
Emphysema or chronic bronchitis (COPD)
A diagnosis of asthma at any time in the past
Wheezing (during or apart from colds, daytime or nighttime)
A history of workplace exposures to dust, fumes, smoke, or chemicals
Other factors associated with restriction of lung volumes
Dyspnea on exertion
Obesity or malnutrition
Hypertension or hypotension
Major ECG abnormality
Pitting ankle edema
Diabetes, on medication
Prior chest surgery

lungs below the resting respiratory position. The load on these respiratory muscles increases with aging, because chest wall compliance decreases.

Diaphragm strength may be easily and inexpensively measured in the outpatient office. The patient exhales slowly, then makes a maximal attempt to inhale from a mouthpiece connected to a pressure gauge (−200 cm H<sub>2</sub>O range, with a small leak) for 2 seconds. The largest pressure from five such maneuvers is reported as the Maximal Inspiratory Pressure (MIP). Respiratory muscle strength is stronger in men, but declines with aging in both sexes. The mean MIP for healthy 85-year-old men is approximately 30% lower than that for 65-year-old men (65 vs. 90 cm H<sub>2</sub>O). A lower MIP is associated with many factors, including decreased handgrip strength, lower body mass index (malnutrition), and current smoking. A low MIP often causes a low FVC.

## ARTERIAL BLOOD GASES

Acid–base balance is tightly controlled, and therefore, normal values for arterial pH and PaCO<sub>2</sub> (partial pressure of carbon dioxide in arterial gas) do not change throughout adult life in healthy persons. However, because of increased nonuniformity of ventilation with aging, mean arterial oxygen tension (PaO<sub>2</sub> [partial pressure arterial oxygen]) declines during middle life even in healthy never-smokers. Mean PaO<sub>2</sub> remains relatively constant at about 80 mm Hg from age 65 to 90 years in healthy elderly persons at sea level (Figure 82-3).

## DIFUSING CAPACITY

A test of the single-breath pulmonary diffusing capacity for carbon monoxide (DLCO) is available at hospital-based pulmonary function laboratories. The 15-minute noninvasive DLCO test is easier to perform than spirometry, yet clinically valuable for the differential diagnosis of both airway obstruction and restriction of lung volumes. DLCO is the amount of carbon monoxide (from a test gas containing 0.3% CO) that is absorbed into the blood during a 10-second breath-hold. The DLCO is an index of the ability of the

**FIGURE 82-3.** Arterial oxygen (PaO<sub>2</sub>) decreases throughout middle age in healthy persons but stabilizes beyond age 65 years in healthy persons.

lungs to take up oxygen from the environment and deliver it to red blood cells.

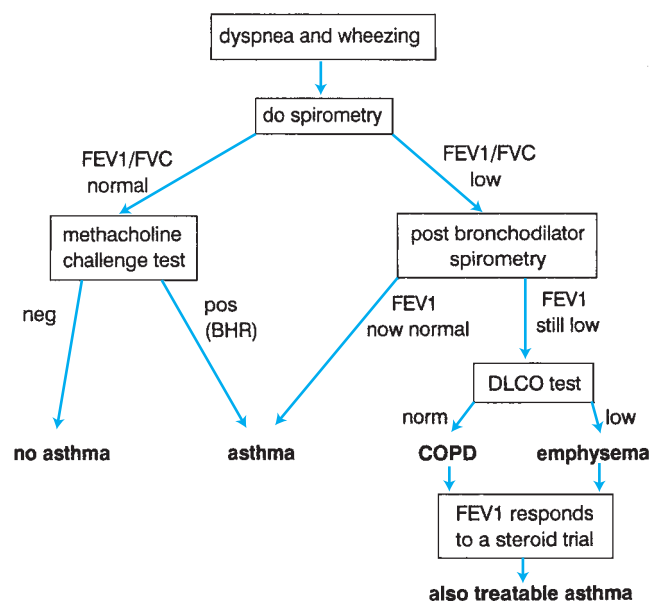

In smokers with airways obstruction, the DLCO is an excellent index of the degree of anatomic emphysema; a low DLCO correlates highly with a low mean lung tissue density on lung computed tomography (CT) scans and the degree of anatomic emphysema. Smokers with airways obstruction but normal DLCO values usually have chronic “obstructive” bronchitis but not emphysema, and non-smoking patients with asthma and borderline to moderate airways obstruction have normal or high (percent predicted) DLCO values.

In healthy persons, the absolute value of DLCO in adults varies with height, age, gender, and race. As with spirometry, reference values from the healthy subset of large population studies are used to obtain percent predicted values for individual patients. DLCO is higher in very obese persons and lower in patients with anemia. The DLCO declines about 5% per decade after age 40 years, even in healthy persons.

## Differential Diagnosis of Asthma and COPD

The differential diagnosis of asthma and COPD in elderly persons is often more difficult than in younger adults because of the higher prevalence of comorbidity. The elderly are much more likely than middle-aged adults to have COPD and cardiovascular disease, both often a result of cigarette smoking, and both with symptoms that may mimic asthma, increasing the value of objective pulmonary function (PF) tests in the elderly patient.

Because intermittent airway obstruction is the primary physiologic manifestation of asthma, the first (and least expensive) PF test to perform is spirometry, especially if the patient is experiencing symptoms at the time of presentation (Figure 82-4). If the FEV<sub>1</sub>/FVC ratio is below the lower limit of the normal range (assuming that appropriate reference equations for elderly patients are used and the quality of the test session was good), the patient has airway obstruction. The degree of severity of the obstruction is then determined by

**FIGURE 82-4.** The role of PF tests in making a differential diagnosis of asthma versus COPD in a patient with chronic or intermittent dyspnea.

the percent predicted FEV<sub>1</sub>. When compared to younger patients with asthma, one will often be surprised by more severe airway obstruction (an FEV<sub>1</sub> below 50% predicted) in elderly patients with asthma.

If the patient has airways obstruction, repeat spirometry approximately 45 minutes after administration of a combination of albuterol and ipratropium (post-BD) spirometry). A positive (significant) BD response is best defined as an increase of at least a 12% (and 0.20 L) improvement in percent predicted FEV<sub>1</sub> or FVC.

With good test quality, baseline airway obstruction followed by a BD response helps to confirm asthma in a patient with a history suggesting asthma. However, the lack of a positive BD response is of no help in making the diagnosis (does not rule out asthma), because chronic asthma often leads to airways inflammation that is not acutely reversible. Furthermore, many elderly patients with a history of smoking, current symptoms suggesting asthma, baseline airways obstruction, and a “positive” BD response, still have some “fixed” obstruction (a low FEV<sub>1</sub>) following aggressive therapy for asthma. Some guidelines consider this pattern evidence for COPD.

Pre- and post-BD spirometry may be normal in patients with a history suggesting asthma. The patient maybe asked to return for retesting when symptoms occur; however, a methacholine challenge test (MCT) or measurement of exhaled nitric oxide (eNO) can quickly and safely detect the bronchial hyperresponsiveness (MCT) or the eosinophilic airway inflammation (eNO) characteristic of asthma. The MCT has optimal clinical utility when the pretest probability of asthma is intermediate. A high PC-20 (above 16 mg/mL) makes asthma highly unlikely, while a low PC-20 (below 4 mg/mL) in a patient with a history of asthma-like symptoms increases the pretest probability of asthma.

Measurement of the DLCO is quick, safe, and helps to distinguish between emphysema and other causes of chronic airway obstruction. Emphysema lowers the DLCO, obstructive chronic bronchitis does not affect the DLCO, and asthma frequently increases the DLCO. A lung CT scan may also differentiate asthma from emphysema in a cigarette smoker, although both diseases may coexist.

## TESTS TO ASSESS RESPONSE TO THERAPY FOR ASTHMA AND COPD

The inhaled corticosteroids used to treat asthma and COPD frequently cause thrush (or other side-effects at high daily doses), while the long-acting BD inhalers may cause muscle cramps, tremors, insomnia, and arrhythmias. These asthma controller medications are usually started at high doses or in combination during an exacerbation of asthma or COPD, but this therapy should be adjusted downward a few months later after maximal control is obtained. When oral corticosteroids such as prednisone are necessary to maintain asthma control, serious morbidity frequently occurs because of ocular disease, osteoporosis, and glucose intolerance; therefore, ob-

jective measurements of the effectiveness of each newly prescribed asthma or COPD medication for each patient is highly desirable.

Two lung function tests are used as asthma therapy outcome measures in the outpatient clinic setting: the pre- or post-BD FEV<sub>1</sub> during a clinic visit, or peak expiratory flow (PEF) measured at home in the early morning. The FEV<sub>1</sub> is more accurate and more sensitive than peak flow for detecting narrow airways, and it is linearly related to the severity of asthma symptoms in groups of elderly patients. Pocket spirometers, which measure both FEV<sub>1</sub> and PEF, are now available for the same cost as a mechanical peak flow meter. Because many elderly patients become tolerant of severe, long-standing airway obstruction and consequently underreport respiratory symptoms, objective measurement of lung function is needed. FEV<sub>1</sub> improvement of more than 20% and 0.20 L is necessary to be confident that the change was not merely a result of measurement noise. The FEV<sub>1</sub> measured 10–30 minutes after albuterol is considered the best lung function that can be achieved on the day of the visit, and therefore, is a more stable measure in asthmatics than comparing visit-to-visit FEV<sub>1</sub> values without prior administration of albuterol. In the future, the availability of less expensive eNO analyzers for monitoring asthma in outpatient settings may complement or replace spirometry for this purpose.

# Chronic Obstructive Pulmonary Disease

*Sachin Yende* ■ *Anne B. Newman* ■ *Don Sin*

The smoking epidemic of the twentieth century has led to an increase in the incidence of chronic obstructive pulmonary disease (COPD), a largely preventable disease. The statistics concerning COPD have caused considerable alarm around the world. Globally, COPD is the fourth leading cause of mortality and the twelfth leading cause of disability. To address this growing problem, the World Health Organization partnered with the National Heart, Lung, and Blood Institute (NHLBI) to form a Global Initiative for Chronic Obstructive Lung Disease (GOLD). In 2001, they offered a global strategy to increase awareness of the disease and offer guidelines for disease prevention and treatment, referred to as the GOLD Guidelines. These guidelines and those created by leading medical societies are incorporated in this chapter.

Most patients are diagnosed with COPD in the sixth decade. Although it is an important chronic disease and a leading cause of disability in the elderly, it remains underrecognized. This chapter will focus on the early recognition and management of COPD, an important component of outpatient geriatric management.

## DEFINITIONS

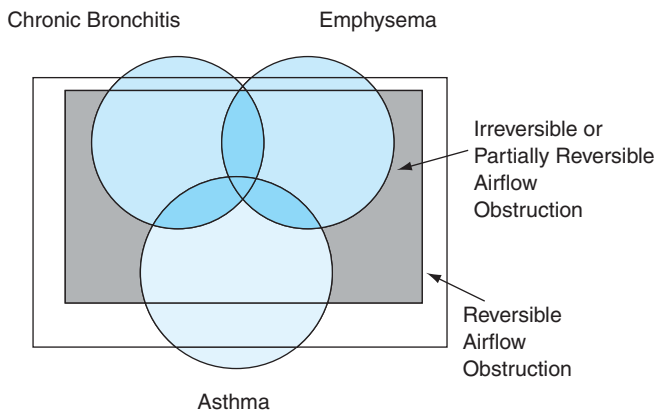

GOLD defines COPD as partially reversible or nonreversible airflow limitation, which is progressive, and cannot be reversed by current therapies. In contrast asthma is defined as a syndrome characterized by reversible airflow limitation. Although GOLD definitions did not include traditionally used terminologies, such as chronic bronchitis and emphysema, these definitions are important to understand the disease spectrum. Chronic bronchitis is defined clinically as cough with sputum production for 3 months of a year for 2 consecutive years. Emphysema is a pathological diagnosis defined as the destruction of alveolar walls with accompanying enlargement of air spaces distal to the terminal bronchiole.

Key differences between COPD and asthma are that, in COPD there is (i) a lack of complete reversibility of airflow obstruction; (ii) neutrophil predominance in the airways, especially in the lumen; (iii) significant smoking history (usually >10 pack years) or exposure to burning biomass fuel, such as wood and manure; (iv) chronic colonization of bacterial organisms in the airways, especially in patients with severe disease; and (v) emphysematous changes in the lung parenchyma often associated clinically with reduced diffusing capacity on a gas diffusion test.

It is important to recognize that some of these distinctions become blurred in the elderly. Firstly, many elderly asthmatics, even those who have never smoked, have evidence of poorly reversible airflow obstruction, similar to COPD. This is caused by permanent remodeling of the airways. Secondly, bronchial hyperresponsiveness, an exaggerated bronchoconstrictive response to a given stimulus, is seen in a majority of middle-aged smokers with COPD and is a strong predictor of progressive decline in lung function. Thirdly, adults with asthma, especially those with severe disease, often demonstrate neutrophilia in their airways. Lastly and perhaps most importantly, many adult patients with asthma are current or former smokers. It is likely that such patients have more than one pathological process and several pathways of inflammation. These patients are likely to have both COPD and asthma. This has raised a complexity of semantic issues that has not been resolved. One attempt has been to combine and describe such patients using the term asthmatic bronchitis (Figure 83-1).

An important limitation of current definitions of COPD is that they fail to identify a precise level of airflow limitation at which clinically relevant outcomes occur for each age group. This is an important issue in the elderly, in whom reduced elastic recoil of lung with aging maybe associated with increased incidence of airways obstruction. Using a commonly used criteria, such as forced expiratory volume in 1st second/forced vital capacity (FEV<sub>1</sub>/FVC) ratio <70% may thus lead to over diagnosis. Using age-specific cutoffs of

**FIGURE 83-1.** Subsets of COPD and asthma depicted by a Venn diagram. (From Mannino DM. COPD: epidemiology, prevalence, morbidity and mortality, and disease heterogeneity [review]. *Chest*. 2002;121(5 Suppl):121S–126S.)

FEV<sub>1</sub>/FVC ratio to diagnose COPD is therefore important in the elderly.

### EPIDEMIOLOGY

The different definitions of COPD, based on spirometry, clinical, or radiographic criteria, have important implications when estimating the global burden of disease. Using patient- or physician-reported diagnosis alone may underestimate the incidence of COPD. More than 50% of individuals with airway obstruction have never been diagnosed with COPD by a health care provider. Underdiagnosis is more common in the elderly because they fail to report symptoms or symptoms are attributed to other conditions.

Several recent studies used multiple approaches, including spirometry and clinical criteria, to estimate the prevalence of COPD. In the United States, the National Health and Nutrition Examination Survey (NHANES) III estimated prevalence of COPD from

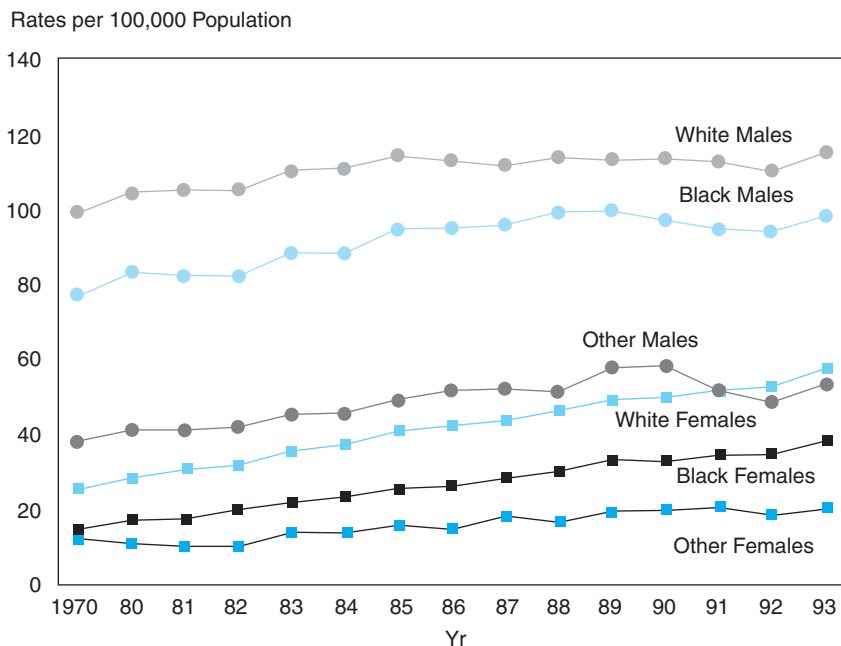

1988 to 1994. In this survey, 14.3% of the adult population or 24.2 million individuals had airflow limitation by spirometry. Of these, 1.5% had moderate to severe disease, evidenced by FEV<sub>1</sub> <50%. However, only 2.9% or 4.8 million adults who met spirometry criteria report symptoms of chronic bronchitis or emphysema.

In the NHANES III survey, the prevalence of airflow obstruction increased with age and was highest among those 65 to 85 years of age. The prevalence of low lung function is higher with increasing age except in individuals 85 years or older, which maybe related to differential mortality or inability to do pulmonary function testing. This survey also underscored the difficulties in differentiating asthma and COPD. More than a fifth of the respondents reported that they had current asthma and current bronchitis or had current asthma and current emphysema.

Similar estimates have been obtained globally. For instance, a prevalence study in Japan estimated the prevalence of COPD in those 40 years or older to be 10.9% by spirometry criteria. In the Platino Study, which evaluated residents 40 years of age or older in five major Latin American cities (Sao Paulo, Santiago, Mexico City, Montevideo, and Caracas), the prevalence estimates ranged from a low of 7.8% in Mexico City to a high of 19.7% in Montevideo. Similar estimates have been reported in European countries.

COPD is a leading cause of death worldwide. Globally, COPD is the fourth leading cause of mortality and the twelfth leading cause of disability. In 2004, chronic lower respiratory diseases, including chronic bronchitis and emphysema, were the fourth leading cause of death in United States and it is estimated that approximately 6% of deaths occur as a result of COPD. Patients with COPD often die as a result of influenza or pneumonia, the sixth leading cause of death in United States. These findings combined with the underdiagnosis of COPD suggests that current COPD mortality estimates maybe underestimated.

An alarming trend has been increasing mortality as a result of COPD over the past two decades. In United States, mortality caused by COPD has increased 44% from 1979 to 1993, and the highest increase in mortality has been experienced by women (Figure 83-2).

**FIGURE 83-2.** Trends in mortality as a result of COPD from 1979 to 1993 in the United States. (From Mannino DM, et al. Obstructive lung disease deaths in the United States from 1979 through 1993. *Am J Respir Crit Care Med* 1997;156(3):814–818.)

This is in sharp contrast to the declining mortality caused by cardiovascular disease and cancer. Worldwide it is estimated that by the year 2020, COPD will be the third leading cause of death and the fifth leading cause of disability.

Although accurate statistics regarding morbidity as a result of COPD are difficult to obtain, it represents an important cause of disability. The average number of days of restricted activities reported by patients with COPD is very high. In 1996, COPD was listed as the eighth leading cause of disability-adjusted life-years (DALYs) in men, and the seventh leading cause of DALYs among women. COPD is a leading cause of hospitalizations in United States. In 1998, nearly 2% of all hospitalizations were attributed to COPD and 7% had COPD as a contributing cause of hospitalization. More striking are COPD statistics regarding the elderly population. Nearly 20% of all hospitalizations in patients older than age 65 years had COPD as a primary or contributing cause. Owing to its impact on reduced physical activity, it is emerging as an important cause of reduced functional status and disability in older adults. The cost implications of treating COPD are huge and those with severe disease account for the highest cost.

## PATHOPHYSIOLOGY

### Risk Factors

Table 83-1 lists important risk factors for COPD. Exposure to inhalants, including tobacco, indoor and outdoor air pollution, are important environmental risk factors. Cigarette smoking is the most important risk factor for COPD. At least 15% of smokers develop COPD, though recent estimates suggest higher incidence among smokers. Both current and previous smokers are at increased risk of COPD. Pipe and cigar smokers and passive exposure to cigarette smoke also increases risk, though these individuals are at lower risk compared to cigarette smokers. In NHANES III survey, obstructive lung disease was present among 12.5% of current smokers, 9.4% of former smokers, and 3.1% of pipe or cigar smokers. Indoor pol-

lution caused by cooking using biomass fuels is an important risk factor, especially for females in developing countries. The role of urban pollution in susceptibility to COPD is unclear.

The vast majority of individuals exposed to cigarette smoke do not develop symptomatic COPD. Thus host factors may explain differences in susceptibility. Genetics, especially gene–environment or gene–inhalant interaction, may play an important role. For instance, several studies in the 1970s observed higher rates of airflow obstruction in first-degree relatives of patients with COPD compared to control subjects. COPD also aggregates in families.

Severe alpha-1 antitrypsin deficiency is an important genetic risk factor and accounts for 1% of COPD patients. Alpha-1 antitrypsin, a serum protein, is synthesized in the liver. It inhibits proteolytic enzymes, such as trypsin, chymotrypsin, and neutrophil elastase. If neutrophil elastases are not inactivated by alpha-1 antitrypsin, these enzymes destroy lung connective tissue, particularly elastin, and cause emphysema. Understanding the role of alpha-1 antitrypsin in COPD has therefore provided a foundation for the protease–antiprotease hypothesis for the pathogenesis of COPD. The phenotype, also called Pi type, is determined by the independent expression of two independent alleles. More than 90% of severely deficient patients are homozygous for the Z allele. Such patients are designated Pi ZZ and have serum alpha-1 antitrypsin levels that are about 20% of the normal level. The phenotypic effects of having a single Z allele, heterozygote with Pi MZ genotype, are less clear. Individuals with alpha-1 antitrypsin deficiency develop COPD during the fourth or fifth decade.

Recent studies have also examined the role of other genes and their interaction with environmental factors to explain differences in susceptibility and outcomes of COPD. Candidate genes include tumor necrosis factor, microsomal epoxide hydrolase, glutathione S-transferases, heme oxygenase-1, and alpha-1-antichymotrypsin. Although preliminary studies suggest that these genetic variants may play an important role in COPD pathogenesis, results have not been consistent across studies.

### Pathogenesis and Pathology

COPD is characterized by chronic inflammation in peripheral airways and alveoli. Macrophages, neutrophils, and CD8+ T lymphocytes are the predominant cells involved in inflammation. In contrast to asthma, eosinophils are not present in lung biopsy specimens. Important mediators include leukotriene B<sub>4</sub>, IL-8, and TNF- $\alpha$ . Cigarette smoking and other irritants activate resident macrophages to release chemotactic factors, which attract inflammatory cells from the circulation and release additional inflammatory mediators. The subsequent interaction between the molecular and cellular mediators is complex and poorly understood.

Two theories have been proposed to explain pathogenesis of COPD: protease–antiprotease imbalance theory and increased oxidative stress theory. These theories suggest that lung inflammation is amplified in the presence of excess proteases or oxidant stress. In the protease–antiprotease imbalance theory, proteases, such as elastase, proteinase 3, and matrix metalloproteinases, are induced by cigarette smoking and lead to alveolar wall destruction and mucus hypersecretion. These proteolytic enzymes are counteracted by antiproteases, particularly alpha-1 antitrypsin, and inhibitors of matrix metalloproteinases. The imbalance between proteases and antiproteases may lead to destruction of connective tissue and cause emphysema.

**TABLE 83-1**

#### Risk Factors for COPD

RISK FACTOR	COMMENT
Cigarette smoking	Most important risk factor and most cases of COPD are caused by smoking
Pipe and cigars	High risk, but lower than observed in cigarette smokers
Occupational exposure	Risk in coal miners, gold miners, grain handlers, cement and cotton workers
Environmental pollution	Indoor use of biomass fuels for cooking and heating in underdeveloped countries and particulate matter from urban pollution
Genetic factor	Alpha-1-antitrypsin deficiency known to cause early onset COPD. Other genetic risk factors may also increase risk
Socioeconomic	More common with low socioeconomic status
Childhood illnesses	Low birth weight, respiratory infections, and symptomatic childhood asthma may increase risk

The oxidative stress theory was proposed because of increase in markers of oxidative stress in exhaled breath and urine in COPD patients. Interestingly, the role of oxidative stress has also been implicated in aging. Oxidative stress is caused by the imbalance between reactive oxygen species and the body's ability to detoxify reactive oxygen species or the damage caused as a result. Excess oxidative stress has several consequences, including activation of inflammatory genes and inactivation of antiproteases, thereby leading to increased local inflammation.

The pathologic changes in COPD are found in the large and small airways and in the lung parenchyma. Structural changes in the airways include mucus hyperplasia, bronchiolar edema and smooth muscle hypertrophy, and peribronchiolar fibrosis. These changes result in narrowing of the small airways. Early pathophysiologic abnormalities in airways that are 2 mm and less in diameter have been referred to as "small-airway disease." Mucus hypersecretion occurs owing to increase in the size and number of the submucosal glands and an increase in the number of goblet cells on the surface epithelium.

Emphysema is a destructive process that occurs in the gas-exchanging airspaces, the respiratory bronchioles, alveolar ducts, and alveoli. It results in obliteration of airspace walls and coalescence of small distinct air spaces into larger ones. An important consequence of emphysema is loss of elastic recoil of the lungs and thereby increases airway obstruction. Emphysema also causes abnormal gas exchange.

In advanced stages, there are also changes in the pulmonary circulation, heart, and respiratory muscles. Alveolar hypoxia causes medial hypertrophy of vascular smooth muscle with extension of the muscularis layer into distal vessels that do not ordinarily contain smooth muscle. Intimal hyperplasia also occurs in advanced stages. These latter changes are associated with the development of pulmonary hypertension and its consequences, right ventricular hypertrophy. Loss of vascular bed also occurs with emphysema as a result of de-

struction of alveolar walls. In some patients with advanced COPD, there is atrophy of diaphragmatic muscle.

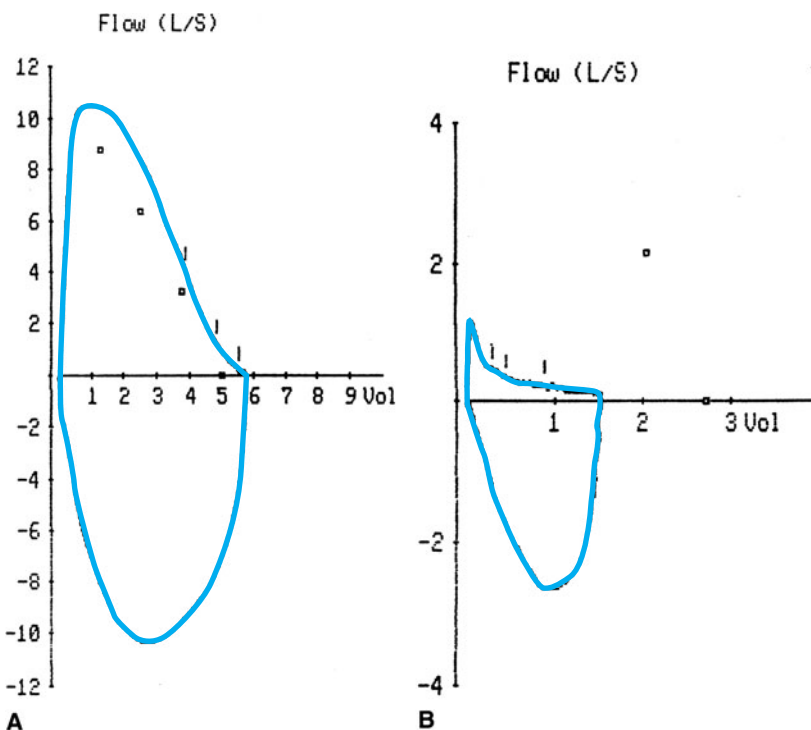

### Changes in Respiratory Physiology in COPD

Pathologic processes affecting airways and lung parenchyma are accompanied by changes in respiratory physiology in COPD. The physiologic hallmark of COPD is the limitation of expiratory flow caused by airway narrowing and emphysematous changes in the lung. This is accompanied by a reduction in the FEV<sub>1</sub>/FVC ratio. Early in the course of COPD, the expiratory flow–volume curve has a scooped out appearance in the expiratory limb as a result of reduced flow at low lung volumes (Figure 83-3). With disease progression, expiratory flow decreases at all lung volumes. Another important effect of decreased expiratory flow is nonuniform ventilation of the lungs, observed even in the earlier stages of COPD. Nonuniform ventilation can lead to ventilation–perfusion mismatches, which reduce arterial oxygen pressures.

Hypercapnia is usually observed in the end-stages of COPD, usually when FEV<sub>1</sub> is 1 L or lower. Pulmonary hyperinflation places the thoracic cage and diaphragm at a mechanical disadvantage and increases the work of breathing. Airflow obstruction also contributes to increased work of breathing. Finally, the destruction of lung parenchyma worsens ventilation perfusion mismatch and worsens both hypercapnia and hypoxemia.

### Nonpulmonary Effects

There has been increased interest in understanding systemic consequences of COPD for several reasons. First, reduced exercise capacity observed in patient's with COPD patients is not limited by respiratory system abnormalities alone. Several studies suggest that cardiovascular and skeletal muscle changes also contribute to reduced exercise capacity. Second, most COPD patients die because

**FIGURE 83-3.** Flow–volume loop of a COPD patient compared to a normal individual. Notice the markedly diminished flow at all lung volumes.

of nonpulmonary causes, such as cardiovascular disease and cancer. Third, COPD patients have higher prevalence of reduced body mass index (BMI), osteoporosis, and increased systemic concentrations of inflammatory markers. These observations are underscored by a recently proposed multidimensional risk prediction score by Celli et al., in which survival prediction was improved by incorporating BMI, dyspnea scale, and exercise capacity in the traditional risk prediction model using FEV<sub>1</sub> alone. Although there is an improved understanding of the systemic consequences of COPD, the biologic mechanisms underlying these effects remain poorly understood.

COPD patients have reduced skeletal muscle strength. Upper extremity grip strength is usually well preserved in COPD, but the strength of the lower extremity quadriceps is reduced compared to age-matched controls. Respiratory muscle strength is also reduced, but it is more likely to occur because of hyperinflation of lung rather than intrinsic defect in the muscles. The decline in skeletal muscle strength in COPD patients is proportional to the reduction in FEV<sub>1</sub>. During hospitalization for exacerbations, skeletal muscle strength is reduced further, but the long-term effect of an exacerbation on skeletal muscle strength is not known. Thigh muscle size and lower extremity lean body mass is also lower in COPD patients. Multiple factors may contribute to reduced skeletal muscle strength, including elevation of systemic inflammatory markers, particularly tumor necrosis factor or cachectin and IL-6, disuse atrophy, hypogonadism, poor nutrition, and hypoxemia.

COPD is also associated with changes in body composition. These patients have lower BMI and lean body mass. However, visceral fat appears to be similar to age-matched control population. Advanced COPD patients have higher risk of osteoporosis as a result of smoking, concomitant vitamin D deficiency, low BMI, hypogonadism, sedentary lifestyle, and use of glucocorticoids. The risk of osteoporosis is often underrecognized until the first fracture occurs.

There is a high prevalence of cognitive impairment in COPD. The most common disturbances are in verbal fluency, memory tasks, attention, and deductive thinking. Cognitive impairment in COPD has been related to age, educational background, depression, disability, exercise tolerance, and duration of respiratory failure. Although it is related to hypoxia, it does occur in nonhypoxemic COPD patients. Relationships between fatigue, depression, and cognitive function are poorly documented.

## CLINICAL MANIFESTATIONS

Most clinical manifestations occur during the fifth and sixth decade of life. However, the onset of COPD symptoms maybe delayed to the seventh decade and beyond in smokers who stopped smoking in midlife. Dyspnea is the most common symptom of COPD and an important reason for reduced physical activity. Initially dyspnea is present only on exertion, but as lung function declines, patients experience dyspnea at rest too. Similar to dyspnea, chronic productive or nonproductive cough is intermittent initially and becomes persistent in severe disease. Chronic intermittent nonproductive cough can be present for several years prior to onset of dyspnea and maybe a subtle manifestation of mild COPD. Wheezing or chest tightness usually occurs with exertion.

An initial assessment of a COPD patient should include past medical history of asthma, detailed history of smoking and occupational exposures, family history of early onset COPD, and frequency

of exacerbations or hospitalizations. Some symptoms may also be related to coexisting chronic health conditions, such as cardiovascular disease, which are common in these patients. Furthermore, COPD patients may develop secondary hypertension (*cor pulmonale*) that manifests as worsening dyspnea and lower extremity swelling. When patients develop rapid worsening of symptoms, alternative diagnoses should be considered, such as exacerbation of underlying disease, pneumothorax, or pulmonary thromboembolism.

Physical examination findings in the respiratory system are present in advanced disease and include barrel-shaped chest on inspection, prolonged expiration, distant heart sounds, and rhonchi on auscultation. Patients often use accessory muscles or pursed lips during breathing. Signs of *cor pulmonale* include pedal edema, a tender congested liver, loud pulmonary component of the second heart sound, and jugular venous distention. Careful attention should be paid to systemic manifestations, including cognitive deficits, reduced muscle strength, and recent weight loss.

Functional status assessment is important in COPD. Subjective and objective evaluations, based on activities of daily living and a 400-meter or a 6-minute walk test, is important to monitor disease progression and are independent predictors of mortality. Oxygen desaturation during an informal walk test in the office setting can identify patients who will benefit with supplemental oxygen.

## DIAGNOSIS

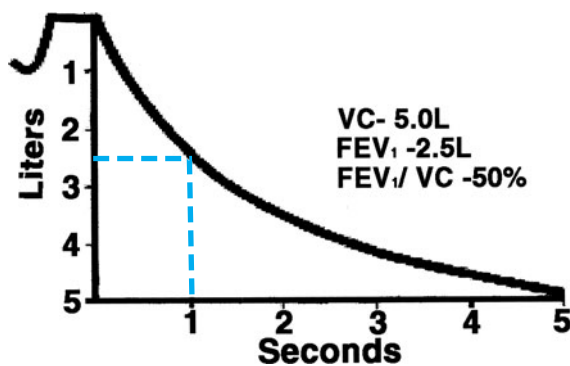

### Spirometry

Underdiagnosis or misdiagnosis of COPD is common in the elderly because symptoms of dyspnea and reduced functional status are often attributed to aging or coexisting disease. Therefore, spirometry, which includes an FEV<sub>1</sub> and FVC measurement with a flow volume loop, should be performed when COPD is suspected. A full pulmonary function test (PFT), which includes FEV<sub>1</sub>, FVC, lung volumes, and diffusion capacity, can be performed in selected patients.

The peak expiratory flow (PEF) meter is often used to monitor disease in asthma. The PEF meter measures airflow obstruction in the larger airways. Since pathological changes occur predominantly in the smaller airways in COPD, the PEF meter underrepresents the severity of airflow obstruction in COPD, and therefore, should not be used for diagnosis or disease monitoring.

Challenges to perform spirometry in geriatric patients include difficulties in comprehension of instructions, dexterity problems, and reduced functional capacity. These problems often lead to poor quality results and are an important deterrent to performing spirometry in the elderly. Simple office-based spirometry tests using handheld spirometer are becoming more reliable and can be done in the outpatient office setting. These devices are easy to use and less demanding, and therefore, maybe particularly valuable in the diagnostic evaluation of older adults with suspected COPD.

A spirometer is a device that measures lung volumes through the forced expiration of air. Flow can also be assessed, by measuring the total volume of air that is expired in the first second of expiration. There are well-defined normal ranges that allow for the effects of age, race, sex, and height. Three measurements from the spirometer are commonly used in the diagnosis of COPD. FEV<sub>1</sub> measures the

**FIGURE 83-4.** Forced vital capacity maneuver of patient with moderate COPD is shown on this spirogram. Both  $FEV_1$  and FVC are reduced.

air exhaled in the first second of expiration. FVC is the maximum volume of air that can be forcibly expired. The ratio of  $FEV_1/FVC$  is expressed as a percentage and is the proportion of total volume of air that can be expired in the first second of expiration.

Spirometry results will only be of value if the tracings are performed satisfactorily and consistently. Two criteria should be met before results of spirometry are interpreted. First, the tracings should be reproducible, where at least two of the three  $FEV_1$  measurements should be within 100 mL or 5% of each other. Second, the results should meet the acceptability criteria, where the measurements must continue until no more air can be exhaled. Exhalation is prolonged in COPD because of expiratory flow limitation and can take up to 15 seconds. Acceptability criteria can be assessed by examining the volume–time curve and at least 6 seconds of exhalation should be present or the exhalation should plateau for the last 2 seconds. Frequent coughing during spirometry may affect results.

COPD is diagnosed based on the  $FEV_1/FVC$  ratio less than 70% (Figures 83-3 and 83-4). However, in older adults, especially those over 70 years, this cutoff will overestimate disease. Therefore, age-adjusted ratios are preferred, though are cumbersome to use. However, for most older adults, a ratio below 60% is abnormal and suggestive of obstructive lung disease. Once obstruction is diagnosed, severity is graded based on the  $FEV_1$  measurement (Table 83-2). The presence of reduced  $FEV_1$ , but a normal  $FEV_1/FVC$  ratio, is

suggestive of restrictive lung disease, such as idiopathic pulmonary fibrosis. These findings should prompt referral for a full PFT and pulmonary consultation.

Improvement in  $FEV_1$  in response to bronchodilators, termed bronchodilator reversibility, is based on increase in  $FEV_1$  by 12% and 200 mL. Though bronchodilator reversibility suggests the diagnosis of asthma, many elderly subjects with asthma do not demonstrate response to bronchodilators. In individuals with an obstructive pattern on spirometry without evidence of airway reversibility, other clinical findings should be taken into account to differentiate asthma versus COPD. However, this distinction is often difficult in the elderly. It is important to emphasize that bronchodilator reversibility of findings on spirometry correlates poorly with clinical response to short or long-acting bronchodilators.

Bronchial or airway hyperresponsiveness is the exaggerated bronchoconstrictive response to nonspecific agonists, such as methacholine, hypertonic saline, adenosine, exercise, and hyperventilation. Although it is a hallmark of asthma, it can be present in several individuals with COPD and is associated with worse prognosis. Routine assessment of bronchial hyperresponsiveness in elderly patients has limited value in clinical practice currently.

### Other Tests

A chest x-ray is helpful during initial evaluation of the patient to rule out alternative diagnoses, such as congestive heart failure, or to identify a large bullous lesion, but is seldom helpful in the diagnosis of COPD. Findings suggestive of COPD on a chest radiograph include a low, flat diaphragm, an increased retrosternal airspace, and a teardrop-shaped heart (Figure 83-5). Pruning of the pulmonary arterial vessels and bullae are seen in emphysema. There is no benefit of obtaining routine yearly chest radiographs. A high-resolution CT scan of the chest maybe helpful when the diagnosis is doubtful or when lung reduction surgery is contemplated (Figure 83-6). Arterial blood gases are often recommended for patients with  $FEV_1 < 50\%$  predicted to identify hypercapnea. Other tests, such as complete blood count, echocardiogram, cardiopulmonary exercise tests, maybe necessary in special circumstances. For instance, a cardiopulmonary exercise will be useful in patients with concomitant

**TABLE 83-2**

#### Severity of COPD\*

	GLOBAL INITIATIVE FOR CHRONIC OBSTRUCTIVE DISEASE (GOLD)	AMERICAN THORACIC SOCIETY (ATS)/ EUROPEAN RESPIRATORY SOCIETY (ERS)
At risk	Risk factors and chronic symptoms but normal Spirometry	-
Mild	$FEV_1/FVC < 70\%$ $FEV_1 \geq 80\%$ predicted value	$FEV_1 \geq 70\%$ predicted value
Moderate	$FEV_1/FVC < 70\%$ $80\% > FEV_1 \geq 50\%$ predicted value	$70\% > FEV_1 \geq 60\%$ predicted value $60\% > FEV_1 \geq 59\%$ predicted value (moderately severe)
Severe	$FEV_1/FVC < 70\%$ $50\% > FEV_1 \geq 30\%$ predicted value	$49\% > FEV_1 \geq 35\%$ predicted value
Very severe	$FEV_1/FVC < 70\%$ $FEV_1 \leq 30\%$ predicted value	$FEV_1 < 35\%$ predicted value

\*Although GOLD recommends using  $FEV_1/FVC$  cutoff of 70 to diagnose obstruction, using age-specific cutoffs is recommended by ATS and preferable in older adults.

COPD and congestive heart failure to assess the contribution of each condition to the patients' symptoms.

### SEVERITY OF COPD

Severity assessment is important for prognosis and to identify patients who are likely to benefit from specific therapies. Traditionally, severity of COPD was based on  $FEV_1$  alone (Table 83-2). A reduction in  $FEV_1$  was used to assess severity in most criteria because it is the most important predictor of mortality in COPD.  $FEV_1/FVC$

ratio is important to diagnose airflow limitation, but has limited value to assess disease severity.

As the systemic consequences of COPD are increasingly recognized, newer severity criteria have tried to incorporate nonpulmonary features of COPD. The BODE index by Celli et al. is the most extensively studied and validated. The BODE score is a 10-point scale and is based on body (B) mass index, obstruction (O) of airflow quantified by reduction in  $FEV_1$ , dyspnea (D) assessed by the modified Medical Research Council dyspnea scale, and exercise (E) capacity based on the 6-minute walk test. Higher scores correlate with higher mortality. The average age of subjects in the derivation

**FIGURE 83-6.** CT scan of a patient with COPD with bullous lesions.

and validation cohorts for this study was 66 years and few individuals over 80 years were included. Whether the BODE index can be generalized to very old individuals is not known.

### NATURAL HISTORY OF COPD

After 25 years of age, FEV<sub>1</sub> declines continuously and smoothly over an individual's life (Figure 83-7). Nonsmokers without respiratory disease can expect to lose 25 to 30 mL per year after age 35 years. The rate of decline appears to accelerate with aging, but sudden large irreversible falls are very rare. Elderly current smokers experience a higher rate of decline compared to nonsmokers, approximately 48 mL per year. The rate of decline is higher among males compared to females and whites compared to blacks, with the lowest rate of decline among black females. When FEV<sub>1</sub> is between 40% and 59%

of predicted value, disability occurs. FEV<sub>1</sub> remains an important predictor of survival and when FEV<sub>1</sub> falls below 1 L, the 5-year mortality approaches 50%.

Few studies have examined the natural history of COPD, especially in the elderly. The Cardiovascular Health Study of 5888 subjects older than 65 years examined the effects of health behaviors and clinically diagnosed COPD on lung function. Spirometry was performed at baseline and at year 4 and 7. A diagnosis of COPD and smoking was associated with lower FEV<sub>1</sub> at baseline. However, current smoking was the only risk factor associated with accelerated FEV<sub>1</sub> decline. Former smokers had similar rate of decline in FEV<sub>1</sub> compared to nonsmokers. Paradoxically, a diagnosis of emphysema was associated with lower rate of decline in FEV<sub>1</sub>. This is most likely because of survivor bias, where participants with the most rapid decline in FEV<sub>1</sub> are unable to perform repeat spirometry because of death or poor health.

**FIGURE 83-7.** Natural history of COPD and effects of smoking cessation. (Adapted from Fletcher C, Peto R: *BMJ*. 1997;1:1645.)

The effect of smoking cessation on FEV<sub>1</sub> decline in susceptible smokers varies with age. When smoking cessation occurs early, before age 45 years, the rate of FEV<sub>1</sub> decline slows and approaches those seen among nonsmokers. A prospective multicenter longitudinal study, the Lung Health Study (LHS), examined effects of smoking cessation in patients identified with mild to moderate air-flow obstruction. The LHS showed that smokers between 35 and 60 years old, who stopped with the help of an aggressive smoking intervention program, significantly reduced the decline in their FEV<sub>1</sub> over a 5-year study period when compared to those who continued to smoke. In contrast, smoking cessation in the elderly has a small effect on FEV<sub>1</sub> decline.

The slowly progressive course of COPD is often interrupted by acute respiratory illnesses or exacerbations, usually caused by viral or bacterial infections. Patients with milder stages of COPD will often develop one to two exacerbations per year; those with more severe disease are likely to have many more. Reduced FEV<sub>1</sub> is also the most important risk factor for community-acquired pneumonia. The risk of pneumonia is modest for mild or moderate reduction in FEV<sub>1</sub>, but those with most severe reduction experience 3.6-fold higher risk. Patients with more frequent exacerbations have higher risk of decline in lung function.

Traditionally, it was believed that COPD survivors died largely as a result of respiratory failure. Recent studies suggest that death caused by cardiovascular disease and cancer is common among COPD patients. Although airway inflammation is a hallmark of COPD, it is increasingly recognized that these patients have higher systemic concentrations of inflammatory markers, including IL-6 and C-reactive protein (CRP). Increased systemic inflammation is associated with increased risk of atherosclerotic disease, including acute myocardial infarction and cerebrovascular accidents. These results suggest that COPD may be associated with abnormalities of the immune system that predispose to increased risk of cardiovascular disease, repeat in-

fections, and cancer. However, the exact biological mechanisms have not been elucidated. An important conclusion of these studies is that COPD is a systemic disease and reducing all-cause mortality may require novel and systemic approaches.

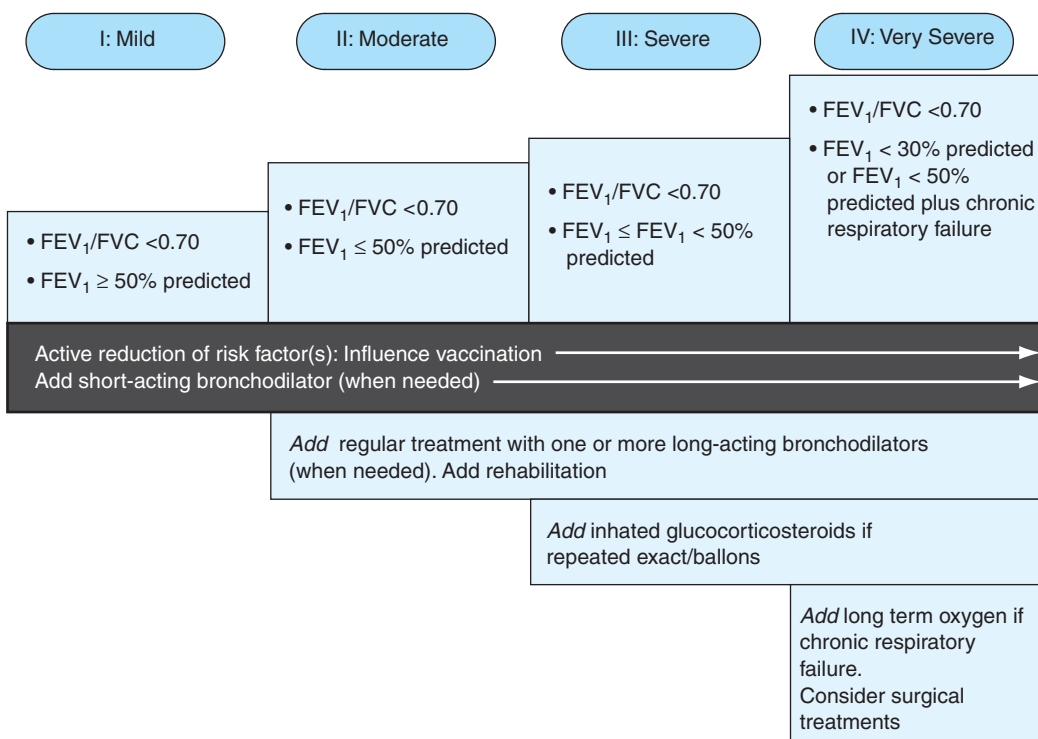

## MANAGEMENT

### Goals of Management of Stable Disease

Goals of management of stable COPD in the outpatient setting include slow disease progression, improvement of symptoms, particularly dyspnea and reduced exercise tolerance, prevent exacerbation, and reduce mortality. Smoking cessation and supplemental oxygen are the only interventions that have shown to reduce all-cause mortality. Current pharmacologic interventions neither reduce mortality nor influence the rate of decline of lung function. An overview of different therapies based on disease severity are shown in Fig. 83-8.

### Smoking Cessation

Smoking cessation is difficult to achieve and more difficult to sustain in the general population. Physician-delivered smoking cessation interventions can significantly increase smoking abstinence rates. An empathetic, nonconfrontational interaction that maximizes patient participation is most effective. The essential elements of a smoking cessation program should include: (1) physician intervention (set a quit date) and appropriate follow-up; (2) group smoking cessation programs; and (3) pharmacologic therapy with nicotine replacement in highly dependent smokers. Such smokers can be identified as those who smoke a pack a day or more, require their first cigarette within 30 minutes of arising in the morning, and find it difficult refraining

**FIGURE 83-8.** Overview of treatment for COPD by disease severity. (From GOLD. [www.goldcopd.com](http://www.goldcopd.com))

from smoking in places where it is forbidden. Therapy with the antidepressants, such as bupropion hydrochloride and nortryptiline, are effective and when used with nicotine replacement can yield quit rates that approach 35%. The LHS showed that despite intensive antismoking efforts, middle-aged smokers with COPD are not likely to quit and only 22% were sustained quitters at 5 years.

Smoking cessation rates are similar in the elderly compared to younger individuals. For instance, the Wisconsin Tobacco Quit Line program, which targeted older smokers by providing free nicotine patches and phone counseling, showed that 43% of the senior participants had successfully quit at 9 months. A recent survey among adult smokers older than 60 years was conducted by the Center of Social Gerontology and revealed that a key motivation to quit smoking was to improve health. There were varying levels of awareness of smoking cessation aids among these participants. The lack of information from physicians recommending or educating them about smoking cessation aids was an important barrier to try these interventions. These observations underscore the need to educate smokers about the health benefits and the various aids to quit smoking. Older adults fear that they will fail to quit smoking and therefore, the elderly patient must be reminded that the average smoker who successfully quits has done so after five to six attempts. The clinician's responsibility is to remember that tobacco addiction is a chronic disease and treatment should be offered at every visit. Several hotlines are offered by the American Cancer Society and the National Cancer Institute to help quit smoking.

## Pharmacologic Management

The goal of pharmacologic management is to provide symptomatic relief, improve exercise capacity, and prevent exacerbations. A step-wise approach is provided in [Figure 83-8](#). The average age of subjects recruited in most clinical trials for COPD is 65 years and few subjects older than 85 years are recruited in these studies. Therefore, the efficacy and side-effect profile of these medications in the very old remains unclear.

### Short- and Long-Acting Beta Agonist

These agents act by relaxing airway smooth muscle by a direct action on the  $\beta_2$ -adrenergic receptors on the cell surface. While oral agents are available, their side effect profile makes them less desirable than the inhaled agents. The short-acting  $\beta_2$  agonists achieve variable degrees of bronchodilatation, with a rapid onset of action of a few minutes, and last for 4 to 6 hours. Short-acting beta2 agonists are used for symptom control. In contrast, long-acting beta2 agonist last for 12 hours and are useful for maintenance therapy. Both improve shortness of breath, cough, and in most patients, improve exercise capacity. Short-acting beta2 agonists are usually prescribed as a metered dose inhaler (MDI) or with a compressor-driven nebulizer.

Despite minimal systemic absorption seen with these agents, slight tachycardia may be observed. This is presumably a result of vasodilatation from stimulation of  $\beta_2$  receptors in vascular smooth muscle. Tremor may also occur and is especially troublesome in the geriatric patient. It is thought to be caused by stimulation of  $\beta_2$  receptors in skeletal muscle. In general, however, when given three or four times a day,  $\beta_2$  agonists are safe and effective even in the elderly. Higher doses should be used cautiously because they may cause hypokalemia, especially when the patient is taking a diuretic.

Salmeterol and formoterol are two long-acting beta2 agonists. In the recent TORCH trial, salmeterol alone reduced exacerbations compared to placebo and the combination of salmeterol and fluticasone provided additional benefit. A similar benefit was seen with salmeterol on health-related quality of life. There is no evidence of tachyphylaxis with these agents. Though beta receptor function diminishes with age, the short- and long-acting  $\beta_2$  agonists should be used because of their proven track record.

### Anticholinergic Agents

Ipratropium and tiotropium are two anticholinergic agents. These agents cause bronchodilatation and are capable of rapidly relieving symptoms. Muscarinic (M) receptors are present in the bronchial smooth muscles. M1 and M3 mediate bronchoconstriction, while M2 inhibits release of acetylcholine and thus results in feedback inhibition. Tiotropium has the advantage of prolonged action, lasting for 24 hours, and specifically inhibits M1 and M3 receptors, while it dissociates more quickly from M2 receptors. Ipratropium bromide has duration of action of 4 to 6 hours. Its onset of action is 30 minutes. This has made a single MDI of the combination of albuterol, a short-acting  $\beta_2$  agonist, and the anticholinergic, ipratropium bromide, very popular.

Tiotropium has a beneficial effect in reducing exacerbation rates compared to placebo or ipratropium bromide and improved health-related quality of life relative to placebo. An important beneficial effect of tiotropium is improvement in baseline FEV<sub>1</sub>. Therefore, tiotropium is preferred over ipratropium in patients with severe COPD.

As these agents are poorly absorbed, the side effects are generally mild. Occasionally, patients complain of a dry mouth or metallic taste. Worsening symptoms of prostate enlargement and acute glaucoma are rare. Plasma concentrations are higher in individuals with moderate or severe renal failure, and therefore should be used cautiously. Ophthalmic complications may occur because of inadvertent spraying of eyes and can easily be avoided with proper inhalation techniques.

### Methylxanthines

Theophylline is the most widely used drug in this class. It is given as a sustained-release preparation and has the advantage of being administered once a day. Small improvements in lung function are seen with chronic use and have been associated with improvement in symptoms and exercise capacity in COPD. Its use has diminished over the past decade because of safety concerns, especially in the elderly. While there is in general a steady decline in drug metabolism from early to late adulthood, theophylline clearance does not appear to be sufficiently altered in the elderly to recommend reducing the dose. The narrow therapeutic range of theophylline, frequency of concomitant illnesses that alter theophylline kinetics, and many drug interactions that affect the clearance of theophylline, make it important to closely monitor the blood theophylline level in older patients.

The clinical manifestations of theophylline toxicity have been correlated with blood levels of the drug. With high serum concentrations (>30  $\mu\text{g/mL}$ ), life-threatening events may occur. They include seizures and cardiac arrhythmias, such as atrial fibrillation, supraventricular tachycardia, ventricular ectopy, and ventricular tachycardia.

The most common cause for theophylline toxicity is a self-administered increase in medication. There is a stepwise increase in the frequency of life-threatening events caused by theophylline toxicity with advancing age. At comparable theophylline blood levels, patients older than age 75 years have a 16-fold greater risk of life-threatening events or death than do patients younger than age 25 years. The risk of theophylline toxicity can be minimized with careful patient monitoring, including checking blood levels and patient education. A range of 8 to 15  $\mu\text{g}/\text{mL}$  is generally considered therapeutic and gives a margin of error that helps avoid toxicity.

### Corticosteroids

Long-term oral corticosteroid treatment is not recommended for COPD. Some have advocated giving a short course of oral corticosteroids for 2 weeks to identify patients with asthma and bronchitis, but such a short-term response is not an effective predictor. Complications include cataracts, osteoporosis, secondary infection, diabetes, skin damage, and steroid myopathy, which contribute to respiratory muscle weakness, poor exercise tolerance, and respiratory failure.

Inhaled corticosteroids reduce exacerbation frequency, health-related quality of life, exercise capacity, and improve FEV<sub>1</sub>. Although observational studies suggest that they may improve mortality, results of randomized clinical trials have failed to demonstrate improvement in all-cause mortality. Treatment with inhaled corticosteroids therefore has been recommended only for patients with moderate to advanced COPD. Two side effects, including bone loss and increased incidence of community-acquired pneumonia, can occur with chronic use, though the clinical relevance of pneumonia is uncertain. Different dosages of inhaled steroids have different potencies. In most clinical trials, 500  $\mu\text{g}$  bid of fluticasone or 400  $\mu\text{g}$  bid of budesonide has been used. Whether lower doses of inhaled corticosteroids can achieve similar efficacy is uncertain.

The combination of salmeterol and fluticasone has recently been shown to be better than individual medication in a randomized controlled trial of more than 6000 subjects. The average age of participants was 65 years. In this study, the combination of salmeterol and fluticasone reduced frequency of exacerbation, lung function decline, and improved health-related quality of life. Compared to placebo, the absolute reduction in all-cause mortality was 2.6% (relative reduction of 17.5%), but the results failed to reach statistical significance when adjusted for multiple interim analyses (adjusted  $p$ -value = 0.052 and unadjusted  $p$ -value = 0.04).

### Inhalation Techniques

The inhaled route of therapy for COPD is preferred because it provides quicker action, fewer side effects, and greater bronchodilatation with smaller doses of medication. MDIs are the most commonly used methods for delivery of bronchodilators and corticosteroids. The great majority of the medication delivered by MDIs is deposited in the oropharynx, with only approximately 10% of the dose delivered to the lungs. Oropharyngeal deposition causes greater systemic absorption, more local irritation, and for corticosteroids, more likelihood of oropharyngeal candidiasis. Inadequate timing of actuation and inhalation is the most frequent error. Impaired mental function, weakened or deformed hands, and motor or musculoskeletal diseases are other reasons for inadequate MDI use. There are several solutions to this problem. One may deliver short-acting  $\beta$  agonists,

ipratropium, and corticosteroid, budesonide, as aerosolized solutions by pressurized handheld nebulizers. Alternatively, there is a breath-actuated pressurized MDI that obviates the need to synchronize activation with inhalation. The use of spacer devices fitted to the mouthpiece of the MDI can overcome most of the drawbacks of MDI therapy. Spacers are cheap, easy to carry, reduce oropharyngeal deposition, and increase intrapulmonary deposition. Lastly, newer dry-powder delivery devices that deliver inhaled corticosteroids and long-acting  $\beta$  agonists provide simple, easy-to-use preparations that do not require coordination or muscle strength.

### Mucolytic Agents

Mixed results have been reported for the use of mucolytic agents, such as *N*-acetyl cysteine, and expectorants, such as Guaifenesin, as chronic maintenance therapy for COPD. Symptoms may improve in some patients with COPD, especially those with viscous sputum. However, overall the benefits are small and their widespread use is not recommended. Randomized controlled trials suggest that they are ineffective at shortening the course or improving outcomes of patients with acute exacerbations of COPD.

### Phosphodiesterase (PDE)-4 Inhibitors

PDE-4 is a major regulator of cyclic adenosine monophosphate metabolism in smooth muscle and immune cells. Since cyclic adenosine monophosphate downregulates the activity of these cells, the inhibition of PDE-4 is an attractive target for COPD drug development. Early studies with a PDE-4 inhibitor, Cilomilast, suggest that it causes bronchodilatation and may improve quality of life. Further studies are necessary before this class of drugs can be recommended for routine use.

### Adjunct Therapies

Treatment with calcium and vitamin D supplementation should be considered in older COPD patients with osteoporosis. Depression and anxiety are common in COPD patients and treatment may improve quality of life. Although pneumococcal and influenza vaccination have limited efficacy in the elderly, routine use is recommended in COPD patients because vaccination is associated with few side effects and these organisms are an important cause of acute exacerbations or community-acquired pneumonia.

### Nonpharmacologic Interventions

#### Oxygen Therapy

Several controlled studies have been done regarding the efficacy of long-term oxygen. These have been summarized by Crockett et al. In addition to smoking cessation, it is the only intervention to improve survival in advanced COPD. The beneficial effect is related to the duration of oxygen use. For example, patients who receive oxygen for 19 hours or more a day are likely to survive longer than those who use it 12 or 15 hours a day. Patients who use chronic oxygen therapy are likely to have a significant fall in their pulmonary artery pressures and an increase in cardiac output. Table 83-3 provides recommendations for long-term oxygen use in COPD. Long-term oxygen therapy does not improve survival in patients with moderate

**TABLE 83-3****Criteria for Home Oxygen in COPD**

## At rest

Arterial partial pressure of oxygen (PaO<sub>2</sub>) less than or equal to 55 mm Hg or arterial oxygen saturation (SaO<sub>2</sub>) less than or equal to 88%  
 PaO<sub>2</sub> levels between 56 and 59 or SaO<sub>2</sub> 89% in the presence of pulmonary hypertension, *cor pulmonale*, edema secondary to right heart failure, or erythrocytosis with hematocrit greater than 55%

## Following exercise (supplemental oxygen to be used during exercise only)

Patients who desaturate to an SaO<sub>2</sub> less than or equal to 88% during exercise and who demonstrate improvement in both the hypoxia and dyspnea and/or exercise capacity when using oxygen

hypoxemia (PaO<sub>2</sub>, 56 to 65 mm Hg) or in patients with nocturnal hypoxemia alone.

**Pulmonary Rehabilitation**

Pulmonary rehabilitation is a multidisciplinary program for patients with moderate to advanced COPD, especially those who have suffered deconditioning, significant weight loss, depression, and social isolation. The goals of a rehabilitation program are to improve exercise capacity, return the patient to more normal activities of daily living, and improve motivation, psychological well-being, and overall quality of life. With the use of lower-extremity exercise training and upper-extremity strength and endurance training, pulmonary rehabilitation improves dyspnea, endurance, and quality-of-life scores. Its effects on exacerbation are less clear and it does not influence survival. The benefits of pulmonary rehabilitation are short-lived and wane once the program is completed. Continuation of these exercises at home may have additional benefit. However, the benefit of repeat rehabilitation is less clear.

**Weight Loss and Malnutrition**

Weight loss, particularly skeletal muscle mass loss, is associated with a systemic inflammatory response in COPD. Resting energy expenditure is elevated and contributes to the negative energy balance. Nutritional supplements alone do not reverse the loss; results with anabolic steroids, growth hormone, and the progestational agent, megestrol acetate, show some effect on appetite and body weight. However, improved exercise tolerance and respiratory muscle function does not always follow, and side effects are often limiting.

**Noninvasive Positive Pressure Ventilation**

The chronic nocturnal use of noninvasive ventilation for COPD is controversial. There are theoretical advantages. Resting chronically fatigued muscles at night might improve daytime function. COPD patients have a high prevalence of nocturnal hypoxemia but the incidence of sleep apnea is similar. They have less rapid eye movement (REM) sleep and shorter sleep duration. Trials have examined the role of nocturnal noninvasive ventilation in COPD patients. These studies were small and have shown conflicting results. In general, nocturnal NIPPV for at least 3 months in hypercapnic patients with stable COPD had no consistent effect on lung function, gas

exchange, respiratory muscle strength, sleep efficiency, or exercise tolerance.

**Surgery for COPD**

Lung volume reduction surgery (LVRS) has emerged as a treatment for far advanced COPD caused by emphysema. It involves resection of functionless areas of emphysematous lung in order to improve lung elastic recoil and lung and chest wall hyperinflation.

The National Emphysema Treatment Trial Research Group examined the role of LVRS in over 1200 subjects. The average age of participants in this study was 65 years. Overall mortality with the procedure ranges between 0% and 6% within 30 days of surgery and between 0% and 8% at 6-months although in patients with very severe degrees of airflow obstruction and/or hypercarbia, the rates are higher. The range of FEV<sub>1</sub> improvement pre- and post-surgery is approximately 250 to 350 mL and dyspnea scores and distance walked on the 6-minute walk test show improvement. Often patients no longer require oxygen following surgery. LVRS did not confer a survival advantage over medical therapy. It does yield a survival advantage for patients with both predominantly upper-lobe emphysema and low baseline exercise capacity. Currently, it is a modality that is being used in specialized centers for selected patients.

Resection of large bullae is occasionally necessary. The best results occur when the bullae occupy more than one-third of the hemithorax. Lung transplantation can be lifesaving in advanced cases, but is not offered to those of advanced age.

**ACUTE EXACERBATION OF COPD**

COPD exacerbation is an important cause of increased morbidity, health care costs, and mortality. Older adults are at higher risk of mortality following hospitalization for an exacerbation compared to younger patients. Exacerbations are also an important cause of disability in the elderly. Therefore, prevention and optimal management of exacerbations is important.

There are many definitions of acute exacerbation of COPD. The most widely quoted criteria, referred to as “the Winnipeg criteria,” are based on worsening of dyspnea, an increase in sputum volume, and sputum purulence. Patients with type I exacerbations have all of the above symptoms. Patients with type II exacerbations have two of the three symptoms, while those with Type III exacerbations have at least one of these symptoms. Patients with COPD are accustomed to frequent symptom changes and thus new symptoms are under-reported to physicians and patients often do not seek medical care. On an average, patients with COPD have three exacerbations every year, while those with more severe COPD have higher frequency of exacerbation.

Before the onset of an exacerbation of COPD, there is a prodromal period up to 1 week with symptoms of increased dyspnea, cough, sore throat, and rhinorrhea. This is not accompanied by a drop in lung function. On the day of the exacerbation, there is a small but significant drop in lung function, including peak flow rates, FEV<sub>1</sub>, and FVC. Airway and systemic inflammatory marker concentrations also increase during an acute exacerbation. Peak flow rate recovery to baseline values is complete in 75% of patients by 1 month. Approximately 7% of patients with a COPD exacerbation

do not return their peak flow rates to baseline by 3 months. This suggests that exacerbations of COPD may result in permanent loss of lung function.

The most frequent cause of an acute exacerbation of COPD is respiratory infection. The most common organisms isolated during an exacerbation are viruses, including rhinovirus, respiratory syncytial virus, coronavirus, influenza, and parainfluenza, and the pathogenic bacteria that colonize these patients. Pathogenic bacteria that colonize COPD patients include *Haemophilus influenzae*, *Streptococcus pneumoniae*, and *Moraxella catarrhalis*. Although these bacteria are often isolated during a COPD exacerbation, whether they play a causal role is unclear. Prior to an exacerbation, new strains of these bacteria are isolated in the lower respiratory tract. Airway inflammation is also higher in patients colonized with pathogenic bacteria. These results suggest that bacterial infection may play an important role in exacerbations. Clearly, environmental factors are also important. Hospital admissions for COPD appear to be high when air pollution levels in the ambient environment are high.

Irrespective of the cause of an acute exacerbation, it is clear that bronchial inflammation is enhanced during this event. Increased levels of myeloperoxidase have been found in the sputum indicating neutrophilic activity, and high levels of IL-8 and LTB<sub>4</sub>, well-known neutrophil chemoattractants, are also seen. During recovery, levels of sputum chemoattractants and inflammatory markers rapidly fall.

### Diagnostic and Therapeutic Approaches

The diagnosis of COPD exacerbation is based on clinical criteria alone. The vast majority of patients with COPD exacerbations are managed in the outpatient setting. When patients present to a local emergency room or hospital with an acute exacerbation of COPD, it is useful to do a chest roentgenogram to rule out community-acquired pneumonia and congestive heart failure. Once a decision has been made to admit the patient, the best indicators for the need for mechanical ventilation include the blood gas values on admission. Significant predictors of hospital mortality include older age, lower BMI, poor functional status prior to admission, lower PO<sub>2</sub>:FIO<sub>2</sub> (fraction of inspired oxygen) ratio, history of congestive heart failure, low serum albumin, and presence of *cor pulmonale*.

Spirometry has not been helpful in decision-making for patients with an acute exacerbation of COPD. There is poor correlation between arterial blood gases and the FEV<sub>1</sub> at the time of presentation. FEV<sub>1</sub> has also not been helpful in predicting need for hospital admission.

Most therapeutic interventions for the treatment of the acute exacerbation of COPD have been studied through randomized controlled trials. Beta<sub>2</sub>-agonists and anticholinergic agents appear to be equivalent in their usefulness and are superior to all parenterally administered medications including methylxanthines (Figure 83-8). The addition of a methylxanthine to inhaled bronchodilators does not improve outcomes. There appears to be only marginal improvement when two inhaled bronchodilators are used. The side effects of anticholinergic therapy are generally few and mild. The adverse effects of using repeated albuterol nebulized treatments in the acute setting include tremors, headache, and palpitations. Changes in heart rate, blood pressure, and electrocardiogram tracings are also possible. Chest physiotherapy and mechanical percussion of the chest are also ineffective and maybe potentially harmful.

Systemic steroids are indicated in the inpatient and outpatient setting for a COPD exacerbation. For patients admitted to the hospital, systemic steroids for 2 weeks improved combined end point of death, need for mechanical ventilation, intensification of pharmacologic regime, and readmission at 30 days, though these benefits were not observed at 6 months. Longer duration of steroid therapy did not demonstrate additional benefits. For patients treated in the outpatient setting, oral prednisone therapy for 10 days improved symptoms and health-related quality of life. The most common adverse effect of steroids is hyperglycemia, which may require at least short-term treatment.

The use of antibiotics for COPD exacerbation is controversial. The beneficial effect of antibiotic therapy is seen patients with severe exacerbation (Type I exacerbation) and those with severe COPD. The choice of antibiotic is influenced by the age of the patient, the severity of underlying COPD, and the risk of antibiotic resistance. Commonly prescribed antibiotics include penicillin, such as amoxicillin with clavulanic acid, doxycycline, macrolides, such as azithromycin and clarithromycin, fluoroquinolones, such as levofloxacin and moxifloxacin. Patients with severe underlying COPD have higher likelihood of being colonized with gram-negative organisms. Furthermore, there is an increasing prevalence of organisms that produce bacterial enzymes that inactivate traditional  $\beta$ -lactam antibiotics, especially with *H. influenzae* and *M. catarrhalis*. Therefore, many of the antibiotics traditionally used for bronchial infections may provide inadequate coverage. Yet, no studies have demonstrated improved outcomes with newer antibiotics. Newer antibiotics are more expensive and cost should be taken into consideration while prescribing antibiotics for the elderly. It is also important to consider local resistance patterns and patient compliance. All of these factors should be considered while prescribing antibiotics for the elderly patient with COPD exacerbation.

Noninvasive positive pressure ventilation (NPPV) is beneficial for patients who have a high likelihood of respiratory failure and thus may prevent need for invasive mechanical ventilation. Optimal NPPV for the COPD exacerbation requires close patient monitoring, usually in an intensive care setting.

### SUMMARY

COPD is an important chronic disease and it is an important cause of disability in the elderly. Over the next decade, COPD will be the third leading cause of death worldwide. Yet, it is often under recognized. In the outpatient setting, spirometry should be performed in older adults with symptoms of persistent dyspnea, cough, or decreased exercise capacity. Prompt identification of cases allows initiation of pharmacological and nonpharmacological therapies. Smoking cessation remains the most important intervention and has shown to reduce all-cause mortality. Although current pharmacologic therapies do not improve mortality, they reduce frequency of exacerbations and improve exercise capacity and quality of life. Most pharmacological trials in COPD do not include individuals older than 80 years and efficacy of current therapies in this population is not known. There is increasing emphasis in understanding the systemic consequences of COPD rather than focusing on pulmonary impairments alone. Systemic approaches, using immunomodulatory agents, maybe necessary to effectively manage this disease in the future.

# Diffuse Parenchymal Lung Disease

Victor J. Thannickal ■ Galen B. Toews

## INTRODUCTION

The lung brings the ambient air that we breathe into close proximity with the systemic circulation. This allows for its essential function in gas exchange. However, this also exposes the lung to a variety of potentially injurious infectious and noninfectious environmental agents. The normal host response to such insults is to eradicate the etiologic agent and to repair the injury caused either directly by the agent or indirectly by the associated inflammatory process. This complex but well orchestrated and tightly regulated host response leads to eventual resolution of injury and restoration of normal lung architecture and function in most cases. However, if the inflammatory and/or repair response is dysregulated, a chronic alveolar/interstitial remodeling process with varying degrees of inflammation and fibrosis ensues. Damage to the pulmonary vascular endothelium via the circulation (e.g., drugs, systemic rheumatic disorders) may produce similar inflammatory/fibrotic reactions in the lung. This results in the restrictive physiology and gas-exchange abnormalities characteristic of the diffuse parenchymal lung diseases (DPLDs). When all potential etiologic agents and associations are considered, the list of DPLDs includes over 150 different clinical entities (Table 84-1). Thus, DPLDs comprise a large and heterogeneous group of diseases that are grouped into a single category based on common features in their clinical, radiographic, and physiological presentations.

The most prevalent and devastating of all the DPLDs is idiopathic pulmonary fibrosis (IPF), a chronic fibrotic disease of unknown etiology. IPF is primarily a disease of elderly patients. Elderly patients may be particularly susceptible to this disease because of inherent deficiencies in immune function and/or in their inability to mount an appropriate repair response. Alternatively, IPF may present in elderly patients as a result of accumulated insults or because early manifestations of the disease are difficult to recognize. In this chapter, we will focus on emerging new concepts regarding IPF pathogenesis and the challenges facing clinicians taking care of these patients.

We will also discuss other selected DPLDs that are relatively more common in the geriatric population.

## EPIDEMIOLOGY

The prevalence of DPLD is estimated at about 20 to 40 per 100 000 in the United States. DPLD accounts for 100 000 hospital admissions yearly. The increased use of pneumotoxic drugs to treat malignant and cardiovascular diseases in the elderly as well the rising median age of the U.S. population contribute to an increased incidence.

IPF has been reclassified into a group of diseases designated as the “idiopathic interstitial pneumonias” (IIPs) (Table 84-1). IIPs are rare in children, but increase with advancing age. IPF, the most common of the IIPs, has a prevalence of 6 to 14.6 per 100 000 persons in different series. In patients older than the age of 75 years, however, the prevalence may exceed 175 per 100 000. The median age of onset of IPF ranges from 50 to 70 years and the diagnosis is almost never made in a patient aged 40 years or younger. In contrast, other IIPs such as nonspecific interstitial pneumonia (NSIP) appear to occur in younger patients.

## PROGNOSIS AND NATURAL HISTORY

DPLDs represent a group of clinical syndromes with varying histopathological patterns ranging from predominantly inflammatory to more fibrotic tissue reactions. This is well illustrated by the IIPs that comprise primarily inflammatory tissue reactions such as desquamative interstitial pneumonia (DIP) and NSIP, in contrast to fibrotic histopathological patterns such as usual interstitial pneumonia (UIP). The histopathological subtype has important clinical and prognostic significance. UIP, the histopathological correlate of IPF, carries the worst prognosis and is, in general, unresponsive

**TABLE 84-1****Classification of Diffuse Parenchymal Lung Disease (DPLD)**

<b>Idiopathic Interstitial Pneumonias</b>	<b>DPLD Associated with Environmental (Occupational) Exposures</b>
Idiopathic pulmonary fibrosis (IPF)/Usual interstitial pneumonia (UIP)	Organic dusts/hypersensitivity pneumonitis (> 40 known agents)
Nonspecific interstitial pneumonia (NSIP)	Farmer's lung
Cryptogenic organizing pneumonia (COP; BOOP)	Air conditioner–humidifier lung
Acute interstitial pneumonia (AIP)	Bird breeder's lung
Respiratory bronchiolitis interstitial lung disease (RB-ILD)	Baggasosis
Desquamative interstitial pneumonia (DIP)	Inorganic dusts
Lymphoid interstitial pneumonia (LIP)	Silicosis
<b>Other DPLD (with Primary Lung Involvement)</b>	Asbestosis
Sarcoidosis	Coal worker's pneumoconiosis
Histiocytosis X	Berylliosis
Lymphangioleiomyomatosis	Gases/fumes/vapors
<b>DPLD Associated with Systemic Rheumatic Disease</b>	Oxides of nitrogen
Rheumatoid arthritis	Sulfur dioxide
Systemic lupus erythematosus	Toluene diisocyanate
Scleroderma	Oxides of metals
Polymyositis-dermatomyositis	Hydrocarbons
Sjogren's syndrome	Thermosetting resins
Mixed connective tissue disease	<b>DPLD Associated with "Alveolar Filling"</b>
Ankylosing spondylitis	Diffuse alveolar hemorrhage
<b>DPLD Associated with Drugs or Treatments</b>	Goodpasture's syndrome
Antibiotics	Idiopathic pulmonary hemosiderosis
Anti-inflammatory agents	Pulmonary alveolar proteinosis
Cardiovascular drugs	Chronic eosinophilic pneumonia
Antineoplastic drugs	Chronic aspiration syndrome
Illicit drugs	Lipid pneumonia
Dietary supplements	<b>DPLD Associated with Pulmonary Vasculitis</b>
Oxygen	Wegener's granulomatosis
Radiation	Churg–Strauss syndrome
Paraquat	Hypersensitivity vasculitis
	Necrotizing sarcoid granulomatosis
	<b>Inherited DPLD</b>
	Familial idiopathic pulmonary fibrosis
	Neurofibromatosis
	Tuberous sclerosis
	Gaucher's disease
	Niemann–Pick disease
	Hermansky–Pudlak syndrome

to anti-inflammatory and immune-modulating therapies. The finding of UIP on lung biopsy predicts a median survival of less than 5 years. Other baseline characteristics that predict a poor prognosis include a low DL<sub>CO</sub>, increased A–a gradient, desaturation during a 6-minute walk test (SaO<sub>2</sub> < 88%), pulmonary arterial hypertension (mPAP >25 mm Hg), and the finding of honeycombing on high-resolution computed tomography (HRCT). Dynamic predictors of poor prognosis include a decline in forced vital capacity (FVC)

≥ 10 (% predicted) over a 6-month period, decline in DLCO ≥ 15 (% predicted) over a 12-month period and serial changes in dyspnea score.

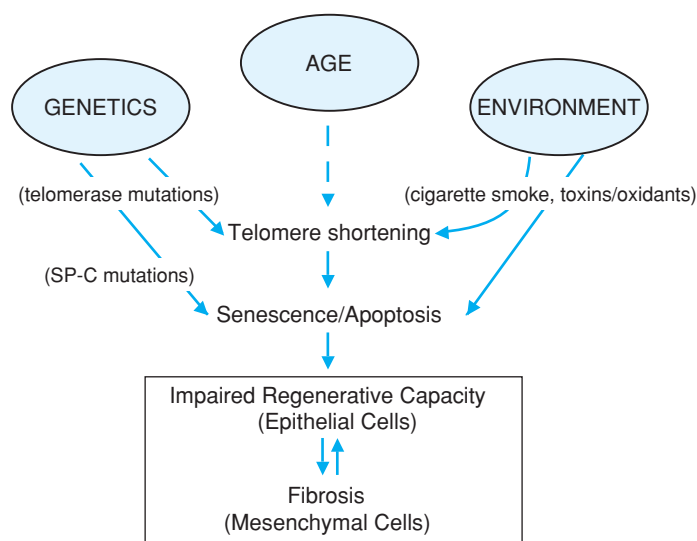

The precise relationships between different histopathological subtypes are not well defined. For example, it is not known if NSIP precedes UIP in the natural history of the disease or if they represent distinct tissue reaction patterns to an unknown injury in patients with varying host genetic/susceptibility factors (see section on "Pathogenesis"). With regard to the natural history of IPF, there is significant heterogeneity in the patient population. While the majority of patients experience a steady and inexorable decline in lung function, a significant proportion of patients with IPF succumb to acute exacerbations of the disease. The etiology and pathogenesis of these acute exacerbations are currently unknown.

## PATHOGENESIS

The pathogenesis of the DPLDs is complex. Significant differences in pathogenesis likely exist among the histopathological subtypes of IIP. Since UIP is also the most common form of IIP and since UIP/IPF exhibits an age-dependent increase in prevalence, we will focus on the pathogenesis of this clinical syndrome. IPF is localized to the lung parenchyma. Early histopathological evidence of alveolar epithelial cell injury and apoptosis suggests an inhaled route of entry for a putative injurious agent and/or an intrinsic abnormality specific to the alveolar epithelial cell. The temporal and spatial heterogeneity of the fibrotic lesions in UIP suggests that the injury may be recurrent and repetitive, occurring over many years. Although the identity of a specific extrinsic agent has not been identified, latent viral infections and environmental toxins, including cigarette smoke, have been implicated. Alternatively, or in concert, intrinsic defects in alveolar epithelial cell function and fate may drive the fibrogenic tissue response (Figure 84-1).

There is an increasing recognition that the aging process per se and the biology of cellular senescence influence tissue repair responses. Cellular senescence may affect the function and behavior of alveolar epithelial cells. Senescent epithelial cells with shortened telomeres are generally more susceptible to apoptosis. Genetic mutations in telomerase and surfactant protein-C have been shown to be associated with familial cases of IPF, suggesting a link to intrinsic defects in alveolar epithelial cell function. Familial pulmonary fibrosis appears to be inherited as an autosomal dominant trait with variable penetrance. No systematic assessment has been made of the heritability of IPF in the general population or the risk to relatives of affected individuals. Various forms of fibrotic lung disease have been associated with gene polymorphisms of interleukin-1-receptor antagonist, tumor necrosis- $\alpha$ , and major histocompatibility complex loci. Transforming growth factor- $\beta$ 1 gene polymorphisms resulting in increased production of this cytokine have been associated with more rapid progression of the disease in patients with established IPF. Thus, aging and host genetic factors are likely to determine the susceptibility to fibrotic sequelae and, perhaps, in the type of pathologic repair that ensues in sporadic cases of fibrotic lung disease.

Complex disorders such as UIP/IPF are influenced by the actions of multiple genes and their interactions with each other and the environment. Environmental factors modulate the response of the lung to injury. Of these, the most intriguing is the role of cigarette smoke. There is a strong association with cigarette smoking in

**FIGURE 84-1.** Host and environmental factors influence epithelial cell regenerative capacity. Mutations in the telomerase and surfactant protein-C (SP-C) genes have been linked to familial idiopathic pulmonary fibrosis; these telomerase and SP-C mutations induce cellular senescence and injury, respectively, leading to increased susceptibility of epithelial cells to apoptosis. Advancing age and extrinsic oxidative stress, including cigarette smoke, is also associated with telomere shortening and cellular senescence. Apoptosis of epithelial cells results in impaired re-epithelialization, loss of alveolar barrier function and activation of the underlying mesenchyme that culminates in fibrosis. The activated mesenchyme, in turn, may contribute to alveolar epithelial cell “dropout” by release of soluble mediators, further promoting epithelial dysrepair.

respiratory bronchiolitis-associated interstitial lung disease (RB-ILD) and DIP; cigarette smoke appears to play an etiologic role in the majority of these cases. Pulmonary histiocytosis X is diagnosed almost exclusively in active smokers. However, there is controversy regarding the role of cigarette smoke in IPF. Previous reports suggested that smoking was an independent risk factor for IPF. However, these studies may have included other cases of IIP, in addition to UIP. Some studies suggest a survival advantage in patients with IPF who

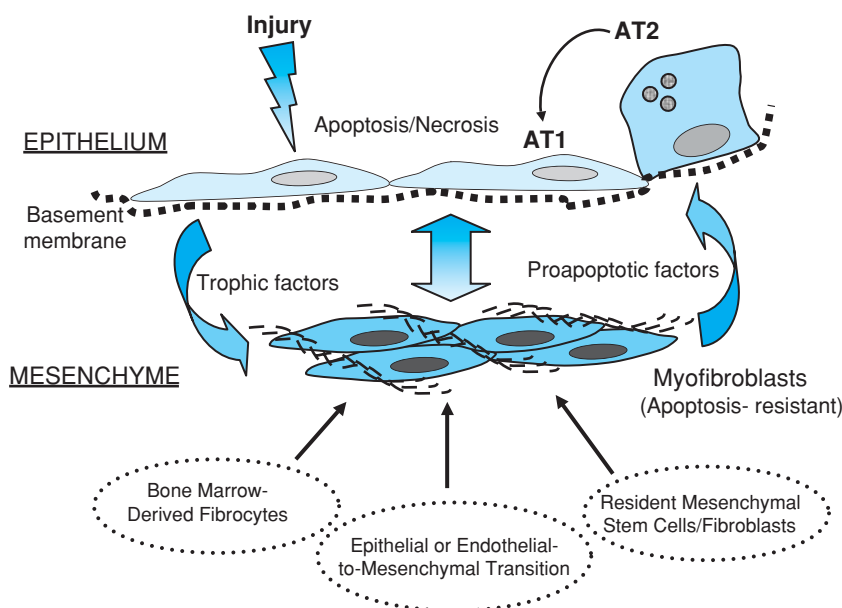

are cigarette smokers at the time of initial evaluation when compared with former smokers or never smokers. Interestingly, this presumed protection is associated with a histopathology that shows less interstitial cellularity and granulation/connective tissue formation but greater alveolar macrophage-predominant inflammation. The effect of cigarette smoke on the progression of IPF maybe as the result of factors that negatively regulate mesenchymal cell (myofibroblast) activation and/or promotes a specific type of inflammatory response.

The mesenchymal tissue response, in addition to the epithelium, may also be influenced by aging and cellular senescence. Age-related changes in extracellular matrix composition, expression of cell adhesion molecules, and altered cellular responses to growth factors have been reported in cells and tissues from various organ systems. For example, gene expression patterns in senescent fibroblasts have been shown to mimic chronic wound repair and, as such, senescent fibroblasts may contribute to ongoing fibrogenesis. Senescent fibroblasts may acquire an apoptosis-resistant phenotype. These observations support the establishment and perpetuation of an epithelial–mesenchymal paradox in which epithelial cells are in a continual state of disrepair and mesenchymal cells, in particular myofibroblasts, acquire resistance to apoptosis. Myofibroblasts in this context of lung injury–repair may derive from several sources, including the differentiation of lung-resident mesenchymal stem cells/fibroblasts, circulating fibrocytes or transdifferentiation from resident epithelial/endothelial cells (Figure 84-2) (Color Plate 12).

## DIAGNOSTIC APPROACH

### History

The most common presenting symptom is the insidious onset of exertional dyspnea that slowly progresses over many months and, in some cases, years. Initially, dyspnea is mild and the patient often does not seek medical attention. Dyspnea maybe attributed to other causes such as being “out-of-shape,” normal aging, being overweight, or a viral infection. Patients may initially be misdiagnosed and

**FIGURE 84-2.** Epithelial–mesenchymal interactions in idiopathic pulmonary fibrosis (IPF). Current concepts on the pathogenesis of IPF suggest that repetitive alveolar epithelial injury result in aberrant or dysregulated repair responses with ensuing fibrosis. Alveolar type 1 (AT1) cells maybe more susceptible to injury/apoptosis, and alveolar type 2 (AT2) progenitor cells normally serve to reconstitute the alveolar epithelium by differentiating into AT1 cells. Recent studies suggest that AT2 cells in IPF may undergo epithelial–mesenchymal transition. Other potential sources of activated mesenchymal cells (myofibroblasts) include circulating fibrocytes and resident mesenchymal stem cells. Myofibroblasts, under the influence of trophic factors such as transforming growth factor- $\beta$ 1 acquire resistance to apoptosis. Additionally, activated myofibroblasts are capable of secreting soluble/diffusible factors such as angiotensin peptides, oxidants, and Fas ligand, which further contribute to impaired reepithelialization and unremitting fibrogenesis.

treated for other ailments (bronchitis, asthma, or heart failure). As the disease progresses, dyspnea occurs at rest. Nonproductive cough and fatigue are also prominent complaints. Cough is a frequent complaint in patients with cryptogenic organizing pneumonia (COP; also known as bronchiolitis obliterans organizing pneumonia, BOOP), eosinophilic pneumonia, RB-ILD, and IPF. Pleuritic chest pain may occur with DPLDs associated with systemic rheumatic disease and some drug-induced disorders. Pleuritic chest pain and sudden worsening of dyspnea should suggest a spontaneous pneumothorax, a characteristic finding in lymphangioleiomyomatosis, neurofibromatosis, tuberous sclerosis, and pulmonary histiocytosis X. Hemoptysis maybe the presenting complaint in patients with diffuse alveolar hemorrhage syndromes or lymphangioleiomyomatosis, but it is infrequent in other DPLDs. Hemoptysis should prompt a search for complications such as malignancy, superimposed infection, or pulmonary embolism.

The history often provides clues to a more specific diagnosis when a DPLD is associated with a systemic rheumatic disorder, an occupational or environmental exposure, or certain drug therapies. Most patients with DPLD associated with rheumatic diseases have an established diagnosis when pulmonary symptoms present or have extrapulmonary manifestations that provide clues to the underlying disorder. A careful history may also reveal an environmental or occupational exposure. A detailed, lifelong occupational history must be obtained because of the long latency periods between exposure and onset of symptoms or radiographic abnormalities for the majority of the occupational DPLDs. Exposure to agents that cause DPLD may also occur as a result of hobbies or recreational activities (bird breeder's lung, wood worker's lung, farmer's lung, sauna taker's disease). Accordingly, exposures outside the occupational setting should be explored. An increasing list of both prescribed and over-the-counter medications can cause DPLD. Chemotherapeutic drugs have variable latency periods ranging from a few weeks to many years; therefore, a history of both current and former drug therapies must be sought.

Other aspects of the history, although not indicative of a specific etiology, may aid in the diagnostic evaluation. A history of smoking has been strongly linked with histiocytosis X, RB-ILD, and pulmonary hemorrhage associated with Goodpasture's syndrome. In contrast, hypersensitivity pneumonitis and sarcoidosis occur less frequently in active smokers. The role of cigarette smoking in IPF is unclear. While it has been reported to be a risk factor for the development of IPF, cigarette smoking appears to have a negative influence on the rate of progression. Age and sex can be useful in initial evaluation. IPF is almost exclusively a disease of middle age and the elderly patient. Sarcoidosis, histiocytosis X, lymphangioleiomyomatosis, and the inherited causes of DPLD (Table 84-1) are generally diagnosed before age of 40 years and, thus are uncommon initial presentations in the geriatric patient. Elderly patients are prone to aspiration; a history of gastroesophageal reflux suggests the possibility of chronic aspiration syndrome. The use of mineral oil nasal drops or petroleum products should raise the possibility of lipoid pneumonia.

### Physical Examination

Patients with IPF and other UIP-associated DPLD typically reveal the characteristic bibasilar, crepitant ("Velcro-like") late-inspiratory rales (crackles) on lung auscultation. Wheezing, rhonchi, and coarse rales are occasionally heard. The lung examination can be normal in

the early course of the disease. With advanced disease, resting tachycardia and tachypnea maybe present. Digital clubbing is relatively common in IPF, but less common in certain other DPLDs such as sarcoidosis. Hypertrophic pulmonary osteoarthropathy is rare. The new appearance of digital clubbing in a patient with known DPLD should prompt a search for complicating lung malignancy. The heart examination maybe normal early in the disease. Later, with the onset of pulmonary hypertension and cor pulmonale, an accentuated P2, tricuspid insufficiency, a right ventricular heave, and peripheral edema maybe noted. Extrapulmonary findings involving the skin and joints may indicate the presence of a systemic rheumatologic disorder.

### Laboratory Tests

Laboratory tests can either confirm or suggest a diagnosis in DPLD, but these studies are seldom diagnostic. Rheumatoid factor and antinuclear antibodies are occasionally present in patients with ILD, but their presence does not necessarily indicate an underlying collagen vascular disorder. Plasma immunoglobulin maybe elevated, but this finding is nonspecific. If hypersensitivity pneumonitis is suspected, serum-precipitating antibodies to a limited number of inhaled organic antigens maybe measured. Tests for antineutrophil cytoplasmic antibodies (ANCA) should be obtained if Wegener's granulomatosis is suspected. Tests for antibasement membrane antibodies should be obtained when Goodpasture's syndrome is suspected. The electrocardiogram (ECG) is usually normal in DPLD. With progressive loss of alveolar capillary units, the ECG may demonstrate a pattern of right atrial and ventricular strain.

### Chest Radiography

The chest radiograph is a practical and useful screen for DPLD. The chest radiograph maybe normal in up to 10% of patients with DPLD detected by HRCT. When abnormal, a characteristic radiographic pattern in combination with the appropriate clinical history and physical examination findings may suggest or support a specific diagnosis. In DPLD, the chest radiograph typically reveals bilateral reticular opacities that are predominantly in the periphery and lower lung fields. With more severe disease, cystic dilatation of the distal air spaces ("honeycombing") and traction bronchiectasis with thickened and dilated airways are seen. In other DPLDs, nodular or reticulonodular infiltrates maybe more common. Alveolar filling diseases often present with ill-defined alveolar nodules (acinar rosettes) and air bronchograms. A diffuse ground glass pattern is often seen in diseases characterized by active alveolitis such as DIP, RB-ILD, "cellular" NSIP, and hypersensitivity pneumonitis.

### High-Resolution Computed Tomography

HRCT, using thin (1 to 2 mm) sections without the use of contrast, offers many advantages over standard chest radiography in the evaluation of DPLD. The improved spatial resolution of HRCT allows characterization of anatomic patterns to the level of the pulmonary lobule. It is useful for the detection of DPLD in cases when the chest radiograph is normal, to quantify the extent and pattern of lung parenchymal involvement and, in a few cases, to make a specific diagnosis with a high degree of certainty. Diseases in which HRCT has been able to detect abnormalities with normal chest radiographs

include asbestosis, silicosis, sarcoidosis, and scleroderma. Conversely, the HRCT maybe normal in some cases of biopsy-proven DPLD; therefore, HRCT cannot be used to exclude ILD with absolute certainty. In such cases, physiologic data such as gas exchange with exertion maybe more sensitive. HRCT is also valuable for following the response to therapy and in identifying a suitable site for transbronchial or open lung biopsy. Recent studies suggest that HRCT data when combined with the clinical information can result in a confident diagnosis of IPF when read by experienced pulmonologists or radiologists; this may obviate the need for a lung biopsy in certain patients.

### Pulmonary Function Tests

Physiologic testing can identify the physiologic abnormalities associated with DPLD, determine the severity, and provide information on prognosis and response to treatment. The classic physiologic alterations in DPLD include reduced lung volumes (vital capacity, total lung capacity [TLC]), reduced diffusing capacity ( $DL_{CO}$ ), and a normal or supernormal ratio of forced expiratory volume in 1 second ( $FEV_1$ ) to FVC. Static lung compliance is decreased (decreased lung volume for any given transpulmonary pressure) and maximal transpulmonary pressure is increased (a very high negative pressure must be generated to open fibrotic alveoli). Exceptions to this classic presentation are histiocytosis X, lymphangiomyomatosis, neurofibromatosis, sarcoidosis, and tuberous sclerosis, in which airways disease can predominate, resulting in an increase in airflow limitation and increased TLC. A mixed restrictive and obstructive pattern is commonly seen in BOOP.

Arterial blood gas analysis typically shows mild hypoxemia. Carbon dioxide retention is rare. Most of the patients with DPLD have marked increases in minute ventilation both at rest and with exercise, resulting in reduced partial pressure of carbon dioxide ( $P_{CO_2}$ ) and compensated respiratory alkalosis. The increased minute ventilation is accomplished by increases in respiratory rate rather than in tidal volume. Hyperventilation is not caused by abnormalities in acid–base status or to hypoxemia, but rather to an increased stimulation of the respiratory center from neural signals arising from altered mechanoreceptors in the deranged lung parenchyma. Exercise tolerance in DPLD patients is markedly limited. With exercise, arterial partial pressure of oxygen ( $P_{O_2}$ ) falls and that of carbon dioxide ( $P_{CO_2}$ ) remain constant. Hypoxemia in patients with DPLD results primarily from abnormal ventilation–perfusion relationships and additionally from diffusion abnormalities with severe disease. The abnormalities in diffusion, which were originally believed to be the result of thickened alveolar walls, are now recognized to be caused by loss of capillary cross-sectional area and the passage of red blood cells through functioning pulmonary capillaries at a rate that is too rapid to permit full saturation of hemoglobin. Arterial pH is usually normal in DPLD but can fall with exercise as a result of anerobic metabolism in oxygen-deprived muscles.

### Bronchoscopic Studies

Bronchoscopy should be performed when tissue abnormalities are distributed in the bronchovascular bundle, an alveolar filling disorder is present, or an infectious disease is suspected. The distinctive histopathologic abnormalities of sarcoidosis, lymphangitic carcinomatosis, and lymphangiomyomatosis are usually found in the

bronchovascular bundle and transbronchial biopsy may demonstrate their characteristic lesions. Bronchoalveolar lavage (BAL) is diagnostic if an infectious agent or neoplastic cells are noted in the lavage specimen. BAL is also used to analyze the cellular constituents, cellular products, and proteins of the distal air spaces of the lung. A predominance of eosinophils in conjunction with appropriate clinical and radiographic picture can be diagnostic of eosinophilic pneumonia. In histiocytosis X, ultrastructural studies of BAL mononuclear cells reveal the typical Birbeck granule of the Langerhan's cell. Special stains for surfactant may suggest a diagnosis of alveolar proteinosis. However, BAL is usually nonspecific and it is not routinely indicated because of its limited ability to predict the underlying pathology (fibrosis vs. inflammation), to stage disease, or to predict response to therapy.

### Lung Biopsy

The diagnosis of DPLDs, if not evident from the clinical, radiographic, and/or bronchoscopic findings, depends on histological studies of lung parenchyma obtained by surgical lung biopsy. Video-assisted thoracoscopic lung biopsy will secure a specific diagnosis in the majority of such cases. The mortality rate for open lung biopsy is less than 1% and the morbidity is less than 3%. The benefits of making a definitive diagnosis must be weighed carefully with potential risks, particularly in elderly patients with comorbid conditions. One must also consider the options for meaningful therapy once a diagnosis is made. Currently, for IPF, effective therapeutic options are limited.

## THERAPEUTIC APPROACH

The principal aims of therapy are to remove exposure to injurious agents, to suppress any active inflammatory component, and to palliate or treat the complications of these diseases. Avoidance of the etiological agent, such as drugs and occupational exposures, should lead to resolution or stabilization. A short course of steroid therapy may also be indicated if the patient is symptomatic. In such cases, care must be taken to exclude infectious etiologies before embarking on empiric immunosuppressive therapy. Treatment of DPLDs associated with rheumatologic diseases is directed at suppressing the systemic immune response with prednisone with or without cyclophosphamide (Cytoxan). There are certain other DPLDs such as sarcoidosis and pulmonary vasculitides that are more responsive to such therapies.

The efficacy of anti-inflammatory agents in IIPs depends on the specific disease entity. In general, NSIP, COP, RB-ILD, DIP, and LIP are steroid-responsive whereas IPF/UIP and AIP are not. In cases where a lung biopsy cannot be obtained and a process other than IPF is suspected, a trial of anti-inflammatory therapy maybe initiated. When *N*-acetylcysteine (NAC) is added to a combination of prednisone and azathioprine, the rate of decline in FVC and DLCO is reduced. Immunosuppressive therapies are best limited to a 3- to 6-month period during which objective improvements in physiologic measures, radiographic findings, and clinical symptoms are assessed. Unfortunately, elderly patients tend to not respond well. In general, patients who respond to therapy are younger than 50 years of age, are likely to have coexistent NSIP, and are more likely to be females. In the absence of improvement, therapy with

immunosuppressive agents must be discontinued. There appears to be no benefit to more potent anti-inflammatory therapy (such as cyclophosphamide) in steroid-unresponsive cases. In symptomatic scleroderma patients with evidence of active alveolitis (by BAL or HRCT), 1 year of oral cyclophosphamide appears to have a modest beneficial effect on lung function, dyspnea, thickening of the skin, and health-related quality of life.

Despite early promise, a Phase III clinical trial of interferon gamma-1b (Actimmune) for IPF was discontinued, as the overall survival result crossed a predefined stopping boundary for lack of benefit; among the 115 deaths in the 826 randomized patients, 14.5% were in the Actimmune group as compared to 12.7% in the placebo group. Other agents in Phase II/III clinical trials include pirfenidone (an orally active small molecule inhibitor of fibroblast activation and proliferation), bosentan (an endothelin receptor antagonist), and imatinib mesylate (a tyrosine kinase inhibitor). Several other agents are in Phase I or earlier stages of drug development. Currently, no FDA-approved drug therapies for IPF exist. Enrollment of such patients in clinical trials, including those sponsored by the National Institutes of Health, is strongly encouraged.

Early institution of oxygen therapy for patients with hypoxemia or desaturation (oxygen saturation  $\leq 88\%$ ) at rest or with exercise is recommended; this is to prevent or delay complications related to pulmonary hypertension. Patients who develop pulmonary hypertension and *cor pulmonale* must be managed supportively with a combination of diuretics, inotropic agents, vasodilator therapy, and anticoagulation. Influenza and pneumococcal vaccines should be administered to all patients with chronic forms of DPLD.

Lung transplantation maybe an option for patients with end-stage DPLD refractory to medical therapy. Single lung transplantation is preferred for most patients. Most transplant centers currently do not list patients over the age of 65 years. Two-year survival ranges from 60% to 80%, with most deaths being caused by infections that complicate immunosuppressive therapy or to chronic allograft rejection. The 5-year survival is approximately 50% and is limited primarily by chronic allograft rejection.

## FUTURE DIRECTIONS

The challenges facing clinicians who care for patients with DPLD, particularly those of the idiopathic variety (IIPs), include the ability to diagnose patients early in the disease course when the underlying

inflammatory and repair processes may be more amenable to therapy and to accurately define the relative degree of inflammation versus fibrosis. In primarily fibrotic processes such as UIP/IPF, anti-inflammatory therapies are of no proven benefit. A number of “anti-fibrotic” strategies are now under investigation. Further understanding of the relationships between inflammation and fibrosis, and the molecular determinants that result in the varied manifestations of the IIPs may aid in the development of more targeted therapies. Evolving systems biology approaches that allow for more accurate genotyping/phenotyping of patients may aid in defining the underlying disease process and allow for more specific “personalized” therapies.

# Changes in Kidney Function

Jocelyn Wiggins ■ Sanjeevkumar R. Patel

## CLINICAL RELEVANCE

Kidney failure is a growing problem in the older population. Data on people reaching end-stage kidney disease (ESKD) is collected by the U.S. Renal Data System (USRDS). All dialysis units that receive funding from Medicare are required to file data with the USRDS, so that nationwide data are available on over 95% of people receiving renal replacement therapy. Information published in the 2006 USRDS annual data report shows that approximately 1.5 in 1000 persons aged 65 years or older are initiating treatment for ESKD each year—the highest rate of any age group. Over the last 10 years, the number of older people enrolling for treatment has increased by 41% in the group of people aged 75 years or older and by 48% in the 80+-year-old age group. Almost 4 in 1000 persons are currently maintained on renal replacement therapy, with the 75+-year-old age group growing at 10% per year. The peak incidence for ESKD is the 70- to 74-year-old age group, while the peak prevalence falls in the 65- to 69-year-old age group. In contrast, the incidence of ESKD in the 20- to 44-year-old age group has remained flat over the last 10 years, with only 6% growth in the 45- to 64-year-old group. Although some of the increase in renal replacement therapy for the older population indicates a greater willingness to offer treatment to older individuals, much of the increase is owing to people surviving to experience the chronic changes that occur with aging. The kidney undergoes significant age-related change. Other common diseases such as hypertension and diabetes accelerate these changes.

## THE AGING PROCESS

Aging in the kidney is characterized by changes of both structure and function. It must be emphasized that many of the aging studies have been performed on laboratory animals, particularly rodents,

that demonstrate quite different patterns of aging from humans. For example, kidney weight increases throughout life in rats while kidney mass and size in humans peaks in the fourth decade and declines thereafter. Care should be taken when reading the literature to keep in mind that changes seen in animal models may not be reflected by parallel changes in humans. Historical data from human postmortems describing changes in the kidney made no effort to exclude patients with kidney disease or significant comorbidities. More recently data on aging has been developed from longitudinal studies, such as the Baltimore Longitudinal Aging Study, in which the medical histories of the study volunteers are well documented. There are also data accumulating from the kidney transplant population. Older living donors are increasingly being used and are put through a rigorous medical workup for renal function and comorbid conditions before being accepted as donors. This has allowed acquisition of data on normal aging in the kidney, uncomplicated by the presence of medical comorbidities. Aging in the kidney is generally characterized by spontaneous progressive decline in renal function accompanied by thickening of the basement membrane, mesangial expansion, and focal glomerulosclerosis.

## Functional Changes

Changes in renal function with age are well documented both in human and animal models. Although baseline homeostasis of fluids and electrolytes is maintained with normal aging, there is a progressive decline in renal reserve. This results in a compromise in the kidney's ability to respond to either a salt or water load or deficit. This manifests clinically in patients being vulnerable to superimposed renal complications during acute illnesses. Chronic conditions such as hypertension accelerate this age-related loss of renal reserve and increased vulnerability in these patients should be anticipated. Age-related changes in function will be considered by separate functional domain within the kidney.

## Renal Blood Flow

Average renal blood flow decreases about 10% per decade, dropping from 600 mL per minute per 1.73 m<sup>2</sup> to 300 mL per minute per 1.73 m<sup>2</sup> by the ninth decade. This is accompanied by increasing resistance in both afferent and efferent arterioles. These changes occur independent of cardiac output or reductions in renal mass. This decline in renal blood flow is thought to contribute to the decline in efficiency with which the aging kidney responds to fluid and electrolyte load and loss.

## Glomerular Filtration Rate

Newer data have shown a wide variation in the rate and extent of changes in the kidney within the older population. Approximately 30% of the population shows no measurable decline in renal function with normal aging. The bulk of the population loses about 10% of glomerular filtration rate (GFR) and 10% of renal plasma flow per decade after the fourth decade of life. Between 5% and 10% of the population shows accelerated loss, even in the absence of identifiable comorbidities. Since there is also a steady loss of muscle bulk with age, with concomitant reduction in creatinine production, serum creatinine should remain constant. Rises in serum creatinine should therefore be taken seriously and not dismissed as normal aging. As can be seen in Figure 85-1, serum creatinines at the upper limit of the “normal range” in an older individual represent significant functional decline, and thought should be given to renal dosing of medications. These curves were calculated using the Cockcroft Gault equation for a 70-kg man:

$$\text{Creatinine clearance} = \frac{(140 - \text{age})(\text{weight [kg]})}{72 \times \text{serum creatinine (mg/dL)}}$$

Results for women should be multiplied by 0.85, which shifts the curves downwards. In frail older women with very little residual muscle mass, this equation probably overestimates GFRs. This steady decline in renal function with age manifests itself clinically as impaired ability to excrete a salt or water load. Extra care should be taken

when replacing fluids in an older individual to prevent extracellular fluid overload.

In 1999, an improved formula for estimating GFR was developed known as the MDRD formula (because it was developed as part of the Modification of Diet in Renal Disease study). Many routine laboratories now automatically calculate an MDRD glomerular filtration estimate when a basic or a comprehensive metabolic panel is ordered. In some institutions, it is necessary to order a “renal panel” for the calculation to be done. It is important to understand that this formula was based on data from community-dwelling volunteers aged 18 to 70 years. It has never been validated in an elderly or frail population. Several investigators have studied its performance in elderly patients and compared its efficacy with Cockcroft Gault, creatinine clearances based on 24-hour urines or iothalamate clearances, or a combination of these methods. All of the studies have shown large discrepancies between these methods in patients with advanced age and at both extremes of the weight spectrum. These limitations should be kept in mind when using the formula in clinical geriatric practice. Although iothalamate clearance is the gold standard, it is expensive and impractical for routine use. The most reliable results come from calculating creatinine clearances based on 24-hour urine collection. This will always be an overestimate of the GFR, since some creatinine is actively excreted into the urine from the proximal tubule, not all of the urinary creatinine is filtered. It is however more reliable than the formula estimations in the very old and the frail.

## Classification of Kidney Disease

The classification of kidney disorders has undergone a major revision over the past few years. A consensus committee, sponsored by the National Kidney Foundation, published new clinical practice guidelines in February 2002. The traditional chronic renal insufficiency (CRI) has become chronic kidney disease (CKD) and end-stage renal disease (ESRD) has become kidney failure. CKD is defined as either kidney damage or decreased kidney function for 3 or more months. Kidney failure is defined as a GFR of less than 15 mL/min or the need to start kidney replacement therapy. Along with renaming kidney disease, the committee also developed a system of staging,

**FIGURE 85-1.** Relationship between serum creatinine and calculated creatinine clearance for men aged 35, 65, and 85 yrs. Calculations are based on a 70-kg man.

**TABLE 85-1****National Kidney Foundation Classification of Chronic Kidney Disease**

STAGE	DESCRIPTION	GFR (mL/min/1.73 m <sup>2</sup> )
1	Kidney damage with normal or increased GFR	>90
2	Kidney damage with mild reduction in GFR	60–89
3	Moderate decrease in GFR	30–59
4	Severe decrease in GFR	15–29
5	Kidney Failure	<15 (or dialysis)

similar to the New York classification of congestive heart failure. It was felt that having a structure would help with standardizing diagnosis and opportunities for preventative management. CKD is now classified into five stages, regardless of underlying diagnosis. The classification defines stage 1 as kidney damage (primarily proteinuria) with preserved GFR and progresses to stage 5 kidney failure (Table 85-1). Declines in GFR are accompanied by a broad range of complications (Table 85-2). Early recognition of impaired kidney function allows the physician to screen for and manage these complications and thus prevent comorbidities and declines in quality of life. National Kidney Foundation Guidelines recommend referral to a nephrologist when a patient reaches stage 4 CKD for management of the complications of impaired function such as acidosis, phosphorus retention, and anemia. Preparation for kidney replacement therapy should also begin during stage 4.

### Proteinuria

Despite the significant decline in GFR that occurs with aging, proteinuria is not a normal feature of the aging process. Proteinuria is always a pathological finding and requires a full workup. In contrast, in most rodent models, particularly in the rat, proteinuria is a normal feature of the aging kidney. This difference between humans and rodents should be kept in mind when reading the aging literature.

### Tubular Function

Older individuals are well known to be more susceptible to acute renal failure. Much of the information on tubular function comes

**TABLE 85-2****Complications of Chronic Kidney Disease**

Hypertension
Anemia
Increased cardiovascular mortality and morbidity
Disorders of calcium and phosphorus metabolism
Compromised nutritional status
Metabolic bone disease
Neuropathy
Impaired functioning and well-being
Depression

from animal studies, particularly rat models. Rats spontaneously develop proteinuria with aging, and this protein load is believed to be toxic to the tubule. Since proteinuria is not a feature of normal aging in humans, these animal studies may not paint an accurate picture of changes in tubular function in humans. There are also large numbers of studies in experimental animals looking at vasoconstrictive and vasodilatory responses in the older kidney. Impaired response to ANP, acetylcholine, and blunted responses of cAMP to  $\beta$ -adrenergic stimulus have all been implicated. Virtually none of these findings have been confirmed in humans. Functional magnetic resonance imaging (MRI) in older volunteers has demonstrated decreased ability to modulate renal medullary oxygenation. Whether this is caused by fixed vascular changes or changes in renal autocrine systems such as prostaglandins, dopamine, nitric oxide (NO), natriuretic peptides, or endothelin is not clear. The clinical result is increased sensitivity to acute ischemic renal failure.

Animal and human studies have shown impaired concentrating ability in the older kidney. Whether this is caused by intrinsic defects in the tubular epithelium or impaired response to ADH is not clear. Studies have also demonstrated impaired capacity to acidify urine manifested clinically as reduced excretion of an acid load. Whatever the underlying mechanism, older individuals are less likely to be able to maintain normal homeostasis when challenged. Although there is an age-related decline in tubular functions such as glucose and amino acid transport, these declines closely parallel the decline in GFR and are believed to correlate with the loss of nephrons rather than aging of the tubule. Age-related changes in sodium and potassium homeostasis, and water handling are discussed in Chapter 88.

Older individuals are also more sensitive to nephrotoxic injury. Careful thought should be given to the choice and dosing of antibiotics and other nephrotoxic drugs. Increased age is a risk factor for the development of radiocontrast nephropathy. Special care should be exercised before tests requiring radiocontrast are ordered.

### Donor Organ Viability

Age also impacts on the viability of kidneys for transplantation. With the steady increase in living related and unrelated donations, more organs have become available for use in the older population. Although nationwide probably less than 5% of older individuals reaching ESKD are being considered for transplantation, many larger transplant programs are routinely offering transplantation to people in their late sixties and early seventies if they are otherwise in good health. Donated organs are commonly coming from a similar aged spouse or a family member. Age of the donated organ appears to be an independent risk factor for graft survival. This does not appear to be immune-mediated, as older recipients have lower risk of rejection. These organs typically show delayed graft function post-transplant, with chronic allograft nephropathy and result in higher baseline serum creatinines in the long term. It has been postulated that this is caused by impaired response to injury in the older kidney, but there is no real scientific evidence to support this at the current time.

### Underlying Structural Changes

There is at least 100 years of meticulous research describing the anatomical changes that underlie the functional changes that we see in our patients as they age.

## Gross Anatomy

Kidneys grow vigorously from birth through adolescence, reaching their maximum weight and volume during the third decade of life. In humans, although not in most laboratory animals, this weight starts to decline after the fourth decade and continues its decline throughout the remaining life span. Most of the decline in weight and volume appears to happen in the cortex, with relative sparing of the medulla.

## Glomerulus

The young healthy human kidney contains roughly 1 million nephrons. There is no evidence for postnatal nephrogenesis. This underlies the hypothesis that low birth weight babies might have fewer initial nephrons and as a result are more susceptible to renal failure in later life. Although there is some observational data to support this hypothesis, no causal relationship has been proved. There is a steady decline in nephron number with age that starts around the fourth decade. This decline is believed to underlie the decline in GFR discussed above. Kidneys obtained at autopsy from patients with no known history of renal disease have been studied. Light microscopy showed the development of a focal sclerosing process, accompanied by thickening of the glomerular basement membrane. There was a steady progression with age in the percentage of glomeruli that were scarred. By age 50 years, all subjects examined had some evidence of sclerosis, with the percentage of sclerotic glomeruli increasing steadily with age.

## Age-Related Glomerulosclerosis

Sclerotic glomeruli typically first appear in the fourth decade of life. This starts as a segmental process with one part of a glomerulus becoming acellular and the normal architecture being replaced by extracellular matrix. The glomerular tuft becomes adherent to Bowman's capsule (Figure 85-2) (Color Plate 13). Gradually an entire glomeru-

lus becomes sclerosed and shrivels down with resultant loss of that nephron and its filtration capacity. It is not known what triggers this pattern of focal sclerosis, which is apparently randomly scattered throughout the cortex. The glomerular tuft increases in size with age. Concomitant with this expansion is an increase in endothelial and mesangial cells, such that the ratio of cells to glomerular area remains constant. Podocytes, the specialized cells that form the filtration barrier in the glomerulus, are postmitotic. They are not able to multiply in response to the increase in tuft volume, and become a progressively smaller percentage of the total cells making up the glomerular tuft. As the filtration area that they have to cover increases, it is believed that they may drop off the basement membrane, leaving a denuded area behind. It is this area of bare basement membrane that acts as the trigger for the sclerosing process. Many different experimental models of glomerulosclerosis have concluded that loss of the podocyte and its inability to be replaced is the sentinel event that triggers sclerosis. In our laboratory, we have developed a transgenic rat that expresses the diphtheria toxin receptor on the podocyte and allows us to deplete podocytes in a dose-dependent manner. We have shown that the loss of podocytes precedes the appearance of sclerosis, and podocytes markers can be detected in the urine prior to the development of global sclerosis.

Models of induced glomerular injury, of course, do not exist in humans. However, research has shown selective loss of podocytes in the kidneys of type I diabetics as diabetic nephropathy progresses. Podocyte number per glomerulus is the best predictor of progression of diabetic nephropathy in Pima Indians with type II diabetes. Thus, studies of the aging process in rat kidneys noted that a decline in podocyte counts accompanies by the appearance of glomerulosclerosis.

Some authors have suggested a role for the mesangial cell in initiating the sclerosis process. Certainly with aging, there is an increase in mesangial matrix and in mesangial cell numbers. However, this increase is just as marked in strains of rat that do not develop age-related glomerulosclerosis, as it is in strains that do. Several authors have looked at mesangial cell activation in rat models of

**FIGURE 85-2.** Renal glomeruli from a 24-month Fischer 344 rat stained with a podocyte marker, GLEPP1, and counterstained with PAS. Left panel: normal glomerulus showing normal architecture of the glomerular tuft. Right panel: age-related glomerulosclerosis showing normal cellular architecture replaced by extracellular matrix and adherence to Bowman's capsule.

glomerulosclerosis and found little or none. This suggests that mesangial expansion is a benign manifestation of the aging process rather than a pathological one.

### Tubule

With the loss of the glomerulus, the tubular section of the nephron usually degenerates and is replaced by connective tissue. Tubular hypertrophy then occurs in the remaining nephrons, principally in the proximal convoluted tubule. This appears to result from both hypertrophy and hyperplasia. With thinning of the cortex, there is a decrease in tubule length and development of diverticuli in the distal convoluted tubule. As nephrons are lost, there is generalized tubular interstitial fibrosis. The structure of the distal tubule does not appear to change significantly with age.

### Vasculature

Renal arteries undergo age-related thickening, similar to that seen throughout the circulation. Smaller arteries may become tortuous and show luminal irregularities. When a glomerulus becomes sclerosed, there is frequent formation of an arteriovenous shunt as the afferent and efferent arterioles develop a direct connection, as the glomerular capillary is lost. This shunt is very important in maintaining medullary blood flow. Physiological studies in both animals and humans have documented a decline in renal blood flow and an increase in vascular resistance with age. Studies of renal perfusion in healthy older individuals from a pool of potential kidney donors have shown steady declines in renal perfusion with age that exceeded the reduction in renal mass, suggesting that declines in blood flow were a significant factor in the changes seen in renal function with age. These changes contribute to the susceptibility of older individuals to acute renal failure, volume overload, and electrolyte abnormalities.

Infarcts may occur in the kidney, just as they do in other tissues of the body. Since one fifth of the circulating volume passes through the kidney each minute, the kidney is also particularly susceptible to embolization. If other signs of embolization are visible clinically, it is highly probable that the kidney is also undergoing embolization, and embolic disease should certainly be kept in mind in an older individual with widespread vascular disease who demonstrates accelerated loss of renal function.

## MECHANISMS UNDERLYING THE DECLINE IN KIDNEY FUNCTION

There is no clear-cut consensus about what mechanisms may underlie the structural and functional changes occurring in the kidney in the older population. It is fairly clear however that there are both predisposing genetic and environmental factors that play a role.

### Genetic Predisposition

There are as yet no genes known to cause age-related glomerulosclerosis. Accumulating evidence from animals studies, combined with evidence of genetic predisposition in humans, has led to a concerted effort to seek genes that may increase susceptibility to renal failure in individuals.

### Animal Models

Rats are particularly susceptible to kidney failure and much of the work with models of renal disease has been carried out in laboratory rat strains. There are very marked strain differences in susceptibility to age-related glomerulosclerosis. Since these rats are maintained in pathogen-free environments and are fed uniform scientifically developed diets, this strongly suggests a genetic basis for the development of age-related glomerulosclerosis. The appearance of glomerulosclerosis has been reported as early as 5 months in the Milan normotensive rat, with extensive disease by 10 months of age. This occurs in the total absence of hypertension and is not ameliorated by administration of ACE inhibitors. Wistar rats were used as controls in this study and showed no significant disease during the same time period. In Sprague-Dawley rats, spontaneous age-related glomerulosclerosis first becomes apparent around 9 months of age, and disease became widespread by 18 months of age. In studies of aging in Fischer 344 rats, little glomerulosclerosis is seen until almost 2 years of age with fairly rapid progression thereafter. Other rat strains appear remarkably resistant to renal disease. Brown Norway rats show minimal sclerosis, even at 32 months of age, an advanced age in rat life span.

### Human Studies

Clearly, these kinds of studies cannot be duplicated in humans. However, there is observational data that would support a similar variation in genetic susceptibility in humans. Cross-sectional studies, donor organ data, and longitudinal studies clearly show a wide variation in kidney function with age. Around 5% to 10% of the population show accelerated loss of kidney function with age even in the absence of accelerating factors such as hypertension, while 30% show no measurable decline. In the presence of predisposing comorbidities, there is also wide variation in the development of kidney disease. Some diabetics may never develop nephropathy, while others develop rapidly progressive kidney disease early in the course of their diabetes, suggesting an underlying genetic susceptibility. Within the African-American population rates of kidney disease are much higher than in the Caucasian population independent of the precipitating cause. Within an ethnic group, there are also distinct differences in vulnerability. An African-American who develops any predisposing disease, be it hypertension, diabetes, or lupus, who has a first degree relative on renal replacement therapy has a ninefold increased risk of developing kidney disease compared to another African-American with the same disease burden who has no family history of kidney disease. Similarly human immunodeficiency virus (HIV)-associated glomerulosclerosis occurs almost exclusively in the African-American population, while HIV-associated mesangial hyperplasia and immune-complex glomerular nephritis occur equally in all ethnic groups. Thus there is suggestive evidence for a genetic predisposition with respect to the development of glomerulosclerosis. Considerable effort and resources are currently being directed toward identifying genes that predispose to kidney disease, so we can expect to have greater understanding of this process soon.

### Environmental Predisposing Factors

It has been well known for many years that several diseases predispose to kidney failure and will accelerate the progress of age-related

glomerulosclerosis. By far the most frequent of these are hypertension and diabetes, both common disorders in the older population. There are however several other mechanisms that have been postulated to underlie the aging changes in the kidney.

### Diet

One of the most striking aspects of rodent models of age-related nephropathy in the kidney is its complete reversal with calorie restriction. Both the anatomical and functional changes related to aging in the kidney are completely abolished in animals that are fed two-thirds of the calories given to their ad libitum-fed litter mates. Even though these animals live one third longer than their ad libitum-fed littermates, they do not develop age-related glomerulosclerosis. Several explanations have been proffered to account for this observation.

### Free Radicals and Lipid Peroxides

One possible explanation for the profound effects of calorie restriction is a reduction in the generation of free radicals and lipid peroxides. There is a wide body of literature discussing the damaging effects of free radicals on cellular systems and the role that this plays in aging. It is not the scope of this chapter to review that literature. The main consequence of free radical production is lipid peroxidation, which results in damage to cellular proteins, lipids, and nucleic acids. Increased calorie intake is believed to fuel increased free radical production with accelerated aging damage. This hypothesis has generated interest in the role of antioxidants in slowing the aging process. The effects of supplementing the diets of Sprague-Dawley rats with vitamin E 50 IU/kg has been studied. Although they were able to measure reductions in markers of oxidative stress, and slowed the rate of decline in GFR, they were unable to prevent glomerulosclerosis. Studies in humans with vitamin E have also been disappointing.

### Protein Restriction

The benefits of calorie restriction have been attributed to concomitant reductions in dietary protein. There is a large body of older literature on protein restriction in experimental animal models of kidney disease. In many of these studies, experimental and control animals were not fed isocaloric diets, and protein restriction also meant calorie restriction. Many of these studies have shown a slowing in the progression of established kidney disease, however the results were not corrected for total calorie content. Studies of spontaneous age-related glomerulosclerosis in Fischer 344 rats have shown that protein restriction was much less effective than calorie restriction in preventing age-related declines in kidney function. Modest benefits from protein restriction when rats were fed isocaloric diets have been demonstrated, as have some benefits when the type of protein in the diet was changed from casein to soy. In contrast, calorie-restricted animals had little or no decline in kidney function and they were not able to show significant glomerulosclerosis despite significantly increased longevity. Rats that were fed a high-protein diet, but restricted to 60% calorie intake compared to their ad libitum-fed litter mates, also showed dramatic reductions in age-related glomerulosclerosis. Clearly, protein restriction does have some benefit in the prevention of age-related nephropathy, but that advantage is small compared to those achieved with caloric restric-

tion. Very few of the studies looked at changes in sodium, phosphate, and calcium content of the experimental diets. Many of the results of protein restriction can be duplicated by phosphate restriction. The relevance of these studies in humans remains unclear. An observational study that included individuals up to 80 years of age compared healthy vegetarians who consume an average of 30 g/day of protein with nonvegetarians who consume an average of 100 g/day showed no differences in kidney function between these groups. There is evidence to support protein restriction in patients with established renal disease to reduce symptoms of uremia, but none to support the role of protein restriction to prevent age-related changes in the human kidney.

### Lipids

There is a well-established link between lipids and cardiovascular disease, and restriction of fat intake accompanied by treatment of hyperlipidemia has been shown to be efficacious in preventing or slowing the progress of cardiovascular disease. Certainly protecting the integrity and function of the vascular supply to the kidney is important to maintaining normal function. Evidence for benefits from the manipulation of lipids in kidney disease comes mainly from animal models of diabetes. Animal studies using high-fat diets have shown accelerated progress of kidney disease, but in most cases, diets were not corrected for total calorie intake. Lipogenic diets fed to Sprague-Dawley rats resulted in earlier appearance of widespread glomerulosclerosis, compared to standard fed animals. Use of lipid-lowering agents in a variety of animal models of glomerulosclerosis has shown reductions in the incidence of glomerular damage. Patients with established renal disease with or without diabetes have more rapid deterioration of kidney function in the presence of hyperlipidemia. The relevance of lipids to the age-related decline in kidney function remains to be established, but it would certainly be reasonable to recommend low-fat diet and lipid management in patients with declining renal function.

### Hyperfiltration

The term hyperfiltration is used to describe putative glomerular injury from long-term increases in intraglomerular pressure. Normal age-related loss of glomeruli causes intraglomerular hypertension with hypertrophy of remaining glomeruli. Persistent intraglomerular hypertension causes pressure-mediated renal injury. Most of the supporting evidence for this mechanism comes from animal models where one kidney and part of the remaining kidney are removed, leaving a partial kidney remnant. These animals develop a pattern of renal damage in the remnant indistinguishable from age-related glomerulosclerosis, but over an accelerated time course. Long-term follow-up in humans for over 20 years has not shown accelerated declines in renal function in people who have donated one of their kidneys for transplantation, even though the remaining kidney does undergo hypertrophy. Nutrition may also play a part in hyperfiltration. After a meal of protein, increases in both renal blood flow and GFR in animals as well as in humans have been demonstrated. Excessive intake, particularly of animal proteins, therefore could cause constant hyperperfusion in the kidney, leading to intraglomerular hypertension and accelerated glomerulosclerosis. This would certainly help to explain the benefits so clearly seen with calorie restriction in laboratory animals.

The efficacy of ACE inhibitors in preventing renal hyperperfusion damage early in the course of diabetes and hypertension would also lend support to the hyperfiltration hypothesis. Angiotensin II appears to be important in maintaining glomerular filtration pressure by vasoconstricting the efferent arteriole. ACE inhibition is believed to preserve renal function by blocking the vasoconstriction of the efferent arteriole and reducing intraglomerular pressure. Long-term ACE inhibition dramatically reduces the incidence of age-related glomerulosclerosis in Munich-Wistar rats. However, a sufficient dose of ACE inhibitor to significantly lower systolic blood pressure was administered in the treatment group as compared to the control animals. Whether low doses of ACE inhibitors would help to maintain normal renal function in humans, and prevent the appearance of age-related glomerulosclerosis is a matter of speculation. There is no doubt about their efficacy in preventing progressive decline in renal function when there is an underlying disease. It remains to be seen whether they have any role in modifying age-related changes.

## CONSEQUENCES OF IMPAIRED KIDNEY FUNCTION

Patients who show signs of significantly diminished kidney function should be managed aggressively, regardless of their age. Individuals who reach dialysis have a mortality rate four to five times that of age-matched controls (Table 85-3) and are at 10 times the risk of a cardiovascular event. It costs more than \$70 000 per annum to maintain someone on dialysis, without including the cost of treatment for any other health problems. Transplantation is also expensive and requires the patient to remain on toxic immunosuppressive regimens for the rest of their life. Patients who show signs of impaired kidney function should be managed with the idea of preventing them from reaching end-stage disease. Aggressive measures should be taken to reduce blood pressure with a goal of 125/75 if tolerated. A regimen should be used that includes an ACE inhibitor or an angiotensin receptor blocker. However, it should be kept in mind that neither of these classes of drug will confer significant renal protection in the absence of good blood pressure control. Lipids should also be aggressively managed, as should blood sugar and other potential accelerators of renal decline. Overweight patients should be encouraged to lose weight. Great care should be taken to avoid potential renal toxins, such as aminoglycoside antibiotics, nonsteroidal anti-inflammatory drugs (NSAIDs), and radiocontrast dyes.

**TABLE 85-3**

### Life Expectancies for Selected Age Groups, Comparing Dialysis Patients with General Population Statistics

AGE (yr)	DIALYSIS POPULATION	U.S. POPULATION
40–44	6.7–9.2	30.1–40.8
50–54	5.1–6.9	22.5–31.5
60–64	3.7–5.1	16.0–22.8
70–74	2.7–3.5	10.8–15.2
80–84	2.0–2.4	6.9–8.8

Numbers are shown as ranges to accommodate differences by gender and ethnic group.

Medications excreted by the kidney should be appropriately dosed in amount and frequency. Maintaining residual renal function confers on the patient a greatly superior prognosis when compared to those on renal replacement therapies. Hopefully the current emphasis on finding genes that predispose to declines in kidney function and the development of age-related glomerulosclerosis will help us to identify those at greatest risk before major losses of function have occurred. As with recent gains in the prevention of cardiovascular disease through control of risk factors, we anticipate that similar guidelines will be available for the prevention of age-related declines in kidney function.

In summary, kidney disease and failure are predominantly diseases of the older population. All older patients should have an estimate made of their GFR. If they have a deficit in their kidney function, they should be managed aggressively to prevent progression to kidney failure. As CKD progresses, special attention should be paid to choice of drugs and their dosing and to the use of contrast dyes for imaging.

# Renal Disease

Lynn Schlanger ■ Jeff M. Sands ■ James L. Bailey

The normal aging process induces structural and functional changes in the kidney characterized by progressive development of glomerulosclerosis and interstitial fibrosis. The timing of these changes is highly variable and is not necessarily inevitable, and appears to hinge on associated comorbid factors. Nearly one-third of the elderly population will not demonstrate a decrement in glomerular filtration rate (GFR) with aging. Nevertheless, the average individual can expect to lose 0.8 mL/min/1.73 m<sup>2</sup>/year. Because the decline in GFR in individuals with aging is masked by a proportional decline in muscle mass, the serum creatinine generally remains constant. Failure to understand this fact can result in inappropriate dosing of medications with their associated morbidity. It can also result in underrecognition of renal pathology, for even subtle increases in serum creatinine in the elderly can represent a significant loss of renal function. This chapter reviews aspects of renal disease that are prevalent in the geriatric population.

## EPIDEMIOLOGY

There has been an increase in the prevalence of renal disease with increasing age as a consequence of improved patient survival with comorbid conditions that result in renal dysfunction, such as congestive heart failure, hypertension, diabetes, and atherosclerotic vascular disease. Currently, more than 20% of individuals older than age 65 years who are living in the United States have some degree of renal impairment, and 60% of the patients with end-stage renal disease (ESRD) who are on chronic dialysis are older than age 65 years. Men and women are affected equally. This is surprising given the higher incidence of renal disease in young men; however, these statistics may reflect the higher survival rate for women in general.

The true incidence of acute renal failure (ARF) in the elderly population is unknown. Multicenter studies from Europe report a threefold increase in the prevalence of ARF in older people. In a recent prospective multicenter European study of ARF involving hos-

pitalized patients, more than 60% were older than age 60 years, with about one-third being older than age 70 years. The most frequent causes of ARF were acute tubular necrosis (ATN) (45%), prerenal azotemia (21%), acute on chronic renal failure (CRF) (13%), and obstructive uropathy (10%). Nearly half of the patients who later developed ARF had normal renal function on presentation to the hospital, and the mortality rate was 45%. The incidence of prerenal azotemia in the elderly population is probably much higher; data from a series of elderly patients in the United Kingdom and Spain show that of 571 patients with azotemia, approximately 40% had evidence of prerenal ARF.

The true incidence of glomerular disease cannot be determined in elderly patients because there are no population-based studies. Until recently, glomerulonephritis in geriatric patients received little attention because of fear of an increased risk of morbidity and mortality associated with renal biopsy, and to the more difficult interpretation of histopathological findings. The increased proportion of elderly people entering renal replacement therapy programs has prompted nephrologists to reconsider the actual prevalence of glomerulonephritis occurring in this population. Referral patterns suggest that proteinuria or renal dysfunction is the most common reason for renal biopsy. Of these cases, nearly one-third of the renal biopsies performed were for nephrotic syndrome, while another 50% were divided fairly equally between evaluation of acute and chronic renal insufficiency. Because of concerns for the safety and efficacy of the biopsy procedure in the past, older studies may not reflect the true incidence of disease. In fact, the Medical Research Council's glomerulonephritis registry in the United Kingdom shows that the percentage of elderly patients in this registry has increased from 6% in 1978 to 21% in 1990, suggesting that the number of geriatric patients undergoing a renal biopsy for the diagnosis of glomerular disease has also increased. As a result, the incidence of glomerulonephritis in the elderly population may be much higher than previously recognized and is probably higher than in younger groups less than 60 years of age. Idiopathic glomerulonephritis is

**TABLE 86-1****Histology of Nephrotic Syndrome in Geriatric Patients**

the most common diagnosis, accounting for 65% to 70% of all reported cases. Whatever the histology, a renal biopsy from an elderly individual is more likely to show more than one pathological lesion as well as more evidence of senescence; there is more likely to be more glomerular scarring, interstitial fibrosis, and tubular dropout. Among the glomerulonephritides (Table 86-1), membranous appears to be most common (37.7%) while minimal change (11.2%), amyloidosis (11.1%), focal segmental (7.4%), membranoproliferative (mesangiocapillary) (6.6%), other proliferative (13.3%), and nonproliferative (9.0%) account for the bulk of the rest. Because most patients with diabetic nephropathy can be presumptively diagnosed based on certain clinical criteria, its true incidence is underreported. For patients presenting with ARF, crescentic glomerulonephritis (31%), acute interstitial nephritis (18.6%), ATN with nephrotic syndrome (7.5%), atheroemboli (7.1%), light-chain cast nephropathy (5.9%), and postinfectious (5.5%) are the most commonly reported lesions. Longitudinal studies from Italy depict a changing pattern of glomerulonephritis in the elderly population with a much higher incidence of crescentic glomerulonephritis. Elderly patients with chronic renal insufficiency are most likely to have hypertensive nephrosclerosis, focal segmental glomerulosclerosis, interstitial nephritis, or amyloidosis on renal biopsy.

There has been very limited information on the prevalence of renal disease in the very elderly (aged 80 years or older). Recently, a retrospective study reviewing renal biopsies from 2001 to 2003 compared the very elderly with other age groups. The most common indications for performing a renal biopsy in the very elderly group were ARF (23%), nephrotic syndrome (33%), and acute glomerulonephritis (20%). Other indications included: (1) rapidly progressing renal failure (6%), (2) chronic kidney failure (17%), and (3) asymptomatic urinary abnormalities (1%). Surprisingly, membranous nephropathy accounted for only a small percentage of idiopathic nephrotic syndrome (15%), while pauci-immune crescentic glomerulonephritis was the most common diagnosis (19%). At least

40% of the biopsies performed revealed pathological findings that would benefit from therapeutic intervention, suggesting that kidney biopsies can be beneficial in the very elderly.

Epidemiological surveys from England report that the prevalence and incidence of nephrotic syndrome in geriatric populations are similar if not higher than those in adult populations of all ages, with about 11 new cases per million people per year. Approximately 18% of newly diagnosed adults with nephrotic syndrome are aged 60 years or older. The incidence may be higher, but many geriatric patients are not referred for renal biopsy because of age and functional status. This is especially true for patients older than 80 years of age. Geriatric patients with type II diabetes mellitus are also generally underreported in renal biopsy registries because diabetic nephropathy may go unrecognized and because the diagnosis can often be made without the necessity of a renal biopsy. Yet, more than 40% of elderly patients with ESRD have underlying diabetic nephropathy as the etiology of their ESRD.

The frequency of renovascular disease in elderly patients is unknown. It may be an unexpected finding in patients investigated for nonrenal disease, but the prevalence of severe renal artery stenosis increases with age. Autopsy studies show that among those persons older than age 70 years at the time of death, 62% had severe renal artery disease. When present, renal artery stenosis was bilateral in 50% of cases.

A high incidence of renal artery stenosis among normotensive subjects also has been found in several patient cohort studies undergoing angiography. In one report of patients older than 50 years of age, 69% of patients with hypertension and 35% without hypertension had identifiable renal artery atherosclerotic disease. A prospective study from Duke University of 1302 patients undergoing elective diagnostic cardiac catheterization showed significant unilateral renal artery stenosis in 11% of patients and bilateral stenosis in 4%. Multivariate and univariate analyses identified several predictors of increased risk for significant renovascular disease,

including older age, multivessel coronary artery disease, and congestive heart failure. Interestingly, a history of hypertension did not predict the presence of renal artery stenosis in this cohort. Other angiographic studies evaluating the prevalence of renal artery stenosis in patients with vascular disease have shown similar findings with a prevalence between 11% and 42%. The highest prevalence is found among patients with peripheral vascular and aorto-occlusive disease or aneurysms.

Renovascular disease may also occur in the setting of renal insufficiency. A recent report from Italy of a study that included elderly patients with renal insufficiency of unclear etiology and mild proteinuria (less than 1 g/d) showed a 56% prevalence of significant (>70%) stenosis at angiography. Other investigators have done angiographic screening of patients older than age 50 years entering renal replacement therapy programs and report finding renal artery stenosis in 11% to 16% of these patients.

## ACUTE RENAL FAILURE

### Definition

ARF is defined as a sudden deterioration in renal function, sufficient to cause retention of nitrogenous waste in the body. The anatomic and physiological changes occurring in the aging kidney, the presence of comorbid medical conditions, the use of excessive numbers of medications, and the higher prevalence of obstructive uropathy are all contributing factors that can cause ARF in the elderly.

### Clinical Presentation

Prerenal azotemia, or functional ARF as a result of extracellular fluid contraction, is the main cause of ARF in the geriatric population (Table 86-2). The reduced renal blood flow and GFR associated with aging leads to a reversible state of ARF in the setting of superimposed volume contraction. Loss of fluids, internal fluid redistribution, decreased cardiac output, and medications are responsible for the majority of cases of prerenal ARF in older individuals. Common medications associated with ARF are nonsteroidal anti-inflammatory drugs (NSAIDs), angiotensin-converting enzyme inhibitors (ACEIs), and angiotensin II type 1 receptor antagonist blockers (ARBs). The development of ARF secondary to ACEIs or ARBs in patients with renal artery stenosis is well known; however, recent publications also report cases of ACEIs and ARB-related ARF in patients without renovascular disease. Furthermore, a study from France reported that 67.5% of ACEI-induced cases of ARF in elderly patients occurred in the absence of renal artery stenosis.

NSAID-induced ARF occurs more frequently in the elderly than in the general population, mainly because of the coexistence of conditions associated with decreased effective intravascular volume or true volume depletion. Under these conditions, the kidney is dependent on prostaglandins to maintain renal perfusion. Loss of this important autoregulatory mechanism results in ARF. Advanced age is an independent risk factor for developing ARF in patients taking NSAIDs, presumably because of the normal, aging-related decrease in GFR.

Parenchymal causes of ARF include ATN, acute interstitial nephritis, acute glomerulonephritis, and renovascular disease. The

most common cause of biopsy-proven intrinsic renal failure in geriatric patients is rapidly progressive glomerulonephritis (RPGN). Vasculitis and idiopathic crescentic glomerulonephritis make up more than half of these cases.

ATN results from prolonged renal ischemia or from exposure to nephrotoxins. The causes of ATN are multifactorial; however, the most common cause in elderly patients is volume depletion associated with renal hypoperfusion and ischemia. Complications of major surgery including intraoperative hypotension, postoperative fluid loss, and arrhythmias account for approximately one-third of the cases of ATN in the elderly. Sepsis-induced ATN occurs just as commonly. Nephrotoxic drugs may also cause ATN. The former often results from a failure to consider age-related decreases in GFR while the latter is responsible for 10% of the cases or ARF. Aminoglycoside nephrotoxicity and radiocontrast-induced ARF are just two examples of drug-induced renal failure.

Cholesterol emboli are another important cause of ARF in the geriatric population. Cholesterol crystals can become dislodged from atherosclerotic plaques during intra-aortic procedures, or may even arise spontaneously, and cause ARF by obstructing small renal arteries. This entity is important to consider in any patient with ARF following cardiac catheterization or aortic angiography. Rhabdomyolysis, in the settings of acute immobilization, infectious disease, cerebrovascular accidents, crush injury, hyperosmolar conditions, hyponatremia, hypothermia, or falls is being recognized as a prevalent and underdiagnosed cause of ATN in the elderly.

Postrenal or obstructive renal failure is one of the most significant causes of ARF in the elderly and may occur in 5% of the cases presenting with ARF. Common causes of obstruction in the geriatric population include benign prostate hypertrophy; prostate carcinoma; retroperitoneal or pelvic neoplasms such as non-Hodgkin's lymphoma, carcinoma of the bladder, cervix, ovaries, or rectum; and neurogenic bladder caused by diabetes mellitus. Prompt diagnosis is extremely important because prognosis for recovery of renal function depends on the length of time that the kidney is obstructed. As such, it is considered a true urological emergency. Therefore, it is imperative to exclude the possibility of obstruction in any elderly patient presenting with ARF, especially in those situations of previous urological pathology or recent abdominal surgery.

### Diagnosis

A complete history, with special attention to potential nephrotoxic drugs and clinical clues of obstruction, is fundamental in establishing the diagnosis of ARF. Physical findings may be very subtle in the elderly but postural hypotension is usually present in states of true volume depletion. The use of urinary sodium concentration or the fractional excretion of sodium as markers to differentiate between acute prerenal azotemia and established ATN are less reliable in the geriatric population than in the general population. Elderly individuals have a decreased ability to concentrate their urine or respond to sudden changes in sodium and water balance because of aging-related disturbances in the tubular handling of water and/or sodium reabsorption. Thus, in geriatric patients, the urinary indices may not be helpful in differentiating between prerenal and ATN as a result of the physiological changes associated with aging, and early nephrologic consultation is warranted in any patient with ARF. The most reliable indicator of prerenal azotemia is its reversal following

**TABLE 86-2****Acute Renal Failure in the Elderly**

Prerenal (acute reversible renal hypoperfusion) ARF	Renal or intrinsic ARF	Obstructive ARF
Hypovolemia	Acute glomerulonephritis	Ureteral and pelvic

ACEI, angiotensin-converting enzyme inhibitor; ARF, acute renal failure; NSAID, nonsteroidal antiinflammatory drugs; SLE, systemic lupus erythematosus.

Modified from Macias-Nunez JF, et al. Acute renal failure in the aged. *Semin Nephrol.* 1996;16:333.

volume repletion, and a judicious volume challenge is indicated if the patient is not volume overloaded.

In the setting of ARF, ultrasonography is the imaging procedure of choice for the diagnosis of obstruction, kidney stones, or renal masses, and for the determination of renal size. Although there are a few case reports of urinary tract obstruction secondary to prior malignancy with minimal or no dilation of the collecting system on ultrasonography, these cases are rare, and duplex Doppler ultrasonography may prove to be a useful diagnostic tool in these instances. Computerized tomography (CT) scans often do not provide any further diagnostic information and should be reserved for the cases in which the kidneys are poorly visualized.

Indications for renal biopsy in elderly patients with ARF include the following: (1) prolonged oliguria (3 to 4 weeks); (2) ARF associated with systemic illnesses such as vasculitis; (3) RPGN; (4) acute tubulointerstitial nephritis; and (5) anuria in the absence of obstruction. Advanced age alone is not a contraindication for renal biopsy.

### Treatment

The management of ARF in the elderly should follow the same principles as in the general population. Maintenance of adequate intravascular volume is paramount in maintaining renal blood flow. Hemodynamic monitoring in critically ill patients is preferable with right-heart catheterization as indicated to measure pulmonary capillary wedge pressure. The routine use of renal dose dopamine for ARF should be discouraged because of the lack of demonstrated efficacy in this setting. Fenoldopam, a dopamine-1 receptor agonist, has not been shown to have any benefit in the outcome of ATN. Moreover, combinations of  $\alpha$ - and  $\beta$ -adrenergic agonists, or colloid and blood transfusions to increase cardiac output to supranormal levels are not helpful in the setting of established ATN. Medications should be adjusted for the degree of renal insufficiency and appropriate dietary sodium, potassium, and protein restrictions instituted. A Foley catheter should be placed to rule out and treat bladder outlet obstruction. A previously placed Foley catheter should always be replaced regardless of whether it flushes.

The indication for renal replacement therapy in ARF must be individualized for each patient and depends upon the volume status of the patient and the need for solute clearance. Timely renal consultation early in the course of ARF often obviates the need for dialysis intervention. For those patients with ARF requiring dialysis, the required dialysis dose has not been established and may hinge on volume status and catabolic state. Acute peritoneal dialysis (PD) and hemodialysis have been used in elderly patients with ARF with similar results and complications as in younger adult patients. Continuous renal replacement therapy (CRRT) offers the advantages of slow controlled ultrafiltration and efficient removal of small and middle molecules. The CRRT multicenter trials have shown mixed results in mortality compared with conventional dialysis but promising results with large volume hemofiltration CRRT. Biocompatible membranes are used routinely now because of improved outcomes in patients with ARF.

Nutritional considerations warrant special consideration for any elderly patient with renal disease. There are advantages in early appropriate restriction of sodium, potassium, phosphorus, and protein for the elderly patient with ARF. Restricting the dietary protein

intake to 0.6 to 0.8 g/kg ideal body weight for those patients not yet on dialysis results in maintenance of nitrogen balance, control of metabolic acidosis, and control of elemental phosphorus normally excreted by the kidney. Potassium and sodium are restricted to 2 g per day based on nutritional requirements. For those patients on dialysis, the dietary protein restriction can be liberalized to 1 to 1.2 g/kg ideal body weight for hemodialysis patients and 1.2 to 1.4 g/kg ideal body weight for patients on PD.

### Prognosis

The mortality rate for ARF remains high. For critically ill patients, mortality rates approach 60% with sepsis-induced ARF having a worse prognosis than nonseptic ARF. The influence of age on outcome of ARF is debated; however, the elderly patient generally has less renal reserve than a younger individual and is more prone to ARF. As a result, an elderly patient has a moderately worse prognosis than a corresponding younger patient. Nevertheless, age alone should not be used as a discriminating factor in therapeutic decisions concerning ARF.

## GLOMERULAR DISEASES

There has been a change in the clinical approach toward patients with ARF or nephrotic syndrome in the geriatric population. Because of the routine use of ultrasonographic guidance for renal biopsies, as well as improvements in the size and accuracy of the biopsy needle, the success rate in obtaining a diagnostic renal biopsy that provides clinically useful information has improved to greater than 90%. This is important because ESRD caused by glomerulonephritis currently accounts for approximately 24% of patients requiring dialysis in Europe and a higher percentage in the United States. Recent reviews suggest that the clinical features, histopathologic classification, and clinical outcome of glomerulonephritis in elderly patients are comparable to those of younger adults. Based on these observations, a reliable diagnosis and an effective therapeutic plan have to be advocated in elderly patients similar to the approach taken in younger adult patients.

### Clinical Presentation

Elderly patients with biopsy-proven glomerulonephritis usually present with the following major clinical syndromes (Table 86-3): (1) nephrotic syndrome (50% to 60% in some series), characterized by heavy proteinuria and a variable tendency toward edema, hypertension, renal failure, and hyperlipidemia; (2) acute glomerulonephritis or acute nephritic syndrome, characterized by the abrupt clinical onset of hematuria, proteinuria, decreased GFR, fluid and salt retention, hypertension, and occasionally, oliguria; (3) RPGN, whose clinical pattern includes a more insidious onset, progressive loss of renal function, and, frequently, oliguria; (4) chronic glomerulonephritis, characterized by CRF accompanied by various degrees of proteinuria, hematuria, and hypertension, and a clinical course that is usually progressive but which may be protracted over several years; and (5) urinary abnormalities with few or no symptoms. Although an asymptomatic urinary abnormality is the single most common clinical presentation in younger patients, it is rarely found

**TABLE 86-3**

**Comparison of Mode of Presentation Between Patients Aged Older Than 65 Yrs and Those Aged 20 to 65 Yrs at the Time of Biopsy and Reported as Having Idiopathic Glomerulonephritis**

MODE OF PRESENTATION	AGE			
	>65 Yrs		20–65 Yrs	
	(n)	(%)	(n)	(%)
Acute renal failure	37	14	240	11
Asymptomatic urinary abnormality	17	6	841	38
Chronic renal failure	54	20	168	7
Hypertension	4	1	40	2
Nephrotic syndrome	140	52	715	32
Unknown	19	7	226	10
Total number	271	100	2230	100

Modified from Davison AM, Johnston PA. Idiopathic glomerulonephritis in the elderly. *Contrib Nephrol.* 1993;105:41.

in geriatric populations (age  $\geq 60$  years). The reason for this difference may be the aging-related reduction in renal function, or the lack of routine urine testing in elderly patients even though they are more likely to be seeking advice for medical complaints.

### Acute Glomerulonephritis and Rapidly Progressive Glomerulonephritis

These two clinical syndromes often present as ARF in the elderly. The glomerular findings are similar to younger adults presenting with crescentic glomerulonephritis. Indeed, crescentic glomerulonephritis is the most common lesion found on renal biopsy in this group of geriatric patients. With aging, the glomerular basement membrane (GBM) becomes thickened and the glomerular surface area decreases. These changes tend to render the glomerulus more liable to immune complex-mediated damage. In addition, the increased prevalence of autoantibody and immune complexes in the elderly increase the risk of immunological-mediated glomerular injury, but these factors may be offset by the reduced renal plasma flow and the aging-associated impairment of cell-mediated immunity. This leads some investigators to believe that there may be other, currently unrecognized factors that increase the risk of developing glomerulonephritis in geriatric patients.

Postinfectious glomerulonephritis is present in approximately 6% to 8% of biopsy series of geriatric patients presenting with ARF. The clinical features are similar to those found in younger adults, but the clinical course is associated with a higher incidence of hypertension, azotemia, and ESRD. Underrecognized is postinfectious glomerulonephritis associated with aortofemoral bypass graft infections, especially those caused by *Salmonella*, which result in increased risk for morbidity and mortality.

Renal biopsies from patients with RPGN demonstrate extensive accumulation of cells in Bowman's space (crescents). Although the disorders associated with RPGN can be classified as either primary glomerular disorders or secondary forms associated with infectious processes, multisystem disorders, or drug reactions (Table 86-4), three disorders deserve special attention in the elderly: antineutrophil

**TABLE 86-4**

**Classification of Rapidly Progressive Glomerulonephritis**

Primary diffuse crescentic glomerulonephritis
Type I: anti-GBM-mediated disease without pulmonary hemorrhage (with anti-GBM)
Type II: immune complex-associated disease (without anti-GBM or ANCA)
Type III: pauci-immune (with ANCA)
Type IV: mixed pattern (with anti-GBM and ANCA)
Type V: pauci-immune (without ANCA or anti-GBM)
Fibrillary and immunotactoid glomerulonephritis
Focal sclerosis (rare)
IgA nephropathy
Mesangiocapillary glomerulonephritis (especially type II)
Membranous glomerulonephritis (with or without anti-GBM)
Superimposed on another primary glomerular disease
Associated with infectious disease
Hepatitis B and C
Histoplasmosis
Infective endocarditis
Influenza (?)
Mycoplasma infection
Poststreptococcal glomerulonephritis
Visceral abscesses
Associated with multisystem disease
Carcinoma (lung, bladder, prostate)
Goodpasture disease (anti-GBM with pulmonary hemorrhage)
Lymphoma
Mixed (IgG/IgM) cryoglobulinemia (hepatitis C)
Relapsing polychondritis
Henoch–Schönlein purpura
Systemic lupus erythematosus
Systemic polyangiitis
Churg–Strauss syndrome
Microscopic polyangiitis (with ANCA)
Wegener granulomatosis (with ANCA)
Other variants
Associated with medications
Allopurinol
Bucillamine
D-Penicillamine
Hydralazine
Rifampin

ANCA, antineutrophil cytoplasmic antibodies; GBM, glomerular basement membrane.

Modified from Glasscock RJ. *Syndromes of glomerular diseases*. In: Massry SG, Glasscock RJ, eds. *Textbook of Nephrology*. 4th ed. Baltimore: Williams and Wilkins; 2000:650.

cytoplasmic antibody (ANCA)-associated renal disease, hepatitis C-associated cryoglobulinemia, and Henoch–Schönlein purpura.

ANCA-associated renal disease presents as a small-vessel systemic vasculitis or as an isolated primary pauci-immune necrotizing and crescentic glomerulonephritis. The clinical manifestations depend on the severity and stage of the underlying renal injury. The light microscopy morphologic findings range from focal sclerosing glomerulonephritis associated with hematuria and/or proteinuria, to more aggressive patterns including necrosis with a few crescents to overt cellular crescentic changes associated with acute nephritis and a rapid loss of renal function. In addition, a few biopsy specimens will depict changes compatible with chronic glomerulonephritis and global glomerular sclerosis associated with slowly progressive nephritis and CRF.

The most common finding in elderly patients undergoing renal biopsy for the clinical syndrome of RPGN is isolated primary pauci-immune glomerulonephritis. The ANCA is positive in approximately 45% to 55% of these cases. Another 20% to 25% of patients present with identical histological findings associated with small vessel vasculitis in an extrarenal location. This group of patients has been classified as microscopic polyangiitis (MPA) according to the Chapel Hill Consensus Conference on the Nomenclature of Systemic Vasculitis. In addition to the renal histological pattern described above, another 12% to 15% of patients present with granulomatous inflammation involving the respiratory tract and will be diagnosed with Wegener's granulomatosis.

The two known staining patterns of ANCA are perinuclear and cytoplasmic. The perinuclear pattern (P-ANCA) is usually associated with specific reactivity against myeloperoxidase and is associated with MPA in approximately 40% to 55% of cases. This pattern is strongly associated with primary pauci-immune crescentic glomerulonephritis in 60% to 70% of cases. Finally, approximately 15% to 25% of patients with Wegener's granulomatosis present with reactivity to perinuclear ANCA.

The cytoplasmic ANCA (C-ANCA) pattern is associated with reactivity against a serine proteinase (proteinase 3, PR3), and is found in 65% to 75% of patients classified as Wegener's granulomatosis, 35% to 45% of patients with MPA, and 30% to 40% of patients with primary pauci-immune glomerulonephritis. Patients with one of these three diagnoses are ANCA-negative in 10% to 20% of the cases. The treatment of this group of disorders has only been reported in uncontrolled studies.

In addition to testing patients presenting with vasculitis for ANCA, it is important to test for antiglomerular basement membrane (anti-GBM) disease and for systemic lupus erythematosus, because the treatment options for these two diseases are quite different. Referral to a nephrologist is essential for proper diagnosis and therapy.

Most patients with MPA or primary necrotizing and crescentic glomerulonephritis achieve remission with therapeutic regimens based on corticosteroids in combination with either intravenous or oral cyclophosphamide. Recent reviews report a long-term remission rate of 60% to 85% in patients with these disorders, but relapse occurs in up to 40% of patients within 18 months. For those patients with systemic vasculitis such as Wegener's granulomatosis, long-term remission is not possible without the use of cyclophosphamide. The 5-year survival rates cited for patients older than 60 years of age at the time of diagnosis (31%) compared with those subjects younger than 60 years of age (83%), is partly a result of the reluctance of clinicians to use cyclophosphamide in the elderly patient. Although the toxicity and side effects of steroids and cytotoxic drugs increases with age, these medications should not be necessarily withheld in the elderly patient. Careful examination of the renal biopsy, clinical presentation, and the ANCA reactivity are needed to design an appropriate treatment strategy with the benefits and risks of therapy individualized for each patient. The reader is referred to reference sources listed at the end of this chapter for details about specific therapeutic protocols.

Hepatitis C-associated cryoglobulinemia associated with vasculitis and hepatitis can also present with RPGN. Associated findings include purpuric and necrotizing skin lesions in exposed areas, fever, acroparesthesia, Raynaud's phenomenon, urticaria, neuritis, arthralgia, and hepatosplenomegaly. Some series from Italy report hepatitis

C as the second most common cause of secondary glomerulonephritis in the elderly population; amyloidosis is the most common cause. Warm serum immunoelectrophoresis shows abnormal circulating immunoglobulins that precipitate in the cold with a polyclonal immunoglobulin (Ig) G component and a monoclonal IgM or IgA with rheumatoid factor activity (type II cryoglobulinemia). Light microscopic examination of renal biopsies reveals diffuse endocapillary proliferation with a few crescents. Electron microscopic findings of typical intracapillary deposits and subendothelial electron-dense deposits, with a crystalline substructure, confirm the diagnosis.

In the past, immunosuppressive therapy was used for cryoglobulinemia-related vasculitis, but the effect of immunosuppression on chronic hepatitis C infection has not been well defined and could potentially accelerate viral replication. Reduction in the level of cryoglobulins by intensive plasma exchange may be associated with clinical remission, while the administration of interferon- $\alpha$  and ribavirin have the potential to revolutionize therapy for this disease but await future controlled trials.

Henoch-Schönlein purpura presents as a small-vessel vasculitis with IgA-dominant immune deposits, typically involving the skin, gut, and glomeruli, and is frequently associated with arthralgias or arthritis. Potential precipitating conditions in the elderly include alcohol abuse, malignancies, and some medications. This pattern of etiologic agents contrasts with the pattern in younger patients in whom infections are the most common etiologic agent. In general, Henoch-Schönlein purpura is a benign, self-limited disorder, but the renal dysfunction is significantly worse in geriatric patients than in younger adults. Elderly patients present with a higher prevalence of hypertension, azotemia requiring renal replacement therapy, and histopathological features of IgA mesangial deposits and proliferation with crescentic glomerulonephritis. Improvement in renal function has been noted in some patients after plasma exchange and immunosuppressive therapy, but the small number of cases reported and the lack of a controlled study prevent any firm therapeutic recommendations.

## NEPHROTIC SYNDROME

### Definition

The nephrotic syndrome consists of urinary protein losses in excess of 3.5 g per 1.73 m<sup>2</sup> body surface area per day in association with hypoalbuminemia, hypercholesterolemia, and peripheral edema. The onset is usually insidious but it can be explosive. As the major clinical manifestation of nephrotic syndrome is generalized edema, many geriatric patients are often misdiagnosed as having congestive heart failure. The etiologies of nephrotic syndrome include the primary glomerular diseases (minimal change disease, focal and segmental glomerulosclerosis, membranous glomerulonephropathy, membranoproliferative glomerulonephropathy), and glomerulonephritis secondary to systemic infiltrative diseases, neoplasms, chronic infectious diseases, atheroembolic disease, or medications.

### Pathophysiology

The glomerular capillary wall consists of three components: the endothelial cells, basement membrane, and the podocytes. The

membrane component or components responsible for the loss of the filtration barrier have been debated. Over the past decade, the podocytes' molecular structure has been found to play a major role in maintaining the integrity of the basement membrane. The molecules in the slit diaphragm allow for interdigitation of adjacent podocytes, maintenance of distance between the slits (35 to 45 nm), and the polarity of the podocytes. Loss of the function of certain podocytes molecules, podocin, nephrin, CD2AP, and  $\alpha$ -4 actinin, are responsible for congenital nephrotic syndrome. Immunohistochemical studies in rats and human with nephrotic syndrome have shown redistribution of the nephrin in the podocytes. The function of these various molecules in the podocytes may have a major effect on the course of treatment in adult nephrotic syndrome.

### Clinical Manifestations

The nephrotic syndrome often goes unrecognized in geriatric individuals since it frequently presents in an atypical manner. Because many geriatric patients have poor tissue turgor, edema frequently develops only in dependent portions of the body. Moreover, many geriatric patients with nephrotic syndrome will develop edema at higher plasma albumin concentrations than younger adults, who, in turn, develop edema at higher albumin levels than children. Hypercoagulability is a frequent complication of nephrotic syndrome and is particularly concerning in a geriatric patient who is bedridden. In some series, the proportion of patients who present with a significant complication such as deep venous thrombosis (DVT) or pulmonary embolus (PE) approaches 50%. Compared to younger adults, geriatric patients with nephrotic syndrome have a higher incidence of hypertension, hypercholesterolemia, and nonselective proteinuria, a lower value of GFR, and often present with microscopic hematuria. Microscopic hematuria is particularly common in geriatric patients with minimal change disease or hypertensive glomerulosclerosis. Geriatric age individuals with biopsy-proven minimal change disease present with persistent hematuria in 30% of cases and with hypertension in 44% of cases.

The pathogenesis of coincident nephrotic syndrome and ARF remains obscure. Some investigators suggest that ARF results from an increase in intrarenal pressure and the presence of proteinaceous casts, which obstruct tubule lumens. This pathogenetic mechanism suggests that a renal biopsy should be obtained to aid in the management of the nephrotic syndrome in the elderly.

Approximately 5% of geriatric patients who present with nephrotic syndrome will have an underlying malignancy or develop one within 1 year. Of these patients, 33% will be diagnosed with membranous glomerulonephritis. In older series, 10% to 33% of geriatric individuals with nephrotic syndrome caused by membranous glomerulonephritis were found to have a malignancy, but recent studies suggest that patients with nephrotic syndrome do not have a higher incidence of malignant disease when compared to age-matched individuals without nephrotic syndrome. Currently, most investigators recommend that the only test that should be performed in all patients presenting with nephrotic syndrome is a chest x-ray, because carcinoma of the lung is the most common malignancy associated with membranous glomerulonephritis, and a stool guaiac, because carcinoma of the colon is the next most common location for an unsuspected malignancy. If no evidence for a malignancy is found on physical examination, chest x-ray, or by occult blood testing, the patient should be carefully followed for the next 15

months for the appearance of a malignancy, and receive routine care thereafter.

The clinical presentation of nephrotic syndrome secondary to another systemic illness does not differ substantially between geriatric and younger adult patients. All patients presenting with nephrotic syndrome should be evaluated for amyloidosis, plasma cell dyscrasias, diabetes mellitus, hepatitis, syphilis, human immunodeficiency virus (HIV), collagen vascular disorders, and cryoglobulins.

### Histopathology Findings

The interpretation of the histologic appearance of renal biopsy specimens from geriatric individuals with nephrotic syndrome represents a challenge to the nephropathologist because of the normal aging-related changes that occur in the kidney. Glomerulosclerosis (which can occur in up to 40% of remaining glomeruli), vascular changes (especially hypertension-induced changes), and interstitial fibrosis are common findings in normal kidneys from geriatric individuals and must be considered in evaluating renal pathology. However, minimal change disease and membranous glomerulopathy retain their typical histological appearance and can be diagnosed by an experienced nephropathologist.

Secondary amyloidosis should be distinguished from primary amyloidosis because its prognosis is better and specific therapy aimed at the underlying disease may be available. Special stains including immunofluorescent antibodies against amyloid A protein are useful in diagnosing cases of secondary amyloidosis. Amyloid may be found infiltrating the glomerulus and may also be found infiltrating blood vessels and, occasionally, peritubular spaces. Light-chain glomerulopathy is characterized by the deposition of immunoglobulin light chains in a nodular or diffuse fashion along the basement membranes within the kidney. Kappa light chains are found more frequently than lambda light chains.

Occasional patients will show histological findings compatible with nonamyloid fibrillary glomerulopathies. Two categories are recognized on the basis of their ultrastructural appearance: fibrillary glomerulonephritis with extracellular deposits randomly oriented (10 to 30 nm diameter fibrils) and immunotactoid glomerulonephritis characterized by microtubular structures in a parallel array (25 to 45 nm diameter). Because these entities are fairly uncommon, the prognosis and therapeutic interventions remain obscure.

Focal segmental glomerulosclerosis was recently associated with atheroembolic renal disease. The pathologic changes produced by cholesterol atheroemboli show distinctive pathological findings including glomerular collapse, foot process fusion, podocyte hypertrophy, and frequently, acute tubular injury. Very few elderly patients present with IgA nephropathy with nephrotic range proteinuria.

### Diagnosis

Nephrotic syndrome is often masked by other comorbid conditions in geriatric individuals. The patient evaluation should include microscopic examination of the urine by a nephrologist; serum creatinine; blood urea nitrogen (BUN); albumin; and cholesterol; 24-hour urine collection to quantitatively measure proteinuria and creatinine clearance; serum protein electrophoresis and immunoelectrophoresis; urine protein electrophoresis and immunoelectrophoresis; antinuclear antibody (ANA); antideoxyribonucleic acid (anti-DNA)

antibody titer; hepatitis B and C serologies; syphilis serology; complement profile; cryoglobulins; lipoprotein profile; HIV; chest x-ray; and stool guaiac. Renal biopsy is essential for establishing the definitive histopathological diagnosis.

### Treatment and Prognosis

Definitive treatment for the nephrotic syndrome depends upon the histologic type. Regardless of the histology, some generalizations about therapy can be made. Every effort should be made to control blood pressure. ACEIs and ARBs are rapidly becoming mainstays in treatment because of their efficacy in reducing proteinuria and numerous studies suggesting that they may slow progression of renal disease. If these agents are not tolerated, other agents can be substituted with a goal of maintaining the blood pressure at around 125/75 mm Hg. Low-protein diets also have their utility, especially for those patients with heavy proteinuria and dietary counseling, which is reimbursed by Medicare, can prove to be invaluable. The value of hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase inhibitors remains unproven in patients older than age 75 years, but should be considered for younger patients. Any discussion of therapy should take into consideration the patient's financial status, as some medications may prove to be prohibitively expensive.

The treatment of membranous nephropathy remains controversial because the natural history of the disease includes spontaneous remissions and exacerbations. In general, one third of patients will be expected to improve; another third will follow an indolent course, while the final third will progress to ESRD. Risk factors for progression include male sex, poorly controlled hypertension, renal insufficiency, and heavy proteinuria. Recent reevaluation of data from multiple trials suggests that targeted therapy to those individuals most likely to progress is beneficial. ACEIs and/or ARBs should be considered for control of both hypertension and proteinuria. Likewise, for those individuals likely to progress, a combination of steroids with cytotoxic agents or cyclosporine A should be considered with careful consideration of dose, duration, and other comorbid factors, but treatment with steroids alone is not beneficial. In most instances, it may be more prudent to carefully observe the patient and watch for signs of progression before embarking on a course of steroids and immunosuppressive therapy. Because therapy continues to evolve, nephrology consultation is appropriate.

Geriatric patients with minimal change disease tend to have a favorable prognosis as younger cohorts and respond equally well to corticosteroid therapy. Moreover, relapses following cessation of prednisone therapy are relatively infrequent. For some individuals, stopping NSAID therapy is the only intervention necessary. Otherwise, patients with minimal change disease should be treated with prednisone for 2 to 4 months before they are diagnosed as corticosteroid-resistant. If a relapse does occur, these patients should be treated in the same way as younger adults. In steroid-resistant geriatric patients, cyclophosphamide can be used, but the normal age-associated decrease in GFR should be taken into account in determining the appropriate dose. In most instances, a dose of 1 to 2 mg/kg body weight per day that is commonly used in younger patients must be reduced, and the white blood cell count monitored carefully. Other treatment options include calcineurin inhibitors or mycophenolate.

The management of renal amyloidosis is supportive and specific treatment depends on the type: primary versus secondary. For primary amyloidosis, there is no specific therapy but selective cases may benefit from chemotherapy and autologous or allogeneic hematopoietic cell transplantation. The role of this therapeutic approach is difficult to define in geriatric populations since many patients die before any benefit can be seen. For secondary amyloidosis, further amyloid deposition can be prevented if the underlying disease process can be treated. No therapy is available that effects the resolution of amyloid deposits, but treatment that reduces the supply of amyloid fibril precursor proteins can improve survival and preserve renal function.

Patients presenting with histologic features of light chain glomerulopathy have a 5-year renal survival of 40%. These patients should undergo bone marrow examination to test for the presence of multiple myeloma. Treatment with cytotoxic drugs (melphalan and prednisone) may diminish proteinuria and preserve renal function. However, cytotoxic therapy in the absence of multiple myeloma is controversial. Plasmapheresis, in addition to cytotoxic therapy, should be considered for patients with ARF caused by multiple myeloma, but the likelihood of success of this intervention hinges on the blood paraprotein level.

## RENOVASCULAR DISEASE

### Definition

Renovascular disease is an important cause of secondary hypertension and progressive renal insufficiency in the elderly population. The spectrum of diseases that can cause anatomic narrowing of a main renal artery or its branches include many different disease entities (Table 86-5). The two main types of renal arterial lesions are atherosclerosis and fibrous dysplasia, but atherosclerosis accounts for almost 90% of cases in the elderly population.

**TABLE 86-5**

#### Categories of Renal Artery Disease

Aneurysms
Arteriovenous malformations
Atherosclerosis
Dissection of the aorta
Embolic disease
Fibrous dysplasia
Kawasaki disease
Neurofibromatosis
Other systemic necrotizing vasculitides
Polyarteritis nodosa
Takayasu arteritis
Thromboangiitis obliterans
Thrombotic diseases
Trauma
Vasculitis involving the renal artery

Modified from Greco BA, Breyer JA. Natural history of renal artery stenosis. *Semin Nephrol.* 1996;16:5.

## Clinical Features

As mentioned above, the clinical presentation of renal artery stenosis ranges widely from asymptomatic forms to the two well-known clinical syndromes: renovascular hypertension and ischemic nephropathy (Table 86-6). Renovascular hypertension is defined as the secondary elevation of blood pressure produced by any of a variety of conditions that interfere with the kidney's arterial circulation and cause renal hypoperfusion. With the exception of oral contraceptive use (not common in the elderly) and alcohol ingestion, renovascular hypertension is the most common cause of potentially remediable secondary hypertension. Renovascular hypertension has an estimated prevalence of 2% to 3% in the general hypertensive population. It is important to differentiate between renal artery stenosis and renovascular hypertension because the diagnosis of the latter requires verification that sufficient stenosis (>75% to 80%) is present to produce renal tissue ischemia and to initiate the sequence of events leading to hypertension. Clinical clues that might prompt the clinician to diagnose renal artery stenosis in elderly patients are onset of hypertension after the age of 50 years; accelerated or difficult to control hypertension; coexisting diffuse atherosclerotic vascular disease; acute or subacute renal insufficiency after initiation of therapy with ACEIs or ARBs; recurrent pulmonary edema; grades III to IV hypertensive retinopathy; abdominal or flank bruit; hypokalemia in the absence of diuretic use; erythrocytosis; microangiopathic hemolytic anemia; and hyperuricemia. Although renovascular hypertension is thought to occur primarily in white patients, recent cohort studies report a similar prevalence in selected African-American and white patients. Whether these racial variations are a result of differences in screening and referral patterns or true differences in the prevalence of renovascular hypertension remains to be determined.

Ischemic nephropathy can be defined as a clinically significant reduction in the GFR resulting from a partial or complete luminal obstruction of the preglomerular renal arteries of any caliber. It occurs in patients with hemodynamically significant stenosis in the renal artery of a solitary kidney or in both renal arteries if two kidneys are present.

Patients with atheromatous renovascular disease may present with different clinical courses. ARF can be precipitated by treatment of hypertension with ACEIs or ARBs during a period of days to weeks after initiating therapy. This form of ARF may be associated with hypoperfusion of the kidneys caused by inhibition of angiotensin II-dependent autoregulatory pathways in the glomerulus. Nevertheless, many patients with renovascular disease tolerate these agents and are usually not referred for additional noninvasive studies. Thus, the sensitivity of using the response to ACEIs or ARBs as a screening test for the presence of renovascular disease is unknown. Currently available clinical data estimate that 6% to 38% of patients with significant renal vascular disease will develop ARF following ACEI or ARB therapy. Other antihypertensive agents have been reported to cause reversible ARF in the setting of ischemic nephropathy. These cases should be distinguished from those hypertensive patients without ischemic nephropathy who develop ARF in the setting of renin-dependent decreases in renal perfusion such as intravascular volume depletion or low effective circulating volume states such as congestive heart failure or cirrhosis.

Renovascular disease may also present as progressive azotemia in a patient with suspected or documented renovascular hypertension (Table 86-7) or as recurrent pulmonary edema associated with poorly controlled hypertension and renal insufficiency (23% prevalence in some series). Postulated mechanisms include angiotensin II-induced myocardial dysfunction, diastolic dysfunction secondary to left ventricular hypertrophy, and reduced pressure natriuresis in conjunction with subsequent volume expansion. Azotemia in an elderly patient, in the absence of clinical and laboratory signs, that is suggestive of another renal disease, or of unexplained azotemia requiring initiation of renal replacement therapy, should prompt an evaluation for renovascular disease. Because the age of patients with ESRD is increasing, there is a significant proportion of patients on dialysis with renovascular disease.

Atheroembolic renal disease falls into the category of renal insufficiency induced by glomerular ischemia. This entity has been usually described in patients with clinical evidence of atheromatous occlusive disease following invasive intra-aortic diagnostic or

therapeutic procedures, although spontaneous embolic episodes have been described. Important clinical clues associated with this disease are the presence of unexplained eosinophilia, purpuric-ischemic skin lesions, and the presence of heavy proteinuria, which can be in the nephrotic range.

### Diagnostic Approach

There are three basic steps in making the diagnosis of renovascular hypertension: (1) renal artery stenosis must be demonstrated by angiography; (2) the stenotic lesion must be pathophysiologically significant; and (3) the hypertension is corrected by intervention to relieve the stenosis. In practice, the diagnosis of ischemic nephropathy is almost always made in the context of coexisting hypertension.

In the appropriate clinical setting such as those just described (worsening renal failure, bland urinary sediment, proteinuria <1 g/day, hypertension, and evidence of peripheral vascular disease), the clinician should develop a high index of suspicion for the disease. According to the triage approach proposed by Mann and Pickering, the patient may be classified as having a low (less than 1% prevalence), moderate (5 to 15% prevalence), or high (>25% prevalence) pretest probability for renovascular disease. Patients classified in the low-risk group should not undergo further workup. The presence of azotemia in the high-risk group may impair the reliability of the noninvasive tests and may justify performing renal angiography regardless of the results of noninvasive tests. In patients with intermediate probability, noninvasive testing has the most important diagnostic role.

ACEI radionuclide scintigraphy is currently the most thoroughly evaluated noninvasive test for the diagnosis of renovascular hypertension. This study should be preceded by measurement of a random morning plasma renin activity (PRA). Evaluation of ACEI renography by using technetium-99m diethylenetriamine pentaacetic acid (<sup>99m</sup>Tc-DTPA) has shown high sensitivity and specificity (91% to 94%) for renovascular hypertension. Currently, renal scintigraphy with Hippuran or Mag3 (renal plasma flow tracers) before and after ACEIs is the functional test of choice to diagnose ischemic nephropathy. Two limitations should be kept in mind: (1) these tests have not been evaluated in patients with azotemia and (2) while a positive test predicts an improvement in blood pressure, it is not known whether it also predicts an improvement in renal function.

Duplex ultrasound scanning of the renal arteries is a screening tool with promising early results. Duplex ultrasound scanning also

allows measurement of kidney size and is not affected by medications or the level of GFR. The reported sensitivity and specificity values are in the low to mid-90% range. The main disadvantage of this test is that it is technically demanding and has a steep learning curve for each center that performs this test. Another caveat is that accessory renal arteries are difficult to detect and study.

The magnetic resonance angiography (MRA) has been effective in screening for the presence of renal artery stenosis with the advantage of being less exposure to contrast media and less invasive than the arteriogram. A publication from Italy reports overall accuracy of 97% for correct depiction of severe renal artery stenosis when compared head-to-head to conventional angiography. However, there have been recent case reports of patients with chronic kidney disease (CKD) developing nephrogenic systemic fibrosis (NSF)/nephrogenic fibrosing dermopathy (NFD) thought to be secondary to gadolinium exposure. Therefore, the future use of MRA for defining renal artery stenosis in patients with kidney disease needs to be redefined. Another highly accurate noninvasive study for screening for renal artery stenosis is the spiral (helical) CT scan with CT angiography, but there is a risk of contrast nephropathy with the spiral CT scan in patients with CKD.

The gold standard for diagnosing renal artery stenosis is selective renal angiography. Intra-arterial digital subtraction angiography (IADSA) or a CO<sub>2</sub> angiogram also provides excellent anatomic detail and requires less contrast than conventional angiography. The technique of intravenous DSA, although less invasive, does not provide comparable resolution to the aforementioned tests because of the high degree of bowel gas and motility artifacts, and usually requires a significantly larger amount of nephrotoxic contrast material.

The second step in making the diagnosis of renovascular hypertension is to determine the pathophysiological significance of the lesion. Some of the diagnostic tests already mentioned are also used to assess this issue. Selective renal vein renin measurement is the gold standard for establishing the functional nature of the stenotic lesion and helps predict the blood pressure response to revascularization. In general, a renal vein renin ratio of  $\geq 1.5$  between the two renal veins is predictive of a beneficial blood pressure response following surgery or angioplasty, but failure to lateralize does not predict a negative response. Overall, the blood pressure response to revascularization cannot be determined with confidence by using renal vein renin measurements. A positive captopril renogram with <sup>99m</sup>Tc-DTPA has been reported to accurately predict the blood pressure response to revascularization. The predictive value of all of these

**TABLE 86-8****Results of Surgical Revascularization for Atherosclerotic Ischemic Nephropathy**

Study No.	Year	No. of Patients	No. (%) Improved	No. (%) Stable	No. (%) Deteriorated

tests in terms of the renal function outcome after revascularization is largely unknown and awaits further study.

### Treatment

Several studies clearly demonstrate that renovascular disease is a progressive disease. Of patients with the disease, 50% can expect their stenosis to worsen, with reported rates varying between 1.5% and 5% per year. In general, the rate of progression of renal insufficiency and the likelihood of deterioration of renal function correlates positively with the extent of stenosis at the time of diagnosis. This implies that correction of renal artery stenosis might be worthwhile in preventing renal failure or to improve renal function. This is important because elderly patients with progressive atherosclerotic renal artery obstruction leading to ESRD do not respond well to renal replacement therapy. Of all geriatric patients with ESRD, these patients have the poorest overall survival, with a 27-month median survival rate and only a 12% 5-year survival rate.

There is no universally accepted treatment in patients with renovascular disease. Therapy must be individualized and based upon the general status of the patient, the presence of any concomitant disease, and the local surgical or angiographic experience of the center. The role of surgical revascularization in the management of renovascular hypertension was first established by the U.S. Cooperative study 20 years ago. Increasingly good results have been reported (Table 86-8). The combined cured and improved rate is reported to be approximately 82% with a mortality rate of approximately 1% when one includes patients of all ages. The results are less favorable in elderly patients with atherosclerotic renal artery stenosis because their prognosis is determined by the extent of atherosclerosis elsewhere and the potential risk of cholesterol embolization during the operation.

Recovery of renal function after surgical revascularization depends upon whether the patient has unilateral or bilateral atherosclerotic renal disease, or a solitary kidney. With regard to unilateral stenosis, revascularization has only a modest beneficial effect on renal function. This occurs mainly because any increase in GFR in the revascularized, poststenotic kidney, is often offset by a decrease in the GFR of the contralateral kidney. Furthermore, when severe azotemia is present in a patient with unilateral stenosis, it is usually a result of severe bilateral nephrosclerosis, that is, bilateral renal parenchymal damage, which will not be improved by revascularization.

In bilateral stenosis, there are two possible clinical presentations. The first is bilateral occlusion of the renal arteries. This situation does not necessarily imply irreversible damage because the viability

of the kidneys may be maintained by a collateral blood supply. This is particularly true in patients who have a gradual onset of arterial occlusion. Clinical clues suggesting parenchymal salvageability include the following: angiographic demonstration of retrograde filling of the distal renal arterial system by collateral vessels; renal biopsy showing preserved glomerular architecture; kidney size >9 cm by ultrasound; and function of the involved kidney on renal scintigraphy. Some centers perform kidney biopsies in surgical candidates if their serum creatinine is higher than 4 mg/dL. In patients with serum creatinine less than 3 mg/dL, improved renal function (defined as a reduction in serum creatinine of >20% from the baseline value) postrevascularization can be expected in nearly half of patients undergoing this procedure.

The second scenario is bilateral stenosis without total occlusion or stenosis in a solitary kidney. Improvement in renal function is frequently seen after reconstructive surgery in 75% to 89% of these patients. Unlike cases with total renal occlusion, revascularization to preserve renal function is not worthwhile in patients with severe renal insufficiency (serum creatinine >4 mg/dL) because they usually have advanced underlying renal parenchymal disease (nephrosclerosis and/or atheroembolic disease), which is not improved by revascularization. In older patients, severe atherosclerosis of the abdominal aorta may render an aortorenal bypass technically impossible. In such cases, alternate bypass techniques have been used, such as splenorenal bypass for left-kidney revascularization and hepatorenal bypass for right-kidney revascularization. Considering the significant risks of progressive renal occlusive disease and renal failure that are associated with medical management of this condition in elderly patients, the surgical results showing a favorable influence of revascularization on the natural history of untreated atherosclerotic renal artery disease are of interest and merit further study.

Initially percutaneous transluminal renal angioplasty (PTRA) had a limited role in elderly patients because of the concomitant presence of aortic atherosclerotic disease, making any endovascular procedure hazardous and technically difficult. Restenosis following dilatation of atheromatous lesions was quite common and a significant number of elderly patients present with ostial lesions, which are not amenable to PTRA. PTRA with the use of endovascular stenting devices have come into vogue with improved outcome of the revascularization of these ostial lesions. Surgical intervention is presently recommended for more complicated lesions, or angioplasty failures. One advantage of angioplasty over surgery is that it can be undertaken in patients who have prohibitively high surgical risks that are related to systemic atherosclerosis.

## TUBULOINTERSTITIAL NEPHRITIS

Tubulointerstitial nephritis involves a heterogeneous group of disorders that primarily affect the renal interstitium and tubules and only secondarily involve the other structures of the kidney. The etiology of these diseases includes medications, infectious agents, physical, chemical, immunological, hereditary, and unknown causes. Elderly patients are predisposed to the development of this entity because of the high prevalence of polypharmacy, comorbid diseases, and impaired immunological mechanisms to control infections. Interstitial disease in the geriatric patient should be thoroughly investigated. Aging-related interstitial changes may precipitate clinical features compatible with tubulointerstitial nephritis but should be considered as a diagnosis of exclusion after other possible underlying conditions are ruled out.

### Functional Defects

The pattern of tubular dysfunction will vary depending on the major site of injury. Salt retention, hypertension, edema, and heavy proteinuria are absent in the early phases of the disease. The tubulointerstitial lesions are localized either to the cortex or to the medulla. Cortical lesions can affect either the proximal or distal tubule. Proximal lesions are characterized by Fanconi's syndrome (bicarbonaturia, glucosuria, hyperuricosuria, hyperphosphaturia, and aminoaciduria). Distal lesions are associated with impaired ability to secrete protons (distal tubular acidosis) and potassium, and decreased reabsorption of sodium. Medullary lesions that involve the papilla manifest by sodium wasting and an impaired ability to concentrate the urine maximally.

In addition to abnormalities associated with tubular defects, other clinical features are also suggestive of tubulointerstitial nephritis. Anemia that is out of proportion to azotemia may signify the early failure of erythropoietin synthesis. High levels of parathyroid hormone (PTH) with mild azotemia may be secondary to reduced tubular generation of the biologically active form of vitamin D, 1,25-(OH)<sub>2</sub>D<sub>3</sub>. Microscopic examination of the urine sediment typically shows leukocytes and white cell casts, but may be surprisingly bland as well. Eosinophiluria, detected by Hansel's stain, may be seen in the setting of drug-induced tubulointerstitial nephritis, especially when it is secondary to  $\beta$ -lactam antibiotics. Despite the number of typical clinical manifestations, early renal consultation should be obtained because the diagnosis of tubulointerstitial disease can only be established by renal biopsy.

### Acute Tubulointerstitial Nephritis

Tubulointerstitial nephritis can be divided into acute and chronic forms. Of the etiologies associated with acute tubulointerstitial nephritis, two entities deserve special attention in geriatric populations: acute bacterial pyelonephritis and acute drug-induced hypersensitivity reactions.

#### Acute Bacterial Pyelonephritis

For most, but not all, elderly individuals, the presentation and course of infection involving the urinary tract is no different from that found in younger patients. Bacterial pyelonephritis occurs equally in both

sexes and is the most common form of renal disease in the elderly. Prostatic hypertrophy and the decreased antimicrobial properties of prostatic fluid may be the cause of increased incidence in elderly men. In geriatric-aged women, the vaginal pH changes as the epithelium atrophies, resulting in replacement of the usual microbial flora by gram-negative organisms. These changes predispose the patient to infection. Urinary tract infection is strongly correlated with dementia, which may be caused by fecal incontinence and perineal soiling in women, although the reason in men is unknown.

In those patients with an atypical presentation, the disease is a diagnostic challenge. Costovertebral angle tenderness and urinary symptoms may be absent, whereas bacteremia (>50%), central nervous system changes, tachypnea, and hypotension are common. There are even case reports of asymptomatic acute pyelonephritis presenting as ARF.

Therapy includes hemodynamic support and eradication of the infection. Uncomplicated pyelonephritis improves within 48 to 72 hours after initiation of adequate antimicrobial agents. Ultrasonographic surveillance is indicated if no improvement is noted in this time frame to exclude obstructive lesions or perinephric abscess.

### Drug Hypersensitivity

Drug-induced acute interstitial nephritis has been reported with most medications. The classic description is the one associated with methicillin (and other  $\beta$ -lactam antibiotics). The sulfonamides were the first antibiotics reported to cause acute interstitial nephritis and were followed by the penicillins in the 1950s. Methicillin was implicated in numerous, well-documented, biopsy-proven cases and became the prototype for drug-induced acute interstitial nephritis. Subsequent reports included a vast number of antibiotics as the cause of this syndrome. Unfortunately, many of the anecdotal reports lack large numbers of cases and do not include biopsy findings, thereby bringing into question the validity of the causal association. A high index of suspicion of acute interstitial nephritis in the clinical setting of acutely deteriorating renal function is the key to diagnosis.

The clinical presentation is characterized by the tetrad of rash, arthralgia, fever, and ARF, which are present in only 10% of cases. The urine sediment shows nonnephrotic range proteinuria, white cell casts, and eosinophiluria in 40% of the cases.

The other significant group of drugs causing acute interstitial nephritis in the elderly population are the NSAIDs. All classes of NSAIDs induce this syndrome, with or without minimal change nephropathy. Acute interstitial nephritis has been reported after 2 to 18 months of NSAID therapy and may be sufficiently severe as to require renal replacement therapy. Most cases are reversible after the drug is stopped. Unlike antimicrobial-induced interstitial nephritis, signs of hypersensitivity (fever, rash, eosinophilia, eosinophiluria) are usually absent. Some cases are associated with nephrotic range proteinuria and glomerular lesions similar to minimal change or membranous nephropathy. The most culpable NSAID appears to be fenoprofen, although all NSAIDs induce this pathology.

The best therapeutic option for treating drug-induced acute interstitial nephritis is to identify and withdraw the offending agent, although this may not be obvious in a hospitalized patient on multiple medications. Although there are anecdotal reports of using corticosteroids for treatment, there are no controlled trials showing that their use alters the rate or extent of renal recovery.

## Chronic Tubulointerstitial Nephritis

The clinical course of tubulointerstitial disease depends on the primary cause and the magnitude of the renal insult. Sporadic exposure to nephrotoxic materials results in a more indolent clinical course and progressive loss of renal function. Chronic tubulointerstitial nephritis is associated with tubular atrophy and interstitial polymorphonuclear and mononuclear cell infiltrates. The etiological factors and the pathogenetic mechanisms are essentially the same as in the acute forms of interstitial nephritis. Special considerations in elderly populations are the chronic forms associated with analgesic abuse, neoplasms, and aging-associated interstitial disease.

### Analgesic Nephropathy

There are no scientifically acceptable data documenting the safety of NSAIDs on renal structure and function when taken chronically. Epidemiologic data show a ninefold increased relative risk of ESRD in subjects ingesting 5000 or more doses of NSAIDs when compared with age-matched control subjects; however, it has been difficult to demonstrate a cause-and-effect relationship between analgesic use and CRF or ESRD. In an intriguing study from Sweden, regular use of acetaminophen and aspirin as analgesics was associated with an increased risk of CRF. In fact, subjects who chronically took more than 1.4 g of acetaminophen per day had a fivefold increased risk for CRF. The risk was higher in those patients with preexisting CRF. This is particularly germane to the elderly population, which has a high incidence of CRF. Although the incidence of analgesic nephropathy in the ESRD population has declined in those countries where analgesic combinations containing phenacetin were removed from the market, the incidence of this condition appears to be increasing in the elderly population in some countries outside of the United States. The frequency of renal papillary necrosis, the hallmark lesion of analgesic associated nephropathy, as a primary cause or contributing cause of ESRD is unknown because of the infrequent radiographic proof of this diagnosis.

A review of the literature that included studies from Europe, Australia, and North America concluded that the use of NSAIDs in the general population is safe and effective when used in therapeutic dosages for a limited period of time. There are no acceptable epidemiologic or clinical data regarding the risk of NSAIDs for CRF, renal papillary necrosis, or ESRD. There are also no experimental or clinical data on whether NSAIDs affect the rate of progression of renal disease. Consequently, the National Kidney Foundation recommends the design and implementation of controlled studies on the renal and cardiovascular safety of chronic NSAIDs by themselves, or in the presence of another known cause of renal disease, and the prospective evaluation of combinations of NSAIDs and other analgesics prior to their release onto the market.

### Neoplastic Diseases Associated with Interstitial Nephritis

Many neoplastic diseases infiltrate the interstitium of the kidney with variable clinical implications. Leukemias and lymphomas are the most common malignancies associated with direct invasion of the renal parenchyma. Multiple myeloma may affect the kidney by several different mechanisms. One is involvement of the tubulointerstitial structures resulting from the filtration of toxic light chains and the formation of intratubular casts from aggregates of light chains

and Tamm–Horsfall mucoprotein. This clinical entity is known as myeloma kidney and may present as an indolent, chronic form of renal failure, or as isolated tubular dysfunction with well-preserved GFR. The clinical manifestations of the tubular involvement include the Fanconi's syndrome, renal tubular acidosis types I or II, and hyperphosphaturia.

The diagnosis of myeloma kidney should be confirmed by kidney biopsy when the clinical picture suggests tubulointerstitial involvement. The presence of tubular involvement has important therapeutic implications. Even though plasmapheresis has been used with rewarding results in the settings of acute myeloma kidney, the role of plasma exchange in chronic tubulointerstitial nephritis secondary to light chain cast nephropathy awaits further investigation and definition. The addition of high-intensity chemotherapy has improved survival rates in cases associated with ARF but optimal therapy for chronic tubulointerstitial nephritis is less certain. Prevention is the most effective therapy for myeloma kidney. Institution of effective chemotherapy and prevention of tubular obstruction are fundamental. The role of colchicine to inhibit the intratubular cast formation is still experimental and should be used only in controlled studies.

### Aging-Associated Interstitial Disease

Tubulointerstitial nephropathy of the elderly is defined as the decreased renal tubular function associated with aging, including decreased ability to concentrate urine; decreased renin and aldosterone production; and histologic changes, including interstitial fibrosis and mononuclear cell infiltrates. The clinical presentation is essentially identical to any other form of interstitial nephritis. This entity should be considered only as a diagnosis of exclusion.

## CHRONIC KIDNEY DISEASE

The clinical presentation of CDK as a result of irreversible damage to renal parenchyma in elderly patients includes essentially the same constellation of symptoms and signs as in the general population. Medical management directed to potassium homeostasis, sodium and water balance, acid–base status, calcium and phosphate metabolism, hypertension, cholesterol, anemia, and nutritional support, follow the same guidelines and parameters as described for the general population. The reader is referred to a general nephrology textbook for details.

Recently, CDK has been divided into various stages ranging from CKD stage 1 to 5 depending on the estimated glomerular filtration rate (eGFR) (Table 86-9). Levey's formula for eGFR was derived from data obtained from the Modification of Diet in Renal Disease (MDRD) Study and takes into account various variables including age, gender, race, serum creatinine, serum albumin, and serum urea. The eGFR was initially established primarily in Caucasians with moderate renal insufficiency, but was later validated in African-Americans, diabetic and renal transplant recipients. However, the equation has not been validated in the elderly (older than 70 years). Another limitation of the eGFR is that the assay used for measurement of the serum creatinine has not been standardized, making it difficult to interpret between different institutions. Although there are limitations with the eGFR, it is recommended for clinical use by established organizations with some exceptions, including muscle

wasting states, ARF, pregnancy, paraplegic, vegetarian, and extreme weights.

In the NHANES III, the prevalence of CKD in the United States was 11% (19.2 million). A large percentage had CDK stage 3 (7.6 million) with a smaller percentage had CKD stage 4 (400 000). The elderly account for approximately 60% to 80% of those with eGFR less than 60 mL/min/1.73 m<sup>2</sup>. The rate of progression in elderly is similar to the general population in those with diabetes and severe CDK.

CDK has been associated with an increase in cardiovascular risk and metabolic derangements. Fried et al. demonstrated that there is an increased association in both morbidity and mortality in the elderly with CKD stage 3. Cardiovascular morbidity and mortality increased with worsening renal function compared with those with normal renal function. The high incidence of cardiovascular disease in the elderly is probably secondary to both traditional and non-traditional risk factors (elevated homocysteine, C-reactive protein, albuminuria, uremic toxins, anemia, and renal bone disease). Interestingly, elderly patients with mild decrease in eGFR (50 to 59 mL/min/1.73 m<sup>2</sup>) have been shown to have less increase in mortality than their younger cohorts. But when the eGFR decreases further, there is an increase in mortality similar to the younger cohorts, suggesting that mortality stratification may differ in different age groups at certain CKD stages.

The renal osteodystrophy from secondary hyperparathyroidism begins at CKD stage 3. The interplay between the decreased production of 1,25-(OH)<sub>2</sub> vitamin D<sub>3</sub>, an increased serum phosphate, and a low serum calcium results in hyperplasia of the parathyroid gland and increase production of the PTH. In the elderly, there is less exposure to ultraviolet rays, resulting in a decreased synthesis of vitamin D<sub>3</sub>, cholecalciferol, which is the substrate for 25-hydroxylase in the liver. Because of the low level of 25-(OH) vitamin D<sub>3</sub>, there is less conversion to the active form, 1,25-(OH)<sub>2</sub> vitamin D<sub>3</sub>. Both the decreased sun exposure and the gradual loss of renal function contribute to the low level of 1,25-(OH)<sub>2</sub> vitamin D<sub>3</sub>. Acceptable intact PTH levels for CKD stages 3, 4, and 5, are 35 to 70, 70 to 110, and 150 to 300 pg/mL, respectively. For values over these limits, the patient is considered to have secondary hyperparathyroidism. Both the 25-(OH) vitamin D<sub>3</sub> and PTH level should be measured. If the intact PTH level is elevated, 25-(OH) vitamin D<sub>3</sub> should be replaced for CKD stages 3 and 4 according to Tables 86-10 and 86-11. For CKD stage 5, the active form of vitamin D, 1,25-(OH)<sub>2</sub> vitamin D<sub>3</sub>

should be prescribed to maintain the intact PTH level between 150 and 300 pg/mL. The complications from renal osteodystrophy can have a significant morbidity in the elderly, with an increased incidence of bone fracture, height loss, soft tissue deposition of calcium, and cardiovascular disease. The early detection of secondary hyperparathyroidism lessens the likelihood of parathyroid hyperplasia and associated morbidities.

Anemia is a common finding in the elderly and has been linked to an increased morbidity and mortality associated with left ventricular hypertrophy, worsening congestive heart failure and myocardial ischemia. The NHANES III study found that CDK accounted for 12% of all causes of anemia in the elderly. As kidney disease advances, the production of erythropoietin is decreased and accounts for the anemia; however, other causes for anemia need to be excluded. For CKD stages 3, 4, and 5, the goal for anemia management is a hemoglobin between 11 and 12 mg/dL. Higher hemoglobin values have not been found to decrease cardiovascular events.

Renal replacement modalities are initiated at CKD stage 5 and have become commonplace for the elderly within the last decade. The U.S. Renal Data System (USRDS) from 2006 show that approximately 48% of the incident patients receiving some form of renal replacement therapy are older than 65 years of age and 25% are older than 75 years of age. Those patients older than 75 years of age constitute the fastest growing segment on dialysis, with their numbers tripling in the last decade. Moreover, it is estimated that 60% of all ESRD patients are older than age 65 years. These statistics should not be surprising given the high incidence of hypertension and diabetes mellitus in the elderly, accounting for 40% to 60% of the new cases of ESRD. Tubulointerstitial disorders (13.5%),

TABLE 86-10

## Stages of Chronic Kidney Disease

CKD stage	GFR (mL/min/1.73m <sup>2</sup> )	description
Stage 1	>90	kidney damage
Stage 2	60–89	kidney damage mild dec GFR
Stage 3	30–59	kidney damage mod dec GFR
Stage 4	4–15	29 kidney damage sever dec GFR
Stage 5	< 15	end stage (dialysis)

**TABLE 86-11****Vitamin D Supplement Therapy for CKD Stages 3 and 4**

<b>25(OH)VIT D</b>	<b>ERGO-CALCIFEROL DOSE (VIT D2)</b>	<b>DURATION</b>
<5 mg/dL recheck 25 (OH) vit D	50 000 IU/wk orally × 12 weeks then monthly or 500 000 IU IM	6 months
5–15 mg/dL recheck 25 (OH) vit D	50 000 IU/wk orally × 4 weeks then 50 000 IU/ month	6 months
16–30 mg/dL	50 000 IU orally every month	6 months

obstructive uropathy (11%), glomerular disease (10.5%), and polycystic kidney disease (2%) account for other causes of ESRD.

The selection of the type of renal replacement therapy for a geriatric patient must be individualized and requires a comprehensive evaluation that takes into account the medical and psychosocial problems that affect each individual patient. The fact that life expectancy is limited for the aged population does not justify depriving them of treatment. In fact, the first year survival on hemodialysis for octogenarians and nonagenarians can be greater than 50% and in a selective population of octogenarians 2-year survival rate can exceed 75%. Elderly patients with ESRD have multiple therapeutic options available, including center or home hemodialysis, PD, renal transplantation, and acceptance of death from uremia. Consultation with a nephrologist is essential for counseling the patient on the advantages and disadvantages of the various types of renal replacement therapy; planning for the start of renal replacement therapy, for provision of renal replacement therapy, and for formulating advance directives regarding cessation of renal placement therapy.

## HEMODIALYSIS

The primary treatment modality for geriatric patients with ESRD is in-center hemodialysis (78%). Despite their complex medical and psychosocial conditions, survival rates and rehabilitation rates are acceptable in elderly patients undergoing dialysis. In addition, these patients tend to be more compliant. The risk of death in patients undergoing dialysis increases with age and with coexisting diseases. Several studies report that age, diabetes, and cardiovascular disease are associated with a shorter survival. Survival for at least 5 years was 15% lower for patients older than 65 years of age at the initiation of hemodialysis than for younger adults in Europe. Early mortality (within the first 90 days after starting hemodialysis) is mainly secondary to comorbid conditions. The principal reported causes of death are acute myocardial infarction, cardiac arrest, sepsis, and malignancies. There are no significant differences in the percentage of deaths as a result of these various causes between geriatric patients and those younger than 65 years of age with the exception of cachexia, which accounts for 10% of the deaths in patients younger than age 65 years and increases to 36% in geriatric patients. Withdrawal from dialysis has been reported as the leading cause of death in dialysis patients older than 70 years of age. Other important factors associated with the decision to withdraw from dialysis are malnutrition, cancer, and dissatisfaction with the quality of life.

The success rate for vascular access for chronic hemodialysis in the elderly is similar to the rate in younger patients. The USRDS 2006 annual report indicated that the types of access for patients

older than 65 years of age were catheters, arteriovenous fistulas, and polytetrafluoroethylene grafts. There has been a noticeable change in the type of access placed with a decrease in the grafts, doubling of the catheters and no significant change in arteriovenous fistulas. The elderly experienced more access-related hospital stays than younger patients. Many investigators report a greater number of hospitalization days per year for the elderly patient on hemodialysis. This higher morbidity rate in geriatric patients on hemodialysis is the result of complications secondary to hypertension, cardiovascular disease, coronary or cardiac insufficiency, or left ventricular hypertrophy. Nevertheless, multiple surveys on geriatric patients with ESRD report a more positive overall satisfaction with life when compared to younger dialysis patients. Other investigators have reported that age has no value as a predictor of quality of life in patients with ESRD.

It is important to note that the quality of hemodialysis has improved markedly during the past decade facilitated by both new technology and new medications. Thus, historical data on hemodialysis may not be applicable to the way hemodialysis is performed currently in state-of-the-art hemodialysis centers. Technologic improvements include the development of high-flux hemodialysis, improved biocompatible membranes, bicarbonate dialysis, computer-controlled hemodialysis machines, and improved vascular accesses that can produce the high blood flows needed for high-flux hemodialysis. Major medical improvements include the availability of erythropoietin and intravenous iron for treating the anemia of ESRD, and intravenous vitamin D or its analogs and calcimimetic agent for preventing and treating secondary hyperparathyroidism. These advances have resulted in improved hemodialysis with shorter treatment times, less cardiovascular stress during hemodialysis, and an improved quality of life for hemodialysis patients of all ages.

## PERITONEAL DIALYSIS

Peritoneal dialysis has undergone dramatic changes within the last decade with the development and introduction of smaller, portable cycling dialysis machines that introduce and remove dialysis fluid in a timely, programmed manner. This has resulted in alterations in the dialysis prescription such that in most cases, the bulk of the dialysis exchanges can be done mechanically at night, limiting manual exchanges to one a day. The percentage of elderly patients treated with PD varies from country to country; in the United Kingdom 50% of elderly ESRD patients are treated with this modality, while in the United States, fewer than 10% of the geriatric patients with ESRD are on PD.

For the elderly patient, PD has important advantages, including decreased cardiovascular instability and arrhythmias, better maintenance of residual renal function, good control of hypertension, no need for vascular access surgery, efficacy of intraperitoneal insulin therapy (for diabetics), and better clearance of middle molecules. Despite its many advantages, many elderly patients do not choose this mode for psychosocial reasons such as inadequate family support, poor eyesight, and physical and mental impairment. Unlike in center hemodialysis, PD must be done daily and does require manual strength to lift 5-kg bags if a cycling dialysis machine is used.

The rate of infectious complications in elderly patients on PD is similar to that of younger patients, but elderly patients tend to have a more protracted course with increased morbidity and longer hospital

stays. Unfortunately, the incidence of peritonitis is still unacceptably high and varies from 0.5 to 3 episodes per patient per year. Moreover, more frequent episodes of peritonitis are associated with catheter loss.

As in hemodialysis patients, the incidence of malnutrition is increased in the elderly patient. The causes of malnutrition include comorbid conditions, as well as protein losses of 7 to 15 g/day with the dialysis procedure.

The choice of dialysis modality ultimately hinges on patient preference. Each modality has its own advantages and disadvantages and optimal rates of survival can be garnered through careful and planned counseling of the pre-ESRD patient.

## RENAL TRANSPLANTATION

Despite the high incidence of ESRD in the aged population, the USRDS indicates that fewer than 5% of geriatric ESRD patients have a working renal allograft as renal replacement therapy. Previous studies reported a higher mortality rate in older patients receiving a renal transplant. One-year patient and graft survival for patients older than 60 years of age averaged 62% and 57%, respectively, before the introduction of cyclosporine A. Improved pre- and post-operative management and better immunosuppressive therapy have improved survival to rates equivalent to those obtained in younger transplant populations. The reluctance for renal transplant in the elderly patients with ESRD is a result of their limited life expectancy. The probability of 10-year patient survival for deceased donor transplant recipients aged 65 to 69 years in the United States is 8%, contrasting with 50% to 85% 10-year survival rates in patients younger than 44 years of age.

Current data on elderly patients receiving transplant of deceased donor renal transplant report a 1-year patient survival rate ranging between 80% and 91% and 5-year survival exceeding 55%. Graft survival has increased to 80% at 1 year and 55 to 60% at 5 years. Patients dying with functioning renal allografts account for the majority of graft loss in older recipients (50%). Review of the USRDS database shows a lower incidence of rejection (accounting for 11% to 28% of graft loss at 1 year) when compared with younger renal allograft recipients. This difference may be explained by age-related "tolerance." Living-related transplantation offers improved patient and graft survival, and should be investigated in elderly patients with ESRD who are suitable candidates for transplantation. Another option for the elderly recipients is to be placed on the kidney transplant list for extended criteria donors (ECD). The ECD kidneys are marginal but allow for a larger donor pool and a decrease in waiting time for the elderly patients.

The leading causes of death in elderly patients receiving transplant are cardiovascular and infection. The majority of infections occur in the first 6 months posttransplant and are related to the degree of immunosuppression. Other series report cardiovascular events as the major cause of death in older transplant patients. Underlying cardiovascular disease may be a natural consequence of older age that is exacerbated by transplant-related complications such as posttransplant hypertension and steroid-induced diabetes. Other important causes of death include malignancy (13% to 16%) and gastrointestinal hemorrhage (16%).

The selection of transplant recipients in the elderly should follow the same clinical practice guidelines dictated for younger patients. In addition, a routine voiding cystourethrogram is recommended

for this age group. Careful attention should be given to the effect of transplantation on the quality of life and should ensure that patient's expectations as to benefits of transplantation are realistic.

Attenuated immune responsiveness in elderly patients undergoing transplant decreases the likelihood of immunologic rejection, but it is offset by a potentially increased risk of infection. The goal of any immunosuppression protocol in an elderly patient should be to decrease the risk of infection without causing rejection. Acute rejection requires the use of high doses of immunosuppression to prevent graft loss. The optimal immunosuppression regimen, involving cyclosporine A, prednisone, rapamycin, mycophenolate mofetil, tacrolimus, and azathioprine for long-term immunosuppression has not yet been addressed in prospective studies of elderly recipients undergoing renal transplant. In addition, new immunosuppressive agents, such as monoclonal antibodies, may confer a greater potential for reducing steroid and other immunosuppressive dosages while retaining excellent graft and patient survival.

# End-Stage Renal Disease

*Mark L. Unruh*

## DEFINITION

End-stage renal disease (ESRD) or kidney failure has been defined as having kidney function less than 15 mL/min/1.73 m<sup>2</sup>. Kidney failure may be caused by progression of a chronic nephropathy or by acute kidney injury (AKI). Kidney failure is associated with the inability to excrete waste products, control serum electrolytes, handle the daily dietary and metabolic acid load, and maintain fluid balance. In addition, kidney failure causes inadequate production of erythropoietin, deranged calcium and phosphorous metabolism, high blood pressure, and accelerated progression of cardiovascular disease. Uremia is the term used to describe the symptoms or symptom complex attributable to advanced kidney failure or ESRD. Most chronic nephropathies demonstrate inexorable progression to kidney failure. In general, there is a straight line relationship between the decrement in kidney function over time when the kidney function is plotted longitudinally. The rates of decline in kidney function vary by underlying nephropathy, by severity of hypertension and proteinuria, by modifying factors, and between individuals. Historically, the rate of decline could be estimated as 7 to 10 mL/min/year in those with untreated chronic nephropathies such as diabetic nephropathy. However, chronic nephropathies have similar effects on electrolyte homeostasis, causes of progressive decline in function, and manifestations of kidney failure so that classification by severity permits a better understanding of underlying routes to progression, symptoms, and hopefully, treatments of chronic kidney disease (CKD). In parts of the world with access to dialysis and kidney transplantation, renal replacement therapy (RRT) has been thought to be necessary when the glomerular filtration rate (GFR) decreases to less than 15 mL/min. “Kidney damage” has been defined as structural or functional abnormalities of the kidney, initially without decreased GFR, which over time can lead to decreased GFR. Markers of kidney damage include abnormalities in the composition of the blood or urine, or abnormalities in imaging tests. Proteinuria as a marker of

kidney damage has been studied most thoroughly. CKD is the term used to describe patients with a chronic decrease in GFR. There are different levels of CKD, and these levels have underpinned an international classification system (Table 87-1). It has been proposed that advanced CKD (GFR estimated <15 mL/min/1.73 m<sup>2</sup>) be classified as CKD Stage 5 with a suffix to classify the treatment modality. For example, a person treated by hemodialysis would be characterized as CKD Stage 5-D.

## EPIDEMIOLOGY

The prevalence of kidney failure is increasing rapidly worldwide; the projections are that the number of patients with kidney failure will double in the next 10 to 15 years. However, this is just the tip of the iceberg. Estimates are that there are 30 times as many people with CKD as compared to kidney failure. Approximately 14.7% of the U.S. adult population is thought to have some form of CKD. The majority of those with CKD Stage 1 and Stage 2 may not even be aware of their kidney disease. Nonmodifiable risk factors are important for risk stratification and for understanding the pathophysiology of CKD progression (Table 87-2). African-American patients with diabetes have a two- to threefold higher risk of developing kidney failure compared to white patients. Modifiable risk factors are important for both understanding disease progression and as a possible option for prevention or therapy. For example, the heavy consumption of analgesics has been associated with the development of kidney failure. The number of patients who develop kidney disease and at risk for developing kidney disease will increase with the increasing prevalence of diabetes and the aging of the population.

The burgeoning number of elderly with kidney failure has been caused by an increased incidence of kidney failure, greater access to RRT, and improved survival of both dialysis patients and kidney transplant recipients. The majority of patients in the United

**TABLE 87-1****Classification of Chronic Kidney Disease**

STAGE	DESCRIPTION	GFR mL/min/ 1.73 m <sup>2</sup>	RELATED TERMS	CLASSIFICATION BY TREATMENT
1	Kidney damage with normal or ↑ GFR	≥90	Albuminuria, proteinuria, hematuria	
2	Kidney damage with mild ↓GFR	60–89	Albuminuria, proteinuria, hematuria	
3	Moderate ↓GFR	30–59	Chronic renal insufficiency	
4	Severe ↓GFR	15–29	Chronic renal insufficiency, pre-ESRD	
5	Kidney Failure	<15 (or dialysis)	Renal failure, uremia, end-stage renal disease	D if dialysis T if kidney transplant recipient

Adapted from KDIGO definition and classification of chronic kidney disease: a position statement from *Kidney Disease: Improving Global Outcomes* ([www.kdigo.org](http://www.kdigo.org)).

States receiving hemodialysis are aged 65 years and older and the proportion of older patients undergoing hemodialysis is rapidly increasing (Figure 87-1). Hence, the growth of the ESRD population has been driven by those patients older than 65 years. This has been a worldwide phenomenon with a sevenfold increase in the rate of incident dialysis patients older than 75 years over the past two decades in Canada. Similar rates of increase of kidney failure in the elderly have been noted in Europe and Japan with a 10-fold increase in octogenarian hemodialysis patients in Japan. Indeed, the very recent marked increase in incidence of end-stage kidney failure documented by renal registries suggests that this spike of disease has been driven by the increased access to RRT. Older and sicker patients have been referred for hemodialysis in Asia, Australia, Europe, and North America as a result of perceived improvements in quality of life on dialysis, as well as economic and cultural factors. Once referred for kidney failure, older patients have been surviving longer with RRT as dialysis adequacy has increased and kidney transplant outcomes have improved. As a result of improvements in technology and greater access to dialysis, the increased prevalence of older adults undergoing RRT generally mirrors the aging trend of the general population.

### Acute Kidney Injury in the Elderly

AKI has been defined as an abrupt decrease in kidney function. This decrement in kidney function is reflected by an increase of serum creatinine from baseline of at least 50% often in the setting of reduced urine output. More than 50% of patients with AKI are older than 60 years of age. The elderly are thought to be predisposed to AKI owing to a reduced GFR, comorbid illness, and use of medications such as nonsteroidal anti-inflammatories and angiotensin-converting enzyme inhibitors. AKI may occur in elderly patients both in the outpa-

tient or inpatient setting. Obstruction from prostatic hypertrophy, volume depletion, and medications are prominent causes of AKI among the community-dwelling elderly. In the hospital setting, AKI may occur in up to 25% of critically ill patients and has been associated with a marked increase in mortality. Among hospitalized patients, AKI often arises from acute tubular necrosis or acute interstitial nephritis, although AKI merits a thorough evaluation for reversible causes. At present, the care of patients with AKI has been supportive care with acute dialysis and avoidance of further kidney injury from nephrotoxins. The indications for initiation of emergent or acute dialysis therapy in the elderly population vary little from younger patients (Table 87-3). The prognosis for survivors of AKI depends on severity of illness, chronic health conditions, length of time requiring dialysis, and preexisting kidney disease. A majority of patients who survive the initial insult of acute renal failure caused by acute tubular necrosis requiring dialysis will recover renal function and have adequate long-term kidney function. A large randomized trial of AKI in the hospitalized patient will determine the optimal frequency and intensity of dialysis following kidney failure caused by AKI in both young and old critically ill patients.

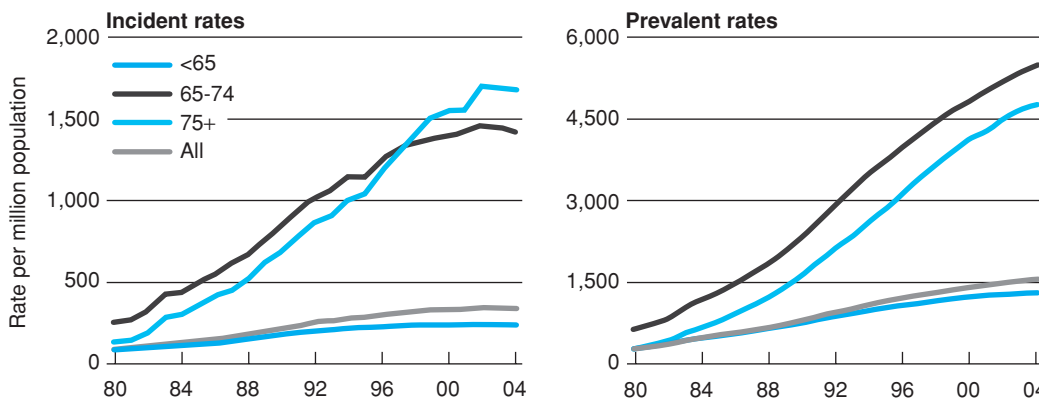

### PRESENTATION

#### Etiology of End Stage Renal Disease in the Elderly Population

The most common reported causes of ESRD in the elderly population have been shown to diabetes and hypertension in the United States and worldwide (Figure 87-2). The high proportion of kidney failure diagnosed as nephropathy as a result of diabetes and hypertension maybe in part because of a hesitance to perform a kidney biopsy in elderly patients in the face of usual indications such as nephrotic range proteinuria or unexplained renal failure. It may also be that age-related changes seen in many kidneys contribute to the disease-related changes of diabetes and hypertension to cause kidney failure in the elderly. However, several disease processes including primary kidney and vascular diseases present in older patients with kidney failure. Minimal change disease, usually more associated with a pediatric population, has a second peak in incidence during the sixth decade of life. The declining immunity associated with aging may also play a role in the second peak in incidence of post-streptococcal glomerulonephritis seen in the elderly. Pauci-immune necrotizing glomerulonephritis is also more common among those

	Smoking

**FIGURE 87-1.** Incident and prevalence rates for ESRD patients aged 75 yrs and older from 1980 to 2004. Rates adjusted for gender and race. (2006 Annual Data Report: Atlas of End-Stage Renal Disease in the United States. Bethesda, MD: National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases; 2006.)

older than 65 years. In addition to immune-mediated kidney disease, renovascular disease, a term used to describe arterial sclerosis in the kidney, is more common in older individuals. The presence of a clinically significant narrowing of the renal artery may lead to marked hypertension and kidney failure. Diagnosis involves magnetic resonance angiography, renal ultrasounds with Doppler, or a captopril renogram. The treatment of renal artery stenosis depends on the severity of the lesion and the clinical presentation. Options for treatment include renal angioplasty and stenting, renal bypass surgery, or medical management. The best treatment of renal artery stenosis among the elderly remains controversial with the current literature supporting conservative medical management. When older patients with CKD present with an acute increase in creatinine, they should be evaluated for reversible causes of their kidney failure such as obstruction or volume depletion.

## REFERRAL OF PATIENTS TO NEPHROLOGY

The geriatrician can influence the outcome of kidney failure with the timing of referral. In the past, physicians would limit access to dialysis and transplantation simply by not sending a patient to a nephrologist. While this still happens widely and is common in certain practices and in parts of the world with more limited health care, many patients should be referred for kidney-targeted therapy. Older patients with kidney failure maybe referred late to nephrologists with resulting poor outcomes. These patients may lose the opportunity to consider conservative therapy and require dialysis. The National Kidney Foundation Kidney Disease Outcomes Quality Initiative (“K/DOQI”) CKD Guidelines advises referral to a nephrologist after diagnosis under the following circumstances: a clinical action plan

cannot be prepared based on the stage of the disease, the prescribed evaluation of the patient cannot be carried out, or the recommended treatment cannot be carried out. In general, patients with GFR  $<30$  mL/min/1.73 m<sup>2</sup> (CKD Stages 4 and 5) should be referred to a nephrologist. It is difficult to estimate the proportion of late referrals that have been caused by the failure to recognize kidney failure in the elderly.

While most geriatricians may feel comfortable managing CKD and the concomitant metabolic and endocrine derangements, it is important to have nephrology involvement for patient education and preparation for dialysis. As outlined below, older patients with worsening CKD have a wide spectrum of choices for the treatment of kidney failure. It may take some time for the older patient to be educated and accept another chronic illness in the form of CKD, and then time to select a therapeutic approach to the kidney failure. Once therapy has been selected, some of the treatments require lead time prior to the development of an urgent indication for dialysis. For example, the placement of a vascular access may require a referral to a vascular surgeon, vein mapping, and months for fistula maturation and monitoring. A large European Study has demonstrated that late referral was associated with poor outcomes and that outcomes among older patients referred late were significantly worse than younger patients referred late. In many studies of referral timeliness, the cut-point has been arbitrarily set at 3 to 4 months; however, it is likely that this is still too short of a time to optimize the care of the older patient with kidney failure.

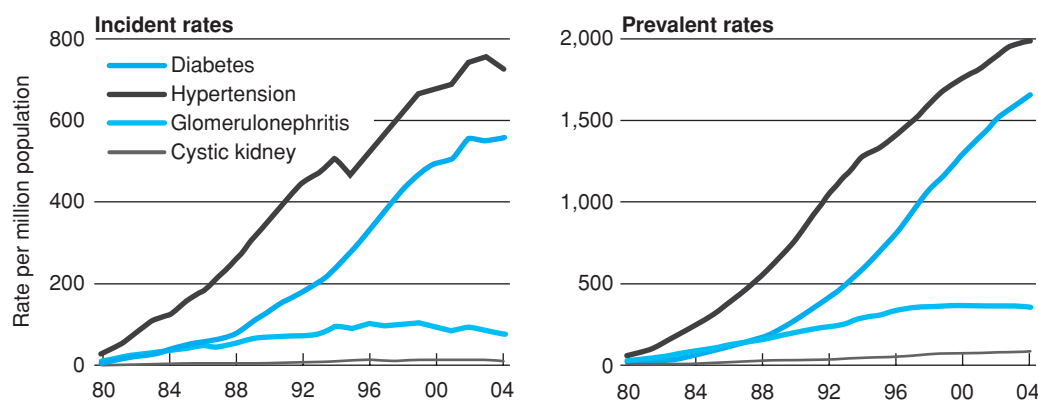

## Chronic Kidney Disease and Management of Chronic Health Conditions

Since the access to dialysis and kidney transplantation has been liberalized, there has been a steady shift of the population to not only older patients, but also to those burdened with comorbid disease. In one cohort of adult patients treated with maintenance hemodialysis in the United Kingdom, 90% of patients older than 65 years of age had two or more chronic health conditions. These findings are underscored by data from the 2006 United States Renal Data System, which demonstrate that patients 65 to 74 years of age have the multiple chronic health conditions and that the number of comorbid illnesses has been steady or increased in this population (Figure 87-3). Cardiovascular, musculoskeletal, and neurological problems predominate and adversely affected morbidity, hospitalizations mortality, and quality of life. Given the complexity of managing older patients with a high burden of comorbid disease, the geriatric team has the opportunity to play a crucial role in the care of these patients.

**TABLE 87-3**

### Indications for Urgent Hemodialysis

Refractory
Progressive fluid overload
Hyperkalemia
Metabolic acidosis
Uremia
Nausea, vomiting, poor appetite
Altered mental status (encephalopathy)
Bleeding diathesis (uremic platelet dysfunction)
Pericarditis

**FIGURE 87-2.** Incident and prevalent rates, by primary diagnosis from 1980 to 2004 for patients aged 75 yrs and older at initiation, and December 31 point prevalent ESRD patients, aged 75 yrs and older. Rates adjusted for age, gender, and race. (2006 Annual Data Report: Atlas of End-Stage Renal Disease in the United States. Bethesda, MD: National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases; 2006.)

The role of the primary care provider for older patient on dialysis or following kidney transplantation varies by local practice patterns and resources. At times, the nephrologist may subsume the role of the geriatric team given the frequent interaction with the patient at the dialysis units or the complexities of immunosuppressant following kidney transplantation. In other instances, geriatricians retain the primary role and nephrologists administer the dialysis in more of a consulting role. Those with advanced CKD have been shown to have gaps in their primary care, diabetes care, and cardiovascular disease care. This has been illustrated by The U.S. Renal Data System (USRDS) data demonstrating worse diabetes care among CKD Stage 4 to 5 patients compared to the general Medicare population as assessed by the performance of screening tests (Figure 87-4). It may be that nephrologists would benefit from targeted geriatric training, or as some propose, that there should be special geriatric dialysis units in order to address these gaps in care.

## INDICATIONS FOR INITIATION OF DIALYSIS

The most common symptoms present before initiation of maintenance dialysis in older patients tend to be anorexia, weight loss, fatigue, nausea, and vomiting. The recognition of uremia in the elderly patient, however, may prove more difficult than in the younger patient. Behavioral changes, unexplained dementia, “adult failure to thrive,” unexplained worsening of congestive heart failure, or a change in sense of well-being may represent uremia in the geriatric patient.

The trend has been for earlier initiation of dialysis in older patients, perhaps because of the increased burden of comorbid dis-

ease (Figure 87-5). The Center for Medicare and Medicaid Services (CMS) bases reimbursement for chronic hemodialysis upon a creatinine clearance below 10 mL/min for patients not having diabetes and less than 15 mL/min for patients with diabetes. Creatinine clearance can be calculated by using one of the formulas illustrated in Chapter 44 or with a 24-hour urine collection.

Timely initiation of RRT (Table 87-4) not only avoids the need for urgent dialysis, but also is associated with decreased mortality. A strong correlation between “baseline” serum albumin just prior to initiation of dialysis and patient survival has been demonstrated. Although hypoalbuminemia itself does not necessarily indicate protein-energy malnutrition, it is believed to be a major contributing factor. Analysis of the Modification of Diet in Renal Disease (MDRD) study showed that patients tend to adapt to their declining GFR and associated uremic symptoms by reducing their protein intake. Nevertheless, approximately 60% of American ESRD patients experience nausea and vomiting at the time dialysis is initiated. NKF-K/DOQI guidelines (Table 87-5) recommend evaluating renal function by monitoring weekly urea clearance ( $K_t \# / V_{\text{urea}}$ ). Once the  $K_t \# / V_{\text{urea}}$  falls below 2.0 (equivalent to a creatinine clearance of 9 to 14 mL/min/1.73 m<sup>2</sup>), there is increased risk for development of uremic anorexia leading to malnutrition, and RRT should be considered.

## Contraindications to Renal Replacement Therapy

There are few absolute medical contraindications to RRT. Some authors propose that advanced dementia, metastatic cancer, and advanced liver disease are reasons for withholding RRT. However, progressive dementia can be confused with uremia-induced delirium in

**FIGURE 87-3.** Comorbid conditions developed in the 2 yrs prior to ESRD initiation. Mean glomerular filtration rate (GFR) at initiation of hemodialysis by age for incident patients in 1999. (2006 Annual Data Report: Atlas of End-Stage Renal Disease in the United States. Bethesda, MD: National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases; 2006.)

**FIGURE 87-4.** Percent of diabetic patients receiving all four diabetic preventive care tests. General Medicare: patients diagnosed with diabetes in each year, aged 67 yrs and older on December 31 of the diagnosis year, and continuously enrolled in Medicare during the diagnosis year and the previous year. Claims from diagnosis year and the previous year searched for eye examination codes; claims from diagnosis year searched for lipid, HbA1c, and microalbuminuria testing codes. Pre-ESRD: incident patients aged 67 yrs and older at initiation, and with diabetes 1 yr prior to start of ESRD. Eye examinations tracked 2 yrs prior to start of ESRD; lipid, HbA1c, and microalbuminuria testing tracked 1 yr prior to start of ESRD. (2006 Annual Data Report: Atlas of End-Stage Renal Disease in the United States. Bethesda, MD: National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases, 2006.)

a patient with advanced kidney dysfunction, and a “trial” of dialysis is often justified. It may take as long as 3 to 4 weeks to clear uremic symptoms with dialysis. The patient’s family should be aware that if the patient’s mental status fails to improve, RRT may be inappropriate. Similarly, providing dialysis for a patient with metastatic cancer or end-stage liver disease may allow the patient to get their affairs in order and spend some quality time with friends and family. Cognitive and behavioral contraindications may play an even larger role in the elderly than medical contraindications. Dialysis units are communities where a patient with inappropriate, unsafe, or violent behavior adversely impacts care provided to others at that unit. For example, most nephrologists would discourage the use of dialysis in a patient who is severely cognitively impaired and unable to understand the requirements for safe dialysis treatment.

### Health-Related Quality of Life

Maintaining health-related quality of life (HRQOL) may be the most important role of health care in elderly patients with chronic illness. Studies of older patients undergoing dialysis have shown markedly lower functional status compared to older community-

dwelling adults. However, hemodialysis has improved since these early studies and there have been advances in technology, treatment of comorbidities such as anemia and hyperparathyroidism, and quality improvement initiatives that have improved the HRQOL of patients on dialysis. While HRQOL was impaired in the hemodialysis population, the HRQOL scores at baseline reflect a preserved multi-dimensional quality of life among respondents in the HEMO Study >70 years compared to younger hemodialysis patients. A large study in the Netherlands demonstrated decline in scores on physical domains over time in the age groups >55 years. Stability of mental domains is consistent with a previous study of incident patients remaining on hemodialysis over 18 months. These authors also suggest that comorbid disease burden rather than age was associated with a composite outcome of hospitalization, decline in albumin, and a quality of life score of 2 standard deviations below the general population mean score. These longitudinal HRQOL data are also consistent with the North-of-Thames Study findings showing rather moderate use of resources and cross-sectional differences in quality of life among hemodialysis patients older than 65 years. In cross-sectional studies of HRQOL in the ESRD population, there have been larger differences in HRQOL for younger patients on hemodialysis compared to younger norms than for older patients

**FIGURE 87-5.** Estimated glomerular filtration rate, by age. (2006 Annual Data Report: Atlas of End-Stage Renal Disease in the United States. Bethesda, MD: National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases; 2006.)

**TABLE 87-4**

#### Timely Initiation of Renal Replacement Therapy

- RRT should be initiated when:
- GFR of approximately 10 mL/min/1.73 m<sup>2</sup>
  - Protein-energy malnutrition develops or persists because of decreased nutrient intake without apparent cause for malnutrition
- Unless there is:
- Stable or increased edema-free body weight
  - Complete absence of clinical signs or symptoms of uremia
  - Serum albumin within normal range and stable or increasing

Data from The National Kidney Foundation Kidney Disease Outcomes Quality Initiative (KDOQI) Clinical Practice Guideline on Peritoneal Dialysis Adequacy, 1997 and modified using KDOQI Dialysis Adequacy 2006.

**TABLE 87-5****Indications for Trial of Dialysis in Elderly Patients**

- Uremia
- Potentially reversible acute renal failure
- Unexplained dementia
- Unexplained worsening of congestive heart failure
- Personality change (e.g., irritability/irascibility or newly subdued demeanor)
- Adult failure to thrive
- Change in sense of well-being

on hemodialysis compared to older norms. While these findings may be informative to older patients and health care providers, they also underline the need to improve HRQOL among all patients undergoing dialysis. Interventions aimed at preserving residual renal function, monitoring HRQOL, treatment of anemia, engaging the patient in physical therapy and rehabilitation, applying palliative care principles, and perhaps more frequent and longer hemodialysis treatments may preserve HRQOL among elderly patients undergoing hemodialysis.

## Management

### Choice of Renal Replacement Modality

When faced with kidney failure, the elderly patient has a number of choices to make regarding therapy consistent with their level of care and plans for the future. The most common form of RRT are three times weekly outpatient hemodialysis, peritoneal dialysis, and renal transplantation. There has been a proliferation of home therapies and therapies tailored to the elderly such as nursing home-based dialysis units. The elderly patient may also choose conservative management and thereby avoid dialysis. The patients should have time to develop a relationship with the nephrologist and team in order to have discussions of goals for care and how RRT may be tailored to meet those goals.

**Hemodialysis** Hemodialysis removes excess fluids and solutes from the blood in order to maintain euolemia and homeostasis. The conventional hemodialysis schedule requires three treatments for 1 per week for approximately 4 hours per treatment. In order to perform hemodialysis, the patient must have an access placed to circulate the blood through the hemodialysis filter. The three options for hemodialysis access include arteriovenous (AV) fistula, AV graft, and temporary hemodialysis catheters. Permanent hemodialysis access requires minor surgery in the arm or leg. The AV fistula, which creates a connection between the native artery and then the AV fistula vein, matures and thickens to handle the higher blood flow rates and permit the use of a needle for access after approximately 3 months. The use of an AV fistula has been associated with better access survival, fewer infections, fewer hospitalizations, and longer patient survival. The AV Graft uses a synthetic bridge between the artery and the vein. The graft has been used in a broader population than the AV fistula but has the major limitations of shorter access survival as well as more infections and hospitalizations. For elderly patients who have been referred late or who have acute kidney failure, hemodialysis is performed using a dialysis catheter. This is a large bore catheter placed in a major vessel such as the superior vena

cava. In the outpatient setting, these catheters are usually tunneled under the skin and treated with sterile precautions by the dialysis unit when accessing the catheters for blood. They have been associated with high rates of bacteremia, catheter malfunction, venous stenosis, and increased costs.

By far, in-center hemodialysis is the predominant form of RRT in the United States. Data derived from the USRDS for patients 65 years of age and older show the incident rate of hemodialysis (by first modality) in 1999 was 2336 per 1 million population, representing 50% of that population initiating RRT. Only 10% of patients older than age 65 years were treated with peritoneal dialysis, and 5% with renal transplantation.

Many elderly patients tolerate hemodialysis well. In addition, some studies demonstrate that older dialysis patients seem to enjoy the scheduled social interaction that in-center dialysis provides them. While most patients maintain a certain quality of life on hemodialysis, the drawbacks to in-center hemodialysis therapy include pain, fatigue, depression, loss of freedom, dietary restrictions, and concern about burden to caregivers.

**Peritoneal Dialysis** Peritoneal dialysis (PD) permits elderly patients to maintain more control over their schedule and play a larger role in the management of their kidney failure. PD uses the peritoneal membrane as a dialysis membrane by drawing excess fluid and toxins from the blood and into the peritoneal cavity where the fluid will then be drained through a plastic catheter that has been placed into the abdomen. Depending on the dialysis prescription, the peritoneal cavity is filled with fluid and drained a number of times over the course of the day or night. The advantages to using PD include a less-restrictive diet and avoiding the need to travel to a dialysis unit for treatment. However, the disadvantages include back pain, peritonitis, hyperglycemia, obesity, and hernia formation. PD has been successfully used in elderly patients, but its use in patients with poor functional status depends on a caregiver willing to commit to performing the daily therapy. PD can also be performed safely and effectively in a long-term care facility by staff with specialized training. The preferred mode of peritoneal dialysis in this setting is continuous cyclic peritoneal dialysis or nocturnal peritoneal dialysis, which requires less nursing time, allows patients to be more fully integrated into social activities, and allows interruption-free intensive rehabilitation.

**Kidney Transplantation** Kidney transplantation represents the optimal therapy for those with kidney failure and access to kidney transplant has increased among elderly patients. Elderly patients, in fact, currently make up the fastest growing segment of the kidney transplant population. Kidney transplant recipients demonstrate improved survival over wait-listed patients on dialysis across all age groups, including the elderly, and across many comorbid diseases, including diabetes. In addition to extending life expectancy, patients both young and old report an improved quality of life following kidney transplantation. Not only do individuals benefit from kidney transplantation, but health care systems also face lower costs in patients receiving a kidney transplant compared to those maintained on hemodialysis, including those aged 60 years and older.

Older kidney transplant recipients have a lower rate of acute rejections and may benefit from tailored immunosuppressant therapy, but have a higher risk of infection, cardiovascular events, and malignancy after kidney transplantation compared to younger patients. Furthermore, older patients may experience more drug toxicity and more

drug side effects compared to their younger counterparts. Many older kidney transplant recipients face not only immunological risk but also significant nonimmunological risk of baseline medical comorbidity that may increase their vulnerability to morbidity and mortality associated with delayed or suboptimal graft function.

Because the deceased donor kidney remains a scarce resource, the pursuit of an allocation policy that maximizes the life-year benefit of donor organs has generated strategies, which include matching kidneys with lower expected graft survival time to older patients with lower expected longevity. The elderly are more often offered and more likely to accept expanded criteria donor (ECD) kidneys. ECD kidneys are obtained from donors aged 60 years and older or from donors between the age of 50 and 59 years with at least two of the following risk factors: death from cerebrovascular accident, serum creatinine greater than 1.5mg/dL, or history of hypertension, which carry a higher relative risk of graft failure compared to a reference group of donors aged 10 to 39 years without any of these three conditions. However, older patients may be at increased risk of morbidity and mortality following transplantation with ECD kidneys because of increased baseline comorbidity and decreased physical reserve. Recent discussions focusing on the development of kidney allocation systems to maximize the life-year benefit of donor kidneys has involved “old kidney-for-old recipient” strategies. A potential increase in overall graft survival, with significant associated cost savings to society might be realized by allocating younger kidneys to younger recipients. However, it is important to assess the perception of fairness of such a potentially age-ist allocation schema. In the United States, transplant centers rarely discourage elderly patients from seeking kidney transplantation. Some physicians may be reluctant to encourage elderly transplant candidates to accept kidneys presumed to be of lower quality for the objective of maximizing social justice. Others will be willing to accept such kidneys, using the argument of medical efficacy, while providing subtle or even overt encouragement to the elderly to accept ECD kidneys by framing the option as a means to decrease time on the waiting list. This may in part explain why the odds ratio for willingness to accept an ECD kidney increases significantly with age. In an attempt to ensure good outcome of their grafts in elderly recipients, strict rules have been imposed to limit ischemic damage in the donor and immunological risk by the Eurotransplant Senior Program. Preliminary reports from this program have been positive and this may serve as a model for maximizing kidney resources while offering older patients an opportunity for kidney transplantation.

The degree to which comorbidity influences graft and patient outcomes is significantly less in recipients of living donor kidneys compared to recipients of deceased donor kidneys. A living donor kidney may offset some of the risk of increased comorbidity in the elderly recipient and highlights living donor kidney transplantation as an important opportunity for elderly patients with kidney failure to receive optimal treatment. If the allocation of deceased donor kidneys in the future increasingly favors younger patients over older patients in the distribution of this scarce resource, living donor kidney transplantation may become the only realistic chance at successful kidney transplantation for older patients.

### Time-Limited Trial of Dialysis

When the patient, family, or physician is unsure about the prognosis or the impact that dialysis will have upon the patient's quality of life,

it is reasonable to offer a time-limited trial of dialysis. If a trial of dialysis is to be conducted, it is important to predetermine a time period (usually 4 to 6 weeks) and to inform all the members of the dialysis team. Such measures will ease the appropriate withdrawal from dialysis.

### Conservative Management

It is difficult to assess the frequency of conservative palliative therapy, but it is likely that the geriatrician plays a primary role in the decision-making process and management of these patients. In a study from the UK, 84% of patients with CKD Stages 3 to 5 were not referred to nephrology. The proportion of referred patients declined dramatically with older age, with a maximum referral rate of 68% for those 40 to 49 years of age, and 4% of those older than 80 years of age. Another study presented 19% with palliative care as a recommended option based on age and comorbid disease burden; 76% of those recommended for palliative care followed through with management of kidney failure without dialysis. While it was somewhat difficult to provide accurate comparisons of survival times, these investigators reported no substantial difference in expected survival time for those undergoing palliative care compared to hemodialysis. Significantly fewer palliative care deaths (27%) took place in the hospital compared to the proportion of deaths among those patients undergoing hemodialysis (67%). In a study of octogenarians in a single-center where older patients were advised not to undergo dialysis, 25% were conservatively managed. In this report, the median survival of those undergoing conservative management was 8.9 months compared to 28.9 months among those undergoing dialysis. In addition, the cause of death of those managed without dialysis was uremia or pulmonary edema in approximately 60%.

Conservative management should aim to maintain quality of life while keeping in mind the shared decision to avoid dialysis therapy. In addition to continuing to manage fluid status, anemia, electrolytes, and bone metabolism, symptoms should be addressed by the geriatric, nephrology, and palliative care teams. Among both groups of patients undergoing dialysis and receiving palliative care, symptoms should be treated since pain, dry itchy skin, poor sleep, and fatigue impact mood and quality of life. A study has recently shown improvement in pain among ESRD patients managed using the World Health Organization (WHO) three-step analgesic ladder. A nutritional approach to avoiding dialysis therapy was assessed in nondiabetic patients older than 70 years. In this randomized study, patients with kidney failure were assigned a supplemented very low protein diet compared to usual care with dialysis. This study found that those patients assigned the dietary intervention spent an additional 10.7 months off dialysis without substantial differences in survival between groups. These findings suggest that nutrition may play an important role in managing patients who elect to avoid dialysis.

### Management of End Stage Renal Disease on Dialysis

#### Anemia

Anemia is a common problem with CKD and kidney failure. The fall in hematocrit correlates roughly with the severity of the renal disease, although individual variation is considerable. In general, anemia presents when the GFR is around 35 mL/min. The bone marrow is hypoproliferative while peripheral blood (red cell) indices

are normal unless there is superimposed deficiency of iron or folic acid. Thus, the anemia seen with kidney failure is typically a normochromic, normocytic anemia. The lack of erythropoietin production, which occurs with CKD, is the primary cause of anemia with kidney failure. Since erythropoietin production occurs primarily in the kidney, erythropoietin levels are inadequate with CKD, thus depriving the bone marrow of the stimulus necessary for production of red blood cells. The isolation of human erythropoietin and subsequent production of recombinant erythropoietin has been a major advance in the care of those with CKD. Beginning in 1989, synthetic erythropoietin has been available and effectively treats the anemia of CRF. Recently another recombinant form, darbepoetin, has become available and permitted less frequent dosing regimens. Correction of anemia has improved quality of life, reduced the need for transfusions, improved cognitive performance, and decreased left ventricular hypertrophy. There are adverse effects of using erythropoietin in the patient with CKD, including iron deficiency (the stimulation of red blood cell production outstrips iron stores), hypertension, and vascular thrombosis.

The optimal hemoglobin target for patients with anemia caused by chronic kidney failure remains somewhat unclear. Recent data in the CKD population suggest untoward cardiovascular outcomes at higher hemoglobin levels. The current conservative target is a hemoglobin count between 11 and 12 mg/dL. In addition to close attention to erythropoietin dosing and hemoglobin levels, adequate anemia management requires routine analysis and treatment of iron deficiency. Iron levels tend to drop in patients on erythropoietin therapy because of increased iron utilization. All patients, however, should receive routine screening of stool for occult blood and periodic screening colonoscopy. Iron-deficient ESRD patients usually receive intravenous replacement iron at the end of their dialysis treatments, either as dextran, gluconate, or sucrate solution. Because they absorb oral iron poorly, ESRD patients have “functional” iron deficiency when their transferrin falls below 100 ng/mL or their iron saturation is less than 20%.

### Cardiovascular Disease

Many more patients have CKD compared to the numbers receiving RRT. The disparity between the number receiving RRT and the number with CKD is explained by the high mortality from cardiovascular disease prior to needing dialysis in the CKD population. Even on dialysis, the risk of death from cardiovascular disease remains 10 to 100 times higher than the risk of a person from the general population. While traditional risk factors account for only a portion of the increased risk associated with kidney disease, the etiology of the increased cardiovascular risk is unclear. There are a number of potential factors that represent classical risk factors shared between atherosclerosis and kidney disease such as age, hypercholesterolemia, hypertension, smoking, and obesity. In addition, there are a number of factors specific to kidney failure such as anemia, hyperhomocysteinemia, hypervolemia, and hyperparathyroidism. These factors can act to promote both cardiomyopathy and ischemic heart disease. The current treatment recommendations focus on optimizing management of known cardiovascular risk factors and on recognizing harbingers of active cardiovascular disease. Those caring for patients with CKD should consider the cardiovascular disease management as an important part of their care.

### Calcium, Phosphorous, Hyperparathyroidism, and Bone Disorders

Kidney failure is associated with abnormalities of divalent ions ( $\text{Ca}^{2+}$ , P) and of the hormones that regulate the concentration of these minerals in body fluids. One of the earliest detectable abnormalities in kidney failure is a rise in parathyroid hormone (PTH), which can occur at a GFR of 40 mL/min. Secondary hyperparathyroidism is a major cause of bone disease in patients with kidney failure. Two inhibitors of parathyroid hormone are ionized calcium (the active form of calcium) and  $1,25\text{-(OH)}_2\text{D}_3$ , which has an independent inhibitory effect on parathyroid hormone release. No difference has been found in hyperphosphatemia or severity of renal osteodystrophy in elderly dialysis patients as compared with younger dialysis patients, and there is no correlation between plasma  $1,25\text{-dihydroxyvitamin D}_3$  levels and age in patients with kidney failure. Elderly female dialysis patients have significantly lower bone mineral content and bone width when compared with younger dialysis patients matched for duration of dialysis. There is a higher incidence of pathologic fracture, vascular or metastatic calcification, and bone pain in elderly patients on dialysis than in younger patients. The overall result of these disturbances is that patients with ESRD may develop a complex form of bone disease (renal osteodystrophy). Furthermore, there has been a strong association of disordered bone and mineral metabolism and risk of cardiovascular disease. This association between calcium and phosphate metabolism has been most striking when images of the heart demonstrating extensive calcification have been related to levels of both calcium and phosphate.

Treatment of renal osteodystrophy and secondary hyperparathyroidism in the geriatric renal patient is similar to the younger patient. However, the optimal management of patients has been controversial. Hyperphosphatemia is treated with a low phosphate diet and with various phosphate binders. Recent recommendations advise that daily calcium in the phosphate binder should be less than 2 g. Hypocalcemia can be treated with oral calcium, oral or intravenous calcitriol, or other Vitamin D analog, or higher dialysate calcium. Refractory hyperparathyroidism can be treated with parathyroidectomy or with a trial of a calcimimetic. While the agents used to regulate calcium and phosphate levels remain controversial, the goals of normalizing calcium and phosphate levels and improving bone health are widely accepted as important in the management of CKD patients.

### Metabolic Acidosis

The acidosis associated with renal disease is not more severe in the elderly patient despite the decreased ability to handle an acid load seen with normal aging. Acidemia caused by metabolic acidosis is associated with increased oxidation of branched chain amino acids, increased protein degradation, and decreased albumin synthesis. Because of the adverse metabolic effects of chronic acidosis, such as accelerated bone loss and muscle wasting, goals of therapy should be directed at achieving predialysis serum bicarbonate levels of at least 22 mmol/L. If predialysis levels routinely fall below 22 mmol/L, acidemia may be treated by increasing the dialysis bicarbonate in those undergoing hemodialysis, or supplementation with oral sodium bicarbonate tablets.

## Malnutrition

Nutrition plays an important role in the health and well-being of patients with kidney failure. Patients with kidney failure are thought to benefit from intensive monitoring of nutritional status. The recommended assessments include body weight, dietary interviews and diaries, serum albumin, and total nitrogen appearance. A renal dietitian may offer alternative foods and recommendations to patients that feel limited by fluid, sodium, potassium, and phosphate restrictions. Weight loss and inability to maintain nutritional status are indications for initiating hemodialysis and adequacy of dialysis therapy should be evaluated to avoid anorexia and nausea. Dietary supplements and vitamin and mineral supplements, such as zinc or oral pyridoxine (50 mg/day), might be helpful. It is unclear whether intradialytic parenteral nutrition offers real benefit. There are no controlled studies available, and are very expensive to conduct. Dietary restrictions in the elderly patient undergoing dialysis should be minimal. Patients with inadequate intake rarely need food restrictions.

## Pruritus

Itching in patients with kidney failure can adversely affect sleep and quality of life. The causes of itching in elderly patients with kidney failure would include xerosis, uremic itching, medication sensitivity, and other chronic health conditions such as diabetes. Pruritus is common in the elderly dialysis patient, possibly because of skin changes seen with aging. As a part of an approach to managing uremic itching, it has been recommended to optimize dialysis treatment by increasing dialysis dose, treating anemia and iron deficiency, and maintaining a low serum phosphate. Treatment of itching caused by xerosis or uremia has been largely symptomatic local treatment consisting of keeping the skin moist with emollients, bathing less frequently and with tepid rather than hot water, and increasing ambient humidity with vaporizers or humidifiers. Capsaicin cream may also be effective. A promising new approach has been tested in two randomized trials of nalfurafine, a  $\kappa$ -opioid receptor agonist. These studies of patients with severe uremic itching demonstrated improvement in itching intensity and sleep disturbances compared to placebo. Antihistamines such as diphenhydramine or hydroxyzine may be used, but may cause sedation and cognitive impairment in elderly patients.

## SPECIAL ISSUES

### Prognosis and Survival

Kidney failure is associated with a decrease in life expectancy for all age groups when compared to age-matched patients. The need for dialysis impacts the risk of death in the patient older than age 75 years to a lesser degree than it impacts patients 45 years of age, with a threefold versus 20-fold increased risk as compared to nondialysis patients, respectively. The survival of older patients undergoing dialysis has been recently assessed in the USRDS. The number of patients older than 80 years of age roughly doubled from 1996 to 2003. Overall, the 1-year survival rate for octogenarians and nonagenarians after dialysis initiation was 54%. The characteristics strongly associated with death were older age, nonambulatory status, and

more comorbid conditions (Figure 87-6). In addition to survival, it is important to convey the impact of dialysis on HRQOL. In the HEMO Study, a randomized clinical trial of dialysis dose and membrane flux, patients were assessed for HRQOL at baseline and annually. Among those with HRQOL data at the first three annual assessments, there were no substantial mean declines in physical or mental well-being over the 3-year period. However, there were high rates of adverse HRQOL events in all age groups and significantly higher adverse event rates of either death or clinically significant decline in HRQOL over 3 years among those older than 70 years. The composite outcomes of clinically significant decline in HRQOL or death of those older than 70 years over 3 years was approximately 70%. These findings underline the importance of conveying the limited life expectancy of those patients who are not transplant candidates, and particularly those with limited functional status and comorbidity. While life span is limited, it remains up to the individual whether to pursue dialysis or palliative therapy.

### Withdrawal from Dialysis

Stopping dialysis has been a common reason for death in the dialysis population, especially for older patients. Up to one-third of patients are withdrawn or voluntarily withdraw from dialysis therapy annually. The factors associated with dialysis discontinuation in the United States include white race, diabetes, female sex, symptoms, and older age. While dialysis patients should understand that they have the right to stop treatment, the health care team should ensure that the patient is not withdrawing because of “burdens” that can be ameliorated. One prospective observational study of 131 adult (average age 70 years) maintenance dialysis patients examined the quality of dying following dialysis termination. Quality of death was evaluated by the use of a quality-of-dying tool that quantified the duration (length of time it took to die), pain and suffering, and psychosocial factors. Death occurred on average 8 days after the last dialysis treatment. Thirty-eight percent of the patients on dialysis had a “very good” death, 47% had “good” deaths, and only 15% had “bad” deaths. However, during the last day of life, 42% of the patients had some pain (5% severe) reiterating the importance end-of-life palliation once the decision to withdraw therapy is made. While the end-of-life issues in renal failure have received increasing attention, there remain many barriers to management of these issues, as underscored by the fivefold lower use of hospice among patients undergoing hemodialysis compared to those older patients not using dialysis. In order to overcome the barriers to a good death for those on dialysis, it is important to have a multidisciplinary approach and an awareness of local hospice services.

### Advance Directives

A complete review of treatment options, prognosis, and quality of life should be included when discussing advanced directives of a patient with CKD Stages 4 and 5. Having the patient's wishes expressed prior to starting dialysis makes the burden of decision-making much easier for the families and physicians should the patient become critically ill. It is crucial to involve the family and surrogates in the advanced directives process and to fully document the directives in order to avoid a change in direction with an unplanned hospitalization. Patients who decide not to undergo dialysis should have clear documentation

**FIGURE 87-6.** Survival of octogenarians and nonagenarians at dialysis initiation by age group (top), ambulatory status (middle), and number of comorbid conditions (bottom). (Kurella M, Covinsky KE, Collins AJ, et al. Octogenarians and nonagenarians starting dialysis in the United States. *Ann Intern Med.* 146:177–183, 2007.)

in their medical records. There should be similar documentation of do-not-resuscitate orders, wishes regarding artificial nutrition and other measures, and identification of their health care surrogate.

## SUMMARY

As the population ages, there will be increasing numbers of older patients with advanced CKD and kidney failure. The elderly patient

with kidney failure now has a multitude of choices for RRT including hemodialysis, peritoneal dialysis, conservative management, and kidney transplantation. Primary care physicians and geriatricians should identify CKD in older patients who have risk factors and refer them kidney disease management. After referral, the geriatric team may remain in the key role of addressing advanced directives and planning long-term care, since they may have a long-standing relationship with the patient and have the best insight into the patient's goals and values. In addition, the geriatric team may choose

to continue managing other health issues in the kidney failure patient so that it remains clear who will manage comorbid illnesses. Elderly patients with CKD will remain an economic and medical challenge, but a multidisciplinary approach to care of these patients will provide the best long-term outcomes.

# Disorders of Fluid Balance

*Myron Miller*

Characteristic of the normal aging process is a decline in physiologic reserve in many body regulatory systems, including those involved in the maintenance of fluid balance. The confluence of normal aging changes, common diseases, and the administration of many classes of drugs can readily lead to clinically evident disturbances of fluid balance, such as water retention or loss and to hyponatremia or hypernatremia with resultant symptomatic consequences. In some individuals, an impaired ability to conserve water may underlie the development of nocturnal urinary frequency as well as urinary incontinence.

The normal regulation of water and electrolyte balance involves the interplay of many homeostatic systems that operate to maintain the composition of fluid and electrolyte compartments within a narrow range. Because of alterations in the normal aging process, these homeostatic systems may be compromised. The key regulatory components of fluid balance include (1) thirst perception, which governs fluid intake, (2) the kidney, which is governed by hemodynamic forces, and (3) hormonal influences of arginine vasopressin (AVP) or antidiuretic hormone (ADH), atrial natriuretic hormone (ANH), and the renin–angiotensin–aldosterone system, which control renal water and electrolyte excretion. Clinicians who are involved in the care of the elderly recognize that disturbances of water and electrolyte balance are common in this age group, especially when older persons are challenged by disease, drugs, or extrinsic factors such as access to fluids or control of diet composition.

## EFFECTS OF NORMAL AGING ON FLUID REGULATORY SYSTEMS (Table 88-1)

### Body Composition

Aging effects on body composition have the potential to contribute to derangements in fluid balance. Normal aging is accompanied by a

decrease in lean body mass, an increase in fat mass, and a decrease in total body water. Thus, total body water declines from the approximate values of 60% of body weight in young men and 52% in young women to 54% and 46%, respectively, in individuals older than age 65 years, primarily through a decrease in the intracellular fluid compartment. The decrease in total body water may place the elderly patient at increased risk for dehydration and/or hyponatremia when challenged by fluid loss or decreased fluid intake and at increased risk for fluid overload and hyponatremia when exposed to excessive oral or parenteral fluid intake.

### Thirst and Fluid Intake

The ability to ingest a sufficient volume of fluid to meet body needs requires that thirst perception be present, that a suitable source of fluid be available, and that the individual be physically capable of obtaining and consuming the fluid. Under normal conditions, the requirement for daily fluid intake is approximately 30 mL/kg body weight. This requirement is further increased when there is high environmental temperature, fever, increased gastrointestinal, urinary, or respiratory fluid loss. Urine production typically ranges from 1.0 to 2.5 L per 24 hours and is modestly higher in men older than the age of 60 years. Older persons may be challenged by increased amounts of fluid by either oral or parenteral routes, especially when they are in institutional acute care or long-term care settings and not in control of their fluid intake. In this circumstance, there is risk of volume overload and hyponatremia.

In healthy individuals, fluid intake is largely controlled by thirst sensation, which is regulated by both extracellular fluid volume and blood tonicity. Blood osmolality is the most important factor in the day to day perception of thirst. Thirst is usually stimulated when plasma osmolality rises to values greater than 292 mOsm/kg. Healthy persons older than age 65 years have shown evidence of an age-associated impairment in thirst perception so that when they were subjected to water deprivation sufficient to raise plasma osmolality to greater than 296 mOsm/kg, they exhibited diminished subjective

**TABLE 88-1****Aging Effects on Water and Sodium Regulatory Systems**

Increased basal secretion
Increased response to stimulation
Decreased plasma renin activity
Decreased aldosterone production

awareness of thirst and consumed significantly less water than young subjects who were similarly water deprived and whose plasma osmolality rose to a lesser level (mean, 290 mOsm/kg). Other studies of elderly patients with cerebrovascular accidents have similarly documented impaired thirst perception in the face of volume depletion and hyperosmolality, both normally being potent stimuli for thirst. Elderly patients with Alzheimer's disease fail to drink adequately when exposed to water deprivation in spite of the accompanying elevation of blood osmolality to levels above the usual thirst threshold. Further confounding the ability of the elderly person to ingest adequate amounts of fluid is the frequent presence of physical disability (e.g., blindness, arthritis, stroke) and impaired mobility, thus limiting the capacity of the patient to gain access to fluids.

## Renal Changes of Normal Aging (Also See Chapter 85)

### Structural and Functional Changes

Normal aging is accompanied by changes in renal anatomy and in renal function. Kidney mass undergoes progressive decline from a normal combined weight of approximately 250 to 280 g in young adults to between 180 and 200 g by age 80 to 90 years, with corresponding decrease in length and volume. Histologically, the number of glomeruli decline by 30% to 40% with increasing age and the percent of glomeruli that are hyalinized or sclerotic, increase to 10% to 30%. This process accelerates after the age of 40 years, and the residual glomeruli also undergo changes with age. Thus, there is a decrease in effective filtering surface, and an increase in the number of mesangial cells, a decrease in number of epithelial cells, and thickening of the glomerular basement membrane.

As part of the normal aging process, there are changes in the renal vasculature that lead to obliteration of the arteriolar lumen and loss of the glomerular capillary tuft. These changes take place primarily in the cortical glomeruli. In the juxtamedullary area, glomerular sclerosis may lead to anastomosis between afferent and efferent arterioles with direct shunting of blood between these vessels. Blood flow to the medulla, through the arteria rectae, is maintained in old age.

The anatomic changes of the aging kidney are paralleled by alterations in renal function although a direct relationship between anatomic and functional changes is not firmly established. Renal blood flow declines during the course of normal aging by approximately 10% per decade after young adulthood so that by the age of 90 years, the renal plasma flow is approximately 300 mL/min—a reduction of 50% of the value found at 30 years of age. The decrease in renal perfusion is most extensive in the outer cortex with lesser impairment of inner cortex and minimal effect on the medulla.

Glomerular filtration rate (GFR) remains relatively stable until age 40 years, after which it undergoes decline at an annual rate of approximately 0.8 mL/min/1.73 m<sup>2</sup>. Because there is much individual variability within the elderly population, longitudinal studies show that not all aging persons will undergo a decline in GFR. The Cockcroft–Gault formula for creatinine clearance has been used to estimate GFR. A more accurate estimate of GFR is now recommended using the abbreviated version of the Modification of Diet in Renal Disease (MDRD) formula, which is based on serum creatinine, age, gender, and race. The calculation can easily be made by use of a downloadable Web-based calculator (<http://www.nkdep.nih.gov/GFR-cal-adult-htm>). In persons older than the age of 70 years, approximately 26% will have estimated GFR less than 60 mL/min/1.73 m<sup>2</sup>.

### Water Regulatory Capacity

**Renal Water Retention** The aging kidney exhibits a modest age-related impairment in the ability to dilute the urine and excrete a water load. The ability to generate free water is dependent on several factors, including adequate delivery of solute to the diluting region (sufficient renal perfusion and GFR), a functional intact distal diluting site (ascending limb of Henle's loop and the distal tubule), and suppression of ADH in order to escape water reabsorption in the collecting duct. The age-related decline in GFR is the most important factor in the aged kidney's diluting capacity. The presence of an age-related diluting defect that is independent of changes in GFR remains controversial.

The diluting capacity of the aging kidney has been evaluated in men by determining the urine osmolality and free water clearance response to acute water loading. In young men (mean age 31 years), minimum urine osmolality was 52 mOsm/kg, whereas in middle-aged men (mean age 60 years), minimum urine osmolality was 74 mOsm/kg, and in the older men (mean age 84 years), it was 92 mOsm/kg. The free water clearance was lowest in the older group. However, when these results were expressed as free water clearance per mL of GFR, the values were not different, suggesting that the defect in diluting capacity was a consequence of an age-related reduction in GFR. In a similar study in which healthy elderly subjects aged 63 to 80 years (mean, 72 years) and healthy young subjects aged 21 to 26 years (mean, 22 years) were administered a water load, the peak free water clearance was 5.7 mL/min in the older group and

8.4 mL/min in the younger group. However, when adjustments were made for changes in creatinine clearance, the difference in these indices was not statistically significant.

Other studies suggest that age-related free water clearance defects persist following correction for a lower GFR. A significantly lower free water clearance/creatinine ratio was found in elderly nursing home residents as compared to healthy younger subjects. The maximal urinary dilution (urinary/plasma osmolality) declined from 0.247 in younger subjects to 0.418 in elderly subjects.

In addition to impaired diluting capacity, the age-related decrease in renal plasma flow and GFR can lead to passive reabsorption of fluid, thereby increasing the risk of water overload and hyponatremia. This effect is clinically evident in elderly patients who have congestive heart failure, extracellular volume depletion, and hypoalbuminemia.

Diuretics, especially thiazides, can decrease renal diluting capacity. In the elderly, this effect becomes especially important when it is superimposed on the already diminished diluting capacity of the aged kidney, thus increasing the risk of developing water intoxication by impairing the ability to excrete excess water promptly.

**Renal Water Loss** It has been known for many years that there is an age-related change in renal concentrating capacity. In a study of healthy men aged 40 to 101 years who underwent 24 hours of water deprivation, maximum attainable urine specific gravity declined from 1.030 at 40 years to 1.023 at 89 years. Hospitalized men aged 23 to 72 years who underwent 24 hours of dehydration demonstrated a progressive decline in maximum urine osmolality with increasing age. In healthy, active community-dwelling participants in the Baltimore Longitudinal Study of Aging, young subjects responded to 12 hours of water deprivation with a marked decrease in urine flow ( $1.02 \pm 0.10$  to  $0.49 \pm 0.03$  mL/min) and a moderate increase in urine osmolality ( $969 \pm 41$  to  $1109 \pm 22$  mOsm/kg), whereas elderly subjects were unable to significantly alter urine flow ( $1.05 \pm 0.15$  to  $1.03 \pm 0.13$  mL/min) or osmolality ( $852 \pm 64$  to  $882 \pm 49$  mOsm/kg). This age-related decline in urine concentrating ability persisted after correction for the age-related decrease in GFR.

The effect of age on renal tubular response to vasopressin has been assessed by measuring the urine-to-plasma inulin concentration ratio in men who ranged in age from 26 to 86 years and who were free of clinically demonstrable cardiovascular and renal disease. The ratio fell from 118 in young men (mean age 35 years) to 77 in the middle-aged group (mean age 55 years) and to 45 in the older men (mean age 73 years). The decreased renal sensitivity to vasopressin with age maybe a result of an age-related increase in vasopressin secretion. Animal studies demonstrate that chronic exposure of the kidney to increased vasopressin results in diminished renal responsiveness to the hormone. Thus, an age-related increase in vasopressin secretion may result in down-regulation of renal AVP receptors and be the basis for decreased renal concentrating capacity in the elderly.

### Sodium Regulatory Capacity

**Renal Sodium Retention** Several situations may lead to sodium retention and accompanying water overload in the elderly. The previously described age-related decrease in renal blood flow and GFR favors enhanced conservation of sodium. Disease states resulting in secondary hyperaldosteronism, such as congestive heart failure,

cirrhosis, or nephrotic syndrome, are common in the elderly. In addition, drugs such as nonsteroidal anti-inflammatory agents, which are frequently used in the elderly, may promote sodium retention.

**Renal Sodium Loss** Elderly individuals are more likely to have exaggerated natriuresis after a water load than are younger subjects. Patients with benign hypertension have an excess of sodium excretion in association with increased age. The aged kidney's response to salt restriction is sluggish so that restriction in sodium intake to 10 mEq/d was followed by a half-time for reduction of urinary sodium excretion of 17.6 hours in young individuals and 30.9 hours in old individuals. These data suggest that the aging kidney is more prone to sodium wasting. Mechanisms underlying this tendency maybe multifactorial and are related to the effects of age on ANH, the renin-angiotensin-aldosterone system, and renal tubular function.

### Vasopressin System in Normal Aging (Table 88-2)

#### Neurohypophyseal System

The magnocellular neurons of the hypothalamus where AVP is synthesized do not appear to undergo age-related degenerative changes. There is no evidence of the cell destruction, neuronal dropout, or loss of dendritic arborization found in other segments of the aged brain. Moreover, neurosecretory material in supraoptic nuclei (SON) and paraventricular nuclei (PVN) in elderly persons does not appear to differ in amount from that in younger subjects.

Morphologic data provide evidence that these nuclei, in fact, become more active with age. In the human hypothalamic neurohypophyseal system of subjects ranging from 10 to 93 years of age, a gradual increase in the size of the SON and PVN was observed after 60 years of age, suggesting that AVP production increases in senescence. Similar changes have been observed in the nuclear size of AVP neurons. Possibly contributing to the maintenance of normal or increased amounts of AVP in the magnocellular neurons is the observation of a 25% reduction in the rate of axonal transport of AVP and its associated neurophysin with advancing age. Thus, it appears that neurosecretory activity of hypothalamic AVP neurons

**TABLE 88-2**

#### Aging Effects on the Vasopressin System\*

Morphology of the neurohypophyseal system
Normal or increased supraoptic nucleus cell number/AVP content
Normal or increased paraventricular nucleus cell number/AVP content
Decreased supraoptic nucleus cell number/AVP content
Normal extrahypothalamic nuclei cell number/AVP content
Hypothalamic vasopressin content
Normal or increased
Cerebrospinal fluid vasopressin concentration
Normal
Blood vasopressin concentration
Normal or increased basal
Increased after osmotic and pharmacologic stimulation
Decreased response to volume/pressure stimulation
Decreased nocturnal secretion
Renal response to vasopressin
Decreased

\*Changes are in comparison to values observed in the young.

does not decrease but, in fact, remains constant or is elevated with age.

### Basal Plasma Vasopressin Levels

There are conflicting data regarding basal concentration of AVP in the blood during normal aging. In young normal individuals, there is a diurnal rhythm of vasopressin secretion, with greatest AVP secretion occurring at night. This rhythm appears to be linked to the wake–sleep cycle rather than to time of day. The sleep-associated peak is absent in the majority of healthy elderly persons. Low AVP levels and the lack of definite diurnal rhythm may, to some extent, explain increased diuresis during the night in some elderly individuals.

Healthy elderly subjects have been found to have basal plasma AVP levels that were significantly lower than in young subjects. In association with the reduced AVP concentration, plasma osmolality was elevated, suggesting that the elderly subjects had a water-losing state similar to partial diabetes insipidus.

Other studies indicate that basal plasma levels of AVP did not differ among young, middle-aged, and elderly healthy individuals who were studied under both supine and ambulatory conditions. Furthermore, there were no differences in plasma osmolality between the groups.

In contrast to the above are reports of elevated basal vasopressin levels in healthy elderly persons as compared with younger individuals. Healthy human subjects aged 20 to 80 years have been observed to exhibit a progressive rise in plasma AVP concentration with age, which become most evident in subjects older than age 60 years. Baseline plasma AVP correlates with serum osmolality in younger adults but not in elderly subjects.

Debate exists regarding a sex-related difference in plasma AVP levels in the elderly population. There are reports of a twofold higher plasma AVP concentration in elderly men as compared to women, while other studies fail to identify a gender effect on basal plasma AVP.

A rise in basal plasma AVP with age cannot be attributed to age-related changes in vasopressin metabolism. No differences were found between young and old subjects in vasopressin half-life, volume of distribution, or clearance. Thus, evidence of increased basal plasma vasopressin most likely reflects age-related changes in central control systems for vasopressin release.

### Vasopressin Stimulation

Secretion of AVP normally varies in response to changes in blood tonicity, blood volume, and blood pressure. Hormone release is also affected by other variables such as nausea, pain, emotional stress, a variety of drugs, cigarette smoking, and glucopenia. In recent years, a growing body of information suggests that normal aging affects the way these stimuli act and interact to influence AVP release.

The major physiologic stimulus for vasopressin secretion in humans, plasma osmolality, is regulated by hypothalamic osmoreceptors. Osmoreceptor sensitivity in the elderly population has been assessed by comparing the AVP response to hypertonic saline infusion in healthy elderly persons (age 54–92 years) to the response in younger individuals (age 21–49 years). Hypertonic saline raised plasma osmolality with a consequent increase in plasma AVP in both groups, but the hormone concentrations in the older subjects were almost double those in the younger subjects. Thus, for any given level

of osmotic stimulus, there was a greater release of AVP in the elderly, suggesting that aging resulted in osmoreceptor hypersensitivity.

Use of water deprivation as a stimulus for vasopressin secretion has supported the concept of an age-related enhancement in vasopressin secretion. Water deprivation for 24 hours in young healthy individuals (age 20–31 years) and healthy elderly men (age 67–75 years) demonstrated that the older persons responded with higher serum concentrations of AVP than the younger individuals.

The sensitivity of the hypothalamic–neurohypophyseal axis to volume/pressure stimuli has been studied. In response to acute upright posture after overnight water deprivation, older subjects (age 62–80 years) demonstrated the expected changes in pulse and blood pressure but only 8 of 15 older individuals experienced increased plasma vasopressin in contrast to a rise in plasma vasopressin in all young subjects (age 19–31 years). This and other studies suggest the presence of an aged-related impairment of volume-/pressure-mediated vasopressin release.

The ability of intravenous ethanol infusion to inhibit AVP secretion has been evaluated in young (age 21–49 years) and old (age 54–92 years) subjects. Younger subjects demonstrated a sustained inhibition of AVP secretion during the infusion of ethanol, whereas there was a paradoxical response in the older group with initial AVP inhibition followed by breakthrough secretion and rebound to twice basal levels. Not only was ethanol less effective in inhibiting AVP release in the elderly, but it eventually lost its suppressive effect entirely as a result of the introduction of a hyperosmotic stimulus resulting from the ethanol-induced constriction in plasma volume.

Metoclopramide can stimulate vasopressin secretion in humans through cholinergic mechanisms. Intravenous metoclopramide administration to normal elderly subjects aged 65 to 80 years and to normal young subjects aged 16 to 35 years produced significantly higher plasma AVP concentrations in the older group with no significant changes in plasma osmolality, blood pressure, or heart rate. Response of AVP to cigarette smoking and insulin-induced hypoglycemia, as well as to metoclopramide, has been evaluated in male subjects aged 22 to 81 years. The AVP response to metoclopramide and to smoking was significantly higher in the older group as compared to two younger groups. In contrast, the AVP response during the insulin hypoglycemia test was identical in pattern and magnitude in all age groups.

The stimulation studies indicate that, in aging, AVP response to osmotic stimuli is increased because of a hyperresponsive osmoreceptor, whereas AVP response to upright posture is reduced because of impaired baroreceptor function. Input from the baroreceptor to the osmoreceptor is usually inhibitory, so that a defect in this reflex arc would result in lesser dampening and consequent heightening of osmotically stimulated ADH release. When coupled with the many alterations in renal function that occur with aging, these changes can increase the risk of elderly persons for hyponatremia by impairing their ability to excrete excess water promptly.

### Age-Related Changes in Atrial Natriuretic Hormone Secretion, Regulation, and Action

ANH is synthesized, stored, and released in the atria of the heart. Through its action on the kidney, ANH produces a pronounced natriuresis and diuresis; through its action on blood vessels, it produces vasodilation and decreases blood pressure in both normal and hypertensive individuals. As an important regulator of sodium

excretion, ANH maybe a significant factor in mediating the altered renal sodium handling of age.

In a comparison of young normal men with elderly male nursing home residents, a fivefold increase in mean basal ANH levels and an exaggerated ANH response to the stimulus of saline infusion has been observed in the elderly group. In response to the stimulus of head-out water immersion, ANH levels in healthy old individuals (age 62–73 years), which were twice as high at baseline than in young subjects (age 21–28 years), rose to a greater extent than in the young. Healthy male and female subjects aged 22 to 64 years have been studied to determine the influence of age on circulating levels of ANH, both under basal conditions and after the physiologic stimulation of ANH release by controlled exercise using a bicycle ergometer to increase heart rate to 80% of maximum predicted rate. Subjects older than 50 years of age had higher baseline levels and a greater response to exercise when compared to subjects younger than age 50 years. Thus, increasing age results in increased ANH basal levels and an increased ANH response to both physiologic and pharmacologic stimuli, perhaps as a consequence of age-related decrease in cardiac muscle compliance.

The renal effects of ANH maybe exaggerated in elderly versus young individuals. The natriuretic response to a bolus injection of ANH was higher in older individuals (mean age 52.3 years) as compared with younger subjects (mean age 26 years). No change with age was noted in the blood pressure response to ANH intravenous infusion after correction for higher ANH levels in the elderly.

ANH is known to interact with the renin–angiotensin–aldosterone system. Increases of ANH result in suppression of renal renin secretion, plasma renin activity, plasma angiotensin II, and aldosterone levels, suggesting indirect inhibition of aldosterone secretion by ANH. Minimal increases in ANH within physiologic levels produced by slow-rate ANH infusion can inhibit angiotensin II-induced aldosterone secretion in normal men, suggesting a direct inhibitory effect of ANH on aldosterone release. Thus, ANH may promote renal sodium loss both through inhibition of aldosterone release and through a direct natriuretic action.

ANH maybe an important mediator of age-related renal sodium loss. This effect maybe the consequence of increased basal ANH levels, increased ANH response to stimuli, increased renal sensitivity to ANH, and ANH-induced suppression of adrenal sodium-retaining hormones.

### Renin–Angiotensin–Aldosterone

A substantial body of evidence indicates that the normal aging process affects the renin–angiotensin–aldosterone system. Healthy older individuals (age 62–70 years) with normal dietary sodium intake have lower plasma renin activity and aldosterone concentration while in the supine position than do young healthy persons (age 20–30 years). Under the stimuli of upright posture and sodium depletion, significant increases in circulating renin and aldosterone occurred in both age groups, but mean values achieved were always significantly lower in the elderly group. The decrease in plasma renin activity in the elderly population is not a result of changes in plasma renin substrate concentration; rather, it is a result of a decrease in active renin concentration, perhaps caused by decreased conversion of inactive to active renin. The decrease in plasma renin activity may also be related to the inhibitory effect of increased amounts of ANH on renin secretion (see above). Decreased aldosterone concentration

with age appears to be a direct result of age-related decrease of plasma renin activity and not to aging changes in the adrenal gland because aldosterone and cortisol responses to corticotropin infusion are not altered in the elderly person. It is likely that the age-related decrease in aldosterone concentration is a predisposing factor to renal salt wasting in the elderly person.

Intrinsic renal tubular changes may also play a role in sodium wasting. An impaired capacity to reabsorb sodium has been described along with decreased tubular responsiveness to aldosterone administration. However, a subsequent study failed to find an effect of age on renal tubular sensitivity to aldosterone.

The age-associated decline in the renin–angiotensin–aldosterone system maybe linked to alterations in potassium regulation. Hyporeninemic hypoaldosteronism occurs most commonly in elderly persons, especially those with diabetes mellitus. The hyperkalemia characteristic of the disorder responds to treatment with mineralocorticoid and maybe the consequence of interaction of chronic renal disease with the hormonal changes of normal aging. The risk of angiotensin-converting enzyme (ACE) inhibitors in producing hyperkalemia is especially high in elderly persons, and may also be related to the interplay between drug action and physiologic alterations caused by aging.

## DISORDERS OF FLUID REGULATION

### Hyponatremia

Despite wide ranges in intake of sodium and water in normal persons, serum sodium concentration is tightly maintained within the range of 136–144 mEq/L. Hyponatremia is usually defined as a serum sodium concentration of  $\leq 135$  mEq/L. It appears when there is an excess of water relative to sodium in the extracellular body fluid compartment and can be the consequence of either a decrease in extracellular sodium content (i.e., sodium depletion) or an increase in extracellular water (i.e., dilutional hyponatremia). In the elderly person, dilutional hyponatremia is the more common mechanism and most frequently is caused by the syndrome of inappropriate antidiuretic hormone secretion (SIADH).

The altered relationship of sodium to water can occur in the setting of decreased (hypovolemic), normal (euvolemic), or increased (hypervolemic) intravascular volume. Hypovolemic hyponatremia can result from increased sodium loss from the gastrointestinal tract, from increased urinary loss, and from sweat. Euvolemic hyponatremia is characteristic of SIADH. Hypervolemic hyponatremia is seen in edematous states such as congestive heart failure, cirrhosis with ascites and nephrotic syndrome.

### Dilutional versus Depletional Hyponatremia

A key determination in the patient with hyponatremia is whether hyponatremia is of dilutional, depletional, or mixed origin and can generally be made by history and physical examination and by commonly available laboratory measurements (Table 88-3). The characteristic features of dilutional hyponatremia and SIADH are hyponatremia and serum hypoosmolality with clinical euvolemia and absence of edema, failure of the urine to be appropriately dilute, excretion of sodium in the urine at a concentration of  $>20$  mEq/L, and

**TABLE 88-3****Clinical Features of Depletional versus Dilutional Hyponatremia**

Feature	Depletional	Dilutional
History	Low dietary Na intake	Increased fluid intake (oral, IV)
	Na loss	Drugs
	Vomiting	Diseases
	Diarrhea	CNS
	Nasogastric suction	Pulmonary
		Malignancy
	Use of diuretics	
	Diseases	
	Renal	
	Adrenal	
Physical examination	Dry mucous membranes	Euvolemia or edema
	Decreased skin turgor	Evidence of CNS, pulmonary disease, malignancy
	Hypotension, tachycardia, orthostatic changes	
Laboratory evaluation	Increased hematocrit, BUN, creatinine	Normal or decreased BUN, creatinine, uric acid, albumin
	Urinary Na excretion <20 mEq/L	Urinary Na excretion >20 mEq/L

BUN, blood urea nitrogen; CNS, central nervous system; NA, sodium.

Reproduced with permission from Miller M. Hyponatremia: age-related risk factors and therapy decisions. *Geriatrics*. 1998;53:32.

the absence of other hyponatremia-producing disease states such as hypothyroidism, adrenal insufficiency, congestive heart failure, cirrhosis, or renal disease.

Depletional hyponatremia typically results from a prolonged period of inadequate sodium intake and/or from increased gastrointestinal tract or urinary sodium loss. Extracellular fluid volume depletion is often present with physical findings and laboratory values related to hypovolemia.

### Epidemiology

Hyponatremia is a common finding in elderly persons. Analysis of plasma sodium values in healthy individuals has shown an age-related decrease of approximately 1 mEq/L per decade from a mean value of  $141 \pm 4$  mEq/L in young subjects. In a population of individuals older than age 65 years who were living at home and who were without acute illness, a 7% incidence of serum sodium concentration of 137 mEq/L or less was observed. Similarly, there was a 11% incidence of hyponatremia in the population of a geriatric medicine outpatient practice. In hospitalized patients, hyponatremia is even more common with an incidence of about 1% and a prevalence of 3% to 4%, increasing to as high as 30% in intensive care unit patients. An analysis of 5000 consecutive sets of plasma electrolytes from a hospital population with a mean age of 54 years revealed a mean serum sodium of  $134 \pm 6$  mEq/L, with the values skewed toward the hyponatremic end of the distribution curve. A high prevalence of hyponatremia has been found in patients hospitalized for a variety of acute illnesses, with the risk being greater with increasing age of the patient.

Elderly residents of long-term care institutions appear to be especially prone to hyponatremia. In a study of patients with a mean age of 72 years who resided in a chronic disease hospital, 22.5%

had repeated serum sodium determinations of less than 135 mEq/L. Of patients admitted to an acute geriatric unit, 11.3% were found to have serum sodium concentrations of  $\leq 130$  mEq/L. A survey of nursing home residents aged >60 years revealed a prevalence of 18% with serum sodium less than 136 mEq/L. When this population was observed on a longitudinal basis over a 12-month period, 53% were observed to experience one or more episodes of hyponatremia. Persons with central nervous system (CNS) and spinal cord disease were at highest risk, and water-load testing indicated that most hyponatremic patients had features consistent with SIADH.

### Risk Factors (Table 88-4)

A major risk for the development or worsening of hyponatremia is the administration of hypotonic fluid, either as an increase in oral water intake or as intravenous 0.45% saline solution or 5% glucose in water, a finding in 78% of nursing home residents with hyponatremia. Low sodium intake coupled with age-associated impaired renal sodium-conserving ability can, over time, lead to sodium depletion with hyponatremia. Many patients whose nutritional support is primarily or entirely provided by tube feeding develop either intermittent or persistent hyponatremia. The underlying cause appears to be sodium depletion because of the low sodium content of most tube-feeding diets. The hyponatremia usually resolves in response to increasing the dietary sodium intake.

**TABLE 88-4****Risk Factors for Hyponatremia in the Elderly Person**

Physiologic changes of normal aging
Decreased renal sodium-conserving ability
Altered renal tubular function
Increased atrial natriuretic hormone secretion
Decreased renin-angiotensin-aldosterone secretion
Decreased renal water-excretion ability
Decreased renal blood flow and glomerular filtration rate
Decreased distal renal tubular diluting capacity
Increased renal passive reabsorption of water
Increased vasopressin secretion
Diseases accompanied by SIADH (see Table 88-5)
Drugs accompanied by sodium loss or SIADH (see Table 88-6)
Increased water intake
Oral fluids
Intravenous hypotonic fluids
Decreased sodium intake
Low-sodium diet
Tube feeding
Increased sodium loss
Renal disease
Gastrointestinal tract
Vomiting
Diarrhea
Gastric suctioning
Cerebral salt wasting
Idiopathic SIADH of the elderly person
Age >80 yr
Race other than African-American

SIADH, syndrome of inappropriate antidiuretic hormone secretion.

Reproduced with permission from Miller M. Hyponatremia: age-related risk factors and therapy decisions. *Geriatrics*. 1998;53:32.

Advanced age itself may be a risk factor for hyponatremia. SIADH has been described in elderly individuals, generally older than age 80 years, in whom no identifiable cause for hyponatremia could be found, suggesting that there is an idiopathic form of SIADH that may represent the clinical expression of physiologic changes that take place in the regulation of water balance during aging. Race may play a role because African-Americans appear to be at lower risk than whites or Hispanics.

Hyponatremia often is a marker for severe underlying disease with poor prognosis and high mortality. The presence of hyponatremia in patients with congestive heart failure is an independent risk factor for death. Hyponatremia is common in patients with liver cirrhosis, in whom it is associated with a significantly worse prognosis. It is unclear whether hyponatremia is the direct cause of death in these patients, but its prompt diagnosis and effective treatment are important in improving patient outcomes.

### Syndrome of Inappropriate Antidiuretic Hormone Secretion

**Diseases** Many diseases that are common in the elderly population can cause SIADH (Table 88-5). Almost all CNS disorders can lead to dysfunction of the hypothalamic system involved in the normal regulation of AVP secretion with resultant increased secretion of the hormone and consequent risk for water retention and hyponatremia. Such CNS disorders include vascular injury (thrombosis, embolism, hemorrhage), trauma with subdural hematoma, vasculitis, tumor, and infection. Malignancies can cause SIADH as a result of autonomous release of AVP from cancer tissue where it is synthesized, stored, and discharged in the absence of known stimuli. The

malignancy most commonly associated with SIADH in the elderly population is small-cell carcinoma of the lung, in which as many as 68% of patients have been found to have evidence of impaired water excretion and elevated blood AVP concentration. Other malignancies include pancreatic carcinoma, thymoma, pharyngeal carcinoma, lymphosarcoma, and Hodgkin's disease. Inflammatory lung diseases can also cause SIADH, perhaps as a result of AVP production by diseased pulmonary tissue, and include such entities as bronchiectasis, pneumonia, lung abscess, and tuberculosis.

**Drugs** Numerous drugs taken by elderly persons can affect water balance by direct action on the kidney or by altering AVP release from the neurohypophyseal system or its action on the kidney (Table 88-6). In particular, many drugs increase the risk for SIADH.

Hyponatremia with the characteristics of SIADH is recognized as a side effect of several older antipsychotic agents, such as fluphenazine, thiothixene, and phenothiazine, and the tricyclic antidepressants. There is evidence that the selective serotonin reuptake inhibitors (SSRIs) antidepressants can also induce SIADH, with a reported incidence of 3.5 to 6.3 per 1000 people treated per year. Although fluoxetine is the SSRI most commonly reported to produce hyponatremia, other SSRIs, including paroxetine, sertraline, fluvoxamine, citalopram and escitalopram, have also been involved. Individuals at highest risk for SSRI-induced hyponatremia are those older than age 65 years in whom the onset of hyponatremia typically occurs within 2 weeks after initiation of drug therapy. More recently, there is evidence that drugs with combined SSRI/norepinephrine reuptake inhibitor (SNRIs) activity, such as venlafaxine and duloxetine, are also capable of producing SIADH-type hyponatremia.

ACE inhibitor use in the elderly population is associated with the development of hyponatremia. In most of the cases, the level of hyponatremia has been clinically significant with serum sodium concentrations as low as 101 mEq/L and with symptoms ranging from confusion to seizures and coma. Although initial reports indicated that the risk was greatest when ACE inhibitors were used in combination with thiazide diuretics, it now appears that the ACE inhibitors alone can precipitate hyponatremia. The hyponatremia appears to be dilutional with features of SIADH and maybe mediated by potentiation of plasma renin activity with subsequent increase in brain angiotensin levels, which, in turn, stimulate both release of AVP from the hypothalamus and an increase in thirst. Discontinuing the ACE inhibitor is associated with rapid resolution of the hyponatremia.

Diuretics, both of the loop and thiazide types, can produce hyponatremia. Loop diuretics appear to have a greater natriuretic effect in older persons than in younger persons. Hyponatremia can occur when diuretic-induced sodium and water loss are replaced by hypotonic fluids, resulting in a combined depletion and dilutional hyponatremia. With thiazide diuretics, the induced sodium loss is often accompanied by loss of total body potassium with consequent decrease in intracellular solute content and decreased cell volume. This circumstance can activate hypothalamic pathways, leading to increased AVP discharge, water retention, and SIADH. This form of thiazide-induced hyponatremia occurs almost entirely in the elderly population and can be reversed by correcting the underlying potassium depletion.

Other drugs associated with development of hyponatremia in the elderly population include the sulfonyleurea chlorpropamide, the anticonvulsant carbamazepine, and the antineoplastic agents vincristine, vinblastine, and cyclophosphamide. Analgesics, particularly the narcotics, maybe responsible for the occurrence of hyponatremia in the elderly postoperative patient.

**Cerebral Salt Wasting** Renal sodium excretion from the excessive release of natriuretic factor in the brain can lead to cerebral salt wasting (CSW). CSW and SIADH are both syndromes of hypoosmotic serum and increased urine sodium excretion. Patients with CSW, however, have a low effective intravascular blood volume as a consequence of marked natriuresis and secondary osmotic diuresis. In contrast, patients with SIADH are usually euvoletic or have mildly increased extracellular fluid volume. CSW can be diagnosed by the clinical and laboratory findings that define diminished extracellular fluid volume, including orthostatic hypotension, tachycardia, and elevated hematocrit, blood urea nitrogen (BUN), and creatinine levels.

## Clinical Presentation

Mild chronic hyponatremia may appear to be asymptomatic. However, recent evidence from a case-control study suggests that mild chronic hyponatremia may have serious consequences in the elderly, even when symptoms appear to be absent. This study examined the frequency of falls in 122 patients (mean age 72 years) with chronic hyponatremia (serum sodium 115–132 mEq/L) admitted to a medical emergency department. The frequency of reported falls was significantly greater among patients with hyponatremia (21.3%) than among control subjects (5.3%) and was unrelated to the level of serum sodium. Alterations in gait and attention were detected in patients with hyponatremia and suggest that these impairments may have contributed to the higher incidence of falls in this group. The data suggest that prompt recognition of even apparently asymptomatic hyponatremia and early initiation of appropriate treatment maybe important for preventing hyponatremia-related consequences.

The clinical severity of hyponatremia is dependent on both the magnitude of the hyponatremia and the rate at which the serum sodium level has declined. There is often a poor correlation between serum sodium concentration and severity of symptoms. Serum sodium levels <125 mEq/L maybe accompanied by lethargy, fatigue, anorexia, nausea, and muscle cramps. With worsening hyponatremia, CNS symptoms predominate and range from confusion to coma to seizures. There is substantial risk of death in severely symptomatic patients with serum sodium <110 mEq/L who also have underlying disease with cachexia.

## Management (Table 88-7)

Treatment of hyponatremia is based on the absence or presence of symptoms and their severity, whether the onset is acute or chronic, and if acute, the rapidity of onset. Hyponatremia caused by sodium depletion is often accompanied by extracellular fluid volume depletion and treatment is directed at correcting the volume deficit with intravenous 0.9% saline. Milder depletion hyponatremia, such as that occurring in persons whose nutrition is predominantly from enteral feedings, can be corrected by adding saline solution or crushed sodium chloride tablets to the enteral feedings.

For patients thought to be asymptomatic, conservative management is appropriate with fluid restriction and an attempt to identify and correct the underlying cause, if possible. Mildly symptomatic patients with serum sodium >125 mEq/L can be treated with fluid

**TABLE 88-7**

### Treatment of Dilutional Hyponatremia

Presentation	Treatment Modality	Potential Adverse Outcomes
Acute	IV 3% saline, 300–500 mL over 4–6 h, followed by 100 mL/h until serum Na reaches ~125 mEq/L at rate of increase of 0.5–1 mEq/L/h (maximum increase 12 mEq/L over 24 h) IV furosemide 1 mg/kg body weight	Central pontine myelinolysis, congestive heart failure Hypokalemia, hypomagnesemia
Chronic	Correction of underlying cause Fluid restriction to 800–1000 mL per 24 h Demeclocycline 600–1200 mg per 24 h	Thirst stimulation, dehydration Photosensitivity, azotemia, nephrotoxicity in patients with hepatic disease or congestive heart failure

Reproduced by permission from Miller M. Hyponatremia: Age-related risk factors and therapy decisions. *Geriatrics* 1998;53:32.

restriction to a level of 800 to 1000 mL/24 hours. The patient with acute onset of symptomatic dilutional hyponatremia requires prompt intervention and is best managed in an intensive care unit setting and treated with intravenous 3% saline infusion at a rate sufficient to raise serum sodium by 0.5 to 1 mEq/L/h. The goal is a maximum increase in serum sodium of no more than 12 mEq/L in the first 24 hours, and to a value no higher than 125 mEq/L, in order to avoid central pontine myelinolysis. Occasionally, patients either with fluid overload and pulmonary edema or with symptoms of coma or seizures who have very low serum sodium levels may require initial treatment with intravenous furosemide in a dose 1 mg/kg body weight along with the 3% saline. In this circumstance, attention will need to be given to possible diuretic-induced potassium and magnesium depletion.

Strategies currently used for the treatment of stable, asymptomatic or mildly symptomatic chronic hyponatremia include mainly fluid restriction and occasionally demeclocycline. Demeclocycline in doses of 600 to 1200 mg daily blocks AVP effect on the renal distal and collecting tubules with production of a mild state of nephrogenic diabetes insipidus, thus promoting an increase in urine production and a corresponding increase in serum sodium. Both chronic fluid restriction and demeclocycline administration are limited by poor compliance, inconsistent or delayed response and, in the case of demeclocycline, renal and hepatotoxicity.

### Role of Aquaretics in the Treatment of Hyponatremia

AVP receptor antagonists, a new class of drugs called “aquaretics,” which promote electrolyte-free excretion of water, may provide a more reliable approach to the treatment of both acute and chronic hyponatremia. AVP promotes renal water reabsorption by increasing the water permeability of epithelial cells in the renal-collecting ducts. This and other biological effects of AVP are mediated by the interaction of the hormone with various receptors:  $V_{1A}$ ,  $V_{1B}$ , and  $V_2$ . It is the binding of AVP to  $V_2$  receptors in renal collecting duct cells that promotes renal reabsorption of water. Interaction of AVP with these receptors initiates a series of events culminating in the insertion of aquaporin-2 water channels in the apical plasma membrane. The interaction of AVP with  $V_{1A}$  receptors in vascular smooth muscle cells, hepatocytes, and platelets mediates vasoconstriction, glycogenolysis, and platelet aggregation. Corticotropin release is regulated via  $V_{1B}$  receptors located predominantly in the anterior pituitary.

Excess or inappropriate secretion of AVP acting on renal  $V_2$  receptors causes the retention of water and can lead to dilutional hyponatremia. The blockade of these AVP  $V_2$  receptors thus represents a rational approach to the treatment of hyponatremia. The development of AVP receptor antagonists began several decades ago with the synthesis of peptide AVP analogs capable of antagonizing the water-reabsorbing effect of AVP in a number of animal species. A major advance in the early 1990s was the development of nonpeptide molecules, which were able to bind to AVP receptors and function as  $V_1$  and/or  $V_2$  receptor antagonists. The nonpeptide AVP receptor antagonists subsequently created—tolvaptan, lixivaptan, sativaptan, and conivaptan—exhibit a long half-life and no agonist activity.

At the present time, conivaptan is the only agent in this class to be approved by the Food and Drug Administration and is limited to its intravenous form for the treatment of euvolemic hyponatremia in hospitalized patients. Conivaptan blocks the action of AVP at both the  $V_2$  receptor that mediates renal excretion of water and the

**TABLE 88-8**

#### Aquaretic Agents

Drug	Route of Administration	Hyponatremic Population Studied
Conivaptan*	i.v.	SIADH
Lixivaptan	Oral	Cirrhosis with ascites, CHF, SIADH
Sativaptan	Oral	SIADH
Tolvaptan	Oral	Cirrhosis with ascites, CHF, SIADH

SIADH, syndrome of inappropriate antidiuretic hormone secretion; CHF, congestive heart failure.  
\*Only drug listed approved by the U.S. Food and Drug Administration.

$V_{1A}$  receptor that mediates systemic vasoconstriction. Several of the other aquaretic agents have been studied extensively in normal human subjects and in clinical trials in patients with hyponatremia. Tolvaptan, lixivaptan, and sativaptan are effective by oral administration and bind to  $V_2$  receptors in the renal tubules to block the action of AVP. In clinical trials, these three drugs have been demonstrated to promote acute aquaresis in patients with SIADH and in patients with hyponatremia caused by congestive heart failure and also to maintain improvement in serum sodium for up to 12 months of chronic treatment (Table 88-8).

The AVP receptor antagonists may provide a more direct approach to the treatment of both acute and chronic euvolemic and hypervolemic hyponatremia than currently available therapies. Preliminary experience with the AVP receptor antagonists suggests that these agents are effective and well tolerated both acutely and following prolonged administration. Continued investigation should further define the role of AVP receptor antagonists in the treatment of acute and chronic hyponatremia in the elderly. The ability of the drugs to normalize serum sodium in patients who have chronic and apparently asymptomatic hyponatremia will help determine the clinical significance of this common electrolyte disturbance.

### Hypernatremia and Dehydration

Hypernatremia, generally defined as a serum sodium of  $\geq 148$  mEq/L, most commonly occurs when there is excessive loss of body water relative to loss of sodium in association with inadequate fluid intake. In this circumstance, hypernatremia is accompanied by dehydration. When fluid loss is accompanied by sodium loss, dehydration can occur without associated hypernatremia. In rare circumstances, hypernatremia can be caused by excessive sodium intake without corresponding increased fluid intake and thus be associated with euvolemic or hypervolemic volume status.

### Epidemiology

In a study of 15,187 hospitalized patients older than age 60 years, a 1% incidence of hypernatremia was reported, with a mean serum sodium concentration of 154 mEq/L. Similarly, a study of elderly residents in a long-term care institution revealed a 1% incidence of hypernatremia, which increased to 18% over a 12-month observation period. Of 264 nursing home residents in whom acute illness developed requiring hospitalization, 34% became markedly hypernatremic with serum sodium concentration greater than 150 mEq/L.

**TABLE 88-9****Risk Factors for Hyponatremia in the Elderly Population**

Increased water loss
Renal
Age-associated impaired concentrating capacity
Resistance to vasopressin action
Age-associated
Acquired (drugs, hypokalemia, hypercalcemia)
Osmotic diuresis (glycosuria, diuretic-induced natriuresis)
Renal tubular disease
Gastrointestinal tract
Vomiting
Diarrhea
Skin (sweating)
Lung (tachypnea)
Decreased water intake
Impaired thirst perception
Impaired cognition (delirium, dementia)
Impaired access to fluids

**Risk Factors**

The renal and hormonal alterations of aging described above are physiologic factors associated with an increased risk for hyponatremia (Table 88-9). Frequent pathologic factors are febrile illness with increased insensible fluid loss, tachypnea with increased water loss from the lungs, vomiting or diarrhea, and osmotic-induced polyuria from poorly controlled diabetes mellitus or use of loop diuretics. There is a high morbidity and mortality in elderly patients who develop serum sodium concentrations above 148 mEq/L and such elevations of serum sodium are often a consequence of a severe underlying disease process.

CSW, described above, can lead to marked intravascular volume depletion and hypotonic dehydration. Typical clinical features are related to the volume depletion and include orthostatic hypotension, tachycardia, and increases in blood hemoglobin, hematocrit, urea nitrogen, and creatinine.

**Clinical Presentation**

The symptoms of both moderate hyponatremia and dehydration may be nonspecific and commonly include weakness and lethargy. More severe hyponatremia, often with serum sodium concentration >152 mEq/L, may be accompanied by obtundation, stupor, coma, and seizures. The clinical signs are those of volume depletion and dehydration with weight loss, decreased skin turgor, dry mucous membranes, tachycardia, and orthostatic hypotension. In addition to the elevated serum sodium, laboratory findings are those of hemoconcentration with increased hematocrit, BUN, creatinine, and serum osmolality. Urine osmolality may not be greatly increased because of age-related impairment in renal concentrating capacity.

**Management**

The correction of hyponatremia requires replacement of body water deficits, which may be as large as 11 L or 30% of total body water. When hyponatremia is caused almost entirely by water loss

alone, the water deficit can be estimated by means of the following calculation:

$$\text{Current total body fluid volume (L)} = \frac{140 \text{ mEq/L} \times \text{basal body weight (kg)} \times 0.45}{\text{current serum Na (mEq/L)}}$$

where 0.45 represents the approximate proportion of body weight that is water. Total body water is subtracted from estimated normal total body water of  $0.45 \times \text{body weight}$  to give an approximate value for the water deficit.

Modest fluid deficits of 1 to 2 L can be corrected by oral fluid intake. More significant volume deficits require intravenous fluid therapy, preferably starting with 0.9% saline given at a rate sufficient to resolve orthostatic hypotension and tachycardia and to replace approximately 50% of the estimated fluid deficit in the first 24 hours and to reduce serum sodium by no more than 2 mEq/L/h. Excessively rapid correction can lead to cerebral edema with consequent brain damage or death. The goal is then to correct remaining volume depletion and hyponatremia over 48 to 72 hours by using 0.45% saline.

Treatment of dehydration without hyponatremia is directed at correction of intravascular volume depletion and involves fluid replacement with intravenous 0.9% saline. Clinical indicators of effectiveness of therapy are correction of orthostatic hypotension and tachycardia and reduction in BUN and serum creatinine concentrations.

**Nocturnal Polyuria**

In normal young persons, there is a diurnal pattern of vasopressin secretion with highest levels occurring during sleep. This is reflected by a lower rate of urine flow at night (40–60 mL per hour) than during the daytime (60–80 mL per hour) so that nighttime urine volume is approximately 25% or less of total 24-hour urine volume. In many older persons, there is loss of nocturnal vasopressin secretion and an accompanying reversal of day/night urine production so that nighttime urine flow rate exceeds the daytime flow rate. This alteration in renal function leads to a diabetes insipidus-like nocturnal polyuria. Nocturnal polyuria is considered to be present when any of the following criteria are met: urine production during 8 hours of sleep is  $\geq 33\%$  of 24-hour urine production; nighttime urine production rate is  $\geq 0.9$  mL/min; 7 P.M. to 7 A.M. urine volume is  $\geq 50\%$  of total 24-hour volume (Table 88-10). Nocturnal

**TABLE 88-10****Nocturnal Polyuria****Definitions**

- Urine production during 8 h of sleep  $\geq 33\%$  of 24-h urine production
- Nighttime urine production rate  $>0.9$  mL/min
- 7 P.M. to 7 A.M. urine volume  $\geq 50\%$  of total 24-h volume

**Causes**

- Normal aging
- Multiple system atrophy
- Alzheimer's disease
- Spinal cord injury

polyuria is a common finding in community-residing elderly persons with nocturia. The prevalence can be as high as 50% in nursing home residents, particularly those with Alzheimer's disease. It is also often seen in patients with central autonomic insufficiency (Shy-Drager syndrome/multiple system atrophy) or spinal cord injury (Table 88-10).

Both reduced bladder capacity and detrusor instability are commonly present in elderly persons, with prevalence in both men and women increased with increasing age. High nighttime urine production in persons with nocturnal polyuria coupled with these bladder alterations may be a contributing factor to the nocturnal urinary frequency seen so commonly in older persons.

### Evaluation

Individuals with nocturia can be evaluated for the presence of nocturnal polyuria by means of a voiding diary in which the time and volume of each void is recorded for a 72-hour period. In addition, urine production during 8 hours of sleep can be measured in a timed urine collection and compared with urine production during the remainder of a 24-hour period. Both approaches allow demonstration of increased nocturnal urine production meeting the above cited criteria.

### Management

The vasopressin analog DDAVP (deamino-8-D-arginine vasopressin) may be helpful in treating both nocturnal frequency and nocturnal urinary incontinence among patients without other treatable causes of these symptoms. DDAVP can be given either intranasally in a dose of 5 to 20  $\mu\text{g}$  or orally in a dose of 200 to 400 mg taken in the evening. Because DDAVP has a duration of action of 12 to 24 hours, care must be taken to monitor serum sodium to avoid the possible development of dilutional hyponatremia. A meta-analysis of published reports on the use of either intranasal or oral DDAVP in treatment of nocturia in older adults has identified hyponatremia as a common occurrence with a pooled incidence of 7.6%. In the authors' experience, hyponatremia has been observed in as many as 20% of older persons treated with oral DDAVP. Patients treated with DDAVP should therefore have serum sodium monitored within 3 to 7 days of initiating therapy, and periodically thereafter.

### Water Balance in Alzheimer's Disease

Persons with Alzheimer's disease are at increased risk for disturbed water regulation (Table 88-11). The secretion of vasopressin may be lower in those with Alzheimer's disease than in comparably aged persons with normal cognitive function and there is absence of the nocturnal rise in hormone secretion. Following dehydration, individuals with Alzheimer's disease show a lesser rise in plasma vasopressin than do age-matched normal subjects. Similarly, pharmacologic stimulation with metoclopramide or physostigmine is accompanied by marked blunting of plasma vasopressin response. These changes contribute to a high prevalence of nocturnal polyuria and nocturia in patients with Alzheimer's disease. In patients with Alzheimer's disease, the cognitive impairment can cause the nighttime polyuria to be clinically expressed as urinary incontinence.

**TABLE 88-11**

#### Alzheimer's Disease and Disordered Water Regulation

Alterations in water regulation
Impaired thirst perception
Decreased vasopressin secretion
Basal
Response to stimulation
Diurnal pattern
Clinical consequences
Increased risk of dehydration
Hypertonicity (increased serum sodium and osmolality)
Reversal of day/night urine flow rate
Nocturnal polyuria and incontinence

Clinically, the combination of impaired water conservation along with an impairment of thirst perception puts patients with Alzheimer's disease at increased risk for dehydration. In studies of patients with Alzheimer's disease, overnight fluid restriction results in greater rise in plasma osmolality, greater water loss, and, in spite of these stimuli for thirst, marked reduction in spontaneous water intake. A direct correlation has been demonstrated between minimal status examination score and impairment of water intake.

### SUMMARY

Normal aging is accompanied by many changes in the various regulatory systems involved in the control of sodium and water balance. As a consequence of these alterations, the elderly person has a diminished capacity to withstand the challenges of illness, drugs, and physiologic stresses, and, thus, has an increased risk for the development of clinically significant alterations in sodium and water balance, which may have adverse effects on functional status and mortality. Awareness of the limitations of homeostatic ability can allow the physician to anticipate the impact of illnesses and drugs on volume and electrolyte status of the elderly patient and lead to a more rational approach to therapeutic intervention and management.

The recent availability of AVP antagonists should make it possible to normalize serum sodium in persons with chronic hyponatremia and, in so doing, allow the impact of hyponatremia on many areas of function to be clarified, especially the role of hyponatremia on worsening cognitive function in persons who already have underlying disorders of cognition. The potential ability of long-term treatment with AVP antagonists to alter diminished quality of life and mortality of persons with hypervolemic hyponatremia, such as occurring in congestive heart failure and in cirrhosis with ascites, remains an area for future investigation.

# Effect of Aging on Gastrointestinal Function

*Karen E. Hall*

The aging process has clinically significant effects on oropharyngeal and upper esophageal motility, colonic function, gastrointestinal (GI) immunity, and GI drug metabolism (Figure 89-1). On the other hand, because the GI tract exhibits considerable reserve capacity, many essential aspects of GI function, such as intestinal secretion, are preserved with aging. Despite such adaptation, superimposed effects of chronic diseases and environmental/lifestyle exposures (medications, alcohol, tobacco) can further impair GI function in older patients. A modest decline in gastric mucosal cytoprotection or esophageal acid clearance may become significant when superimposed side effects of certain medications or concurrent disease are also present. Certain age-related changes in GI function, such as constipation, are viewed as dysfunctional by patients and health care providers. Research areas that have been identified as important in aging include the pathophysiology of swallowing disorders, esophageal reflux, dysmotility syndromes, GI immunobiology, and the cellular mechanisms of neoplasia in the GI tract. Animal studies provide important insights into the cellular physiology of aging, despite the issue of species variation.

## OROPHARYNGEAL FUNCTION

The increasing likelihood of dental decay and tooth loss with aging affects the efficiency and completeness of mastication (also see Chapter 42). Chewing and swallowing are impaired by xerostomia, which affects roughly 25% of older patients, while as many as 50% have subjective complaints of dry mouth. Medication side effects are a common cause of xerostomia, while a minority is caused by specific diseases affecting the salivary glands, such as Sjogren's syndrome. A mild loss of saliva production appears to occur with normal aging.

After food is broken up in the mouth by mastication, the act of swallowing moves the food bolus from the oral cavity into the pharynx and esophagus (also see Chapter 41). The oral and pharyngeal stages of swallowing are regulated by cortical input to medullary swal-

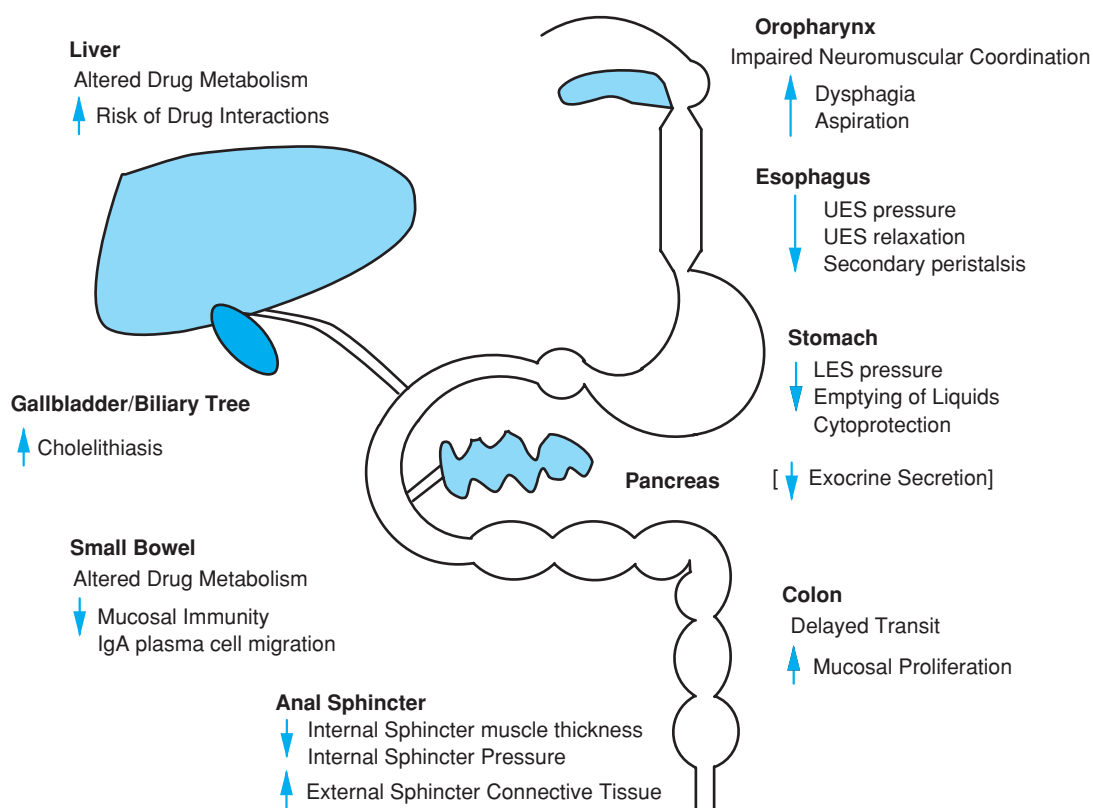

lowing centers, which innervate skeletal muscle groups in the pharynx. The proximal esophagus contains skeletal muscle controlled by nerves from the medullary swallowing centers, whereas the mid- and distal esophagus consists of smooth muscle regulated by intrinsic enteric innervation and extrinsic innervation by the vagus nerve.

Oropharyngeal swallowing disorders are most commonly observed in patients with cognitive and/or perceptual dysfunction secondary to stroke or dementia, or chronic neurodegenerative diseases that affect the brainstem or motor neurons, such as Parkinson's disease, myasthenia gravis, or amyotrophic lateral sclerosis. Normal aging, however, is associated with alterations that predispose older individuals to dysphagia. Video fluoroscopy demonstrates abnormal transfer of a food bolus from the oral cavity to the pharynx in up to 60% of elderly patients without dysphagia. Other anatomic changes in esophageal neuromuscular anatomy occur in the aged oropharynx, such as cricopharyngeal bars caused by osteoarthritic spine disease. The pathophysiological significance of these are not clear, however, as they are seen in older patients with normal deglutition. Upper esophageal sphincter pressure gradually decreases with age, and is associated with a delay in relaxation after deglutition. Aspiration risk is increased in older subjects by delayed elevation of the larynx and decreased ability to clear food from the pharynx compared to younger subjects. However, clinically significant aspiration usually does not occur unless there are superimposed risk factors such as neurodegenerative diseases (e.g., Parkinson's disease) or medications that affect neuromuscular function. Figure 89-2 illustrates how various risk factors may interact with aging effects to lead to clinical swallowing problems, and is a model that may apply to how aging contributes to other GI tract disorders as well.

## ESOPHAGEAL FUNCTION

Age-associated changes in the anatomy of the esophageal body appear to be minimal. Thickness of esophageal smooth muscle and

**FIGURE 89-1.** Effects of physiological aging on the gastrointestinal tract. This schematic diagram summarizes significant effects of aging on various divisions of the gastrointestinal tract. Key: up arrow, increased, down arrow, decreased. (Revised from Hall and Wiley. *Age-associated changes in gastrointestinal function*. In: Hazzard et al., eds. *Principles of Geriatric Medicine and Gerontology*, 5th ed. New York, New York: McGraw-Hill; 2003 [chapter 63].)

amplitude of peristaltic contractions appear unaffected by aging. Although the number of myenteric neurons in the esophagus decreases with age, the functional significance is unclear. While some studies have reported impaired relaxation or decreased contractions of the lower esophageal sphincter (LES) with aging, more recent reports suggest that concomitant disease accounts for altered resting pressure of the aged LES.

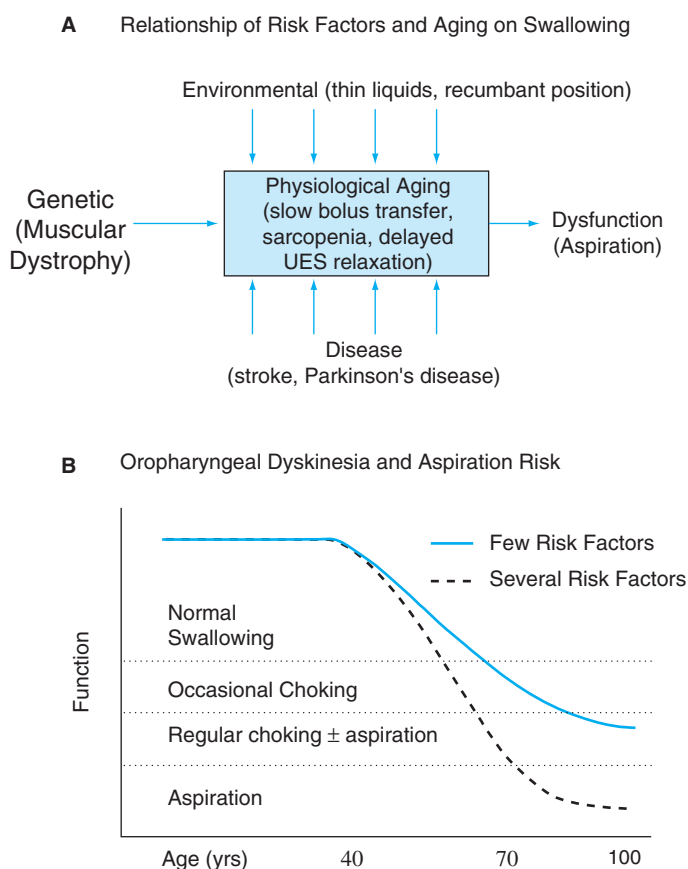

Complaints of dysphagia, regurgitation, chest pain, and heartburn are fairly common in the geriatric population, with a prevalence of 35% reported in the general population aged 50 to 79 years (see Chapter 91). However, it is difficult to demonstrate a consistent relationship between symptoms and underlying pathophysiology, as demonstrable esophageal abnormalities are found in only 20% to 30% of symptomatic patients. A particular concern in an elderly patient is that symptoms of dysphagia are more likely to have a serious underlying etiology, such as malignancy. Elderly patients also appear to be more susceptible to complications of inadequately treated chronic esophageal disease, such as aspiration, malnutrition, and Barrett's metaplasia. Attempts at symptom analysis to identify subgroups at risk for serious underlying disease have met with mixed success.

The term "presbyesophagus" was coined to describe age-related changes in esophageal function, including decreased contractile amplitude, polyphasic waves in the esophageal body, incomplete relaxation of the lower esophageal sphincter, and esophageal dilation. The most common alteration in motility observed in older subjects was an increase in rapidity of propagation of the peristaltic wave, together with increased simultaneous contractions. Esophageal dysmotility in older patients is more often a result of diabetes mellitus and neurological disorders, or the side effects of medications, rather than aging per se.

Symptoms related to gastroesophageal reflux disease (GERD) are a frequent complaint of elderly patients (see Chapter 91). Risk factors for reflux-induced esophageal damage include decreased esophageal clearance, gastric factors such as decreased emptying or increased gastric pressure, decreased LES pressure, inappropriate LES relaxation, or the presence of a hiatal hernia, and increased gastric acid exposure and longer duration of reflux episodes. This may be caused by decreased occurrence of secondary esophageal peristalsis, an important clearance mechanism for refluxed acid. Other factors, such as gastric emptying and frequency of LES relaxation, are relatively unchanged with aging. Concurrent disease and side effects of medications may play an important role in the pathophysiology of GERD in older patients.

## GASTRIC FUNCTION

Decreased clearance of liquids from the stomach has been documented in older patients, and can be exacerbated by anticholinergic medications. Aging is also associated with decreased perception of gastric distension as measured by subjective fullness during inflation of a gastric barostat balloon. Delayed emptying may prolong the gastric contact time of noxious agents, such as nonsteroidal anti-inflammatory drugs (NSAIDs). This may have serious consequences, as significant age-related changes do occur in gastric mucosal defense mechanisms. These may predispose aged people to gastric mucosal injury and subsequent complications of ulceration. Increased risk of gastric injury does not appear to be the result of excessive secretion of agents that promote mucosal injury, as most healthy older individuals have decreased, not increased, acid and pepsin output.

**FIGURE 89-2.** (A) Physiological aging may be thought of as a baseline state upon which can be superimposed the effects of risk factors such as genetic predisposition, environmental exposure, and superimposed disease. The net result is symptomatic dysfunction in senescence that results in impairment. An example of this kind of synergy is dysphagia, which can manifest as a result of a combination of superimposed risks such as neurodegenerative disease and drug-induced damage on age-related oropharyngeal dyskinesia. UES, upper esophageal sphincter. (B) Graph illustrating how risk factors may affect swallowing function at various ages. Horizontal solid lines indicate three theoretical thresholds for clinically significant dysphagia (mild, moderate, severe symptom). Physiological aging of the gastrointestinal tract in individuals with few risk factors for dysphagia (solid blue line) results in minimal alterations in swallowing in middle age through the sixth decade. Superimposed risk factors such as neuromuscular disease (dashed line) can lead to earlier onset of dysphagia, and increased risk of moderate or severe dysphagia.

A small minority has severe acid hyposecretion (achlorhydria) associated with atrophic gastritis. Animal studies have shown a small age-related reduction in gastric acid secretion. Gastrin levels tend to rise with age in humans, possibly as a compensatory response to decreased acid production as a result of increased gastric autoantibodies and *Helicobacter pylori* colonization. The increased prevalence of *H. pylori* carriage in the elderly population does not appear to result in increased rates of duodenal ulceration, but is associated with increased risk of pernicious anemia and gastric lymphoma.

Increased susceptibility to gastric mucosal injury from NSAIDs in elderly people appears to be caused by a reduction in gastric mucosal cytoprotective factors such as mucosal prostaglandins. Human and animal aging is associated with a significant decrease in gastric bicarbonate, sodium ion and nonparietal fluid secretion, and thinning of the mucus gel layer, particularly in *H. pylori*-positive individuals. Aging is also associated with a decrease in the basal and

injury-induced rate of proliferation of stem cells in the neck of gastric glands in rats. In vivo expression and activity of several intestinal growth factors, such as transforming growth factor alpha (TGF $\alpha$ ) and epithelial growth factor (EGF), is decreased in animal models of aging. However, activation of EGFR by membrane-bound TGF-alpha in vitro is actually increased in gastric and colonic mucosa of aged rats, suggesting that the relative lack of activity may not be caused by intrinsic inactivation.

Mucosal blood flow plays an essential role in maintaining gastric mucosal integrity. In rats, aging is associated with a decrease in basal gastric blood flow associated with impaired healing of acid-induced mucosal lesions. Impaired healing of gastric ulcers has also been associated with underlying impairment in sensory neuron function in several aging models.

Gastric secretion of intrinsic factor is necessary for vitamin B-12 absorption in the small bowel. Decreased secretion of intrinsic factor in aging is invariably caused by atrophic gastritis, not aging per se.

## SMALL INTESTINAL FUNCTION

The small intestine has a large functional reserve capacity, because of the substantial mucosal surface area available for secretion and absorption. Intestinal surface area does not change after 6 weeks of age in rats. It is unclear whether the specific activity of intestinal disaccharidases and amino-peptidases is affected by aging, as both higher and lower activity has been reported in aged animals compared to youthful controls. Delayed maturation and expression of brush-border enzymes in small intestinal villous epithelial cells during crypt-to-villous migration appears to be the underlying cause. However, absorption of lactose, mannitol, and lipid in individuals greater than 60 years of age is unaffected. Vitamin D absorption and sensitivity is significantly impaired in aged rats. This is also a concern in human studies, which have documented decreased uptake of vitamin D, folic acid, vitamin B-12, calcium, copper, zinc, fatty acids, and cholesterol in aged subjects. Current recommendations by the U.S. Department of Agriculture to increase calcium, B-12, and Vitamin D supplementation in persons older than 70 years of age reflect this new information. Iron is one nutrient that is usually present in overabundance in the diet for older individuals. Older patients maybe at risk of diseases such as hepatic iron overload (particularly in individuals who are monozygotic for hemochromatosis), and iron overload has been implicated in some models of oxidative stress. Older men and postmenopausal women do not require additional iron unless there is superimposed blood loss or bone marrow impairment.

There is little evidence that older individuals are at risk for impaired absorption of most macronutrients in the absence of superimposed disease or surgical resection of small bowel. Limited data suggests that absorption of raw and heat-treated soybeans is impaired in old rats compared to youthful animals, while casein, skim milk powder, and autoclaved soybean powder were absorbed equally well. This may have implications for older individuals who follow a macrobiotic diet. Studies of protein turnover indicate that rapidly absorbed proteins such as whey protein resulted in greater net protein gain in older subjects compared to younger individuals, although the effect disappeared if fat and carbohydrate were added to the test meal. It is not clear whether this indicates a true impairment in protein absorption, or effects of fat and carbohydrate on small bowel motility.

Aging may alter visceral chemosensitivity or hormone responsiveness, as an enhanced satiating effect of carbohydrates delivered into the small intestine by infusion has been reported in older men. Mucosal regeneration is actually increased in aging. Crypt cell proliferation rates in all segments of the small intestine were found to be greater in aged rats compared to their youthful counterparts. These studies suggest that aged animals have increased cell production as a result of greater number of crypt cells undergoing cell division.

Minor effects of aging on small bowel motility have been described despite reports that several neuronal subtypes (substance P-, VIP-, somatostatin-, and nitric oxide-containing) are decreased in aged animals models. Studies in cats do not demonstrate significant effects of age on small bowel transit of radiolabeled lipids. In human studies, small bowel transit time measured by breath hydrogen was shorter in elderly males, but not women. Caloric restriction to 70% of normal intake prevents ileal myenteric neuronal loss in Sprague-Dawley rats up to 30 months of age, similar to beneficial effects of calorie restriction on other changes in aging.

## COLONIC FUNCTION

Aging is associated with diverse effects on the large intestine including alterations in mucosal cell growth, differentiation, metabolism, and immunity. Disorders commonly observed in elderly patients include colon cancer, diverticulosis, and altered bowel habits, leading to constipation or diarrhea (see Chapters 92 and 93). While constipation is a common complaint in elderly people, age-associated alterations in colonic motility have been difficult to demonstrate. Some studies indicate that colonic transit slows with aging, particularly in women, while others found no significant difference in transit between young and elderly subjects. Inclusion of chronic laxative users in investigations of colonic function in aging should be interpreted cautiously, as chronic use of phenolphthalein results in loss of interneurons. Other cathartic laxatives, such as senna, do not cause significant anatomic damage in animal studies when used for up to 5 months.

Age-associated reduction in the nitric oxide-containing neurons in the myenteric plexus involved in receptive relaxation has been reported. The remaining myenteric neurons maybe functionally impaired. Release of the excitatory neurotransmitter acetylcholine was diminished in the colon of aged rats, an effect that appeared to be caused by decreased calcium influx. Neurotransmitter release from myenteric neurons in the aged colon could be restored to youthful levels by use of calcium ionophores that bypass membrane calcium channels. Similar impairment of calcium signaling with aging has also been demonstrated in peripheral sensory neurons and muscle.

Diverticulosis is an abnormality commonly described in the aging colon, and predisposes to the subsequent development of diverticulitis. By 50 years of age, one-third of Americans will have diverticulosis coli, and by 80 years of age, approximately two thirds. Most are asymptomatic, with 10% to 20% developing complications such as diverticulitis or hemorrhage. Diverticulosis is an abnormality commonly described in the aging colon and predisposes to the subsequent development of diverticulitis. Diverticulosis is observed in otherwise healthy individuals, suggesting that some effect of aging on colonic neuromuscular anatomy or function maybe responsible. Decreased tensile strength of the muscle wall and increased intra-abdominal pressures required for evacuation have been implicated

in the development of diverticuli. Human aging is associated with an increase in collagen in the colon wall that is accompanied by a significant decrease in tensile strength, which may predispose to herniation of the mucosa. Other observations include slow colonic transit and increased frequency of segmenting contractions, resulting in increased water resorption and hard feces. Decreased fiber intake likely also contributes to the production of hard feces and excessive straining, as both animal and human studies indicate that addition of fiber decreases intraluminal pressures in the colon.

Elderly patients may present with new-onset fecal urgency and frequency that is similar to diarrhea-predominant irritable bowel syndrome. The onset may coincide with an acute diarrheal illness caused by viral or bacterial infection. However, many patients continue to have distressing urgency, resulting in considerable lifestyle impairment. Many curtail their travel and social activities outside the home for fear of fecal incontinence. The etiology is often multifactorial. Side effects of medications that increase small bowel and colonic motility should always be considered. Decreased rectal compliance occurs with aging, and may contribute to sensations of fecal urgency in these patients.

Fecal incontinence is uncommon in the general population (2.2%) but has a significantly higher incidence (10%) in older patients, particularly nursing home residents and hospitalized elderly patients. Fecal incontinence can result from fecal impaction and subsequent overflow, internal anal sphincter incompetence, decreased rectal or anal sensation, or from other structural impairments in the pelvic floor or anorectal neuromuscular function caused by trauma or iatrogenic damage from surgery or irradiation. In younger patients, fecal incontinence and fecal impaction are most commonly seen in the setting of structural or neuromuscular disease. In older patients, the added risks of immobility and use of anticholinergic drugs can dramatically increase the risk of constipation and subsequent fecal impaction. Aging maybe associated with a reduction in anal function in women. Healthy elderly women demonstrated thinning of the internal anal sphincter, resulting in decreased resting and maximum squeeze pressures in the anal canal. Although thickening of the external sphincter is also observed, it does not correlate with increased ability to maintain continence. In the absence of disease, the effects of aging on male anal sphincter function appear minimal. Other pathological factors that contribute to fecal incontinence in elderly people are the presence of neurological disorders that may predispose to impairment in the ability to interpret the need to defecate (dementia) or in the ability to coordinate defecation (myasthenia gravis or stroke).

## COLONIC NEOPLASIA

Colon cancer is a common disorder in older patients, primarily because most colon cancers occur sporadically and are associated with polyp formation. The observation that crypt cell production rate is significantly higher in colonic tissue from aged rats raises the question of whether normal aging predisposes the colon to malignant transformation. The aged colon maybe more sensitive to the oncogenic effects of growth factors and carcinogens. Methylazoxymethanol, the active metabolite of the colonic carcinogen azoxymethane, induces a greater stimulation of ornithine decarboxylase activity and tyrosine kinase activity in aged rats compared to their younger counterparts. Similar results have been reported with TGF $\alpha$  and insulin-like

growth factor-1 (IGF-1), both potent mitogens for a variety of tissues in the GI tract including the colon. It is not yet clear whether changes in the expression and/or affinity of TGF $\alpha$  receptors or altered postreceptor events contribute to this process.

## HEPATIC AND BILIARY FUNCTION

There is no effect of age on conventional liver function tests, such as serum concentrations of aminotransferases, hepatic alkaline phosphatase, and bilirubin. However, dynamic assessments of liver function do show a decrease with aging. In healthy subjects, liver size, blood flow, and perfusion decrease by 30% to 40% between the third and tenth decade. Aminopyrine demethylation, galactose elimination, and caffeine clearance decrease in parallel with the reduction in liver volume and blood flow. Studies in isolated perfused livers from young adult and senescent Sprague-Dawley rats indicated age-associated reductions of approximately 50% in bile acid-dependent and -independent bile flow as well as hepatocellular uptake of taurocholate and rates of bile acid secretion. Tight junction permeability and transcellular transport were decreased modestly in senescent rats. Based on studies of hepatic impairment, including subtotal resection and diseases such as hepatitis or cirrhosis, it is likely that a decrease of greater than 70% of the total functional hepatic reserve would result in clinically relevant impairment of hepatic function in aging. In general, physiologic aging does not result in this degree of diminution in hepatic function.

However, the senescent liver may be more susceptible to stress insult from diet, alcohol consumption, tobacco use, nutritional status, coexistent diseases, and genetic factors. Liver injury is associated with a regenerative response characterized by increased hepatocyte mitogen-activated protein (MAP) kinase activity. Aged animals have an age-associated decline in MAP kinase activity and epidermal growth factor-stimulated hepatocytes. Specific impairment of intracellular transcription factors that are involved in transduction of growth hormone receptor activation has been reported in senescent mice. Mitogenic stimulation of these pathways in aged mice results in hepatic regeneration following partial hepatectomy that is equivalent to that seen in younger animals. This has potential implications for management of hepatic resection in older patients, such as that used in treatment of solitary hepatoma. Animal studies suggest that hepatic damage may also be related to accumulation of oxidative metabolites with age.

The prevalence of cholelithiasis increases with age (see Chapter 90). Bile appears to become increasingly lithogenic as a function of aging, with precipitation of supersaturated bile and concomitant crystallization of cholesterol or calcium bilirubinate. Much of the available human data has been obtained from subjects aged younger than 65 years, therefore it is unclear whether gallbladder function is altered in old age. Some studies have demonstrated impaired gallbladder function in older subjects. Fasting and postprandial gallbladder volumes are increased in subjects older than 35 years of age, with less complete emptying following a meal observed in older individuals. Increased gallbladder volumes correlate with cholelithiasis, however no difference in fat-induced gallbladder emptying is observed in either male or female subjects older than 50 years of age, compared to younger individuals. As in younger age groups, aged females may be more susceptible to impaired gallbladder contractility, with decreased contractile response to acetylcholine in post-

menopausal females compared to aged males. Animal studies in aged guinea pigs suggest that decreased density of receptors for hormones such as cholecystokinin (CCK) and galanin may underlie the decreased gallbladder contractility and increased gallstone formation in this model. Impairment in intracellular calcium mobilization and decreased muscle compliance correlate with decreased CCK responsiveness. The functional significance of these animal studies to humans is unclear, as decreased CCK responsiveness in older human subjects may be compensated by increased CCK release, with no net change in gallbladder kinetics in aging.

## PANCREATIC STRUCTURE AND FUNCTION

The exocrine pancreas possesses adequate reserve to maintain normal digestive capacity with aging. While there are some contradictory reports, there is little evidence for clinically significant decreases in pancreatic exocrine function in the elderly human. Age-related changes in pancreatic anatomy and histology include decreased pancreatic weight after the seventh decade in humans, with ductal epithelial hyperplasia, interlobular fibrosis, and acinar cell degranulation. A modest decrease in bicarbonate and enzyme output in response to secretin and caerulein in elderly subjects compared to their younger counterparts has been reported. However, secretin and caerulein (CCK receptor agonist)-mediated stimulation of sphincter of Oddi motor function, pancreatic bicarbonate, enzyme and volume output are not significantly changed in individuals older than 60 years of age. In contradistinction to human studies, animal models of pancreatic function do show significant effects of aging on trophic response to hormonal stimulation. Caerulein and secretin administration increased pancreatic weight, protein content, mRNA expression, enzyme, and polyamine concentrations in young and aged rats, but the magnitude of the responses were greater in young rats. The pancreas of aged animals demonstrates a diminished capacity to increase pancreatic lipase and amylase content in response to a high fat or high carbohydrate diet. Given the significant reserve capacity of the exocrine pancreas, the clinical significance of these observations to healthy aged individuals is questionable.

## GASTROINTESTINAL IMMUNITY

The GI tract is the largest immunological system in mammals. Elderly people are relatively susceptible to infections that enter the body via the GI tract. This observation suggests that aging may impair mucosal immunity. The GI mucosal immune response in the small intestine is a complex process that involves a series of events: antigen uptake and presentation of antigen at the mucosal surface by specialized epithelial cells (M cells) overlying Peyer's patches in the small intestine; differentiation and migration of immunologically competent lymphocytes to the lamina propria; regulation of local antibody production in the intestinal wall; and mucosal epithelial cell receptor-mediated transport of antibodies to the intestinal lumen. The effect of aging on the first two steps, antigen uptake and presentation in animal studies is unclear. In rats, there was no change in the number of Peyer's patches or the yield of lymphocytes per patch in the small bowel. Increased T suppressor/cytotoxic lymphocytes could explain the observed decrease in lamina propria IgA plasma cells because of decreased cytokine-mediated differentiation

of B-lymphocytes by helper T cells. Animal studies also confirm that IgA plasma cell recruitment into the lamina propria is decreased in rats and macaque monkeys. Human studies have demonstrated a significant decrease in T lymphocytes and mast cells in the rectal mucosa in normal individuals aged 55 years or older, which was not reflected in other mucosal cell populations, such as neuroendocrine cells. Thus, the third step, differentiation and migration of lymphocytic immunoblasts into the lamina propria, is decreased with aging. IL-2 production in lamina propria lymphocytes and intestinal IgA production is decreased in aged subjects. A tissue-specific, age-associated reduction in transport of polymeric IgA across rat hepatocytes may be the result of decreased synthesis of polymeric immunoglobulin receptors or diminished microtubule-dependent translocation of the receptor–ligand complex.

## GASTROINTESTINAL DRUG METABOLISM

An evolving area of interest to clinicians and investigators is the field of age-associated changes in drug metabolism (see Chapter 8). Elderly patients are at increased risk for drug interactions and adverse drug reactions, primarily because of known side effects of the large number of drugs prescribed in this age group. The cytochrome P450 system plays an essential role in drug metabolism in humans. The CYP3A subfamily expressed in the GI tract and liver is the most abundant form of hepatic cytochrome P450. It oxidizes a wide variety of clinically and toxicologically important agents, including endogenous and exogenous steroids, and activates procarcinogens such as aflatoxins. CYP3A metabolizes numerous drugs including calcium channel antagonists, immunosuppressant agents, cholesterol-lowering agents, benzodiazepenes, non-sedating antihistamines, and macrolide antibiotics. The divergent structures of the drugs metabolized by CYP3A indicate a broad substrate specificity of these enzymes, which contributes to adverse effects reported with the concomitant use of antihistamines, macrolide antibiotics, and prokinetic drugs.

High levels of CYP3A activity present in both the intestinal epithelium and the liver result in significant first-pass metabolism of oral medications. For example, CYP3A-mediated metabolism of cyclosporin results in bioavailability of only 18% of the ingested dose. CYP3A activity is reduced by 25% to 50% in aged individuals, explaining some of the risk for adverse drug effects in elderly patients.

## SUMMARY

As our understanding of how the aging process affects GI function evolves, it is evident that many essential aspects of GI function are preserved with aging. Much of the GI dysfunction in elderly patients can be attributed to the superimposed effects of chronic diseases and environmental/lifestyle exposures (medications, alcohol, tobacco). A modest decline in function with aging, such as decreased gastric mucosal cytoprotection, or decreased esophageal acid clearance, maybe

significant when superimposed on the side effects of certain medications or concurrent disease. The aging process per se has clinically significant effects on oropharyngeal and upper esophageal motility, colonic function, GI immunity, and GI drug metabolism. Age-related changes in GI function will have increasing importance for health care delivery, as the number of elderly individuals increases significantly over the next two to three decades.

## HEPATIC DISEASE

### Introduction

The liver is remarkable in its ability to preserve its function despite advanced age. Elderly patients are at an increased risk of more severe hepatic injury when exposed to hepatic insults. This increased risk is likely related to the liver's age-related decrease in regenerative capacity. We will review the hepatic changes that are known to occur with aging and their pathologic consequences of liver disease in elderly patients (Table 90-1).

### Liver Morphology

Liver volume significantly decreases with age, as shown in both *post-mortem* and *in vivo* ultrasound studies. This decline, which can reach 40% of maximal healthy mass, occurs mostly after the sixth decade of life and is greater in men than in women. There is also a contemporaneous decrease in hepatic blood flow by approximately 35% to 40%. The cause of decreased blood flow is likely multifactorial—as a result of changes in cardiovascular output, diminished splanchnic blood flow, reduced portal vein blood flow, and increased resistance to portal flow. Hepatocytes accumulate lipofuscin with age while undergoing a decrease in the number of mitochondria, the concentration of smooth endoplasmic reticulum (SER), telomere length, and the activity of several liver microsomal enzymes.

### Liver Function

Despite the observed changes in volume and blood flow, age-related changes to hepatic function are less evident in clinical practice (see Table 90-1). The capacity to sustain liver function during aging is reflected in the ability to successfully transplant livers from

older deceased donors. Traditional liver chemistry tests, including serum aminotransferases, bilirubin, alkaline phosphatase, and gamma-glutamyl transpeptidase, do not change with age. Likewise, there are no significant changes in coagulation factors. Serum albumin slightly decreases with age, but typically remains within the normal range. Serum cholesterol and triglycerides increase with age as there is a gradual decline in the metabolism of low-density lipoprotein (LDL) cholesterol.

There are age-related changes in the hepatic metabolism of certain medications, which is important since more than 30% of prescription drugs are prescribed to elderly men and women. The incidence of adverse drug reactions significantly increases with increasing age. Phase I drug metabolism relies on microsomal enzymes and results in metabolism by oxidation, reduction, demethylation, and hydrolysis. Phase II drug metabolism relies on cytosolic enzymes and results in metabolism by conjugation with several different polar ligands. Phase I reactions are usually catalyzed by the cytochrome P450 system in the hepatocyte SER. There is a significant decrease in the Phase I metabolism of several medications by as much as 50% with increasing age. Interestingly, medications that undergo Phase II metabolism remain unaffected by aging. The activity of Phase I metabolism is dependent on oxygen delivery. Thus, some of the age-related decreases in Phase I metabolism could be explained by decreased hepatic blood flow as well as by decreased SER concentration. Medications with known Phase I metabolism should be started at a low dose and titrated slowly in order to circumvent the problems associated with adverse drug reactions in the elderly patients.

Another important aspect of the effects of aging on hepatic function is the diminished ability of the liver to recover and regenerate in response to injury. There is an age-related proliferative decline in the rate at which partial living donor livers regenerate. Also, there is a higher mortality in elderly patients after partial hepatic resection. Lastly, the hepatotoxic effects of hepatitis viruses and medications like acetaminophen and isoniazid are more pronounced in the elderly.

**TABLE 90-1****Effects of Age on the Liver**

Liver chemistry tests: unaffected by age
Coagulation factors: unaffected by age
Serum albumin: slightly decreased but within the normal range
Serum cholesterol and triglycerides: increase with age
Phase I drug metabolism: significantly decreased with age
Phase II metabolism: unaffected by age
Hepatic proliferation after surgical resection: diminished by age
Hepatotoxicity: (hepatitis viruses, acetaminophen, isoniazid) more severe in the elderly

## Liver Diseases

### Hepatitis A Virus

Hepatitis A virus (HAV) is an RNA virus within the picornavirus family (Table 90-2). It is spread via fecal–oral transmission. It is usually a self-limited infection consisting of fatigue, malaise, nausea, vomiting, anorexia, and fever in most adults. Acute HAV infection is diagnosed by the demonstration of HAV IgM antibodies within the serum in symptomatic patients. As the acute illness resolves, anti-HAV IgG antibodies develop conferring life-long immunity. With the development of improved sanitation, the proportion of adults lacking immunity to HAV has increased. At the same time, the severity of acute HAV infection increases with increasing age. Relative to younger patients, acute HAV infection in the elderly has a longer duration, is more severe, is associated with a higher rate of complications, and has a higher mortality rate. This higher mortality rate is owing to an increased incidence of fulminant hepatic failure in elderly patients with acute HAV infection. The increased incidence of fulminant hepatic failure is likely multifactorial because of comorbidities as well as the liver's decreased regenerative capacity. There is a safe and effective vaccine for HAV. Although there are limited available guidelines for vaccinating nonimmune elderly patients, health-care providers of geriatric patients should be aware of the increased morbidity associated with HAV infections and should strongly consider screening and vaccinating elderly patients traveling to endemic areas, living in homes for the elderly, and especially bed-bound institutionalized patients requiring help with evacuation and disposal of excreta.

### Hepatitis B Virus

Hepatitis B virus (HBV) is a DNA virus within the hepadnavirus family. HBV is a blood-borne pathogen. The complete virion, or *dane* particle, is composed of the DNA enclosed within a nucle-

ocapsid surrounded by surface coat. Acute infection is associated with mild constitutional symptoms like anorexia, fatigue, and right upper quadrant discomfort. Approximately 30% of infected adults will develop jaundice. Less than 5% of acute HBV infections arising *de novo* in adults living in the United States will lead to chronic infections. Acute HBV infection is relatively rare in elderly adults, as the primary risk factors associated with transmission are intravenous drug use and high-risk sexual behavior. There is an increased risk of becoming a chronic HBV carrier with increasing age, which is possibly related to an age-related decline in cellular immunity. Similar to HAV, acute HBV infection has an age-related increase in mortality associated with fulminant hepatic failure. Chronic HBV infection is a risk factor for hepatocellular carcinoma, and this risk increases with age. With regards to therapy, the incidence of adverse reactions to interferon is increased in elderly patients and its use should be approached with caution. On the other hand, the recently approved antiviral agents such as entecavir, adefovir, and telbivudine are safe to use irrespective of age. Lastly, there is a significant age-related decreased antibody response rate after immunization with the HBV vaccine. The HBV vaccine is delivered in a series of three injections. Elderly patients might require a fourth injection in order to improve immunogenic HBV vaccine response.

### Hepatitis C Virus

Hepatitis C virus (HCV) is an RNA virus within the flaviviridae family. It is a blood-borne pathogen, and currently intravenous drug use is the major risk factor associated with disease transmission. Most elderly patients with HCV likely acquired the infection 20 to 40 years ago as a result of exposure to unscreened blood or blood products. Approximately 170 million people are infected with HCV worldwide. HCV is the most common cause of viral-induced acute hepatitis in elderly patients. Acute HCV infection in a person not abusing illicit drugs should prompt a search for a source such as an infected medical professional involved in phlebotomy, surgery, or dental care. Acute infection in the elderly usually consists of mild nonspecific symptoms including fever, abdominal discomfort, fatigue, and possible jaundice. Chronic HCV infection develops in 50% to 80% of infected individuals with the subsequent development of cirrhosis in a significant proportion of these patients. The prevalence of chronic HCV infection is increasing in the elderly population. Chronic HCV-related cirrhosis is associated with the development of hepatocellular carcinoma, and this risk is increased significantly with age. Also, the severity of liver disease among patients with chronic HCV infection is worse with increasing age. Similarly, the progression to cirrhosis is faster in older patients, and the serum HCV viral load is significantly higher when compared to younger adults. Any patient who received blood or blood products prior to 1992 should be screened for HCV. Elderly patients initiating

**TABLE 90-2****Hepatotropic Viral Disease**

	GENOME	ROUTE OF TRANSMISSION	OUTCOME	TREATMENT	IMPACT IN ELDERLY
HAV	RNA	Fecal–oral	Acute only	Medical, occasionally transplant	More severe
HBV	DNA	Parenteral	Acute and chronic	Interferon, antivirals, occasionally transplant	More severe
HCV	RNA	Parenteral	Acute and chronic	Interferon, antivirals, transplant	More severe

therapy with ribavirin and interferon should be truly assessed carefully with attention to comorbidities given the known age-related adverse effects with antiviral therapies.

### Drug-Induced Liver Damage

Older patients consume the largest portion of both prescription and over-the-counter medications. Both age and polypharmacy are risk factors for drug-induced hepatotoxicity. Elderly patients often have altered pharmacokinetics and pharmacodynamics caused by changes in renal, hepatic, cardiovascular, and pulmonary function and decreased body mass. Drug-induced liver toxicity occurs more frequently in elderly patients and tends to be more severe. Clinically, drug-induced hepatotoxicity presents with nonspecific symptoms or subclinically, reflected only in serum laboratory abnormalities. Some medications have a well-recognized increased risk of liver toxicity with age. For example, isoniazid frequently causes some evidence of liver toxicity in patients older than 50 years, yet, rarely causes liver damage in patients younger than 20 years. Health care providers taking care of elderly patients should be aware of this increased risk of drug-induced hepatotoxicity and should be vigilant in assessing for hepatic inflammation.

### Primary Biliary Cirrhosis

Primary biliary cirrhosis (PBC) is a disease characterized by an immune-mediated destruction of the intralobular biliary system. It is predominantly regarded as a disease affecting middle aged women; however, greater than one-third of patients with PBC are older than 65 years. Cholestatic features predominate with pruritus presenting as an early symptom. Antimitochondrial antibodies are present in the serum and are a hallmark of the disease. Elderly patients diagnosed with PBC likely have long-standing and slowly progressive disease. Symptomatic elderly patients with PBC are associated with a poor prognosis. Compared to younger adults, the liver-related mortality is greater in patients diagnosed with PBC who are older than 65 years. Treatment should be focused on symptom management of pruritus and malabsorption. Ursodeoxycholic acid slows the progression of the disease. Liver transplantation remains the ultimate therapy and should be considered in well-selected geriatric patients.

### Autoimmune Hepatitis

Autoimmune hepatitis is a condition of unknown etiology leading to chronic hepatic inflammation and destruction, with resultant cirrhosis. It has a bimodal onset, with a second peak of presentation in persons in their sixth decade or older. Elderly patients may present with clinically less aggressive disease. In this regard, the disease may go initially unrecognized in the geriatric population. Liver biopsy is essential for making the diagnosis. Autoimmune hepatitis generally responds well to immunosuppressive therapy. Elderly patients receiving chronic therapy with corticosteroids need to be monitored closely for serious side effects such as osteoporosis, glucose intolerance, and cataract formation. Prognosis is likely similar between elderly patients and younger adults.

### Hepatocellular Carcinoma

In western Europe and North America, hepatocellular carcinoma (HCC) usually occurs in older patients. Major risk factors for the

development of HCC include chronic hepatic inflammation and cirrhosis. Presentation and diagnosis of HCC in elderly patients are associated with a significantly worse prognosis when compared to younger adults. This is likely related to the advanced stage of liver disease and tumor within this patient population. Treatment of carefully selected geriatric patients by surgical resection, liver transplantation, or by anticancer therapies such as chemoembolization or radiofrequency ablation appears to be associated with a similar morbidity and mortality as compared to younger patients. Thus, age should not be a contraindication for therapy for HCC in the appropriate elderly patient.

### Transplantation

Liver transplantation is the ultimate therapy for patients with end-stage liver disease. The number of transplants completed in the United States continues to increase. Alcohol-related liver disease and chronic hepatitis C are the two most common reasons for end-stage liver disease within the elderly population. Unfortunately, there is a growing discrepancy between the patients waiting for a liver transplantation and available donors. This discrepancy will continue to worsen as the population of elderly patients with cirrhosis continues to grow. As a result of this disparity, patients are forced to wait longer periods of time on the transplant recipient list prior to transplantation. Pretransplant evaluation of elderly patients should take into account age-related comorbidities, specifically, cardiovascular disease, osteoporosis, and malignancy. Despite the need for a thorough pretransplant evaluation, advanced age is not a contraindication for liver transplantation. Unfortunately, age is an independent risk factor for perioperative mortality, largely because of nonhepatic causes. Similarly, elderly transplant recipients have a worse postoperative long-term survival. Owing to the risks associated with liver transplantation, geriatric patients should be carefully selected by a multidisciplinary team noting significant comorbid conditions. Post-transplant care should entail continued management of cardiovascular risk factors, assessment and treatment for osteoporosis, and vigilant surveillance for malignancy.

## BILIARY DISEASE

### Cholelithiasis

Table 90-3 outlines the risk factors associated with gallstone formation. Age is a major factor, although the reasons for this are unclear. By the ninth decade of life, the prevalence of gallstones is 38% in women and 22% in men. In men older than 90 years, the incidence increases to 31%. The prevalence of gallstones in the U.S. population increases by 1% per year in women and by 0.5% per year in men after age 15. Native Americans are predisposed to gallstone formation at an earlier age. At age 50, the prevalence of gallstones in Native Americans is 80% in women and 70% in men. The increase in risk in women is related to increased biliary cholesterol excretion by estrogen. Approximately 500 000 people in the United States develop symptomatic gallstones each year.

The great majority of gallstones remain asymptomatic. Gallstones are frequently found incidentally when a patient undergoes abdominal imaging. It is often a challenge to the medical practitioner to

**TABLE 90-3****Risk Factors for Gallstone Formation**

Increasing age

Obesity
Dyslipidemia
Rapid weight loss
Medications
Ethnicity—Caucasian, Native American, and Latinos

determine whether the symptoms that led to the discovery of gallstones, such as mildly abnormal liver tests, or chronic nonsevere abdominal pain are causally related to the newly discovered gallstones. Serious complications that may arise from cholelithiasis include severe abdominal pain (“biliary colic”), sepsis, pancreatitis, or cancer of the gallbladder.

Approximately 80% of gallstones in the United States contain cholesterol as their major constituent and are termed cholesterol stones. Cholesterol crystals tend to precipitate and form stones or sludge when an excess of cholesterol is present in bile relative to the concentrations of bile acids and phospholipids. Pigment stones develop in the setting of excess bilirubin in bile. In conditions such as hemolysis or cirrhosis with high heme turnover, unconjugated bilirubin in the form of calcium bilirubinate crystallizes forming black pigment stones. These account for 10% to 20% of gallstones in the United States. Bacterial colonization of normally sterile bile may lead to an increase in unconjugated bilirubin and in turn calcium bilirubinate. Gallstones arising from this process are brown pigment stones. Black pigment stones are found primarily in the gallbladder, whereas brown pigment stones may be found not only in the gallbladder but also in the intrahepatic or extrahepatic bile ducts.

### Choledocholithiasis

With gallbladder contraction, gallstones can enter and potentially obstruct the common bile duct. Such obstruction can lead to jaundice, ascending cholangitis, liver abscess, and pancreatitis. Stones are present in the common bile duct in approximately 15% of patients undergoing cholecystectomy for chronic cholecystitis with gallstones. The prevalence of stones in the common bile duct increases with age. Although dilatation of the common bile duct correlates with choledocholithiasis, the common bile duct may become dilated as a result of the normal aging process.

The classical signs and symptoms of biliary obstruction are called biliary colic and include epigastric or right upper quadrant pain, nausea, vomiting, and pruritus. Patients may develop dark urine and acholic stools. Tender hepatomegaly may develop because of the increased pressure in the biliary tree. The presence of fever and jaundice is concerning for ascending cholangitis. The constellation of abdominal pain, jaundice, and fever, known as Charcot’s triad, is helpful in making the diagnosis of ascending cholangitis.

### Acute Cholecystitis

Approximately 50% to 70% of cases of acute cholecystitis occur in the geriatric population. This condition is characterized by pro-

longed obstruction of the cystic duct by one or more gallstones. This leads to inflammation and possibly infection of the gallbladder. Acalculous cholecystitis refers to inflammation of the gallbladder in the absence of gallstones. It is usually idiopathic, but tends to occur in debilitated and or vasculopathic patients. Acalculous cholecystitis accounts for 5% to 10% of cases of cholecystitis. The severity of cholecystitis varies from mild edema to severe inflammation and, at its most catastrophic, necrosis or perforation of the gallbladder.

Acute cholecystitis has several classic clinical manifestations. The usual symptoms include abdominal pain, especially in the right upper quadrant or epigastrium. This pain may radiate to the back or shoulder. It is typically continuous and severe. Patients may notice the onset of such pain after eating a fatty meal. Fevers, chills, nausea, and vomiting are common as well.

Physical examination often shows a patient who appears ill and uncomfortable. Pain is usually elicited by palpating the right upper quadrant and/or epigastrium of the abdomen. A Murphy’s sign is characterized by cessation of inspiration while palpating the area of the gallbladder because of extreme discomfort.

Acute cholecystitis may present atypically in the elderly and with delayed recognition results in a greater risk of complications. Elderly patients usually have right upper quadrant or epigastric pain and tenderness, but other signs and symptoms may be lacking. Elderly patients may present without fever, nausea, or vomiting in more than 50% of acute cases. These signs may not be present in 33% even in the setting of gallbladder gangrene or perforation. Acalculous cholecystitis is more common in the elderly, and diagnosis of such cases may be more difficult because of the lack of stones on imaging studies.

### Chronic Cholecystitis

Chronic cholecystitis refers to biliary pain caused by recurrent episodes of cystic duct obstruction leading to a chronic inflammatory response. Ultimately this may lead to scarring and gallbladder dysfunction. On ultrasound, chronic cholecystitis has a more subtle appearance than acute cholecystitis. A review of 412 patients with histologically proven acute or chronic cholecystitis showed gallbladder wall thickening in 80% of those with acute cholecystitis as opposed to 18% of those with chronic cholecystitis. Dilated gallbladder was seen in 60% of acute versus 12% of chronic. Thus, preoperatively, chronic cholecystitis may be difficult to distinguish from noninflammatory symptomatic gallstone disease. As with acute cholecystitis, elective cholecystectomy is the treatment of choice.

### Investigations

Ultrasound is the usual initial diagnostic test of choice for choledocholithiasis with a sensitivity of 20% to 38% and specificity of 80% to 100% (Table 90-4). It has the advantage of being noninvasive, easily tolerable by the patient, widely available, and inexpensive. Magnetic resonance cholangiopancreatography (MRCP) allows for visualization of biliary anatomy as well as stones and has sensitivity of 57% to 100% and specificity of 73% to 100% for common bile duct stones. It also has the advantage of being noninvasive, but its disadvantages include cost and potential patient discomfort from claustrophobia. Endoscopic retrograde cholangiopancreatography (ERCP) is both a diagnostic and therapeutic modality for choledocholithiasis. It has a sensitivity and specificity of greater than

TABLE 90-4

## Imaging Investigations of Gallstones

TESTS	SENSITIVITY	SPECIFICITY	ADVANTAGES	DISADVANTAGES
Ultrasound	20%–38%	80%–100%	Noninvasive Low cost	Low sensitivity Nontherapeutic
MRCP	57%–100%	73%–100%	Highly sensitive	Claustrophobic Expensive Nontherapeutic
CT			Ease for patient	Expensive Nontherapeutic
ERCP	57%–100%	73%–100%	Therapeutic	Pancreatitis Expensive
PTC			Therapeutic	Discomfort (especially in the absence of dilated intrahepatic ducts) Bleeding

95%. The injection of contrast material into the biliary tree allows visualization of all but very small stones. A sphincterotomy is often performed to prevent recurrent obstruction. In the case of cholangitis, a stent is often left in the common bile duct to drain purulent material, stones, and sludge. The disadvantages of ERCP include the potential for acute pancreatitis, technical and infrastructural requirements, and cost. However, ERCP poses no greater risk in the elderly population. One study of ERCP in the geriatric population showed no difference in the rate of therapeutic ERCP complications in patients older than 80 years (6.8%) versus those younger than 80 years (5.1%). Another study evaluated the safety of ERCP in patients older than 90 years, and the complication rate in this age group was 6.3% compared to 8.4% in patients 70 to 89 years of age. Therefore, ERCP is a safe procedure even in those with very advanced age. The rate of recurrence of symptomatic CBD stones after ERCP was higher in patients older than 80 years (20%) versus 4% in patients 50 years old or younger. Thus, the elderly are at higher risk for needing a repeat ERCP.

The diagnosis of acute cholecystitis is based on the combination of findings from history, physical examination, laboratory studies, and abdominal imaging. Ultrasound typically shows gallstones and pericholecystic fluid and/or edema. A sonographic Murphy's sign is helpful in establishing the diagnosis. A HIDA (99mtechnetium-N-substituted hepatoiminodiacetic acid) scan will show opacification of the bile ducts but not of the gallbladder in cholecystitis.

The diagnosis of chronic cholecystitis is established with 95% certainty by demonstration of nonopacification of the gallbladder by oral cholecystography, even after the administration of two doses of iopanoic (Telepaque) dye. Ultrasonography will demonstrate the presence of stones with an accuracy of 90%.

## Treatment

Incidental discovery of gallstones is not an indication for therapy. Approximately 75% of gallstones are asymptomatic and may be found incidentally through imaging or endoscopic procedures. In a study of 123 subjects with silent gallstones, biliary pain occurred in only 16 persons in the follow-up period of up to 24 years. Of those 16 subjects, only three had significant complications: one with acute pancreatitis and two with acute cholecystitis. The cumulative probability of developing biliary pain in this population was 10% at

5 years, 15% at 10 years, and 18% at 15 and 20 years. None of these subjects died as a consequence of gallstone disease. Because asymptomatic gallstones tend to follow a benign course, cholecystectomy should be considered primarily in those with symptoms or complications.

Prompt treatment of acute cholecystitis is warranted to prevent deterioration, complications, and progression to chronic cholecystitis. In addition to intravenous fluids, antibiotics, and pain control, surgery is the mainstay of treatment. Each patient's clinical status and comorbidities must be considered in the decision to proceed with general anesthesia and surgery. Laparoscopic cholecystectomy has several advantages over open cholecystectomy including less discomfort, shorter hospital stay, and lower cost. Complications from this procedure often involve biliary trauma. In a study of 248 patients, 82 of whom were aged 65 or older, who underwent laparoscopic cholecystectomy between 1990 and 2002, the conversion rate to an open cholecystectomy was 3.6%, which was identical to the conversion rate of the nongeriatric patients. There were two deaths in the geriatric population. Most of the procedures done for those of age 65 to 84 years were done on an elective basis, whereas most procedures done in those older than 85 years were done on an emergent basis. Postoperative complications occurred in 7.2% of the geriatric patients. In elderly patients with acute cholecystitis who are felt to be suitable surgical candidates, laparoscopic cholecystectomy is a reasonable option. However, for elderly patients who are very ill or have significant comorbidities, gallbladder drainage prior to surgery may be a viable alternative. This was evaluated in a case series of 84 patients with acute cholecystitis older than 70 years with severe cholecystitis or an American Society of Anesthesiologist score of II to IV. In 83 of these patients, a percutaneous cholecystostomy drain was placed. A transcatheter cholangiogram was done and those with common bile duct stones underwent endoscopic sphincterotomy. Elective cholecystectomy was then performed in 70 patients with no deaths and a 24% morbidity rate. Percutaneous cholecystostomy drainage is an effective and often definitive treatment for acalculous cholecystitis as well. In a study of 15 patients with acute acalculous cholecystitis, prompt improvement was seen in 14 patients after placement of a pigtail catheter into the gallbladder. Morbidity rate after this procedure was 13% and no deaths were seen.

Patients with symptomatic gallstone who cannot or do not wish to undergo invasive procedures may benefit from dissolution of

gallstones with ursodiol. Ursodiol is a naturally occurring bile salt that inhibits 3-hydroxy 3-methylglutaryl coenzyme A reductase, the rate-limiting enzyme in cholesterol synthesis. It also acts by dissolving cholesterol from the stone surface. Therefore, this medication is only useful in the setting of cholesterol gallstones. A meta-analysis of randomized trials using ursodiol for treatment of gallstones found a dissolution rate of 37% after 6 months with doses of at least 7 mg/kg or greater than 500 mg/day. However, at least 50% of patients treated with ursodiol for gallstones will have recurrent stone formation.

## Carcinoma

### Gallbladder Cancer

Cancer of the gallbladder is uncommon in the United States and carries a poor prognosis. Often, this diagnosis is not made until late in its course. The 5-year survival for local disease is 42%, but drops to 0.7% with distant spread of disease. SEER data show that gallbladder cancer occurs primarily in the elderly. Approximately 75% of cases occur in patients older than 65 years. Ninety percent of all gallbladder cancers are carcinomas and occur in approximately 3:1 female to male ratio. Ethnic background and geographic distribution appear to influence the development of gallbladder cancer, as the highest incidence rates are found in those of native North American and Mexican descent and those living in the region of the Andes. It has been noted that 80% of patients with gallbladder cancer have a history of cholelithiasis. Chronic inflammation from gallstones is thought to induce metaplasia of the gallbladder. Size and duration of gallstones appear to be important in carcinogenesis. Prophylactic cholecystectomy in certain higher risk groups is controversial. Among those who may benefit from this procedure include patients with a porcelain gallbladder and patients with a congenital defect in the junction of the pancreato–biliary duct.

### Cancer of the Extra-Hepatic Bile Ducts

Primary bile duct cancers account of less than 3% of all cancers diagnosed in the United States. Cancer of the extrahepatic bile ducts is more common in the elderly, as 65% of cases are found in those

older than 65 years and 69 is the median age. Ninety-nine percent of these are carcinomas. The 5-year survival rate ranges from 26.5% with localized disease to 1.3% with distant spread. The incidence is 1.2 per 100 000 in males and 0.8 per 100 000 in females. The tumors tend to infiltrate along the wall of the bile duct and may be difficult to differentiate from benign strictures. Patients present with signs and symptoms of biliary obstruction with jaundice, pruritus, and weight loss. Treatment is primarily surgical, most commonly with a Whipple procedure. For those who are not surgical candidates, biliary decompression by stent placement is a reasonable option for palliation to maintain patency of biliary drainage.

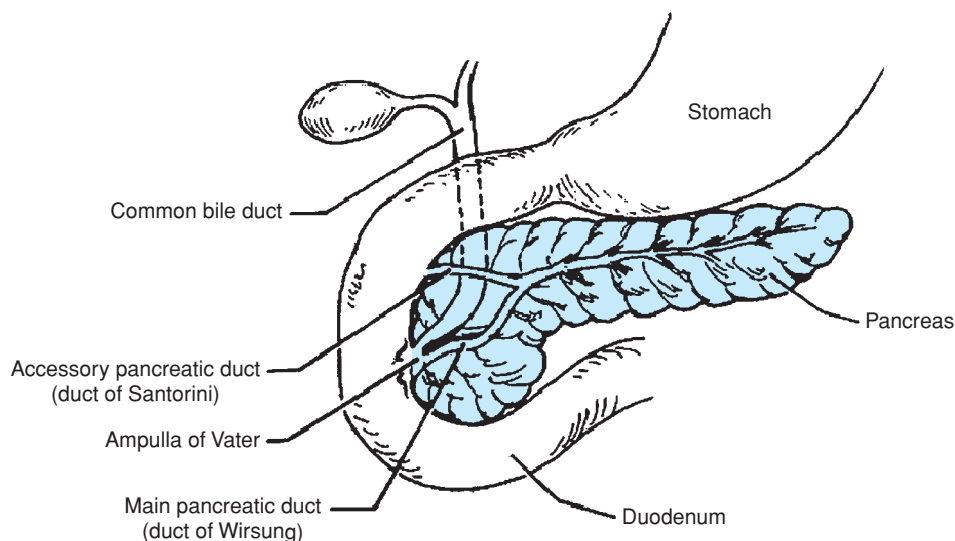

## PANCREATIC DISEASE

### Anatomy

See [Figure 90-1](#) for the gross anatomy of the pancreas. The pancreas can be broken into the endocrine and the exocrine pancreas. Four different types of islet cells comprising the endocrine pancreas produce hormones such as insulin, glucagon, pancreatic polypeptide, and somatostatin. The exocrine pancreas is the focus of this chapter. The exocrine pancreas is composed primarily of acinar cells and duct cells. The acinar cells produce the digestive enzymes. The key enzyme is trypsinogen. The duct cells produce the bicarbonate-rich fluid for secretion.

### Physiology

The exocrine pancreas has proteases, lipases, glycosidases (amylase), and nucleases. The proteases and the nucleases are stored in an inactive form. The proteases constitute greater than 75% of the pancreas by weight. Trypsinogen is the primary protease. Trypsinogen is activated to trypsin in the duodenum by enterokinase—the only physiological function of this enzyme. Trypsin subsequently activates the other digestive enzymes and in the presence of calcium activates trypsinogen to trypsin. In the absence of calcium, trypsin has negative feedback by degrading other trypsin molecules. Trypsin's primary site of action is on arginine and lysine amino acids. The most common defect in hereditary pancreatitis is R122 H or

**FIGURE 90-1.** Normal anatomy of the pancreas. (From Steinberg W, Tenner S. Acute pancreatitis. *N Engl J Med.* 1994;330:1198.)

arginine being replaced at position 122 (important regulatory site) by histidine. This defect negates the negative feedback safety mechanism for trypsin regulation.

There are two additional important mechanisms regulating pancreatic function. First, acid in the duodenum stimulates secretion of the hormone secretin and through vagal mediation leads to the duct cells of the pancreas to secrete bicarbonate. The second regulatory mechanism involves the cholecystokinin (CCK) feedback loop. Human pancreatic acini lack CCK receptors. The presence of protein in the duodenum effectively increases cholecystokinin releasing factor (CCK RF), which stimulates CCK release. The elevated CCK level is recognized by the brain leading to vagal stimulation of the acinar cells of the pancreas to secrete more digestive enzymes.

## Aging and the Pancreas

Table 90-5 outlines the age-related changes of the pancreas. The maximal pancreatic volume excreted in response to secretin and CCK stimulation increases until the fifth decade and thereafter decreases steadily. Bicarbonate decreases steadily after the fourth decade of life. Also, in ERCP studies, a slight increase in size of the pancreatic duct in the head and body but not the tail has been noted with aging. Despite these anatomic and physiologic changes, only rare cases of pancreatic exocrine deficiency are clinically apparent in the healthy elderly.

Over and above the normal changes of aging, advanced age poses other threats to pancreatic structure and function. Pancreatitis secondary to alcohol tends to be a disease of the middle age, while gallstone disease continues to have a relatively high incidence in older cohorts. The biggest risk to the elderly pancreas is an increased incidence of malignancy, particularly adenocarcinoma. In addition, during imaging studies of the abdomen, incidental small cystic and solid lesions of the pancreas are now frequently found.

## Acute Pancreatitis

Acute pancreatitis has a variety of etiologies, but all eventually lead to activation of the digestive enzymes particularly trypsin in the pancreatic acinar cells. The most common etiologies for acute pancreatitis are gallstones and alcohol. However, in an elderly patient without gallstones or a history of chronic excessive use of alcohol, the suspicion for underlying malignancy needs to be especially high. Inherited defects in the trypsinogen to trypsin pathway may lead to rare forms of acute pancreatitis, termed “hereditary pancreatitis.” Obstruction of the pancreatic duct by a gallstone is an important mechanism of initiating pancreatic injury. Alcohol, on the other

**TABLE 90-6**

### Etiologies for Pancreatitis

Post-ERCP
Tumors
Elevated calcium
Idiopathic

hand, causes mitochondrial dysfunction, which allows for increased levels of intracellular calcium and subsequent activation of trypsin. Hypertriglyceridemia is often overlooked as a cause of acute pancreatitis. Triglycerides should be measured on admission to hospital because levels will often quickly decrease with bowel rest and fluids. Many medications may cause acute pancreatitis or elevate levels of triglycerides. See Table 90-6 for etiologies of acute pancreatitis.

The predominant symptom of acute pancreatitis is epigastric pain, commonly with radiation into the back. Nausea and vomiting are also frequently present. The diagnosis is a clinical diagnosis with support from elevated serum amylase and lipase. Levels at least 3 times the upper limit of normal are typical of acute pancreatitis. Many other conditions cause minor elevations in amylase or lipase. Radiographic studies have little role in diagnosis, but do play important roles in evaluating etiology (gallstones, neoplasia, pancreatic calcification indicating chronic pancreatitis) and complications such as necrosis, and pseudocysts. Care needs to be taken in the acute setting not to add intravenous contrast load to a patient that is extremely intravascularly depleted already. Acute pancreatitis can be divided into mild and severe pancreatitis. The range of disease is from self-limited disease to multiorgan failure and death. A variety of grading systems including Ranson criteria, Apache score, Glasgow score, and the Baltazar CT grade +/- necrosis do correlate with morbidity and mortality.

Treatment of mild pancreatitis is accomplished with bowel rest, +/- parenteral feeding, intravenous fluids, and pain control. Gallstone pancreatitis is treated with ERCP, sphincterotomy, and stone extraction if cholangitis or evidence of biliary obstruction is present. Severe pancreatitis often becomes management of multiorgan failure. Placement of nasojejunal tubes with subsequent enteral feedings has become the standard of care at the University of Wisconsin Hospital. Evidence of necrosis on CT scan warrants intravenous antibiotics with good pancreatic penetration such as imipenem. Pancreatic necrosis should be surveyed by radiology by biopsy and culture. Evidence of infection may require surgical debridement.

Pseudocyst formation is an important complication of acute pancreatitis. Approximately 10% of patients with acute pancreatitis proceed to formation of these fluid collections. Most pseudocysts resolve with time; however, if symptoms are present (early satiety, pain, infection, bleeding) then drainage may be necessary.

**TABLE 90-5**

### Aging and the Pancreas

Fat, fibrosis, and reduced weight after seventh decade
Bicarbonate decreases steadily after the fourth decade of life
Pancreatic exocrine deficiency: rare in the elderly without underlying pathology
Alcoholic pancreatitis: a disease of the middle age
Gallstone prevalence, and therefore gallstone pancreatitis, increases with age
Increased incidence of malignancy, particularly adenocarcinoma

**FIGURE 90-2.** Endoscopic ultrasound with FNA needle in pancreatic cyst. This cyst proved to be a serous cystadenoma. (Image courtesy of Deepak Gopal, MD, University of Wisconsin, Madison, WI.)

## Chronic Pancreatitis

Alcohol abuse accounts for approximately 70% of chronic pancreatitis. Idiopathic causes are the second most common cause of chronic pancreatitis. Cystic fibrosis gene mutations are now frequently being identified as an etiology in approximately a third of idiopathic pancreatitis diagnosis. Hereditary pancreatitis frequently leads to chronic pancreatitis at a young age. In the elderly, it is important to evaluate for tumors compressing the pancreatic duct as the etiology.

The diagnosis of chronic pancreatitis can be a challenging diagnosis to make. Amylase and lipase can be mildly elevated or normal. Evidence of calcifications by x-ray or by CT scan is found in 30% to 40% of cases and can give a diagnosis. Often, more advanced imaging studies such as ERCP, MRCP, or endoscopic ultrasound (EUS) are used to evaluate the anatomy of the pancreas and give a diagnosis. The major features of chronic pancreatitis include pain, malabsorption, and frequently diabetes.

Treatment is based on resolving malabsorption with pancreatic enzyme replacement, which also down regulates the CCK feedback loop decreasing pancreatic stimulation. Narcotic pain medication is often needed. If a dilated main pancreatic duct is present, a pancreaticojejunostomy (Puestow procedure) can be helpful. In some cases, near total pancreatectomy is needed with or without islet cell transplantation.

## Pancreatic Cancer

Approximately 33,700 new cases of pancreatic cancer will be diagnosed, and 32,600 patients will die secondary to pancreatic cancer in 2007. Approximately 87% of patients will be older than age 55 at diagnosis with the median age being 72. The overall 5-year survival is 5%. Unfortunately, little progress has been made to change the mortality from this disease over the last several decades. The genetics have now been further elucidated showing that 85% of adenocarcinomas of the pancreas have an activating point mutation in the K-ras oncogene. In addition, 95% have an inactivated p16 tumor-suppressor gene. Genetic changes and new knowledge about the cytokine milieu are current areas of active research.

More than 70% of adenocarcinomas arise in the head of the pancreas, which leads to common presentations including jaundice, gastric outlet obstruction, and pain. Approximately 15% of lesions do not have vasculature invasion or metastatic disease on presentation making surgical resection possible, with curative intent. The 5-year survival in this population is approximately 20%. Staging with CT scans and EUS to evaluate for metastatic disease and vascular invasion is thus important. In addition, tissue diagnosis can be made with EUS and fine needle aspiration (FNA). Autoimmune pancreatitis (sclerosing pancreatitis) can present as a pancreatic head mass and obstructive jaundice making this diagnosis important to consider prior to surgical or medical therapy for presumed pancreatic cancer. Autoimmune pancreatitis has elevated ANA as well as IgG4 autoantibodies in the majority of cases and responds to prednisone.

Other tumors exist in the pancreas including neuroendocrine tumors and many types of cystic lesions of the pancreas. Neuroendocrine tumors of the pancreas are typically solid tumors. Evaluation by EUS +/- FNA and surgical resection are often performed except in multiple endocrine neoplasia (MEN) 1 where the pancreatic lesions are often multifocal in nature. Cystic lesions of the pancreas are becoming increasingly recognized because of more widespread abdominal imaging. These lesions can vary from congenital cysts to pseudocysts to benign cysts to premalignant and malignant lesions. According to the ASGE guidelines, cystic lesions of the pancreas, even when found incidentally, may represent malignant or premalignant neoplasms and require diagnostic evaluation regardless of size. EUS with FNA can obtain fluid for cytologic evaluation and for tumor markers and amylase. See [Figure 90-2](#).

## GASTROESOPHAGEAL REFLUX DISEASE IN THE ELDERLY

### Definition

Gastroesophageal reflux disease (GERD) is defined by symptoms and/or histopathological alterations (esophagitis) caused by reflux of gastric contents into the esophagus. Manifestations of GERD range from mild episodes of heartburn and acid regurgitation, without esophagitis, to chronic mucosal inflammation with erosive esophagitis and ulceration, complicated in severe cases by stricture and bleeding. While it is still unclear whether the incidence and prevalence of GERD symptoms increase with aging, several studies suggest that frequency of esophagitis is significantly higher in the elderly than in adult or young subjects. Indeed, older age was found to be a significant risk factor in the development of severe forms of GERD in both epidemiological and clinical studies from the United States, Japan, and Europe.

### Pathophysiology

Pathophysiological changes in esophageal functions that occur with aging may be responsible, at least in part, for the high prevalence of GERD in old age. These include (1) a shorter intra-abdominal segment of the lower esophageal sphincter (LES), (2) a reduction of secondary peristalsis, (3) an increase in the prevalence of tertiary contractions, (4) alterations in salivary secretion, (5) a reduction in gastric emptying, (6) a decreased esophageal mucosal resistance resulting from impaired epithelial cell regeneration, and (7) duodenogastroesophageal reflux of bile salts (Table 91-1). Elderly subjects have a high prevalence of other risk factors that predispose the aging esophagus to lesions (Table 91-1): (1) difficulty in maintaining an upright position after meals; (2) hiatus hernia associated

with both repeated episodes of acid reflux and with more severe diseases such as Barrett esophagus; (3) increased drug use, including those that may have a directly damaging effect on esophageal mucosa or an indirect effect on reducing LES pressure; and (4) delayed esophageal transit time of many drugs, creating a potentially dangerous situation when it coexists with acid reflux, as reported for alendronate and nonsteroidal anti-inflammatory drugs (NSAIDs) (Table 91-2).

### Symptomatology

Particular attention has been given to the clinical presentation of GERD in the elderly since important differences between young and adult patients have been reported. Indeed, with advancing age, a significantly lower prevalence of typical symptoms, i.e., heartburn, acid regurgitation, and epigastric pain was reported by patients (Figure 91-1). Atypical symptoms also are relatively rare in the elderly (Table 91-3). In contrast, the prevalence of nonspecific symptoms, i.e., vomiting, anorexia, weight loss, and anemia significantly increased with age (Figure 91-2). Reflux esophagitis in the elderly may thus be missed, and a substantial number of patients may suffer subclinical relapses of the disease. The cause of such a different clinical expression of the disease in the elderly is not clear, but a diminished sensitivity to visceral pain has been documented in the elderly. Moreover, 24-hour esophageal pH monitoring and endoscopy examinations demonstrated an age-related reduction in acid chemosensitivity and a reduced symptom severity despite a tendency toward increased severity of esophageal mucosal injury.

### Diagnosis

Since the presentation of GERD is often with nonspecific symptoms in the elderly, *endoscopy* should be undertaken early as the initial diagnostic test in all elderly patients suspected of having GERD. Early endoscopy is very useful in diagnosing the presence and the grade

TABLE 91-1

## Pathophysiological Changes in Esophageal Functions That Occur with Aging

FUNCTIONAL CAUSES	ANATOMICAL CAUSES
Impaired motility of the esophagus	Hiatus hernia
Reduced LES pressure and length	Difficulty in maintaining an upright position
Normal gastric acid secretion	
Delayed gastric emptying transit time	
Reduced salivary secretion	
Decreased tissue resistance as a result of impaired epithelial cell regeneration	
Duodenogastroesophageal reflux of bile salts	

of severity of esophagitis (Table 91-4) and/or hiatus hernia, which are important prognostic factors to be considered in the long-term treatment of patients. Endoscopy will also identify GERD complications, especially esophageal stricture and Barrett esophagus, and concomitant gastroduodenal diseases, that is, gastric or duodenal ulcers and/or *Helicobacter pylori* (*H pylori*) infection. *Barium radiography* of the esophagus is a useful test to establish the presence of a hiatus hernia and is indicated as part of the evaluation of the patient with suspected motility abnormalities or peptic stricture. A barium study may also identify rings and webs or other obstructive lesions. The barium swallow test is also a key test in studying elderly patients with dysphagia, and it should be performed in conjunction with endoscopy in all elderly patients with this symptomatology. Barium studies are widely available and usually well tolerated by older people. *Esophageal 24-hour pH testing* is helpful before antireflux surgery and in those patients not responsive to medical treatment. In the endoscopy-negative patient, an abnormal esophageal pH test may suggest the need for more aggressive drug therapy, whereas a normal test may indicate the presence of a functional disorder. In the patient with persistent esophagitis, a normal test could differentiate

TABLE 91-2

## Drugs That May Increase the Risk of Severe GERD

DIRECT EFFECT ON ESOPHAGEAL MUCOSA	REDUCTION IN LES PRESSURE
Aspirin	Theophylline
NSAIDs	Nitroderivates
Potassium salts	Calcium channel-blockers
Ferrous sulfate	Benzodiazepines
Corticosteroids	Dopaminergics
Alendronate	Tricyclic antidepressants
	Anticholinergics

pathophysiological mechanisms, that is, a drug-induced esophagitis from acid reflux disease. *Esophageal manometry* is useful in identifying abnormalities of LES pressure or esophageal motility. In elderly patients, its major use is reserved for the localization of LES before pH testing and for obtaining preoperative information on esophageal peristalsis.

A therapeutic trial with proton pump inhibitors (*PPI-test*) has been suggested as a useful diagnostic test in patients with GERD. Meta-analyses of clinical studies demonstrated that the PPI test has 78% sensitivity and 54% specificity in confirming the diagnosis of GERD when compared with endoscopy or 24-hour esophageal pH monitoring. In patients with noncardiac chest pain, sensitivity and specificity are reported to be 80% and 74%, respectively. Since typical (heartburn, acid regurgitation) and extraesophageal symptoms (asthma, chronic cough, noncardiac chest pain) of GERD are often absent in elderly patients, the patient's history is less reliable and high prevalences of severe esophagitis are common despite mild symptoms, a trial with PPIs should be used with great caution in older patients, possibly only after endoscopy as a first diagnostic test.

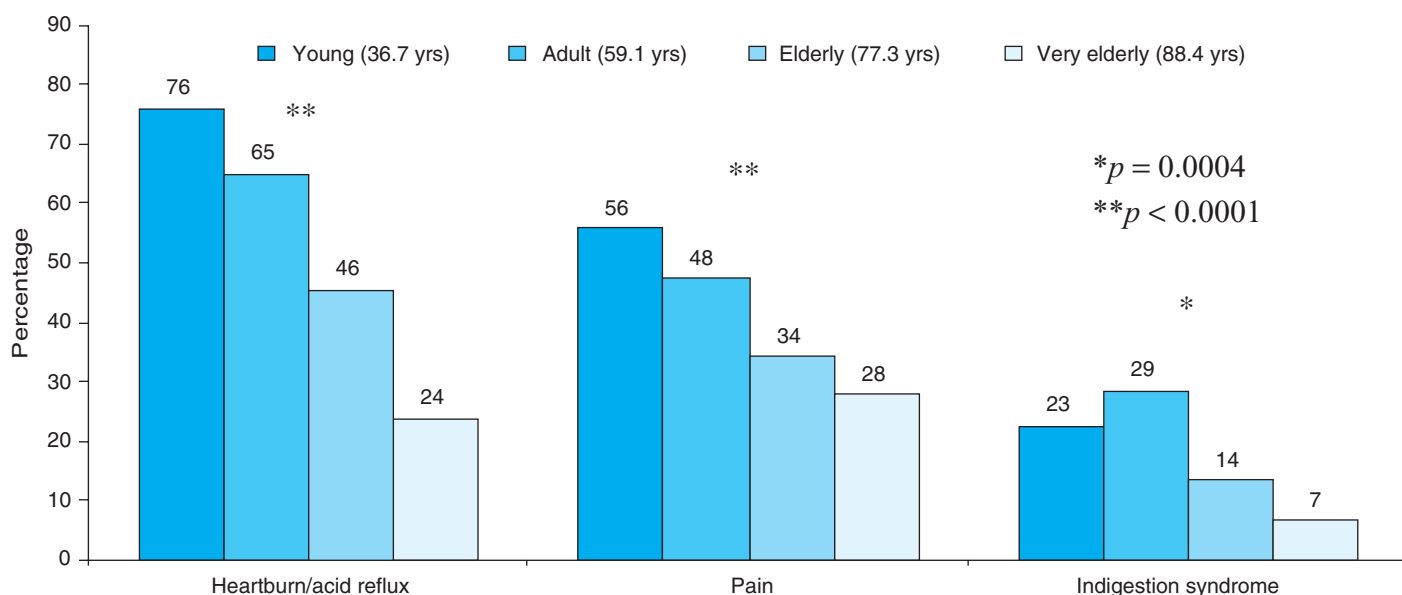

FIGURE 91-1. Prevalence of typical symptoms in 840 subjects with reflux esophagitis divided according to age. (Adapted from Pilotto A, Franceschi M, Leandro G, et al. Clinical features of reflux esophagitis in older people: a study of 840 consecutive patients. *J Am Geriatr Soc*. 2006;54:1537–1542.)

**TABLE 91-3**

**Typical and Atypical Symptoms of Gastroesophageal Reflux Disease**

TYPICAL SYMPTOMS	ATYPICAL SYMPTOMS
Heartburn	Pulmonary symptoms:
Acid regurgitation	Bronchial asthma
Epigastric pain	Bronchiectasis
	Chronic bronchitis
	Chronic cough
	Otorhinolaryngeal symptoms:
	Hoarseness
	Chronic laryngitis
	Odynophagia
	Noncardiac chest pain

**Treatment**

The objectives of GERD treatment are (1) relief of symptoms, (2) healing of the esophagitis, (3) prevention of the relapses of the disease, and (4) prevention of the complications.

**Lifestyle and Dietary Modifications**

Recommendations for lifestyle modifications are based on the presumption that certain foods, body position, tobacco, alcohol, and obesity contribute to a dysfunction in the body’s antireflux defense system. Although there is clinical and physiologic evidence that smoking, alcohol, chocolate, peppermint, coffee, fatty or citrus intake may adversely affect symptoms or esophageal pH, there is little evidence that cessation of these agents will improve GERD variables. Elevation of the head of the bed and weight loss, however, have been associated with improvement in GERD variables in case–control studies. Medications that decrease LES pressure and promote gastroesophageal reflux as well as drugs that may cause direct esophageal

**TABLE 91-4**

**Endoscopic Classification of Esophagitis (According to the Los Angeles Classification)**

GRADE	DESCRIPTION	
Grade A	One or more mucosal breaks no longer than 5 mm, none of which extends between the tops of the mucosal folds	
Grade B	One or more mucosal breaks more than 5 mm long, none of which extends between the tops of two mucosal folds	
Grade C	Mucosal breaks that extend between the tops of two or more mucosal folds, but which involve less than 75% of the esophageal circumference	
Grade D	Mucosal breaks that involve at least 75% of the esophageal circumference	

Lundell LR, Dent J, Bennett JR, et al. Endoscopic assessment of oesophagitis: clinical and functional correlates and further validation of the Los Angeles classification. *Gut*. 1999;45:172–80.

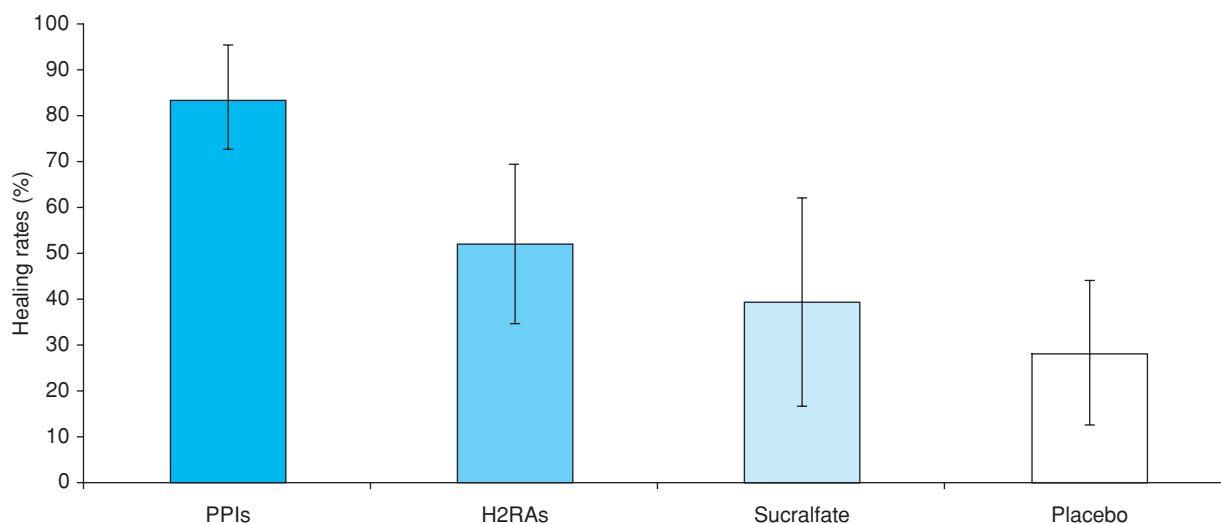

injury (Table 91-2) should be avoided when possible or used with caution in older patients with GERD. In any case, these drugs must be taken while maintaining an upright position and with a full glass of water.

**Pharmacological Treatment: Short-Term Therapy**

Antacids and alginic acid provide symptomatic relief in mild nonerosive esophagitis. Prokinetic drugs, either alone or in combination with antisecretory drugs, are only moderately effective in GERD. Possible side effects of antacids include salt overload, constipation, hypercalcemia, and interference with absorption of other drugs, particularly antibiotics such as tetracycline, azithromycin, and quinolones. Currently, prokinetic drugs include metoclopramide,

**FIGURE 91-2.** Prevalence of nonspecific symptoms in 840 subjects with reflux esophagitis divided according to age. (Adapted from Pilotto A, Franceschi M, Leandro G, et al. Clinical features of reflux esophagitis in older people: a study of 840 consecutive patients. *J Am Geriatr Soc*. 2006;54:1537–1542.)

**FIGURE 91-3.** Percentage of patients that experience complete healing after treatment for grade II to IV reflux esophagitis with the indicated therapies. PPIs, proton pump inhibitors; H2RAs, histamine type 2 receptor antagonists. (Adapted from Chiba N, De Gara CJ, Wilkinson JM, et al. Speed of healing and symptom relief in grade II to IV gastroesophageal reflux disease: a meta-analysis. *Gastroenterology*. 1997;112:1798–1810.)

clebopride, domperidone, and partially levosulpiride. Unfortunately, no controlled clinical trials have evaluated the role of these drugs in the treatment of GERD in the elderly. Antireflux therapy is focused largely on suppressing gastric acid secretion with H2-blockers and proton pump inhibitors (PPI). Meta-analysis of 43 articles including more than 7600 patients aged 18 to 89 years with grade II to IV esophagitis treated for  $\leq 12$  weeks reported higher healing rates with PPIs ( $83.6\% \pm 11.4$ ) than H2-blockers ( $51.9\% \pm 17.1$ ), sucralfate ( $39.2\% \pm 22.4$ ), or placebo ( $28.2\% \pm 15.6$ ). Moreover, PPIs provided faster and more complete heartburn relief than H2-blockers (Figure 91-3). Currently, five PPIs are available: omeprazole, lansoprazole, rabeprazole, pantoprazole, and esomeprazole. Some age-associated differences in pharmacokinetics and pharmacodynamics of the PPIs have been reported. However, it is unknown if these differences are associated with different clinical effects, particularly in older patients. Indeed, a series of meta-analyses evaluating acute therapy of esophagitis reported that the PPIs were superior to ranitidine and placebo in healing erosive esophagitis, without significant differences in efficacy between omeprazole 20 mg daily and lansoprazole 30 mg daily or pantoprazole 40 mg daily or rabeprazole 20 mg daily. Recently, a systematic review of randomized controlled trials comparing standard dose PPIs reported a lower 8-week healing rate of esophagitis with omeprazole 20 mg or lansoprazole 30 mg

daily, but not with pantoprazole 40 mg daily, compared to esomeprazole 40 mg daily (Table 91-5). The recent finding that omeprazole has considerable potential for drug interactions, since it has higher affinity for the cytochrome CYP2C19 than other PPIs, may explain these differences in efficacy, especially in elderly patients who are treated with concomitant therapies.

#### Long-Term Maintenance Therapy

GERD is a chronic disease with a 70% to 90% annual relapse rate after the interruption of an effective antisecretory therapy. Risk factors for relapse of the disease are shown in Table 91-6. Maintenance therapy with antisecretory drugs is a significant protective factor in reducing the occurrence of relapse of GERD in elderly patients. Several studies have shown higher efficacy of PPIs over H2-blockers and prokinetics in maintaining a healed esophagitis. There are two main approaches to drug therapy for GERD: step-up and step-down. In the step-up approach, therapy is initiated with weak inhibition of gastric acid (e.g., an H2-blocker or half dosage of a PPI), and progresses to a higher degree of acid inhibition (standard and then escalating doses of PPI), until adequate symptom control is obtained. The step-down approach involves starting with the most effective regimen (full dosage of a PPI) and switching to lower doses of PPI

**TABLE 91-5**

#### Randomized Controlled Trials Comparing Standard Dose PPIs in the Healing of Esophagitis at 8 Weeks

	TOTAL NUMBER OF PATIENTS	ESOPHAGITIS HEALED	%	<i>p</i>

Esomeprazole	3264	2807	85.9	
Omeprazole	2431	1998	82.2	0.0001
Esomeprazole	2446	2167	88.6	
Pantoprazole	1709	1507	88.2	<i>ns</i>
Esomeprazole	1688	1523	90.2	

(Data from Edwards SJ, Lind T, Lundell L. Systematic review: proton pump inhibitors (PPIs) for the healing of reflux oesophagitis—a comparison of esomeprazole with other PPIs. *Aliment Pharmacol Ther*. 2006;24:743–750.)

**TABLE 91-6****Risk Factors for Relapse of Esophagitis****RISK FACTORS**

## Patient's characteristics

- Old age
- High body mass index (BMI)

## Clinical features

- Long history of reflux symptoms
- Latency prolonged between appearance of symptoms and therapy
- Persistence of symptoms after the healing of esophagitis

## Endoscopic characteristics

- Severity of the esophagitis at baseline
- Presence of a large hiatal hernia

## Pathophysiology features

- Reduced pressure of the lower esophageal sphincter (manometry)
- Modified curve at the 24-h pH-metry

for maintenance therapy once symptoms are under control. This latter approach is perhaps more rational, based on evidence showing superior efficacy of PPIs over H<sub>2</sub>-antagonists across all grades of severity of GERD. Withdrawal of maintenance therapy with PPI after 6 months significantly reduces the percentage of remission of esophagitis at 1 year from 95% to 33% in patients older than 65 years (Figure 91-4). Presently, no comparative studies have been carried out to evaluate which strategy (step-down vs. step-up) is more cost-effective in older subjects.

**Safety of Long-Term Antisecretory Treatment**

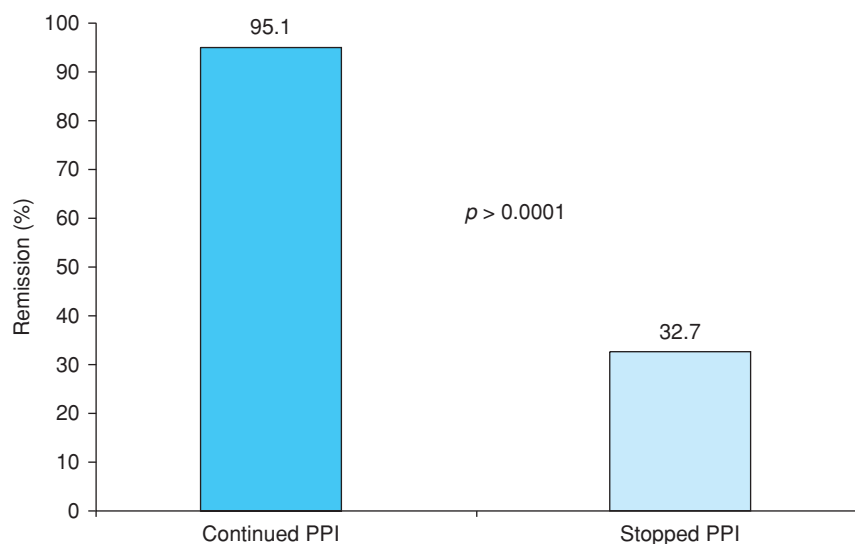

A study explored the long-term safety of omeprazole for up to 11 years in patients (including some elderly) with refractory reflux esophagitis. Annual incidence of gastric corpus mucosal atrophy was 4.7% in *H pylori*-positive individuals and 0.7% in *H pylori*-negative patients. Moreover, mucosal atrophy was mainly observed in elderly patients who had moderate or severe gastritis at entry into the study. Corpus intestinal metaplasia was rare and no dysplasia or neoplasms were observed. Long-term therapy with a PPI does not appear to

have marked effects on protein and carbohydrate digestion. Antisecretory drugs, however, may interfere with calcium absorption through induction of hypochlorhydria; PPIs, moreover, may reduce bone resorption through inhibition of the osteoclastic vacuolar proton pump. Indeed, a long-term PPI therapy has been associated with an increased risk of hip fractures. Inhibition of acid secretion may induce an increase of the bacterial flora at the gastrointestinal level with potential to increase the incidence of systemic infections particularly in immunodepressed elderly subjects. Indeed, the use of antisecretory drugs has been associated with an increased risk of infections of the lower gastrointestinal tract, mainly because of *Salmonella* spp. and *Clostridium difficile*. Recent studies, moreover, reported that the use of PPIs may be associated with an increased risk of community-acquired pneumonia.

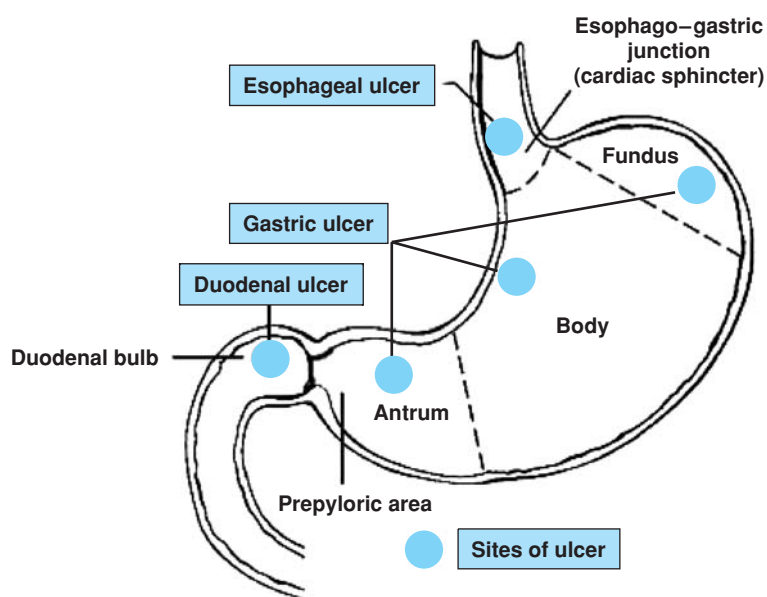

Since PPIs are mainly metabolized by the cytochrome P450 (CYP), particularly the subfamily CYP2C19, clinically relevant drug interactions may occur in case of concomitant administrations of CYP-2C19-metabolized drugs. For these reasons a thorough surveillance of the long-term antisecretory therapy is suggested in elderly patients who frequently present with infections, malabsorption and/or diarrhea, osteoporosis, and/or are treated with CYP450-metabolized medications.

**The Role of Surgery**

The role of surgery in the treatment of GERD is controversial. Laparoscopic fundoplication has greatly reduced the morbidity and mortality of antireflux surgery, also in the elderly. Thus, the indications for surgery seem to be evolving. At present, evidence suggests that surgery may be indicated in elderly patients who (1) are medical treatment failures; (2) have severe complications, i.e., strictures not treatable by endoscopy; (3) have severe dysphagia, aspiration, or atypical symptoms associated with a large hiatal hernia; and/or (4) have preneoplastic lesions, that is, Barrett esophagus with high-grade dysplasia. Randomized clinical studies are needed to compare the outcome of antireflux surgery with that of medical therapy in the elderly. Furthermore, surgery for GERD should be centralized to units specialized in these techniques to reduce surgical complications and improve successful clinical outcomes.

**FIGURE 91-4.** Remission at 12 months in elderly patients with esophagitis who continued versus stopped PPI maintenance treatment after 6 months. (Data from Pilotto A, Leandro G, Franceschi M, et al. Short- and long-term therapy for reflux oesophagitis in the elderly: a multi-centre, placebo-controlled study with pantoprazole. *Aliment Pharmacol Ther.* 2003;17:1399-1406.)

**FIGURE 91-5.** Anatomical location of peptic ulcers.

## PEPTIC ULCER DISEASE

### Definition

Peptic ulcer is a break of the mucosa lining the stomach or the duodenum. According to their anatomical location, peptic ulcers are divided into *gastric ulcers*, i.e., peptic ulcers of the gastric fundus, body or antrum, *prepyloric and pylori ulcers*, i.e., located within 3 cm from the pyloric ring and in the pyloric ring respectively, and *duodenal ulcers*, i.e., located into the bulb or in the second portion of the duodenum (Figure 91-5).

### Epidemiology

The worldwide peptic ulcer prevalence differs, with duodenal ulcers dominating in western populations and gastric ulcers being more

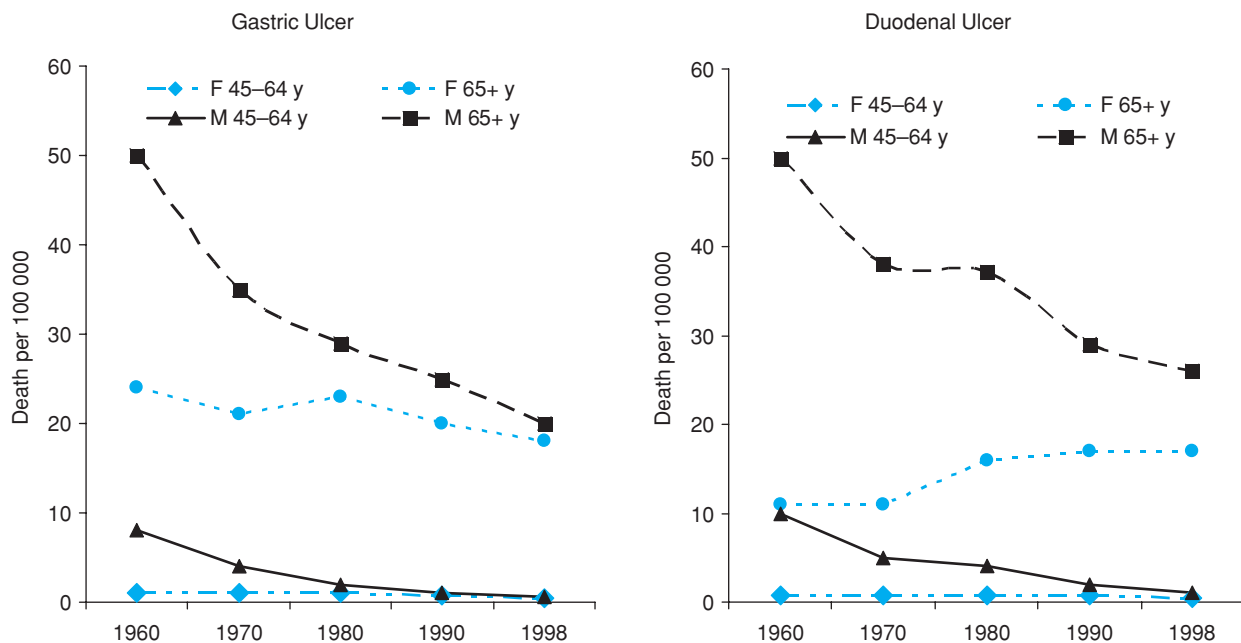

frequent in Asia. Although the incidence of peptic ulcer disease in western countries has declined over the past 100 years, almost 1 in 10 Americans is still affected. Even if the most recent epidemiological studies indicate that the prevalence and the incidence of the peptic ulcer show a constant decline in the general population, the incidence of complicated gastric and duodenal ulcer hospitalization (Figure 91-6) and mortality (Figure 91-7) remain very high in older patients.

### Pathophysiology

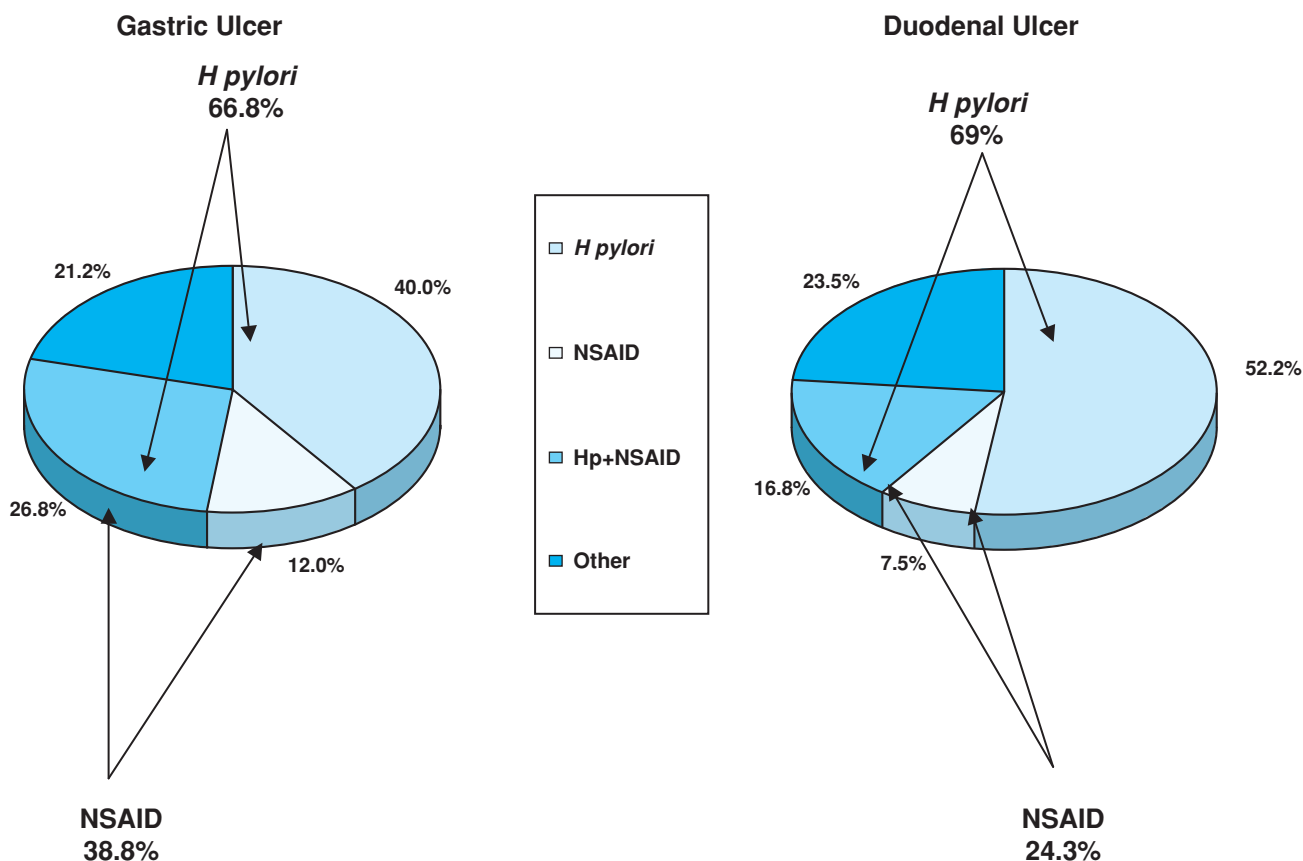

Two main factors that might explain the observed increase in the incidence of peptic ulcer in elderly patients are the high prevalence of *H pylori* infection and the increasing use of damaging drugs, i.e., NSAIDs and/or aspirin. Nevertheless, in elderly subjects, around 20% of all the peptic ulcers are not associated with the use of damaging drugs or with an *H pylori* infection (Figure 91-8). Pathophysiology of these “idiopathic” non-NSAID, non-*H pylori* peptic ulcers

**FIGURE 91-6.** Trends in hospital admission owing to peptic ulcer in England according to age. (Adapted from Higham J, Kang JY, Majeed A. Recent trends in admissions and mortality due to peptic ulcer in England: increasing frequency of haemorrhage among older subjects. *Gut*. 2002;50:460–464.)

**FIGURE 91-7.** Age specific mortality rates for males (M) and females (F) for gastric and duodenal ulcer in England. (Adapted from Higham J, Kang JY, Majeed A. Recent trends in admissions and mortality due to peptic ulcer in England: increasing frequency of haemorrhage among older subjects. *Gut*. 2002;50:460-464.)

**FIGURE 91-8.** Prevalence of gastric and duodenal ulcer in elderly patients divided according to the presence of *H pylori* infection and/or NSAID use. (Adapted from Pilotto. Aging and upper gastrointestinal disorders. *Best Pract Res Clin Gastroenterol*. 2004;18:73-81.)

is still uncertain; a critical disequilibrium between protective and aggressive factors in the gastric or duodenal mucosa, however, seems to be involved. Several studies demonstrated that advancing age is associated with a reduction of the gastric mucosal barrier, i.e., the capacity to resist external damage owing to secretion of gastric mucus, bicarbonate secretion, mucosal prostaglandins, gastric mucosal proliferation and/or mucosal blood flow. Moreover, in elderly patients with peptic ulcer, normal or high levels of gastric acid and pepsin secretions have been observed. Previous studies reported that advancing age was independently related to chronic atrophic gastritis and a functional status of hypo/achlorhydria. More recent data suggested that atrophic changes of the gastric mucosa are associated with *H pylori* infection rather than with aging. Emotional stress, smoking tobacco and/or alcohol use are even potential risk factors that may contribute to the development of peptic ulcer in predisposed subjects.

### *Helicobacter pylori*-Associated Peptic Ulcer

Approximately 70% of elderly peptic ulcer patients are *H pylori*-positive (Figure 91-8). Controlled studies, performed on elderly patients, reported that the treatment of *H pylori* infection healed ulcers in more than 95% of patients and improved symptoms in more than 85% of patients. Moreover, long-term studies performed in elderly patients with peptic ulcer demonstrated that the eradication of *H pylori* infection significantly improved clinical outcome, reducing ulcer recurrences and symptoms. Significant reduction of ulcer relapses after *H pylori* eradication is the main factor that demonstrated the pathogenic role of *H pylori* in peptic ulcer disease. Indeed, health programs leading to widespread eradication of *H pylori* infection in symptomatic patients have significantly reduced the prevalence of peptic ulcer, particularly of duodenal ulcer, both in Europe and in the Far East. Unfortunately, the percentage of elderly patients with peptic ulcer who are treated for their *H pylori* infection is still quite low. A study performed in the United States reported that of patients older than 65 years who were hospitalized for ulcer disease, only 40% to 56% were tested for *H pylori* infection; among the subjects who resulted *H pylori*-positive, only 50% to 73% were treated with specific antibiotic-based anti-*H pylori* therapy.

### NSAID/Aspirin-Associated Peptic Ulcer

In elderly patients, approximately 25% of duodenal ulcers and 40% of gastric ulcers are associated with the use of NSAIDs and/or aspirin (Figure 91-8). The risk of NSAID-related peptic ulcers and their severe complications tends to increase linearly with aging and becomes particularly high in the presence of disability, comorbidity, and comedications. A case-control study performed in more than 3000 elderly patients who underwent an endoscopy has documented that subjects undergoing treatment with NSAIDs and/or aspirin presented a higher prevalence of gastric and duodenal ulcers compared to nonuser controls. Moreover, the risk of peptic ulcer is significantly higher in acute than chronic users of NSAIDs or aspirin (Figure 91-9). The injurious gastroduodenal effects of NSAIDs and aspirin are mainly caused by the inhibition of COX-1 and its role in mucosal defense mechanisms and also through the inhibition of thromboxane A<sub>2</sub>, which reduces platelet functions, resulting in a higher risk of bleeding. However, a direct effect on gastroduodenal

mucosal surface cannot be excluded especially by those NSAIDs that have a high acid/base pK ratio.

### Clinical Features

In the elderly, peptic ulcer is often difficult to diagnose. Indeed, symptoms of peptic ulcer may be atypical in old age. The patient's concomitant diseases and treatments may cause symptoms that mask those of the ulcer. A study reported that in patients older than 60 years, only one-third suffered from typical epigastric pain, and two-thirds experienced vague abdominal pain as a main symptom. Moreover, the intensity of pain may be less severe in older subjects and therefore may not receive the full attention of the physician or may not be taken seriously by the patient him/herself. Frequently, symptomatology includes nausea, vomiting, weight loss, and/or anorexia as the first, or even the only, symptom of peptic ulcer in the elderly. Unfortunately, it is not rare that the first symptom might be owing to a severe complication, especially bleeding or stenosis. In a study carried out in patients aged 80 years or more, the most common symptom was epigastric pain in both gastric and duodenal ulcers, while anemia and vomiting were most common among the patients suffering from duodenal ulcers. Because of the insidious clinical presentation of the disease in elderly patients, the consequences of peptic ulcer disease are more serious than those in younger subjects.

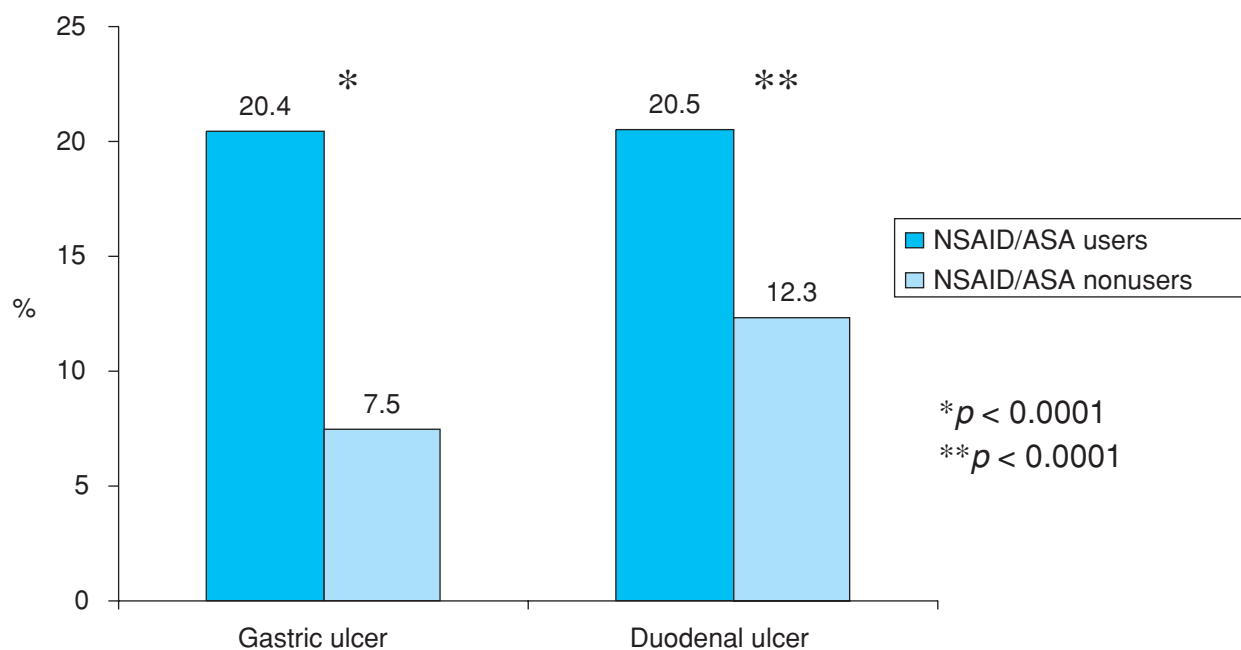

### Diagnostic Tests

Upper GI *endoscopy* is always indicated for elderly subjects with new abdominal symptoms because of the high prevalence of serious gastric diseases in this age group. By direct visual identification, the location and size of an ulcer can be described. Peptic ulcer is a round to oval mucosal defect, from 5 mm to even 4 cm in diameter, with a smooth base and perpendicular borders. To perform a series of biopsies for excluding malignancy is mandatory both in the center and on the borders of the gastric ulcer, even if they are not elevated or irregular as in the advanced gastric cancer-ulcerative forms. Gastric *biopsies* allow for identifying the presence and the severity of chronic gastritis and/or the presence of *H pylori* infection. Endoscopic healing is the gold standard for evaluating ulcer healing in clinical trials. The surrounding mucosa may present radial folds, as a consequence of the parietal scarring. *Barium radiography* of the stomach and duodenum is indicated as part of the evaluation of the patient with suspected motility disorders, peptic strictures, or fistulas. In these last cases, gastrograffin may be used as contrast medium alternative to barium. Radiography is contraindicated in the presence of bleeding, severe vomiting with a high risk of pulmonary aspiration, or in cases of suspected gastric or duodenal perforation. If a peptic ulcer perforates, air will leak from the inside of the gastrointestinal tract to the peritoneal cavity. This leads to "free gas" within the peritoneal cavity that may be observed underneath the diaphragm on an erect or supine lateral *abdominal x-ray*.

### Testing for *Helicobacter pylori* Infection

*H pylori* infection may be easily diagnosed by means of either histology evaluation, rapid urease test, or culture performed on gastric biopsies taken during endoscopy. However, the biopsy site needs to be selected with care, since *H pylori* may only be found in the fundus or body and not in the antral mucosa of elderly patients who

	NSAID Acute Users		NSAID Chronic Users	
	OR	95% CI	OR	95% CI
<b>Gastric ulcer</b>	4.47	3.19–6.26	2.80	1.97–3.99
<b>Duodenal ulcer</b>	2.39	1.73–3.31	1.68	1.22–2.33

**FIGURE 91-9.** Prevalence of gastric ulcer and duodenal ulcer in NSAID users and NSAID nonusers. (Data from Pilotto A, Franceschi M, Leandro G, et al. Proton-pump inhibitors reduce the risk of uncomplicated peptic ulcer in elderly either acute or chronic users of aspirin/non-steroidal anti-inflammatory drugs. *Aliment Pharmacol Ther.* 2004;20:1091–1097.)

are taking antisecretory drugs. Moreover, the presence of chronic atrophic gastritis as a result of a past colonization of *H pylori* may be associated with a lower prevalence of the bacterium in the gastric biopsy specimens in the elderly than in adult or young patients. For the same reasons, the rapid urease test performed on gastric biopsies has lower sensitivity in subjects 60 years and older compared with younger patients. These findings suggest that in the elderly (1) it is advisable to perform gastric biopsies from both the antrum and the body of the stomach; and (2) a second test for *H pylori* should be performed in this age group if a urease-based or histological test is negative.

### Posttreatment *Helicobacter pylori* Evaluation

Successful eradication should always be confirmed by a noninvasive or an invasive test if endoscopy is clinically indicated. Elderly patients with a diagnosis of peptic ulcer (especially gastric ulcer), gastric mucosa-associated lymphoid tissue, lymphoma, or severe gastritis should be evaluated by endoscopy and gastric mucosal histology after completion of anti-*H pylori* therapy. Most experts agree that this evaluation must be carried out at least 1 month after completion of therapy in order to minimize false-negative results. Elderly patients with mild or moderate forms of chronic gastritis may be evaluated after therapy by a noninvasive test. The  $^{13}\text{C}$ -urea breath

test demonstrated significantly higher sensitivity, specificity, and diagnostic accuracy than serology (IgG anti-*H pylori* antibodies) in elderly subjects. An *H pylori* stool antigen (HpSA) test for the detection of *H pylori* was suggested as a valuable option with a high-potential role in the diagnosis after eradication therapy. The HpSA test is an easy and quick procedure that does not require expensive equipment. In hospitalized frail older patients, the HpSA was significantly less accurate than the  $^{13}\text{C}$ -urea breath test, while antibiotic therapy and corpus atrophy decreased the positivity rate. Another study of geriatric subjects reported that HpSA test had a posttreatment diagnostic accuracy comparable to the  $^{13}\text{C}$ -urea breath test (91% vs. 92%) without influence by cognitive status, disability, concomitant diseases, and cotreatments.

### Other Noninvasive Tests

Serum pepsinogen I and II levels (sPGI, sPGII) are known to increase in the presence of *H pylori*-related nonatrophic gastritis. sPGII levels are higher in subjects with both gastric and duodenal ulcer, and levels correlate with the severity of inflammation. A study in older people reported that sPGII levels decreased significantly after a successful *H pylori* cure. The clinical usefulness of serum pepsinogens for monitoring elderly peptic ulcer patients remains to be established.

**TABLE 91-7****Cumulative Results of Clinical Trials Evaluating 1-Week PPI-Based Triple Therapies Against *Helicobacter pylori* Infection in Elderly Patients**

TRIPLE THERAPY	PATIENTS (n)	ERADICATION		DROP OUTS (%)	SIDE EFFECTS (%)

## Treatment Options for Peptic Ulcer Disease

### Eradication of *Helicobacter pylori* Infection

There is currently a worldwide consensus that the first-line therapy for eradication of *H pylori* infection should be triple therapy with a PPI twice daily combined with clarithromycin 500 mg twice daily and amoxicillin 1 g twice daily or a nitroimidazole 500 mg twice daily for a minimum of 7 days. The cumulative results of clinical trials evaluating anti-*H pylori* therapies in elderly subjects confirmed that PPI-based triple therapies for 1 week were highly effective and well tolerated. Adverse event rates of less than 13% were reported, with less than 6% of patients discontinuing therapy owing to these effects (Table 91-7). In elderly patients, a reduction of the dosage of the PPI from a twice to once daily standard dose did not influence cure rates of the PPI-triple therapies. Since aging may modify the pharmacokinetic distribution of clarithromycin, independent of renal function, clinical trials evaluated the efficacy of PPI-based triple therapies including clarithromycin at a low dose of 250 mg twice daily in combination with a PPI and amoxicillin (at the standard dosage of 1 g twice daily) or metronidazole (at the dosage of 400 mg or 500 mg twice daily) in older patients. Results demonstrated no significant differences in cure rates and tolerability between clarithromycin 250 mg versus 500 mg twice daily. All these findings suggest that in elderly patients, 1-week PPI-based triple therapies should include low doses of both PPIs and clarithromycin, in combination with standard doses of either amoxicillin or a nitroimidazole to obtain excellent cure rates and tolerability. Increasing the duration of treatment from 7 days to 14 days is associated with higher eradication rates. At present, however, no studies have evaluated the clinical usefulness of these 2-week triple therapy regimens specifically in elderly patients. Low compliance and antibiotic resistance are the two major reasons for treatment failure. Primary resistance to amoxicillin remains uncommon, but the frequency of clarithromycin resistance is now around 10% in most European countries and the United States. Metronidazole resistance ranges between 20% and 30% and is more frequent among women and in developing countries. Consensus exists in using clarithromycin and metronidazole for *H pylori* eradication therapies when prevalences of antibiotic resistance are lower than 15% and 40%, respectively. A multicenter study from north-eastern Italy, carried out in subjects 25 to 90 years old, documented that primary resistance to metronidazole was 15% and to clarithromycin 1.8%, without significant differences in patients of different ages. Because failure of therapy is often associated with secondary antibiotic resistance, re-treatment

should ideally be guided by data on susceptibility. Since, such information is often unavailable, quadruple therapies, in which a PPI or an H2-blocker is added to a bismuth-based triple regimen with high-dose metronidazole, have been proposed as second-line therapy. Another retreatment approach without susceptibility testing is to prescribe a second course of PPI-based triple therapy, avoiding antimicrobial agents against which prior therapy may have induced resistance. If a clarithromycin-based regimen was used first, PPI-amoxicillin or tetracycline and metronidazole regimens should be recommended if bismuth is not available. Unfortunately, no data in elderly patients are available on possible alternative rescue therapies including rifabutin or the new fluoroquinolones as well as probiotic agents as part of an eradication regimen.

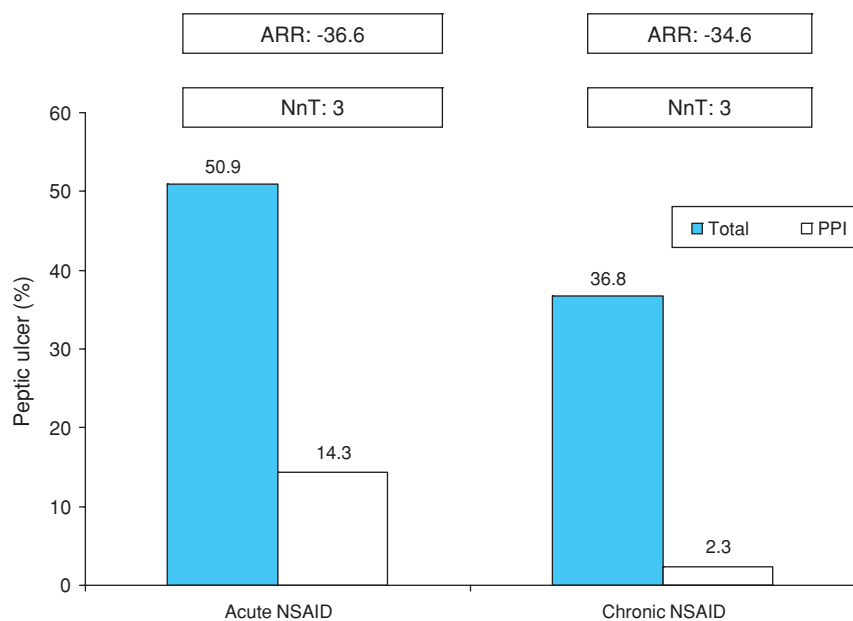

### Treatment and Prevention of NSAID-Related Peptic Ulcer

NSAID- or aspirin-associated peptic ulcers usually heal after 4 to 8 weeks of treatment with a PPI. Healing rates are higher if NSAID or aspirin treatments are stopped. Presently, no consensus exists on the clinical usefulness of a maintenance therapy with antisecretory drugs in patients who stopped NSAID or aspirin treatment after healing an NSAID-related peptic ulcer. The following strategies have been suggested to prevent NSAID- or aspirin-related gastroduodenal peptic ulcer in the elderly (Table 91-8).

**Identify the High-Risk Patient.** Current strategies to reduce ulcer relapse and/or complications are considered cost-effective in

**TABLE 91-8****Strategies for the Prevention of NSAID- or Aspirin-Related Gastroduodenal Peptic Ulcer in the Elderly****STRATEGIES**

1. Identify the high-risk patient
  - History of upper GI symptoms
  - History of peptic ulcer and bleeding
  - Old age
  - Disability
  - Comorbidity
  - Comedications (oral steroids, antiplatelet drugs, warfarin)
2. Reduce dosage and use less damaging NSAIDs
3. Use of coxibs
4. Cotreatment with gastroprotective drugs
5. Eradication of *H pylori* infection
6. Educational programs

**FIGURE 91-10.** Absolute risk reduction (ARR) of peptic ulcer and the number needed to treat (NnT) in elderly acute and chronic users of nonsteroidal anti-inflammatory drugs (NSAID) and/or aspirin concomitantly treated with proton pump inhibitors (PPIs). (Data from Pilotto A, Franceschi M, Leandro G, et al. Proton-pump inhibitors reduce the risk of uncomplicated peptic ulcer in elderly either acute or chronic users of aspirin/non-steroidal anti-inflammatory drugs. *Aliment Pharmacol Ther.* 2004;20:1091–1097.)

high-risk patients. Great importance is placed, therefore, on defining those patients who are at high risk for peptic ulcer when treated with NSAIDs or aspirin. A history of upper GI symptoms, peptic ulcer and/or bleeding; old age; the presence of disability, comorbidity; and concomitant medications, particularly oral steroids, antiplatelet drugs, and warfarin increase the risk of NSAID-related peptic ulcer and/or its complications. Thus, a comprehensive geriatric assessment may be useful in the evaluation of the multidimensional risk of elderly patient.

**Reduce Dosage and Use Less Damaging NSAIDs.** The risk of peptic ulcer and its complications appears to be directly related to dose of the given NSAID and coxib. Lower risk of upper GI damage has been reported with NSAIDs with a short plasma half-life versus those with a prolonged plasma half-time. Independent of this, however, slow release formulations present an augmented risk of ulcer complications.

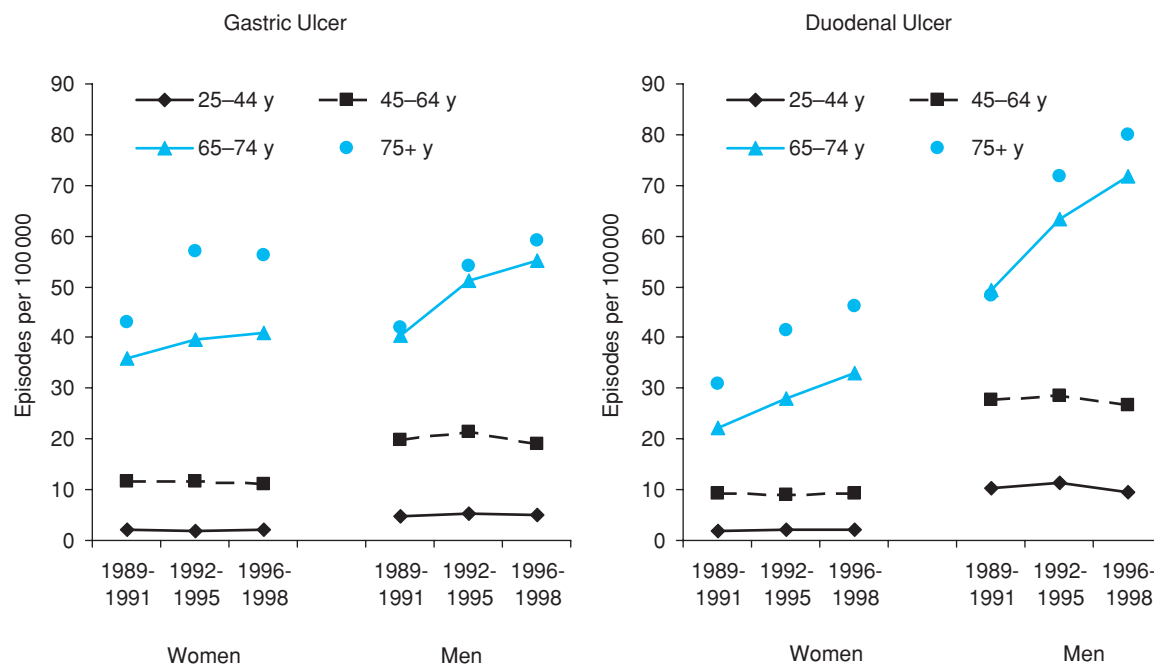

**Use of Selective Inhibitors of Cyclo-Oxygenase-2 (Coxibs).** The selective inhibitors of cyclo-oxygenase (COX)-2 are claimed to be as effective in relieving pain and inflammation in osteoarthritis patients as traditional NSAIDs. Postmarketing observational studies indicate a lower ulcer complications in elderly patients treated with coxibs versus conventional NSAIDs. Concomitant use of aspirin, however, negates their superior gastrointestinal safety over NSAIDs. In high-risk patients, that is, elderly patients with a previous history of NSAID-related ulcer or bleeding, who need anti-inflammatory treatments, the use of celecoxib is not safer than a combination of the NSAID diclofenac and the PPI omeprazole. Moreover, combination treatment with a celecoxib plus a PPI is more effective than coxib alone in preventing peptic ulcer and its complication. Since selective inhibition of COX-2 may induce both cardiovascular and renal adverse events as do traditional NSAIDs, a very careful evaluation of the elderly patient is recommended before prescribing these medications.

**Cotreatment with Gastroprotective Drugs.** Several meta-analyses of controlled trials on gastroprotective drug treatments reported that

misoprostol and PPIs are more effective than H<sub>2</sub>-blockers in preventing both gastric and duodenal severe damage. Indeed, misoprostol administered at effective doses of 200  $\mu$ g four times daily induced significantly higher adverse effects, particularly diarrhea, than PPIs and placebo. PPIs were very effective in preventing gastroduodenal injuries in both acute and chronic elderly users of NSAIDs (Figure 91-10). Similarly, significant efficacy of PPIs for the prevention of peptic ulcer and its complications has been reported in elderly patients treated with low-dose aspirin as antiplatelet therapy, independent of the presence of *H pylori* infection.

**Eradication of *Helicobacter pylori* Infection.** NSAID-use and *H pylori* infection are independent risk factors for peptic ulcer and gastroduodenal bleeding in elderly subjects. In *H pylori*-positive patients who are starting long-term treatment with NSAIDs, the cure of *H pylori* infection significantly reduces the 6-month risk of peptic ulcer. In elderly high-risk patients, however, the use of PPIs concomitantly with the NSAID reduces the occurrence of both acute and chronic NSAID-related gastroduodenal damage more effectively than the eradication of *H pylori* infection. Moreover, after the eradication of *H pylori*, maintenance treatment with a PPI is more effective than placebo in the prevention of ulcer bleeding in elderly patients. All these findings suggest that *H pylori* eradication may be a useful strategy, but it is not sufficient for the prevention of severe gastroduodenal damage in elderly *H pylori*-positive NSAID and aspirin users.

**Educational Programs.** A crucial strategy in the prevention of NSAID-related adverse events is the discontinuation of NSAID therapy. Indeed, a study from Canada reported an estimated 37% of unnecessary NSAID prescriptions in elderly patients with osteoarthritis. Similarly, a study from the United States reported that almost 50% of NSAID prescriptions in elderly patients were inappropriate. Active interventions to improve appropriateness of drug prescription, particularly in the elderly, demonstrated a reduction in NSAID prescriptions. A significant reduction in NSAID use was observed by a nurse-delivered advice intervention on NSAID use involving patients in general practice. A significant reduction in

**FIGURE 91-11.** Average annual age-standardized rate for peptic ulcer hemorrhage in England from 1989 to 1998. (Adapted from Higham J, Kang JY, Majeed A. Recent trends in admissions and mortality due to peptic ulcer in England: increasing frequency of haemorrhage among older subjects. *Gut*. 2002;50:460-464.)

re-hospitalization rates for peptic ulcer as well as mortality rates within 1-year was observed in elderly subjects who participated in a quality improvement project in the United States that involved counseling of patients and their caregivers about NSAID toxicity.

#### Non-NSAID, Non-*Helicobacter pylori* Ulcers

Antisecretory therapy remains the cornerstone of treatment to promote ulcer healing. Standard doses of PPIs should be prescribed at least for 4 weeks in patients with duodenal ulcers and for 8 weeks in patients with gastric ulcers. Generally, patients respond well to these therapies, and no established evidence supports the need for a longer duration or higher dose of antisecretory therapy in uncomplicated idiopathic ulcer. Elderly nonresponders should be investigated for any possible underlying pathophysiology, including compliance, acid hypersecretory state, or use of damaging drugs.

#### Bleeding Peptic Ulcer

Epidemiological studies reported that the prevalence of bleeding complications of peptic ulcer has increased during the last 10 to 15 years in patients who are older than 65 (Figure 91-11). A study performed in elderly residents in the United States has confirmed that the risk of hospitalization for bleeding was significantly associated with an age above 80 years, a limitation in the instrumental activities of daily living, comorbidity, and multiple drugs used. Recent meta-analyses indicate that best management of acute bleeding ulcer includes a combination treatment with endoscopy (heater probe or laser coagulation and/or injection of vasoactive drugs) and PPIs. These treatments might reduce the rates of re-bleeding and surgery interventions; unfortunately, no modification of short- and long-term mortality rates has been observed with all these strategies (Table 91-9). In elderly patients with bleeding, however, a comprehensive geriatric assessment demonstrates a very high prognostic value

**TABLE 91-9**

#### PPI Therapy and Outcome of Endoscopic Hemostasis in Bleeding Peptic Ulcer

	RE-BLEEDING	SURGERY	MORTALITY
EndoTx + PPI vs. PPI alone	0.2 (0.09-0.4)	0.17 (0.06-0.4)	NS
EndoTx + PPI vs. EndoTx alone	0.5 (0.37-0.7)	NS	NS
EndoTx + PPI bolus vs. infusion	NS	NS	NS
PPI after EndoTx vs. EndoTx alone	0.52 (0.4-0.7)	0.53 (0.35-0.8)	NS
Oral PPI	0.32 (0.2-0.5)	0.38 (0.2-0.6)	NS
Intravenous PPI	0.57 (0.4-0.7)	0.67 (0.5-0.9)	NS

for mortality. This finding suggests that general conditions and the severity of multidimensional impairments of elderly patients are crucial points in evaluating the outcome of this severe clinical condition.

## NEOPLASM OF THE ESOPHAGUS

### Esophageal Cancer

Two major histologic types of esophageal cancer are described: squamous cell carcinoma and adenocarcinoma. Although the incidence of squamous cell carcinoma has remained relatively static during the last decades, the incidence of esophageal adenocarcinoma has increased dramatically.

#### Squamous Cell Carcinoma

Esophageal squamous cell cancer accounts for 5% to 7% of all gastrointestinal malignancies. The annual incidence in the United States is 3 to 4 cases per 100 000 persons. The incidence increases with age, being most common in men in their sixth and seventh decades of life. Risk factors (Table 91-10) for squamous cell cancer include alcohol and tobacco use, caustic esophageal injury, chronic strictures, achalasia, squamous carcinoma of the nasopharynx, partial gastrectomy, and human papilloma virus. The incidence and mortality rates are much higher in elderly black men when compared to other group populations. Symptoms of esophageal cancer generally develop only when the tumor has grown to the extent that it has narrowed the lumen of the esophagus substantially, has invaded local structures, or has metastasized. Dysphagia is the most common symptom; other manifestations include coughing and/or choking (because of invasion of the tumor into of the tracheobronchial tree), hoarseness (because of invasion of a recurrent laryngeal nerve), or hematemesis (because of tumor invasion of aorta or the presence of an aorto-esophageal fistula). Ulcerated tumors can cause odynophagia. Since anorexia and weight loss usually precede the onset of dysphagia, the physical examination of these patients at the time of the diagnosis

often reveals malnutrition and dehydration. Metastatic disease may be responsible for bone pain.

#### Adenocarcinoma

Adenocarcinoma of the esophagus has been increasing in frequency at an alarming rate over the past few decades, now accounting for more than 50% of the newly diagnosed esophageal cancers. The annual incidence of adenocarcinoma of the esophagus and gastric cardias is 5.1 cases per 100 000 persons. Unlike squamous cell carcinoma, adenocarcinoma typically affects elderly white males. Barrett esophagus secondary to long-standing reflux disease is the single most important risk factor for adenocarcinoma (Table 91-10). Patients with Barrett esophagus are 30 to 125 times more likely to have adenocarcinoma of the esophagus than the general population. The estimated incidence of adenocarcinoma in patients with Barrett esophagus is 0.2% to 2.1% per year.

The clinical presentation is similar to that of squamous cell carcinoma, but malnutrition, fistulas, and recurrent laryngeal nerve involvement are less common and extension into the stomach, diaphragm, and the liver are more frequent. More than 80% of the tumors are in the distal esophagus. The diagnostic evaluation, treatment modalities, and prognosis are similar to those for squamous cell carcinoma. However, with increased use of endoscopic surveillance, adenocarcinoma can be diagnosed at an earlier stage than squamous cell carcinoma.

#### Diagnosis

*Endoscopy* with biopsies and cytology is the best way to establish the diagnosis. The mid-esophagus and/or the distal esophagus are the most common sites affected. The majority of symptomatic lesions are ulcerated in the center with heaped up margins and encroachment on the lumen. However, early lesions may be subtle and almost normal in appearance. In vivo staining with Lugol iodine or toluidine blue may be helpful for discovering the abnormal mucosa. *Barium esophagogram* may show tumors, but has low sensitivity in the detection of early tumors. Usually *computed tomography* of the chest and abdomen is recommended to assess the extent of disease within the chest and to look for metastases. However, the sensitivity and specificity of CT for determining the depth of esophageal tumor penetration (the T status) and the presence of regional lymph node metastases (the N status) are poor. *Endoscopic ultrasonography* is superior to CT in this regard, accurately predicting the T and N status in 70% to 80% of patients.

#### Treatment

Cancer of the esophagus usually is disseminated at the time of diagnosis and because there is no treatment that reliably eradicates metastatic disease, cure is not possible in most cases. Initial treatment usually involves a choice between surgery, radiation therapy, chemotherapy, and some combination of these three modalities. Squamous cell cancer and adenocarcinoma are treated similarly, with similarly poor survival rates. Overall cure rates for cancer of the esophagus remain below 10%. Treatment and survival, therefore, depends on the stage of the disease. Elderly patients, especially white men, should be screened for Barrett esophagus, and if identified, patients should be placed in endoscopic *surveillance programs* and on aggressive antireflux therapy with PPIs. However, PPIs as

**TABLE 91-10**

#### Common Risk Factors for Esophageal Cancers

SQUAMOUS CELL CARCINOMA	ADENOCARCINOMA
60–70 yrs of age	50–60 yrs of age
Achalasia	Barrett esophagus
Alcohol abuse	Gastroesophageal reflux disease
Black populations	Caucasian populations
Male sex	Male sex
High-starch diet without fruits and vegetables	
Lye ingestion	
Plummer–Vinson syndrome	
Previous head and neck squamous cell carcinoma	
Radiation therapy	
Smoking	

**TABLE 91-11****Endoscopic Surveillance of Barrett Esophagus**

DYSPLASIA	ENDOSCOPY
Absent	Every 2–3 yr after at least two endoscopies negative for dysplasia
Low grade	At 6–12 mo, every yr (in absence of progression)
High grade	Histological confirmation Focal: every 3 mo Focal multiple: esophageal resection or endoscopic ablation

Modified from Sampliner RE. Practice guidelines on the diagnosis, surveillance, and therapy of Barrett's esophagus. The Practice Parameters Committee of the American College of Gastroenterology. *Am J Gastroenterol.* 1998;93:1028–32.

well as antireflux surgery have not been shown to consistently cause regression of the Barrett epithelium or prevention of esophageal cancer. Surveillance involves obtaining four-quadrant biopsies at 2-cm intervals in the Barrett segment using a jumbo biopsy forceps as well as biopsies of any other mucosal abnormalities such as nodules or ulcers. If the biopsies are negative for dysplasia, endoscopy should be repeated within 1 year, followed by endoscopy every 2 to 3 years. If low-grade or indefinite dysplasia is identified, the surveillance interval is shortened to every 6 months for 1 year, followed by annual surveillance. If high-grade dysplasia is found, endoscopy is repeated at 1 month. If high-grade dysplasia is confirmed by two independent pathologists, options include esophagectomy or continued surveillance every 3 months. Ablative endoscopic therapies such as photodynamic therapy, laser, argon plasma coagulation, and multipolar electrocoagulation appear to be very promising especially in patients who are poor surgical candidates (Table 91-11).

*Early cancers*, that is, limited to the mucosa and the submucosa, can be cured by esophagectomy, but cure is not always possible because of presentation of cancers at a late stage. In patients with *superficial cancers* limited to the mucosa who are poor candidates for surgery, options include endoscopic mucosal resection or ablation with electrocautery, argon plasma coagulation, laser or photodynamic therapy. In locally *advanced cancer*, a multimodality approach involving surgery, radiation, and chemotherapy provides the best chance for survival. Squamous cell cancer, unlike adenocarcinoma, is radiosensitive. Majority of patients have some response to radiation therapy, but the response is brief, averaging approximately 3 months. The most widely used combination for chemotherapy, cisplatin and 5-fluorouracil, has shown a response in 20% to 40% of cases, but has no impact on survival.

### Palliative Therapy

In patients with metastatic disease, treatment is mainly palliative. Palliative measures for dysphagia include esophageal dilation, stent placement, or endoscopic tumor ablation. The 5-year survival rates for TNM stage I, II, III, and IV cancers are 60%, 31%, 20%, and 4.1%, respectively.

### Benign Tumors

*Benign tumors* are a rare entity representing less than 1% of all the esophageal neoplasms. Leiomyoma is the most common benign esophageal tumor. Esophageal leiomyomas may produce dyspha-

gia and retrosternal chest pain, but in most cases are asymptomatic. If leiomyomas are symptomatic, surgical enucleation is indicated. Others benign tumors are squamous cell papillomas, fibrovascular polyps, and granular cell tumors.

## GASTRIC CANCER

### Epidemiology

Gastric cancer is an important disease in elderly patients with an estimated 21 700 new diagnoses in the United States in 2001. On a global scale, gastric cancer remains the world's second most common malignancy after lung cancer. The incidence of gastric cancer shows marked worldwide variation; while in industrialized countries, the incidence of gastric cancer is decreasing, in less developed countries gastric cancer is extremely common and often affects younger people. While distal gastric adenocarcinoma is more common in Afro-Asian populations, carcinoma of the cardia and fundus are more common in Caucasians, and their incidence is rising at an alarming rate. Adenocarcinoma makes up 90% of malignant gastric tumors with lymphoma accounting for a further 5%. The Lauren classification is traditionally used to divide adenocarcinoma into (1) an intestinal form, where the malignant cells form a glandular like structure; and (2) a diffuse form, where the cells infiltrate through the wall of the stomach with relatively little disturbance of the mucosa itself, making endoscopic diagnosis more difficult. Despite significant advances in the understanding of its etiology and pathogenesis, the mortality rate remains high and no more than 10% of patients will be alive 5 years from diagnosis. The risk of gastric cancer is strongly related to age. The median age of patients presenting with this cancer is around 72 years, and from the early 1990s, one-quarter of newly diagnosed gastric cancer patients are older than 80 years.

### Etiology and Risk Factors

Pernicious anemia with its hallmark of atrophic gastritis has long been known to confer an increased risk of gastric cancer. Similarly, it is well established that benign ulcer surgery, such as partial gastrectomy, is associated with gastric cancer with a lead in time of 15 to 30 years. Following gastric surgery, inflammation of the gastric remnant is common and usually associated with the reflux of bile. Although the histological appearances are different, both pernicious anemia and the surgical stomach share a common pathophysiological abnormality—hypochlorhydria. Gastric cancer and gastric MALT lymphoma (lymphoma of the mucosa-associated lymphoid tissue) have been associated with *H pylori* infection, and the bacterium has been categorized as a group I carcinogen by the International Agency for Research on Cancer (IARC). *H pylori* infection induces, in genetically predisposed hosts, a cascade of events that could ultimately lead to gastric neoplasia. Several studies reported that the increased proliferation induced by inflammation creates a genetically unstable gastric mucosa, which is further compromised by the presence of genotoxic substances generated by inflammatory and bacterial products. The key pathophysiological events include the onset of gastric atrophy and hypochlorhydria. Hypochlorhydria itself contributes to bacterial overgrowth, which further exacerbates the inflammation and leads to generation of carcinogenic nitro-genous products. Diets that are high in salt content and lacking in

**TABLE 91-12****Risk Factors for Stomach Cancer****RISK FACTORS**

Male sex
Old age
<i>H pylori</i> infection
Foods that contain nitrites and nitrates
Tobacco use
Previous gastric surgery
Adenomatous polyps larger than 1 centimeter in diameter
Familial adenomatous polyposis (mutations in the <i>BRCA1</i> and <i>BRCA2</i> genes)
Hereditary diffuse gastric cancer
Atrophic gastritis
Type A blood group
Environmental cold dust, asbestos, and nickel exposure
Obesity

fresh fruits and vegetables are likely to contribute to the malignant transformation (Table 91-12). The role of time, that is, a long lasting infection with *H pylori*, is probably important in the development of all these mechanisms. Indeed, chronic atrophic gastritis and *H pylori* infection are commonly found in the same elderly subject. Most of the studies suggested that atrophic changes of the gastric mucosa are associated with *H pylori* infection rather than with aging itself. A prospective study was carried out in a group of elderly men with *H pylori* infection and atrophic corpus gastritis. During a 7.5-year period prior to eradication therapy, no significant changes were observed in the mean atrophy and intestinal metaplasia scores. However, after *H pylori* eradication, a significant improvement occurred in the mean histological score of inflammation, atrophy, and intestinal metaplasia. These findings suggest that advanced atrophic gastritis may improve after *H pylori* eradication also in elderly subjects.

### Clinical Features

A symptomatic presentation is very often indicative of advanced stage. In western countries, the most common presenting symptoms are weight loss followed by abdominal pain, nausea and vomiting, anorexia, and dysphagia. Most of these symptoms are nonspecific and are very common in elderly patients for other reasons. In some studies, 40% of patients had symptoms for less than 3 months, but 60% were symptomatic for 3 months or longer and up to 20% for over 1 year. The late presentation of the disease probably explains why its prognosis remains so severe with only 10% of patients alive at 5 years. The clinical manifestations also depend critically on the anatomical location of the tumor. Large tumors in the fundus and body may simply manifest with occult blood loss. In contrast, tumors of the antrum will delay gastric emptying and lead to early satiety, anorexia, and eventually the features of gastric outlet obstruction. Tumors of the proximal stomach may involve the distal esophagus and present with dysphagia.

### Diagnosis

The diagnosis of gastric cancer is easy in advanced cases, but may require a high index of suspicion: a careful history and examination

are essential. Physical examination is frequently unrewarding even in advanced gastric cancer. A hypochromic, microcytic anemia is a common finding and the fecal occult blood test may be positive, although this does not localize the source of blood loss and as such it is not a helpful diagnostic tool in old age. *Upper GI endoscopy* has been shown to be more accurate than *barium radiology* in the diagnosis of gastric cancer. Endoscopy allows a close inspection of the mucosa, which is generally the only circumstance under which early gastric carcinoma is found. *Histological examination* of multiple biopsies is essential for diagnosis. As mentioned previously, gastric atrophy and intestinal metaplasia are common findings in elderly patients. The presence of dysplasia, however, should always be regarded as significant because it may indicate a high risk of malignant transformation, or it may reflect the presence of adjacent malignancy. Currently the diagnostic usefulness of the barium meal is limited in defining the extent of a tumor or in identifying eventual gastroenteric fistulas. *Ultrasonography* of the abdomen is useful for assessing the spread of gastric carcinoma. It may detect evidence of lymphadenopathy but can be particularly valuable in detecting metastases within the liver. A number of studies suggest that *endoscopic ultrasound* has an accuracy of 90% in defining the depth of invasion within the stomach itself. It is also sensitive to wall thickening and will pick up diffuse carcinomas, and it may allow for the identification of regional lymph nodes.

### Treatment of Gastric Cancer

Age in itself is not a contraindication to aggressive treatment including curative surgery. Nevertheless, the operative risk must be well defined by a comprehensive geriatric assessment.

### Surgery and Endoscopic Procedures

Surgical resection remains the only proven method of providing long-term survival in patients with gastric cancer, but it is effective only if a complete macro- and microscopic clearance of the tumor is possible (R<sub>0</sub> resection). In patients with very early tumors, alternatives to resection have been proposed including laser ablation, photodynamic therapy, and endoscopic mucosal resection. Clearly, such treatments avoid both the immediate and long-term morbidity associated with surgery, but can only be recommended for tumors limited to the gastric mucosa in which the incidence of lymphatic spread is minimal. In patients with mucosal disease, a policy of regular endoscopic surveillance combined with ablation of the surrounding mucosa is mandatory. As tumor invades into the submucosa, the incidence of lymphatic spread increases, and mucosal ablative techniques are unlikely to achieve clearance of the disease. If there is evidence of submucosal invasion, a formal resection is performed. Lesions that are ulcerated pose particular problems with infiltration and may also be difficult for the pathologist to interpret. Furthermore, some reports have indicated that such lesions may metastasize early to regional lymph nodes, and accordingly endoscopic mucosal resection is not recommended for these tumors.

### Chemotherapy

The low survival associated with gastric cancer has prompted investigation into postoperative (adjuvant) chemotherapy, and preoperative treatment (neoadjuvant). In patients with gastric cancer, there is no evidence that either adjuvant or neoadjuvant chemotherapy is of

value in patients in whom a complete surgical resection is possible. The elderly are more likely to have cardiac and renal impairments and therefore less likely to tolerate chemotherapy well and have a greater risk of side effects. A comprehensive geriatric assessment that exactly defines the multidimensional impairments of elderly patients is crucial in evaluating the role of adjuvant chemotherapy. This treatment must offer significant survival benefits weighed against the toxic effects and eventual hospitalizations and complications, particularly in very old subjects.

### Palliative Therapy

The majority of elderly patients present with late gastric cancer at an advanced stage. Most will not be amenable to curative surgical resection, and the issue of palliation is therefore very important. Distal tumors involving the antrum frequently progress to *obstruction*. In some patients, this will be owing to physical stenosis of the pylorus, while in others gradual infiltration of the antrum leads to loss of functionality and a failure in gastric emptying. Medical treatment of outlet obstruction with prokinetics is usually unhelpful. The symptoms are usually unpleasant with vomiting, regurgitation and reflux, and rapid nutritional failure. Because of this, palliative surgical therapy is often justified and options include antrectomy or, more commonly, the formation of a gastroenterostomy to relieve obstruction. Alternative approaches may include laser to more localized lesions. If the distal esophagus is involved, patients with large tumors may also develop dysphagia. This complication is usually managed with stenting or sometimes with laser therapy. Large tumors frequently bleed and result in *chronic blood loss*. This may on occasion warrant consideration of surgery, although the difficulties of performing this on frail elderly patients should not be underestimated. Another alternative is to try to shrink the tumor using a neodymium YAG laser, but results on this technique for treating chronic blood loss are conflicting. Most patients with advanced gastric cancer develop *nutritional problems*, and weight loss is almost invariable. Extensive infiltration alters the compliance of the stomach and frequently leads to sensations of early satiety and loss of

appetite. In addition, advanced gastric cancer frequently leads to profound metabolic effects such as cachexia and loss of muscle bulk. Some patients may benefit from radiotherapy, but adenocarcinoma is frequently not radiosensitive. The role of hospice and organized palliative care and pain teams is extremely important in improving the comfort of patients.

# Common Large Intestinal Disorders

Leon S. Maratchi ■ David A. Greenwald

In the elderly, gastrointestinal (GI) disorders, especially those of the large intestine, account for a significant portion of physician visits, inpatient hospitalizations, and health care expenditure in the United States. Not only are large intestinal disorders common, but in the elderly their presentations, complications, and treatment may be different than in the young. This chapter focuses on diagnosis and treatment of a variety of diseases of the large intestine, including diverticular disease, *Clostridium difficile*-associated diarrhea, microscopic colitis, inflammatory bowel disease, colonic ischemia, colonic obstruction, and lower GI bleeding.

Diagnosis of GI disorders in an elderly patient poses several additional challenges to the physician on top of those present for all patients. First, comorbid illnesses are frequent and often numerous, and some such as dementia and depression may impair adequate communication between patient and caregiver. Second, medications and their side effects may cloud the clinical picture; polypharmacy is common in the elderly. Lastly, symptoms attributable to the large intestine may be manifestations of different diseases in the elderly than they would in the young. The astute geriatrician must take these factors into consideration when treating all patients.

## DIAGNOSTIC TESTING

Symptoms of digestive diseases may be misinterpreted or atypical in the aged. For example, constipation may be a symptom of irritable bowel syndrome in a young patient, whereas it might herald an obstructing lesion in an older patient. Rectal bleeding in a young person is most commonly from hemorrhoids or inflammatory bowel disease. In the elderly, diverticulosis or colon cancer more commonly cause rectal bleeding. A complete and thorough history is imperative in patients, especially the elderly. Subtle clues to the diagnosis are sometimes dismissed as physiologic aspects of aging. Physical examination and some laboratory tests including tests of liver function

are unaffected by aging, and any abnormality should be evaluated for the presence of a disease state and not dismissed as an age-related change (Table 92-1).

## Endoscopic Procedures

### Colonoscopy

Colonoscopy in the elderly is safe and well tolerated. Several studies of indications and outcomes of patients older than 80 years having elective and emergency endoscopic procedures found those tests to be safe; advanced age is not a contraindication to endoscopy. Moreover, the yield for diagnostic testing with colonoscopy in the elderly is relatively high.

Adequate bowel preparation is critical to a successful colonoscopic examination. Bowel cleansing in the elderly should be performed with care. Preparation with standard doses of polyethylene glycol based lavage solutions (PEG-ELS) in the elderly is well tolerated and produces satisfactory bowel cleansing in more than 95% of all cases. Sodium phosphate osmotic laxative preparation may also be used for bowel preparation, but causes significant fluid shifts and may cause electrolyte abnormalities or renal failure in this subset of patients. Sodium phosphate laxatives should be used with caution in the elderly and those with kidney or heart disease.

Most colonoscopies are performed under conscious sedation. Sedation for colonoscopy usually includes a combination of a benzodiazepine (midazolam or diazepam) and a narcotic (meperidine or fentanyl), or may include a short-acting anesthetic agent such as propofol. The elderly may be more sensitive to the agents used for sedation in GI endoscopy; small incremental doses should be given and the patient monitored closely for signs of cardiopulmonary compromise. Nevertheless, age alone is not a major determinant of morbidity; rapid or excessive dosing contributes more to complications from sedation than does age itself.

**TABLE 92-1****Influence of Age on Likely Diagnosis of Lower Gastrointestinal Symptoms**

SYMPTOM	YOUNG PATIENT	ELDERLY PATIENT
Rectal bleeding	Hemorrhoids	Diverticulosis
	Inflammatory bowel disease	Vascular ectasia
	Colonic polyp	Colon cancer
Constipation	Irritable bowel syndrome	Obstructing lesion
Anal stricture	Inflammatory bowel disease	Neoplasm
		Radiation-induced injury

### Endoscopic Ultrasound

Endoscopic ultrasound (EUS) can be used to diagnose and manage disease of the anorectum. EUS utilizes high frequency ultrasound waves emitted from a probe attached to an endoscope to delineate the layers of the rectal wall, the internal and external anal sphincters, and the pelvic floor muscles. EUS may be helpful in evaluating these structures in patients with fecal incontinence. EUS also is frequently used to stage rectal malignancy, providing information about the depth of tumor invasion and the status of regional lymph nodes. Direct tissue sampling is available through fine needle aspiration at the time of the EUS.

### Radiology

#### Contrast Studies

Contrast studies of the large intestine involve coating the colonic mucosa with a contrast medium, usually barium sulfate, following thorough colonic preparation. Barium enemas may be performed by either single- or double-contrast method; in the latter, air is insufflated as well as barium. The single-contrast technique often is used to diagnose colonic strictures, fistula, obstruction, or diverticulitis. Double-contrast barium enema more commonly is used to detect polyps or mucosal abnormalities.

There exists some controversy concerning whether double-contrast barium enema is effective as a screening tool for colon cancer. Many experts consider colonoscopy to be the gold standard screening test. Colonoscopy is safe in the elderly and is widely available. However, contrast studies may be reasonable as a first-line test when colonic strictures are suspected or the presence of likely or known obstruction might make colonoscopy unsafe.

#### CT Colonography

CT colonography (virtual colonoscopy) is a radiographic technique that combines helical CT and graphics software to create a three-dimensional view of the colonic lumen. This technology was developed to detect colonic polyps. In preliminary trials of CT colonography, detection rates for polyps greater than 5 mm were similar to those for optical colonoscopy. Debate remains about the significance of finding polyps of different sizes; comparisons of CT colonography with optical colonoscopy rest on what the investigators deem to be a “significant” polyp, with much disagreement about the significance of polyps less than 5 mm. Nonetheless, CT colonography will likely

play an increasingly important role in colon cancer screening in the coming years.

There are several limitations of CT colonography. First, the procedure requires formal bowel preparation, similar to that required for optical colonoscopy. Moreover, polyps and other abnormalities found at CT colonography, detected in 10% to 30% of all examinations, require conventional colonoscopy for removal. Lastly, in addition to colonic lesions, incidental extracolonic findings on CT colonography such as gall bladder, liver, and renal/adrenal abnormalities may require evaluation and possibly further invasive testing.

### DIVERTICULAR DISEASE

Colonic diverticula are herniations of colonic mucosa through the smooth muscle layers of the colon. Strictly speaking, because colonic diverticula do not involve the muscle layer but rather are herniations of the mucosa and submucosa, they are actually pseudodiverticula. Diverticulosis has been increasingly recognized in western society and is thought to be a disorder of older individuals. Diverticula are present in approximately one-third of persons by age 50 and in approximately two-thirds by age 80. In western society, the predominance of diverticula occurs on the left side of the colon, specifically the sigmoid colon, although diverticula can occur anywhere in the colon.

#### Pathophysiology

There are three factors implicated in the pathogenesis of colonic diverticulosis. First, altered colonic motility results in increased luminal pressure along segments of the colon, and the resulting high-pressure areas cause out-pouchings at areas of weakness. Second, low intake of dietary fiber predisposes to diverticular disease, because low stool weights and slower stool transit times allow for relative increases in colonic intraluminal pressure. Third, with age the structural integrity of the colonic muscular wall decreases, and diverticula are more likely to form as a result.

#### Asymptomatic Diverticulosis

Diverticulosis is usually an incidental finding in patients undergoing radiographic studies or colonoscopy for other reasons. There is no clear indication for therapy or follow-up in such patients. Large cohort studies suggest that complications of diverticular disease may be prevented by intake of a high-fiber diet. Although prospective, randomized studies are lacking, a diet high in fiber and low in fat appears to be reasonable, and one that likely provides other health benefits as well as potentially decreasing the risk of complications from diverticulosis.

#### Painful Diverticular Disease

Some patients with diverticulosis have left lower quadrant pain, and when examined, do not have evidence of inflammation. These patients may have painful diverticular disease. Pain often is described as crampy, located in the left lower abdomen, and may be associated with diarrhea or constipation as well as tenderness over the affected area. The pain is often exacerbated by eating and diminished by defecation or the passage of flatus. The symptoms of painful

diverticular disease often overlap with those of irritable bowel syndrome, and therefore painful diverticular disease is considered part of the spectrum of functional bowel disorders. It is important to consider other causes of left lower quadrant pain such as diverticulitis, colonic obstruction, and incarcerated hernias in such patients.

### Diverticulitis

Diverticulitis, defined as having diverticulosis in association with inflammation, infection, or both, is probably the most common clinical manifestation of diverticular disease. Diverticulitis develops in approximately 10% to 25% of individuals with diverticulosis who are followed for 10 years or more; however, less than 20% of these patients require hospitalization.

The process by which a diverticulum becomes inflamed has been compared to appendicitis, in which the diverticulum becomes obstructed by stool in its neck. The resulting obstruction eventually leads to micro- or macroperforation of the diverticulum. Fever, leukocytosis, and rebound tenderness often ensue. In an elderly patient, absence of these findings unfortunately does not rule out diverticulitis, and an aggressive evaluation is indicated if this diagnosis is suspected.

An abdominal and pelvic CT scan often confirms the diagnosis when the clinical suspicion is for diverticulitis, and the radiographic finding may or may not include evidence of a pericolic abscess. Colonoscopy or barium enema should be delayed until inflammation has improved because of an increased risk of colonic perforation with these studies. Patients with severe pain, nausea, and vomiting often require hospitalization and benefit from intravenous antibiotics. Most patients with diverticulitis will improve within 48 to 72 hours, and then a 5 to 7 day course of oral antibiotics with gradual introduction of oral intake is adequate therapy. Selected patients with relatively mild symptoms and who are able to tolerate oral intake may be managed with close outpatient monitoring including oral antibiotics and bowel rest. Given the high incidence of complicated disease, there should be a low threshold for hospitalization in elderly patients with diverticulitis.

Patients with complicated disease including those with abscesses may need drainage by surgery or interventional radiology. Surgery is recommended for patients with diverticulitis who fail to respond to medical therapy within 72 hours, those with two or more attacks, and those with one attack complicated by abscess, obstruction, or when the inflammatory process involves the bladder. The operation can usually be done in one stage with a primary bowel anastomosis. Sometimes, however, a two-stage procedure with a temporary colostomy may be necessary.

### Diverticular Hemorrhage

Three to five percent of patients with diverticulosis have hemorrhage from a diverticulum. Diverticular hemorrhage is the most common identifiable cause of significant lower GI bleeding, accounting for 30% to 40% of cases with confirmed sources.

Bleeding associated with diverticula is typically brisk, and painless. While the majority of diverticula are located in the left colon, bleeding from diverticular disease usually arises from the right colon. Bleeding is said to arise from arterial rupture of the vasa recta as it courses over the dome of a diverticulum. Bleeding ceases spontaneously in 70% to 80% of patients, and re-bleeding rates range

from 22% to 38%. Re-bleeding is more likely when the initial bleed is severe.

The initial step in the management of patients with hemodynamically significant bleeding from diverticulosis is stabilization with intravenous fluid and blood products as necessary. Stable patients with suspected diverticular hemorrhage may undergo colonoscopy following rapid colonic purge. Colonoscopy in this setting allows for the ability to identify a diverticular source, to exclude alternative diagnoses, and to provide therapy of actively bleeding lesions.

In patients with recurrent bleeding, nuclear tagged red blood cell scans (scintigraphy) may localize the bleeding site. A positive bleeding scan may lead to angiography, which may allow for nonsurgical management of diverticular hemorrhage. Patients who require more than three units of packed red cell transfusions over 24 hours, have bleeding refractory to treatment, or are hemodynamically unstable may require surgical management. Preoperative nuclear red blood cell scans or angiography often help localize the diseased segment and allow for limited bowel resections. Blind total colectomy is rarely indicated.

## CLOSTRIDIUM DIFFICILE COLITIS

*Clostridium difficile*, an anaerobic gram-positive, spore forming toxigenic bacillus was first isolated in 1935. It was not until 1978 when the association between the toxin elaborated by this bacteria and antibiotic-associated pseudomembranous colitis was made. The organism is now recognized as the single most important cause of nosocomial infectious diarrhea in the United States.

### Pathogenesis

The pathogenesis of *C. difficile* colitis involves several steps. Patients must first be exposed to antibiotics. While the most common antibiotics associated with *C. difficile* colitis are ampicillin, amoxicillin, cephalosporins, and clindamycin, virtually all antibiotics (including those used to treat *C. difficile* colitis) have been implicated in causing disease (Table 92-2).

Next, exposure to antibiotics leads to altered colonic microflora, which in turn changes the protective barrier typically present in the colon against *C. difficile*. Colonization of the organism in the colon is then possible. *C. difficile* infection may result in an asymptomatic carrier state, or patients may develop diarrhea and colitis. Patients with intact immune systems and an ability to mount an early antibody response to *C. difficile* toxin usually become asymptomatic carriers of the organism. On the other hand, patients lacking sufficient

**TABLE 92-2**

#### Antibiotics Associated with *Clostridium difficile* Colitis

COMMON	LESS COMMON
Ampicillin and Amoxicillin	Chloramphenicol
Cephalosporins	Macrolides

Intensive care unit stay
Length of hospitalization

ability to mount an adequate immune response develop diarrhea and colitis.

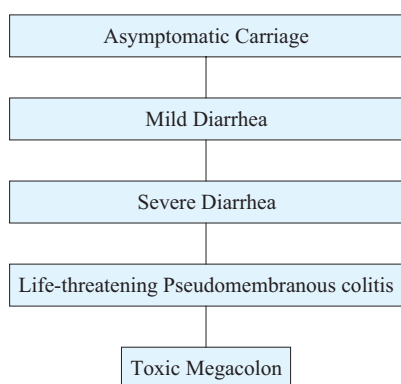

Risk factors for the development of *C difficile* colitis include advanced age, multiple comorbid illnesses, intensive care unit stay, use of a nasogastric tube, acid antisecretory medications, and length of hospital stay (Table 92-3).

### Clinical Manifestations

Clinical manifestations of *C difficile* infection range from asymptomatic carriage to mild to moderate diarrhea to life-threatening pseudomembranous colitis (Figure 92-1). Asymptomatic carriage of *C difficile* is common in hospitalized patients, and in fact, studies have shown that 10% to 16% of hospitalized patients receiving antibiotics are carriers of *C difficile*. Asymptomatic carriers should not be treated. In patients who develop diarrhea with *C difficile*, symptoms often develop soon after colonization. Fever, abdominal pain, and leukocytosis accompany the watery, nonbloody diarrhea. Mucus or occult blood may be present, but hematochezia should prompt an evaluation for other disease states. Patients with more severe disease may develop colonic ileus or toxic dilation without diarrhea. Abdominal radiographs will often reveal the colonic dilation.

### Diagnostic Tests

There are several tests for diagnosing *C difficile* colitis. The most widely used is an enzyme linked immunoassay. This assay detects either one of the two *C difficile* toxins. While the main advantages

**FIGURE 92-1.** Clinical Manifestations of *Clostridium difficile* infection.**FIGURE 92-2.** Pseudomembranes.

are speed, cost, ease of testing, and high specificity, this immunoassay has relatively low sensitivity. Other diagnostic tests including *C difficile* culture, tissue culture cytotoxic assay, and PCR for detection of toxin genes are rarely used because of their high cost, need for specialized laboratory techniques, and length of time to make the diagnosis.

Colonoscopy, or more often flexible sigmoidoscopy, may be helpful in making the diagnosis of *C difficile* colitis but is not necessary. Endoscopy is most useful when the diagnosis is in doubt or when disease severity demands rapid diagnosis. The finding of colonic pseudomembranes in a patient with antibiotic-associated diarrhea is almost pathognomonic for *C difficile* colitis (Figure 92-2).

### Treatment

Therapy for *C difficile* colitis begins with withdrawal of the precipitating antibiotics if possible. Metronidazole and vancomycin are both effective in the treatment of *C difficile*-associated disease. (Note that the only FDA-approved drug for treating *C difficile* colitis in the United States is vancomycin). Metronidazole is by far less expensive, and the use of vancomycin carries with it a concern for the induction of vancomycin-resistant enterococci; therefore, the usual initial therapy is with a 10 to 14 day course of oral metronidazole. This is effective in treating the majority of patients. In patients who are too ill or cannot take oral medication, IV metronidazole can be substituted. Patients who do not respond to metronidazole can be switched to oral vancomycin. Because intravenous vancomycin does not penetrate the colonic lumen, this formulation is not effective in treating *C difficile* colitis. Probiotic agents such as *Lactobacillus* GG and *Saccharomyces boulardii* have been used to reconstitute the colonic microflora, and are occasionally added to metronidazole or vancomycin to treat *C difficile* colitis, but their effectiveness has not been demonstrated in well-designed trials.

Unfortunately, recurrent *C difficile* infection is a common problem and particularly prevalent in older adults. Symptomatic recurrence may result from reinfection with either the same or a different strain of *C difficile*. Resistance to metronidazole or vancomycin is seldom if ever an important factor in recurrence. Therefore,

**TABLE 92-4****Vancomycin Taper for Second Relapse of *Clostridium difficile* Colitis**

Vancomycin 125 mg po qid for 7 days
Vancomycin 125 mg po bid for 7 days
Vancomycin 125 mg po qd for 7 days
Vancomycin 125 mg po qod for 7 days
Vancomycin 125 mg po q 3 days for 7 days

patients with recurrent *C difficile* colitis generally are given another trial with the antibiotic used to treat the initial infection. In some patients, a prolonged taper of vancomycin as well as the addition of cholestyramine over many months may be needed to prevent further recurrence (Table 92-4). A variety of other strategies, including the use of some nonabsorbable antibiotics and fecal transplantation, have been used in the treatment of recurrent *C difficile* infection.

## MICROSCOPIC COLITIS

The term “microscopic colitis” refers to two distinct but similar clinical entities, lymphocytic and collagenous colitis. Combined, they are characterized by chronic watery diarrhea and feature histologic evidence of chronic mucosal inflammation in the absence of endoscopic or radiological abnormalities of the large intestine. They differ principally by the presence or absence of a thickened collagenous band, which when present in collagenous colitis is located in the colonic subepithelium.

Both lymphocytic and collagenous colitis occur most commonly in people in their sixth to eighth decade. There is a strong female predominance. Most patients present with chronic watery stools for months to years. The pattern of symptoms in patients with microscopic colitis fluctuates and consists of exacerbations and remissions over years. Crampy abdominal pain is common, and symptoms often improve with fasting. Physical examination in patients with microscopic colitis is usually unremarkable, and occult blood in the stool is uncommon. Colonoscopic examinations are usually normal. It is important to exclude infectious causes of diarrhea by testing the stool for ova and parasites, bacterial pathogens, and *C. difficile* toxin prior to making the diagnosis of microscopic colitis. The diagnosis relies on histopathologic evaluation of biopsied material from the diseased colon.

### Pathology

Microscopic colitis is characterized by increased mononuclear cells in the lamina propria and between crypt epithelial cells, while collagenous colitis features a thickened subepithelial collagen layer. Contrasted to the normal colon where the collagen layer typically is 4 to 5 micrometers thick, in collagenous colitis the collagen layer is greater than 10 micrometers thick and averages 20 to 60 micrometers. The thickened layer is predominantly made up of type VI collagen, and it is this thickened collagen band that distinguishes collagenous colitis from lymphocytic colitis. Although inflammatory changes may be found diffusely throughout the colon in microscopic colitis,

multiple biopsies of the left colon proximal to the rectosigmoid usually are sufficient to make the diagnosis.

### Treatment

There have been few controlled trials regarding treatment for microscopic colitis, and therapy is largely empiric. Most reports suggest that no single agent works. The pattern of the diarrhea in microscopic colitis often is relapsing; patients sometimes find relief with one agent, but unfortunately symptom improvement may not be permanent. Almost one-third of patients respond to antidiarrheal agents like loperamide as well as stool bulking agents like psyllium or methylcellulose; however, these agents do not improve the subepithelial inflammation or reduce the thickness of the collagen band.

Other treatment trials in microscopic colitis have examined the effect of aminosalicylates, corticosteroids, and bile acid absorbing resins. Alone or in combination, these agents reduce subepithelial inflammation and collagen thickness. Budesonide, an orally administered, topically active synthetic corticosteroid with significant first-pass metabolism has shown considerable promise in the treatment of microscopic colitis. Budesonide is an attractive agent here because of limited systemic side-effects and improvement of symptoms with once daily dosing, but unfortunately relapse after stopping the drug is common. In severe refractory cases, diverting ileostomy or proctocolectomy is a treatment of last resort.

## INFLAMMATORY BOWEL DISEASE

Crohn’s disease and ulcerative colitis comprise the vast majority of inflammatory bowel disease (IBD) (Table 92-5). They are characterized by a tendency for immune activation and inflammation within the GI tract. IBD commonly has its onset in the young adult population, but is found with increasing frequency in the elderly as well.

The age of diagnosis may range from early childhood through the entire lifespan. Epidemiological studies suggest there is a bimodal distribution of the age of onset, with the peak incidence of IBD occurring in the second and third decades, and a second smaller peak in the elderly between the ages of 60 and 70 years. “Late-onset” IBD accounts for approximately 12% cases of ulcerative colitis and 16% cases of Crohn’s disease. However, in the elderly, presenting

**TABLE 92-5****Differentiating Crohn’s Disease and Ulcerative Colitis**

	<b>CROHN’S DISEASE</b>	<b>ULCERATIVE COLITIS</b>
Distribution	Throughout the GI tract, with skipped segments	Continuous disease from the rectum involving only the colon
Rectum	Relatively spared	Typically involved
Mucosal lesions	Aphthous ulcers, cobblestoning	Micro ulcers, linear ulcers
Rectal bleeding	Uncommon	Common
Depth of inflammation	Transmural	Mucosal
Fistulas	Present	Not present

symptoms of IBD often are presumed to be attributable to another cause, and initially the correct diagnosis is sometimes overlooked. On the other hand, many experts believe that much of what was previously considered to be IBD in the elderly is actually attributable to other causes, and in particular, to ischemic colitis.

## Crohn's Disease

Crohn's disease is a chronic inflammatory process of unknown etiology, which most often affects the distal ileum, but can affect any segment of the GI tract including the colon. It is characterized by transmural inflammation of the bowel wall, the presence of aphthae and ulcers, and the interspersing of segments of involved bowel with uninvolved bowel, i.e. skip lesions. Fissures, fistulas, and strictures are common in Crohn's disease. According to most published series, Crohn's disease of the colon, also known as Crohn's colitis, is more common in the elderly than in the young.

## Symptoms and Signs

The presentation of Crohn's disease may be subtle and varies considerably. The clinical picture of Crohn's disease in the elderly as compared to the young has its roots in the propensity for Crohn's disease in the elderly to involve the colon. Consequently, intestinal obstruction, perforation, and fistula—features often associated with small bowel disease are less common. The majority of elderly patients with Crohn's disease manifest their disease with abdominal pain, weight loss, fever, and diarrhea. The diarrhea, typically watery in Crohn's disease can be bloody when the colon is involved.

Common laboratory abnormalities such as anemia, leukocytosis, thrombocytosis, hypoalbuminemia, and elevated erythrocyte sedimentation rate, as well as C-reactive protein levels vary with the severity of the illness. Interestingly, anemia in Crohn's disease can be because of either iron deficiency from chronic GI blood loss or from vitamin B-12 deficiency if the Crohn's disease involves a large enough segment of the distal ileum, the site for B-12 absorption in the small bowel.

Unfortunately, no single symptom, sign, or diagnostic test definitively establishes the diagnosis of Crohn's disease, and prolonged delays in diagnosis probably occur more frequently in elderly patients. Ultimately, a constellation of suggestive symptoms and laboratory abnormalities should prompt further evaluation. Common intestinal infections should be excluded, and tests may include stool cultures, stool examination for ova and parasites, and assays for *C. difficile* toxin.

Ultimately, the diagnosis of Crohn's disease is confirmed by findings on barium studies, colonoscopy, and histopathology. Colonoscopy and barium studies can identify the characteristic linear ulcers, skip lesions, and mucosal edema in Crohn's disease. Barium studies are superior for finding fistulas and defining the anatomic location of disease. CT and MR enterography may play an increasing role in the diagnosis of Crohn's disease. Because of its ability to see the mucosa directly and sample it for histopathologic examination, colonoscopy complements radiologic studies in making the diagnosis of Crohn's disease.

Computed tomography studies provide superior definition of the colon wall, can identify pyogenic complications like abscesses and perforations, and also can detect other intra-abdominal

pathology that might mimic the presentation of Crohn's disease, such as appendicitis or nephrolithiasis. On the other hand, CT does not demonstrate fine mucosal detail and often appears normal early in the course of disease.

## Management

The principles of IBD management are the same regardless of the age of the patient. Nonetheless, there are several important considerations when treating elderly patients with IBD. The most commonly used medications in the treatment of Crohn's disease include sulfasalazine, mesalamine (5-aminosalicylic acid), and corticosteroids; all of these are well tolerated in the elderly population. However, corticosteroid use confers a higher risk of complications in the elderly, including accelerated bone loss and fractures, hypertension, and glucose intolerance (Table 92-6).

Immunomodulators like azathioprine, 6-mercaptopurine, and methotrexate are used effectively in the young to maintain remission of Crohn's disease. These agents are usually well tolerated in the elderly as well; however, some authorities argue against their use in older patients on the theoretical grounds that they may further impair the immune dysfunction associated with aging and result in increased risk of infection or possibly malignancy.

Finally, some antibiotics such as metronidazole and ciprofloxacin have been shown to be effective in inducing and maintaining remission, as well as healing perineal fistulas, in patients with Crohn's disease. The long-term use of antibiotics typically is limited by the occurrence of significant side effects. Specifically, irreversible peripheral neuropathy can occur with the use of metronidazole, while antibiotic-associated diarrhea may be a complication of prolonged ciprofloxacin use.

**TABLE 92-6**

### Doses and Adverse Reactions with Commonly Used Medications to Treat Inflammatory Bowel Disease

MEDICATION	DOSE	ADVERSE REACTIONS
Sulfasalazine	4–6 g/d	Nausea, folate deficiency, hemolytic anemia with glucose-6-phosphatase dehydrogenase deficiency
Mesalamine	Up to 4.8 g/d	Headaches
Prednisone	Up to 60 mg/day	Cushingoid appearance, glucose intolerance, osteoporosis, avascular necrosis, proximal myopathy, irritability, hypertension, cataract, glaucoma
6-Mercaptopurine, azathioprine	6-MP 1.5 mg/kg AZA 3 mg/kg	Pancreatitis, pancytopenia, hepatitis
Metronidazole	Up to 1 g/d	Anorexia, nausea/vomiting, disulfiram-like effect, peripheral neuropathy
Ciprofloxacin	Up to 1 g/d	Nausea/vomiting, rash, hepatitis, spontaneous tendon rupture

Elderly patients with ileal or ileal–colonic Crohn’s disease occasionally require intestinal resection, but generally tolerate surgery well and appear to have low rates of postoperative recurrence. Proctocolectomy with ileostomy is a common surgical option for patients with extensive Crohn’s colitis. In elderly patients who are debilitated or malnourished, an initial subtotal colectomy with ileostomy is less debilitating and permits weight gain and improved physical well-being. If proctocolectomy is subsequently required, it can be done with a low complication rate, but may not be necessary at all if rectal disease is absent. A conventional ileostomy is generally favored in elderly patients following colectomy, because anal sphincter sparing surgical procedures, such as an ileal pouch–anal anastomosis, often have poor functional results in older patients.

### Ulcerative Colitis

Ulcerative colitis (UC) is a chronic inflammatory disorder of the GI tract of unknown etiology that affects the mucosa and submucosa of the large intestine in a continuous fashion. The inflammatory process invariably involves the rectum and extends proximally to variable distances, but does not involve the GI tract proximal to the colon. For many elderly patients, UC is a relatively mild illness, because colonic inflammation often is limited to the rectum or sigmoid colon. This distribution of disease is generally associated with less systemic manifestations, better response to medical therapy, and less need for surgery than more extensive UC.

### Symptoms and Signs

The severity of UC may be subjectively classified as mild, moderate, or severe and is generally proportional to the extent of colonic inflammation. Symptoms in elderly patients are similar to those seen in young patients, and include bloody diarrhea, rectal pain, tenesmus, urgency, and abdominal pain. In comparison to Crohn’s disease, the diarrhea in UC almost always is bloody. Fecal urgency, a sensation of incomplete evacuation, and fecal incontinence also are common. Unfortunately, older patients appear to be more likely than younger patients to present with a severe initial attack, and that first severe manifestation is associated with a relatively high fatality rate.

Laboratory findings in UC are nonspecific and reflect the severity of the underlying disease. In patients with limited distal disease, laboratory abnormalities may be absent except perhaps for mild anemia. In patients with extensive disease, severe iron deficiency anemia, hypoalbuminemia, leukocytosis, and thrombocytosis are common.

Toxic megacolon is a feared complication of UC, and it occurs more frequently in older patients. One should be suspicious of toxic megacolon in a patient whose diarrhea improves but whose abdomen is distended and tympanic. Other markers of worsening systemic inflammation, such as fever and leukocytosis, will also be present. The diagnosis is usually made by abdominal radiography. Colonoscopy should not be attempted when there is a suspicion for toxic megacolon, as perforation may ensue.

Similar to the situation in Crohn’s disease, there is no single test that can definitively diagnose UC with acceptable sensitivity and specificity. In elderly people, it is important to exclude other diseases that may mimic UC, like ischemic colitis, radiation proctocolitis, diverticulitis, malignancy, and infectious colitis.

**FIGURE 92-3.** Ulcerative colitis as seen on colonoscopy.

Again, the constellation of characteristic signs and symptoms often prompts an endoscopic examination, which may show the classic findings of diffuse erythema, mucosal edema, granular mucosa, and ulcerations starting in the rectum without intervening areas of normal mucosa (Figure 92-3). In the proper clinical setting, flexible sigmoidoscopy with biopsy is usually sufficient to establish a diagnosis of UC. Complete colonoscopy with ileoscopy is necessary to determine the extent of disease and to exclude Crohn’s disease. However, complete colonoscopy is not recommended in patients with active UC for fear of perforation; the procedure can be safely performed once active disease has been controlled.

### Management

Most elderly patients with UC respond favorably to medical management. Once in remission, relapse occurs less frequently in the elderly regardless of the severity of the initial attack. A range of agents is available for medical therapy of UC, and these may be administered orally, rectally, or parenterally depending on the site and severity of disease. Pharmacologic agents used to treat UC in the elderly are similar to the ones used to treat Crohn’s disease and include sulfasalazine, mesalamine, corticosteroids, and immunomodulators.

The mainstays of treatment for UC are aminosaliclates, and they may be administered orally or rectally. Formulations designed either for enema or suppositories are reasonable choices when treating distal disease. Unfortunately, distal disease in elderly patients is more refractory to topical therapy than in the young, and so often elderly subjects with distal disease will require oral formulations of aminosaliclates to achieve and maintain remission.

In addition to aminosaliclates, corticosteroids are effective in achieving remission, but steroid use is associated with frequent side effects. Therefore, corticosteroids should only be used temporarily in UC as a means to induce remission. They should not be used long-term as they have not been shown to be effective at preventing relapses, and their side effect profile makes prolonged use unsatisfactory.

In patients who do not respond to aminosalicylates, immunomodulators such as azathioprine or 6-mercaptopurine can be introduced. These drugs are purine analogues, interfere with nucleic acid metabolism and cell growth, and exert their cytotoxic effects on lymphoid cells. Azathioprine and 6-mercaptopurine use is subject to a delayed response; patients may require up to 6 to 12 weeks to see an effect from these agents. Fortunately, they are effective at maintaining remission, once a response is achieved.

Surgery for UC is indicated in patients who fail medical therapy, have acute fulminant disease, are steroid dependent, or develop a dysplastic lesion or cancer. UC is cured following total proctocolectomy. In the elderly, total proctocolectomy with ileostomy remains a popular choice, because restorative procedures like ileo-anal anastomosis are limited by functional morbidity. An alternative surgical procedure is a subtotal colectomy. In patients who have a subcolectomy, a rectal stump is left that provides the patient with an improved chance for fecal continence. Such patients, however, continue to have colonic mucosa, as such have an ongoing increased risk for colon cancer to develop in the diseased segment, and require periodic surveillance of the retained rectum.

### Colon Cancer in IBD

The risk of colon cancer in patients with long-standing IBD is a significant complication of the disease. Colon cancer rates generally are higher in patients with UC than those with Crohn's disease; it appears to be the degree of ongoing inflammation in the colon that confers an increased risk of colon cancer. As such, patients with Crohn's colitis are believed to have an equally high risk of developing colon cancer as their UC peers. In patients with long-standing UC, surveillance for colon cancer includes annual colonoscopy with random mucosal biopsies of the entire colon looking for evidence of early or advanced dysplasia. Areas that appear suspicious are also targeted. The risk of colon cancer increases substantially after 8 to 10 years of disease, and after many years approaches nine times the risk of the general population in patients of the same age group. During surveillance, patients found to have low- or high-grade dysplasia or carcinoma generally are offered proctocolectomy.

## COLON ISCHEMIA

Colon ischemia (CI) is the most common intestinal vascular disorder in the elderly. Until the 1950s, the only well-described form of CI was gangrene. During the 1950s, however, a variety of ischemic manifestations other than gangrene were noted after ligation of the inferior mesenteric artery during abdominal surgery. Careful review of these cases revealed a spectrum of diseases in addition to infarction that included healed ulcers, strictures, pseudotumors, and ischemic UC.

### Pathophysiology

The colon receives its blood supply from branches of the superior mesenteric artery and inferior mesenteric artery. The colon is protected from ischemia by an abundant collateral circulation formed by the marginal arterial complex of Drummond, central anastomotic artery, and arc of Riolan. Occlusion of a major vessel results in opening of collateral pathways in response to arterial

**TABLE 92-7**

### Causes of Colonic Ischemia

Inferior mesenteric artery thrombosis	Volvulus
Arterial embolus	Strangulated hernia
Cholesterol emboli	Vasculitis
Cardiac arrhythmia	Inherited and/or acquired hypercoagulable states
Shock	Medications

hypotension distal to the occlusion. Increased blood flow through collateral pathways maintains adequate perfusion for a variable but brief period of time. If blood flow is diminished for a prolonged period, vasoconstriction develops in the affected bed and may persist after the primary cause of the mesenteric ischemia is reversed.

In most cases, the cause of an episode of CI cannot be established with certainty, and no vascular occlusion can be identified. The causes of CI are vast and include thrombosis, embolus, shock, volvulus, hematologic disorders, infections, trauma, surgery, and medications (Table 92-7). The colon is particularly susceptible to ischemia, perhaps owing to its relatively low blood flow during periods of functional activity, and its sensitivity to autonomic stimulation. What triggers a specific episode of CI, however, usually is not known.

CI encompasses a spectrum of injury. The specific conditions resulting from ischemic injury to the colon are classified as reversible or irreversible, and then can be characterized further as reversible ischemic colonopathy, reversible or transient ischemic colitis, chronic ulcerative ischemic colitis, ischemic colonic stricture, colonic gangrene, and fulminant universal ischemic colitis.

### Clinical Features

Despite a growing understanding of the pathophysiology of CI and its disparate clinical presentations, many cases of transient or reversible ischemia still are missed because diagnostic studies are not performed early enough in the course of disease. This is because patients may not seek medical advice for a disease that is self-limited or the initial symptoms may be confused with other conditions such as IBD.

Approximately 90% of persons with CI are older than age 60 and have widespread evidence of atherosclerosis. Up to 10% of patients may have a potentially obstructing lesion of the colon, including carcinoma, benign stricture, and diverticulitis. Patients with CI usually are not critically ill at the time of diagnosis, and their abdominal pain typically is mild. Mesenteric angiography plays little role in the diagnosis and management of this condition; since colonic blood flow usually has normalized by the time of presentation, the prognosis is excellent.

Typically, CI presents with the sudden onset of mild crampy left lower quadrant abdominal pain. The pain frequently is accompanied, or followed within 24 hours, by bloody diarrhea or bright red blood per rectum. In most cases, blood loss is minimal; hemodynamically significant bleeding should prompt consideration of other diagnoses, such as diverticular bleeding. Severe pain is unusual and may indicate irreversible transmural necrosis.

TABLE 92-8

## Medications Associated with Colon Ischemia

Digitalis	Vasopressin
Gold	Pseudoephedrine
Sumatriptan	Cocaine
Methamphetamine	Nonsteroidal anti-inflammatory drugs
Imipramine	Saline laxatives
Estrogens	Psychotropic drugs

The differential diagnosis of CI includes infectious colitis, IBD, pseudomembranous colitis, diverticulitis, and colon carcinoma. In all patients suspected of having colonic ischemia, infection with organisms such as *Salmonella*, *Shigella*, *Campylobacter*, and *E. coli* O157:H7 should be excluded. In fact, *E. coli* O157:H7 infection induces a colitis that mimics or may even cause CI. Many commonly used medications are associated with CI, and include digitalis, nonsteroidal anti-inflammatory drugs, imipramine, danazol, and sumatriptan (Table 92-8).

An elderly patient who presents with the sudden onset of abdominal pain and rectal bleeding or bloody diarrhea may benefit from a gentle barium enema or colonoscopy within 48 hours, once other more serious life threatening diagnoses are excluded. Colonoscopy is preferable because it is more sensitive in demonstrating mucosal abnormalities and permits histopathologic evaluation of the colon mucosa. Conventional sigmoidoscopy is of value only if the segment of involved bowel is within reach of the sigmoidoscope; CI involves the sigmoid in 50% to 60% of patients and the rectum in less than 10% of cases. Findings vary greatly depending on the stage at which sigmoidoscopy or colonoscopy is performed. At the outset, purplish blebs representing mucosal and submucosal hemorrhage may be seen. As hemorrhage is absorbed, varying degrees of necrosis, inflammation, ulceration, and mucosal sloughing occur, resembling UC or Crohn's disease.

Thumbprinting is the major radiologic finding in the acute presentation of CI. Thumbprints represent submucosal hemorrhage and edema. A barium enema repeated 1 week after an initial study should reflect evolution of the injury; either the areas of hemorrhage resorb and the study returns to normal or the thumbprints are replaced by a segmental pattern of colitis as the mucosa ulcerates.

## Management

The treatment of CI is based on early diagnosis and continued monitoring, with special attention to the radiologic or colonoscopic appearance of the colon. This form of surveillance is essential in that it establishes the diagnosis and verifies its reversibility or shows progression to chronic ischemic colitis or stricture. Management includes stabilization of the patient, optimization of cardiac function, and bowel rest. Systemic antibiotics are administered routinely in most cases. Systemic glucocorticoids are of no proven value and increase the risk of perforation. If abdominal examination, fever, and leukocytosis suggest deterioration or if the patient experiences diarrhea or bleeding for more than 2 weeks, irreversible damage is likely, and surgical resection is usually indicated.

## COLONIC OBSTRUCTION

Colonic obstruction results in dilation of the colon, abdominal distention and in some cases, colonic perforation. The majority of colonic obstructions are the result of mechanical obstruction from cancer, volvulus, stricture, impacted stool, surgical adhesion, or bowel intussusception. Patients with acute colonic obstruction can develop megacolon, the diagnosis of which is based on a cecal diameter of 12 centimeters or greater. Cecal distension is critical, because the cecum is the part of the colon that is most susceptible to ischemia and perforation based on LaPlace's law:

$$T = P \times R,$$

where  $T$  is wall tension,  $P$  is pressure, and  $R$  is the radius. With obstruction, as fluid and gas accumulate in the colon and intraluminal pressure increases, the radius of the colon increases. Wall tension is the greatest, and hence the risk for perforation most acute, at the area of greatest radius, which is generally in the cecum.

### Acute Colonic Pseudo-obstruction

Acute colonic pseudo-obstruction, also known as Ogilvie syndrome, usually presents as intestinal ileus with massive bowel dilation postoperatively or in the setting of a severe intercurrent illness.

### Pathophysiology

The colon is innervated extrinsically via the sympathetic and parasympathetic nervous systems and locally via the enteric neurons. The sympathetic nervous system, by inhibition of acetylcholine release, inhibits colonic motility. On the other hand, the parasympathetic nervous system, via acetylcholine release from the vagus and sacral nerves, stimulates colonic motility. An imbalance of these two systems favoring colonic inhibitory motor input results in colonic ileus and acute colonic pseudo-obstruction.

### Clinical Features

Acute colonic pseudo-obstruction usually presents in patients with severe underlying illness like stroke, myocardial infarction, or sepsis, or after surgical procedures. It is most common after orthopedic procedures of the pelvis, hips or knees, abdominal surgery, or obstetric procedures.

The presentation of acute colonic pseudo-obstruction may be subtle and variable, although the most characteristic clinical feature is severe abdominal distention and failure to pass flatus or stool. Some patients report only mild distention and minimal pain. Indeed, a high level of suspicion is necessary to make the diagnosis, because patients often present after surgery with perioperative bowel cleansing and so early passage of stool is not expected.

The hallmark of the disease is colonic dilation on standard abdominal radiography. The entire colon can be affected, although in some cases just the right sided segments can be dilated. The presence of air in the rectum implies that there is no mechanical obstruction, and is therefore important to note before making a diagnosis of acute colonic pseudo-obstruction.

**TABLE 92-9****Contraindications to Use of Neostigmine**

ABSOLUTE	RELATIVE
Hypersensitivity to neostigmine	Recent myocardial infarction
Mechanical urinary or intestinal obstruction	Acidosis
	Asthma
	Bradycardia
	Peptic ulcer disease
	Therapy with beta-blockers

**Management**

Initial management of acute colonic pseudo-obstruction involves correcting reversible causes of colonic ileus such as electrolyte imbalances, hypoxemia, hypovolemia, and removal of medications that can exacerbate the problem. The vast majority of patients are successfully treated with these relatively simple measures. Bowel rest and intravenous hydration is imperative. Colonoscopic decompression, with or without placement of a decompression tube, is an option in patients with prolonged pseudo-obstruction. In fact, through the 1990s, the primary therapeutic approach for patients with acute colonic pseudo-obstruction who had not responded to conservative measures was endoscopic decompression of the colon.

Recently, a placebo-controlled study confirmed the efficacy of the cholinesterase inhibitor neostigmine (1–2 mg IV or SQ) in patients with acute colonic pseudo-obstruction. Relative contraindications to the use of neostigmine include a heart rate <50 beats per minute or systolic blood pressure <90 mm Hg; sick sinus syndrome or history of second- or third-degree arteriovenous block without a pacemaker; serum creatinine greater than 3 mg/dL; or active bronchospasm requiring medication (Table 92-9). Following neostigmine administration, patients should be monitored closely. A second administration of neostigmine can be attempted if there is partial or no response to the first trial.

In selected patients who fail conservative and medical management, colonoscopic decompression of the unprepped bowel can be attempted. However, care is required since during colonoscopy air is insufflated into an already dilated colon. Recalling the principles of LaPlace's law, by increasing intraluminal pressure, wall tension increases in proportion to the radius of the colon, and therefore additional air insufflation carries with it an increased risk of colonic perforation. Surgical decompression, sometimes via placement of a cecostomy tube, remains another option for patients who do not respond to medical and endoscopic interventions.

The overall prognosis of patients with acute colonic pseudo-obstruction is poor, with an in-hospital mortality approaching 30%, attributable primarily to the severity of the underlying illness. The most significant complication of acute dilatation is colonic perforation, which occurred in 3% of cases in one retrospective series.

**LOWER GASTROINTESTINAL BLEEDING**

Lower GI bleeding is defined as that which arises distal to the ligament of Treitz. Lower GI bleeding occurs less frequently and is less severe than upper GI bleeding.

**TABLE 92-10****Causes of Lower GI Hemorrhage**

Diverticulosis
Ischemic colitis
Vascular ectasia
Hemorrhoids
Neoplasm
Postpolypectomy
Inflammatory bowel disease
Infectious colitis
NSAID-induced colopathy
Radiation colopathy
Dieulafoy lesion
Colonic ulcerations
Meckel diverticulum
Rectal varices
Aortoenteric fistula
Small-bowel sources

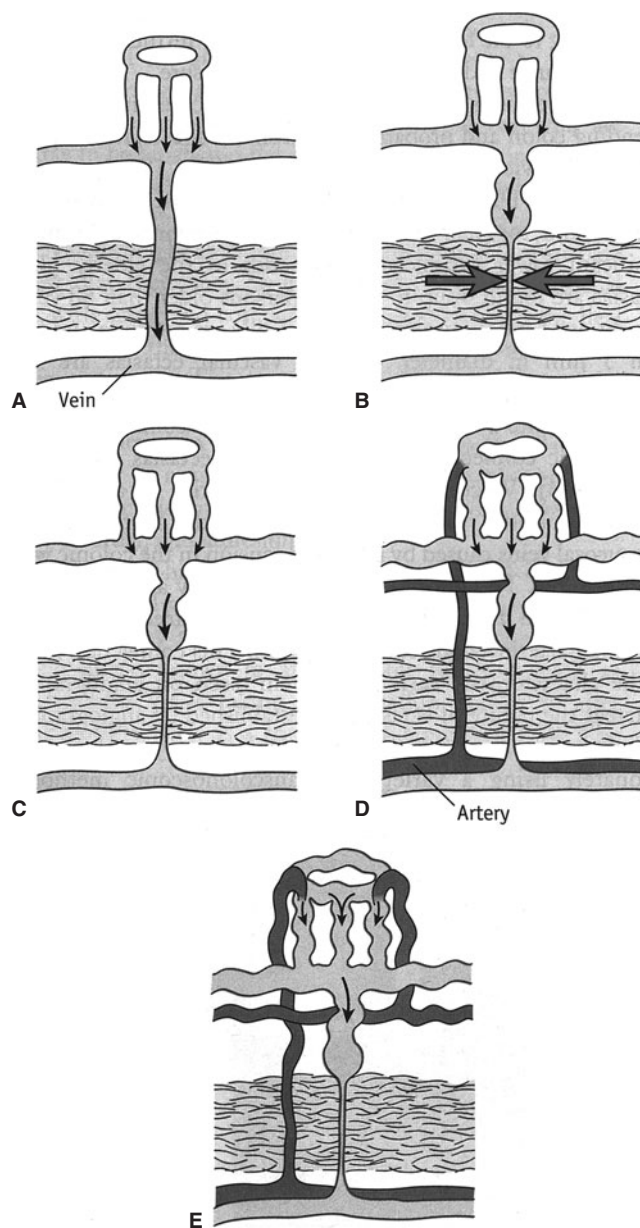

The incidence of lower GI bleeding increases significantly with age. The majority of lower GI bleeding in the elderly is the result of diverticula, vascular ectasias, and CI (Table 92-10). This section will focus on the approach to the patient with lower GI bleeding and bleeding from vascular ectasias. Diverticular hemorrhage and CI were discussed previously.

Acute lower GI bleeding presents with bright red blood per rectum, hematochezia, or melena depending on the location of the bleeding. Bright red blood per rectum usually indicates a distal colonic source or rapidly bleeding upper source. Melena usually indicates a right sided colonic lesion or upper source.

The first goal in the management of a patient with lower GI bleeding is resuscitation and hemodynamic stabilization. This may include administration of crystalloid intravenous fluids and blood products. Initial testing usually includes complete blood count, blood chemistry, coagulation profile, and blood type and cross-match, and the results help guide further management. For example, a low mean corpuscle volume often is a sign of chronic blood loss; a BUN-to-creatinine ratio of greater than 20:1 usually indicates an upper GI source; an elevated INR requires consideration of reversal in the face of hemodynamically significant bleeding.

Approximately 12% of patients thought to have lower GI bleeding have an upper GI bleeding source. It is important to exclude upper GI bleeding in patients with presumed lower GI bleeding, and often this can be accomplished with passage of a nasogastric tube and analysis of the gastric aspirate. Bilioid fluid without blood in the nasogastric tube aspirate usually confirms the suspicion of lower GI bleeding. If an upper GI source is still in question, urgent upper endoscopy may be performed.

Although urgent upper endoscopy for the diagnosis and treatment of upper GI bleeding is predicated on sound data, urgent colonoscopy in lower GI bleeding has been practiced less consistently. Colonoscopy has the advantage of allowing for the diagnosis and immediate treatment of actively bleeding lesions. A number of reports have shown that "urgent colonoscopy" is safe and yields a

**FIGURE 92-4.** Proposed concept of the development of cecal vascular ectasias. **A**, Normal state of vein perforating muscular layers. **B**, With muscle contraction or increased intraluminal pressure, the vein is partially obstructed. **C**, After repeated episodes over many years, the submucosal vein becomes dilated and tortuous. **D**, Later, the veins and venules draining into the abnormal submucosal vein become similarly dilated and tortuous. **E**, Ultimately, the capillary ring becomes dilated, the precapillary sphincter becomes incompetent, and a small arteriovenous communication is present through the ectasia.

specific diagnosis in a high proportion of elderly patients with lower GI bleeding. On the basis of a high diagnostic yield, low rate of complications, and theoretical therapeutic potential, urgent colonoscopy following a rapid colonic purge has been recommended as the diagnostic procedure of choice in most patients with hemodynamically significant lower GI bleeding.

Other diagnostic tests in patients with active lower GI bleeding include scintigraphy (nuclear tagged red blood cell scans) and angiography. Approximately 45% of patients with lower GI bleeding

have positive red blood cell scintigraphy. Tagged red blood cell scans can detect bleeding at a rate greater than 0.1 mL/min and are useful to localize the site of bleeding, but unfortunately offer no option for therapy. If a patient has a positive bleeding scan, angiography with selective embolization can be performed to attempt to stop the bleeding. In order to detect active bleeding, angiography requires a higher rate of bleeding than scintigraphy, 0.5 mL/min compared to 0.1 mL/min. Transcatheter embolization of a lower GI bleeding source is usually effective in 70% to 90% of patients. If bleeding cannot be stopped with angiography, surgery to remove the bleeding colonic segment may be necessary. If a specific bleeding site can be localized with the above studies, a limited surgical resection can be performed rather than a subtotal colectomy.

### Vascular Ectasias

Vascular ectasias, which arise from an age-related degeneration of previously normal blood vessels, typically occur in the cecum and proximal ascending colon. Along with diverticular bleeding, they are responsible for the majority of significant lower GI bleeding episodes in the elderly. Ectasias are found in up to 25% of persons older than 60 years who do not have symptoms; they typically are multiple and less than 5 mm in diameter. Despite a long standing belief to the contrary, there is no etiologic connection between vascular ectasias and aortic stenosis. Vascular ectasias probably arise as a result of repeated episodes of incomplete, low-grade obstruction of submucosal veins caused by increased tension in the colonic wall. The ultimate result is tortuosity and dilation of the venules and the arteriolar–capillary unit that feeds it, resulting in a small arteriovenous communication (Figure 92-4).

Lower GI bleeding caused by a vascular ectasia may be clinically indistinguishable from diverticular bleeding and is characterized by painless hematochezia. Bleeding from vascular ectasias may be hemodynamically significant, and a variety of treatment options exists including electrocoagulation, injection therapy, heater probe application, or argon plasma coagulation.

### SUMMARY

Diseases of the large intestine that occur in the elderly are a heterogeneous group of disorders, which are a major cause of morbidity and mortality in this population. The fundamental principle of thorough history and physical examination skills will aid the clinician at arriving at these diagnoses. With the help of modern therapeutic modalities, we can alleviate the pain and suffering associated with many of these diseases.

# Constipation

*Danielle Harari*

## INTRODUCTION

Constipation is a frequent health concern for older people in every health care setting. Primary care visits for constipation increase markedly in people older than 60 years, as does regular use of laxatives. Self-reported constipation in older people is associated with anxiety, depression, and poor health perception, while clinical constipation in vulnerable individuals may lead to complications such as fecal impaction, overflow incontinence, sigmoid volvulus, and urinary retention. Constipation is an expensive condition, with high costs ranging from laxative expenditure to nursing time. For instance, it is estimated that 80% of community nurses working with older people in the United Kingdom are managing constipation (particularly fecal impaction) as part of their case-load. An Australian study used in-depth, semistructured interviews to explore older individuals' experiences with constipation, and their findings largely summed up feelings and problems, no doubt, shared by many older people across the developed world:

- They feel “not right” in themselves when they are constipated.
- Physicians can have a dismissive attitude about constipation and do not consider the problem seriously.
- Patients are keen to find a solution, but feel useful and empathic advice and information are generally unavailable.
- At the same time, they have a strong imperative for self-management including use of over-the-counter laxatives.
- There are some barriers to lifestyle approaches, for example, expense of fruit and vegetables, fear of urinary incontinence with increased fluid intake, reluctance to walk out alone.
- One-quarter still need to do self-manual removal despite measures taken.

This chapter will describe the epidemiology, risk factors, clinical presentation, assessment, and treatment of constipation in older adults. Data sources were a computer search of the English language

literature (1966 to 2006), systematic review Web sites including the Cochrane database, reference lists from recent systematic reviews and book chapters, and expert committee reports and opinion. Levels of evidence are as used by the U.S. Preventive Task Force:

- Good evidence Level [1]: consistent results from well-designed, well-conducted studies
- Fair evidence Level [2]: results show benefit, but strength limited by number, quality, or consistency of studies
- Poor evidence Level [3]: insufficient because of limited number, power, or quality of studies

## DEFINITIONS

Definitions of constipation in older people in medical and nursing literature have been inconsistent. Studies of older people have tended to define constipation

- subjectively by self-report,
- according to specific bowel-related symptoms, or
- by daily laxative usage.

Few use objective assessment-based definitions (e.g., fecal loading). The feeling of being constipated frequently means different things to different individuals. While the nonspecific self-reporting of constipation (“I suffer from constipation”) provides insight into how individuals perceive their bowel habit, standardized definitions based on specific symptoms (Rome II criteria) are now widely used in both clinical practice and research (Table 93-1). A recent systematic review reported that approximately 63 million people in North America meet the Rome II criteria for constipation with a disproportionate number being older than 65. An important subtype of constipation in older people is rectal outlet delay, which affects 21% of community dwellers aged 65+. The Rome II definitions for constipation and rectal outlet delay are symptom-based;

**TABLE 93-1****Definitions of Constipation***Constipation (Rome II Criteria)*

Two or more of the following symptoms present on more than 25% of occasions for at least 12 weeks in the last 12 months:

- Two or less bowel movements per week
- Straining at stool
- Hard stools
- Feeling of incomplete evacuation

*Rectal Outlet Delay (Rome II Criteria)*

Feeling of anal blockage at least a quarter of the time *and* Prolonged defecation (>10 min to complete bowel movement); or Need for self-digitation (pressing in or around the anus to aid evacuation) on any occasion

*Clinical Constipation*

Large amount of feces (hard or soft) in rectum on digital examination *and/or* Colonic fecal loading on abdominal radiograph

objectively, however, the clinical definition of constipation relies on finding fecal loading in the rectum and/or colon. Such objective assessment is particularly important in frail older people owing to factors listed in [Table 93-2](#).

## PREVALENCE OF CONSTIPATION AND CONSTIPATION-RELATED SYMPTOMS

[Table 93-3](#) provides practice guidance based on evidence from epidemiological studies (prevalence, symptomatology, and risk factors) of constipation in older people.

### Self-Reported Constipation

One older community-based study of 3166 persons aged 65 years and older asked the question, “Do you have recurrent constipation?” and found a prevalence of 26% in women and 16% in men; in the 84+ years age group, prevalence was 34% and 26%, respectively. Age was a strong independent risk factor for self-reported constipation. Other community studies support this relationship with age and show prevalence rates of up to 34% of women and 30% of men older than age 65 years. The preponderance of women over men reporting constipation tends to equalize after the age of 80 years.

**TABLE 93-2****Factors Potentially Leading to Underestimation of Constipation in Frail Older People**

Frail older people may

- be unable to report bowel-related symptoms owing to communication or cognitive difficulties;
- have regular bowel movements despite have rectal or colonic fecal impaction;
- have impaired rectal sensation and inhibited urge to go and so be unaware of rectal stool impaction;
- have nonspecific symptoms associated with colonic fecal impaction (e.g., delirium, anorexia, functional decline).

**TABLE 93-3****Practice Guidance Based on Epidemiological Evidence***Screening*

Constipation symptoms should be routinely asked about in patients aged 65+ in view of the high prevalence of the condition in this population [2] Men and women in their eighth decade and beyond should be regularly screened for constipation symptoms, as prevalence increases with advancing age [2]

Periodic objective assessment for constipation in elderly nursing home residents should be incorporated into routine nursing and medical care [2]. Patients unable to report symptoms owing to cognitive or communication difficulties should be especially targeted [3]. Such an assessment should occur at minimum every 3 months (3 monthly incidence rate of new-onset constipation is 7% in nursing home residents), and optimally monthly [3].

*Identifying Risk Factors*

The identification of risk factors for constipation in older people is critical to effectively managing the condition [2]

Systematic identification of multiple risk factors in vulnerable older people with constipation should be incorporated into good practice guidelines in all health care settings [3]

Patients at increased risk of constipation from recognized comorbidities (e.g., Parkinson disease, diabetes) should be regularly assessed for the condition [2]

*Assessment*

Identifying specific bowel symptoms in older individuals reporting constipation is important to guide appropriate management of this common complaint [2]

Reduced bowel movement frequency is not a sensitive clinical indicator for constipation in older people [2], though it is specific [3]

Difficulty with evacuation and rectal outlet delay are primary symptoms in older individuals [2]

An objective assessment should be undertaken in frail older people with constipation as these patients are at increased risk of developing complications [2]

Older patients being prescribed laxatives on a daily basis should be regularly reviewed for symptoms of constipation and the appropriateness of long-term laxative therapy [3]

Level [1] indicates good evidence, i.e., consistent results from well-designed, well-conducted studies.

Level [2] indicates fair evidence, i.e., results show benefit, but strength limited by number, quality, or consistency of studies.

Level [3] indicates poor evidence, i.e., insufficient because of limited number, power, or quality of studies.

### Infrequent Bowel Movements

Two or fewer bowel movements per week are below normal range and tend to signify slow transit constipation. Weekly frequency of bowel movements does not, however, alter with age alone, in contrast to self-reporting of constipation. In community-based studies, it has been found that

- only 1% to 7% of both younger and older community-dwelling individuals report two or fewer bowel movements a week;
- this consistent bowel pattern across age groups persists even after statistical adjustment for the greater amount of laxatives used by older people;
- among older people complaining of constipation, less than 10% report two or fewer weekly bowel movements, and more than 50% move their bowels daily.

**TABLE 93-4****Complications of Constipation in Older People**

Fecal incontinence [1]
Fecal impaction [1]
Stercoral perforation [3]
Urinary retention [2]
Sigmoid volvulus [2]
Acquired megacolon [2]
Rectal prolapse [3]
Diverticular disease [2]
Impaired quality of life [3]
Agitation in patients with dementia [3]

Level [1] indicates good evidence, i.e., consistent results from well-designed, well-conducted studies.

Level [2] indicates fair evidence, i.e., results show benefit, but strength limited by number, quality, or consistency of studies.

Level [3] indicates poor evidence, i.e., insufficient because of limited number, power, or quality of studies.

**Difficult Evacuation**

So, what are the symptoms other than infrequent bowel movements that drive self-reporting of constipation in older people? These symptoms are predominantly straining and passage of hard stools. Of older people reporting constipation in a U.S. community study, 65% had persistent straining and 39% had passage of hard bowel movements. Difficult rectal evacuation is a primary cause of constipation in older people. Twenty-one percent of community-dwelling people aged 65+ had rectal outlet delay (according to Rome II criteria), and many describe the need to self-evacuate. Among frailer individuals, difficult evacuation can lead to rectal impaction and fecal soiling.

**Constipation Symptoms in the Long-Term Care Setting**

Long-term care residents are at increased risk of developing complications of constipation (Table 93-4) that may precipitate acute hospital admissions. Physical frailty in older persons does increase the prevalence of infrequent bowel movements, with 17% of nursing home residents and 14% of geriatric day-hospital attendees reporting two or fewer bowel movements a week. Among long-term care residents self-reporting constipation, 33% have two or fewer bowel movements a week. A Finnish study showed the prevalence of chronic constipation and/or rectal outlet delay to be 57% in women and 64% in men living in residential homes, and 79% and 81% respectively in the nursing home setting. A U.K. study found that 64% of nursing home residents taking laxatives still reported straining on more than 1 in 4 occasions. This and the fact that 50% to 74% of long-term care residents use daily laxatives suggest that rectal evacuation difficulties are not being well managed in this population.

**PATHOPHYSIOLOGY**

Physiological studies suggest that changes in the lower bowel predisposing toward constipation in older people are not primarily age-related. This is compatible with the epidemiology showing that (1) bowel movement frequency does alter with aging, and (2) constipa-

tion symptoms are more prevalent in older people with comorbidities. Extrinsic causes such as reduced mobility, fluid intake, dietary fiber, comorbidities, and medication all impact colonic motility and transit, and influence the pathophysiology of constipation.

**Colonic Function**

Colonic motility depends on the integrity of the central and autonomic nervous systems, gut wall innervation and receptors, circular smooth muscle, and gastrointestinal hormones. Propagating motor complexes in the colon are stimulated by increased intraluminal pressure generated by bulky fecal content. Studies of total gut transit time (passage of radiopaque markers from mouth to anus, normally 80% passed within 5 days), colonic motor activity, and postprandial gastrocolic reflex show no differences between healthy older and younger people. Older people with chronic constipation do, however, tend to have a prolonged total gut transit time, ranging from 4 to 9 days. Radiologic markers pass especially slowly through the left colon with striking delay in the rectosigmoid, suggesting that total transit time is prolonged because of segmental dysmotility in the “hindgut.” The prolongation in transit time is even greater in institutionalized or bedridden patients with constipation, with total gut transit time ranging from 6 to more than 14 days. Slow transit results in a cycle of worsening colonic dysfunction by reducing water content of stool (normally 75%) and shrinking fecal bulk, which then diminishes the intraluminal pressures, and hence the generation of propagating motor complexes and propulsive activity.

**Intrinsic Mechanisms for Colonic Dysfunction in Older People with Constipation**

Certain intrinsic mechanisms for altered colonic function in older persons with constipation have been postulated from physiologic studies (Table 93-5). Overall collagen deposition in the left side of the colon increases with aging, and this could alter colonic compliance and motility. Direct electrophysiologic measurement of colonic motor activity in elderly subjects has shown that the sigmoid motor response to intraluminal Bisacodyl (a direct stimulant of the myenteric

**TABLE 93-5****Pathophysiological Mechanisms for Constipation in Older People***Chronic Constipation*

Intrinsic myenteric plexus dysfunction  
 Increased collagen deposit in colon (age-related)  
 Reduced inhibitory nerve input to circular muscle (age-related)  
 Increased binding of plasma endorphins to gut receptors (age-related)  
 Prolonged transit owing to extrinsic factors (immobility, diet, drugs, comorbidity)

*Rectal Outlet Delay*

Rectal dyschezia secondary to suppression or disregard of urge to pass stool  
 Sacral cord dysfunction  
 Pelvic floor descent  
 Pelvic floor dyssynergia (paradoxical contraction of pelvic floor muscles and external sphincter)  
 Irritable bowel disease  
 Weak abdominal musculature

plexus) is diminished in patients who are constipated, implying a deficit in intrinsic innervation. Myenteric plexus dysfunction may partially account for impaired gut motility in elderly persons with constipation. The total number of neurons in the myenteric plexus is decreased, and this neuronal loss bears no relation to the presence of pseudomelanosis coli cells, implying that use of anthraquinone laxatives is not the primary cause.

Another possible intrinsic factor is age-related deficit in the density of inhibitory nerves, or in the binding sites on smooth muscle for inhibitory gut neuropeptides. In vitro studies of colons across age groups showed an age-related reduction in the amplitude of inhibitory junction potentials, but no decrease in the levels of inhibitory gut neuropeptides. This age-related decline occurs earlier in women as compared with men. Such a decrease in inhibitory nerve input to the circular smooth muscle could result in segmental motor incoordination, which may lengthen transit time and promote constipation in older persons with other predisposing risk factors. Individuals older than age 60 years have higher plasma concentrations of *beta*-endorphin with increased binding to opiate receptors in the gut wall and myenteric plexus. Higher opiate binding has the effect of relaxing colonic tone, reducing motility, and inhibiting the gastrocolic reflex.

Finally, it is interesting to note that constipation is more prevalent in patients with nonulcer dyspepsia, the two clinical conditions being linked by gastrointestinal hypomotility.

## Anorectal Function

In normal defecation, colonic activity propels stool into the rectal ampulla causing distension and intrinsically mediated relaxation of the smooth muscle of the internal anal sphincter (or anal canal). This is followed promptly by reflex contraction of the external anal sphincter and pelvic floor muscles, which are skeletal muscles innervated by the pudendal nerve. The brain registers a desire to defecate, the external sphincter is voluntarily relaxed, and the rectum is evacuated with assistance from abdominal wall muscle contraction.

## Age-Related Changes in Anorectal Function

There is a tendency toward an age-related decline in internal sphincter tone, particularly in the eighth decade onward. Clinically, this predisposes older individuals to fecal incontinence, particularly with loose stools. There is a more definite age-related decline (greater in women than men) in external anal sphincter and pelvic muscle strength, which can contribute toward evacuation difficulties. Failure of the anorectal angle to open and excessive perineal descent in older women can lead to constipation. In simulated defecation studies, 37% of nonconstipated older subjects were unable to evacuate a small solid sphere. Consequent prolonged straining may compress the pudendal nerve, further exacerbating any preexisting weakness. There appears to be a reduction in rectal motility with normal aging, again in older old age. Rectal sensation does not alter with normal aging.

## Anorectal Dysfunction in Older Persons

There are three types of anorectal dysfunction that predispose older people to rectal outlet delay.

The most common is *rectal dysmotility* characterized by reduced rectal motility, increased rectal compliance with a variable degree of rectal dilatation, and impaired rectal sensation such that the urge to pass stool is blunted. Over time, an increasing degree of rectal distension is required to reflexly trigger the defecation mechanism. These patients have rectal retention of hard or soft stool on digital examination of which they may be unaware. The resulting rectal distension leads to relaxation of the internal sphincter and hence to fecal soiling. One study showed that rectal contractions could be elicited in only 14% of older people with a history of rectal impaction. One postulated cause for rectal dysmotility is diminished parasympathetic outflow as a result of impaired sacral cord function, for example, from ischemia or spinal stenosis (Table 93-5). In a significant number of older people, rectal dysmotility can develop through a persistent disregard or suppression of the urge to defecate as a result of dementia, depression, immobility, or painful anorectal conditions. Voluntary increase in intra-abdominal pressure during defecation could overcome rectal dysmotility to produce enough of an increase in rectal pressure for evacuation to occur, but older people often have weakened abdominal musculature, limiting their ability to compensate in this way.

*Pelvic floor dyssynergia*, though more common in younger women, can cause rectal outlet delay in older people. This is caused by paradoxical contraction or failure to relax the pelvic floor and external anal sphincter muscles during defecation, and manometric studies show paradoxical increases in anal canal pressure on straining. This abnormal expulsion pattern may be seen in individuals with severe and long-standing symptoms of rectal outlet delay, and in patients with Parkinson disease.

Another type of anorectal dysfunction is *irritable bowel syndrome* (IBS) characterized by increased rectal tone and reduced compliance. Sensation of pain on distending the rectum during anorectal function tests has been shown to be greater in patients with IBS than controls. IBS is usually constipation-predominant in older people. These patients are likely to have a many year history of difficult passage of small fecal pellets and other IBS symptoms such as passing mucus, abdominal distension, and pain.

## RISK FACTORS FOR CONSTIPATION IN OLDER PEOPLE

Both the epidemiology and pathophysiology of constipation in older people point to the enormous importance of identifying predisposing causes for the condition in each affected individual. One prospective study examined baseline characteristics predictive of new-onset constipation in elderly nursing home patients, using the U.S. Minimum Data Set instrument. Seven percent ( $n = 1291$ ) developed constipation over a 3-month period. Independent predictors were white race, poor consumption of fluids, pneumonia, Parkinson disease, allergies, decreased bed mobility, arthritis, greater than five medications, dementia, hypothyroidism, and hypertension. The authors postulated that allergies, arthritis, and hypertension were associated primarily because of the constipating effect of drugs used to treat these conditions. Other studies have shown that institutionalization itself is an independent risk factor for symptom-based constipation in older people. Table 93-6 summarizes evidence-based risk factors of constipation in the elderly population.

**TABLE 93-6****Risk Factors for Constipation in Older People**

Medications
Polypharmacy ( $\geq 5$ medications) [2]
Anticholinergic drugs (tricyclics, antipsychotics, antihistamines, antiemetics, drugs for detrusor hyperactivity) [1]
Opiates [2]
Iron supplements [3]
Calcium channel antagonists (nifedipine and verapamil) [2]
Calcium supplements [2]
Nonsteroidal anti-inflammatory drugs [2]
Impaired mobility [2]
Nursing home residency [2]
Neurological conditions
Dementia [2]
Parkinson disease [1]
Diabetes mellitus [1]
Autonomic neuropathy [2]
Stroke [3]
Spinal cord injury or disease [1]
Depression [3]
Dehydration [2]
Low dietary fiber [3]
Metabolic disturbances
Hypothyroidism
Hypercalcemia
Hypokalemia
Uremia
Patients receiving renal dialysis [3]
Mechanical obstruction (e.g., tumor, rectocele)
Lack of privacy or comfort
Poor toilet access [3]

Level [1] indicates good evidence, i.e., consistent results from well-designed, well-conducted studies.

Level [2] indicates fair evidence, i.e., results show benefit, but strength limited by number, quality, or consistency of studies.

Level [3] indicates poor evidence, i.e., insufficient because of limited number, power, or quality of studies.

## Reduced Mobility

Impaired mobility is a common risk factor for constipation in older people. Greater physical activity (including regular walking) is associated with less self-reported and symptom-specific constipation in older people living both at home and in long-term care. Reduced mobility was found to be the strongest independent correlate of heavy laxative use among nursing home residents, following adjustment for age, comorbidity, and other relevant clinical factors. Gut transit time in elderly subjects was measured independently as 3 days in ambulant, and 3 weeks in bedridden patients, although comorbid factors were likely to be contributory. A study of healthy young male volunteers showed that after only 1 week of bed rest, both transit through the sigmoid colon and stool frequency were reduced. It is well documented that exercise increases colonic propulsive activity (“joggers diarrhea”), especially when measured postprandially. In a population survey of younger women (36–61 years), daily physical activity was associated with less constipation (defined as two or fewer bowel movements per week), and the association strengthened

with increased frequency of physical activity. This leads to speculation that increasing physical activity in adulthood may reduce the likelihood of constipation problems in older age.

## Polypharmacy/Drug Side Effects

Polypharmacy itself increases the risk of constipation in older patients, particularly in nursing homes where each individual takes an average of six prescribed medications per day.

*Anticholinergic medications* reduce contractility of the smooth muscle of the gut via an antimuscarinic effect at acetylcholine receptor sites, and in some cases (e.g., patients with schizophrenia taking neuroleptics), long-term use may result in chronic megacolon. In two cross-sectional studies of nursing home residents, anticholinergic antidepressants were independently associated with daily laxative use following adjustment for age, gender, function, and cognition. Anticholinergic neuroleptics and antihistamines were also independently associated in one of the studies; nonanticholinergic sedatives, however, were not found to be constipating. A recent study of 532 community-dwelling older U.S. veterans found that among the 27% using anticholinergic drugs, the rate of constipation (42%) was significantly greater than those not using the drugs.

While older people are very susceptible to the constipating effects of *opiate analgesia*, a recent U.S. study of nursing home residents with persistent nonmalignant pain found that there was no increased rate of constipation in chronic opiate users over a 6 month period compared to those not taking opiates. They also observed a general improvement in functional status and social engagement. Constipation in chronic opiate users can be effectively managed (by laxative or suppository coprescription where needed)—an important finding as chronic pain is often undertreated in frailer older people perhaps owing to fear of the adverse effects of analgesic drugs. In terms of different preparations, community-based studies of adults receiving opiates for chronic pain have shown equal constipation risk for all sustained-release oral preparations. Transdermal patches (e.g., fentanyl), however, are associated with lower risk of constipation than oral preparations.

All types of *iron supplements* (sulphate, fumarate, and gluconate) cause constipation in adults, the constipating factor being the amount of elemental iron absorbed. Slow-release preparations have a lesser impact on the large bowel, but this is because they tend to carry the iron past the first part of the duodenum into an area of the gut where elemental iron absorption is poorer. Administration of iron sulfate in doses greater than 325 mg per day does not substantially increase iron absorption in elderly persons and may significantly increase gastrointestinal side effects. Intravenous iron does not cause constipation and may be an alternative in patients with chronic anemia (e.g., chronic kidney disease) who have symptomatic constipation on oral iron.

In a recent 5-year study of *calcium supplementation* in older women, the only side effect was constipation (treatment 13.4% vs. placebo 9.1%). The study showed that calcium supplementation reduced bone loss and turnover and fracture rates in older women who took it, but long-term compliance was poor, and constipation may have contributed to this.

*Calcium channel antagonists* impair lower gut motility, particularly in the rectosigmoid, by inhibiting calcium uptake into smooth muscle cells and altering intraluminal electrolyte and water

transportation. Severe constipation has been reported in older patients taking calcium channel antagonists, with nifedipine and verapamil being the most potent inhibitors of gut motility in this class of drugs.

*Nonsteroidal anti-inflammatory drugs (NSAIDs)* increase the risk of constipation in older people, most likely through prostaglandin inhibition. In a large case-controlled primary care study, constipation and straining was a more common reason for stopping NSAIDs than dyspepsia. NSAIDs have also been implicated in causing stercoral perforation in patients with chronic constipation. Using 15 or more aspirin tablets a week has been linked to constipation in a middle-aged cohort of women.

*Aluminium antacids* have been associated with constipation in older people living in both nursing homes and in the community.

## Dietary Factors

### Fiber

Low consumption of wheat bran, fiber, vegetables, fruit, rice, and calories can all predispose toward constipation. A U.K. survey showed that consumption of fruit, vegetables, and bread decreases with advancing age. It has been suggested that the prevalence of constipation is rising because modern food processing produces refined food with low roughage. Community studies of older Europeans who eat a Mediterranean diet rich in fruit, vegetables, and olive oil show a low prevalence of constipation (4.4% in people aged 50+). Conversely, a German questionnaire survey of adults with and without constipation reported that chocolate, white bread, and bananas were the foodstuffs most strongly perceived to harden stools.

### Calories

Low calorie intake in older people (adjusted for fiber intake) has been linked to constipation. One study looked at nutritional factors across all nursing homes in Finland and found that malnutrition and constipation were associated. This may be a two-way association in that marked constipation or fecal impaction can cause anorexia, while low calorie intake can promote constipation.

## Enteral Nutrition

Constipation is a recognized problem in patients receiving enteral nutrition. A prospective survey from Spain of hospitalized patients (mean age 76) receiving nasogastric tube feeding identified constipation as a complication of treatment in 30%. Enteric feeding products containing fiber are available, though there are no data on whether constipation is any less of a problem with their use.

## Fluid Intake

### Amount

Low fluid intake in older adults has been related to symptomatic constipation in epidemiologic surveys and (in an unadjusted analysis) to slow colonic transit. In patients with Parkinson disease, low water intake correlated with severity of constipation. Withholding fluids over a 1-week period in young male volunteers significantly re-

duced stool output. Elderly people are at greater risk of dehydration because of

- impaired thirst sensation,
- less effective hormonal responses to hypertonicity,
- limited access to drinks because of coexisting physical or cognitive impairments,
- voluntary fluid restriction in an attempt to control urinary incontinence.

## Alcohol and Coffee

A large Japanese survey of constipation symptoms found that alcohol consumption was a preventive factor in men. A population survey of middle-aged women in the United States showed that daily alcohol consumption (exceeding 12 g/d) and low-moderate caffeine intake were independently inversely related to infrequent bowel movements. Black coffee has been shown to increase colonic motility specifically in the rectosigmoid within 4 minutes of ingestion in young healthy volunteers (a reaction not observed with ingestion of hot water), implying that caffeine triggers the gastrocolic reflex.

## Parkinson Disease

Patients with Parkinson disease suffer from three primary pathologies that lead to constipation:

- Primary degeneration of dopaminergic neurons in the myenteric plexus resulting in prolonged colorectal transit
- Pelvic dyssynergia causing rectal outlet delay and prolonged straining
- Small increases in intra-abdominal pressures on straining (compared with age-matched controls)

Constipation can become prominent early in the course of the disease, even 10 to 20 years prior to motor symptoms. In a 24-year longitudinal study (Honolulu), less than one bowel movement a day was associated with a threefold elevated risk of future Parkinson disease in men. A recent study of patients at a Parkinson disease clinic found that 59% were constipated according to the Rome criteria (vs. 21% in age-matched control group without neurological disease), and 33% were very concerned by their bowel problem. Antiparkinsonian drugs can further exacerbate constipation. Pelvic dyssynergia affects 60% of people with Parkinson disease and may be hard to treat. Botulinum toxin injected into the puborectalis muscle has been used to improve rectal emptying in Parkinson disease patients with good effect, though repeat injections every 3 months are required to maintain clinical benefit.

## Diabetes Mellitus

A Turkish study of outpatients with type 2 diabetes showed that 56% complained of constipation (vs. 30% of controls). Neuropathy symptom scores correlated with laxative usage and straining. Diabetic patients with autonomic neuropathy are more likely to be constipated because of markedly slowed transit throughout the colon and impairment of the gastrocolic reflex. However, one-third of diabetic patients with constipation do not have neuropathic symptoms, so additional potentially reversible factors should be considered

particularly in older people (e.g., drugs, mobility, fluids). Indeed, a U.S. community study found that constipation and/or laxative use was increased in type 1 versus type 2 diabetic men, but this difference was associated with use of calcium channel-blockers rather than with neuropathy symptoms. Acute hyperglycemia inhibits the gastrocolic reflex and colonic peristalsis, so glycemic control is important. Colonic transit time in frail and immobile older people with diabetes is extremely prolonged at  $200 \pm 144$  hours. An Israeli study showed that this very long transit time in long-term care residents with diabetes can be significantly reduced by administering acarbose, an alpha-glucosidase inhibitor with a potential adverse effect of causing diarrhea. Overall, gut dysmotility can lead to bacterial overgrowth and the clinical problem of explosive diarrhea; treatment with erythromycin and long-term motility agents such as metoclopramide should be considered in these individuals.

### Dementia

Dementia predisposes individuals to rectal dysmotility, partly through ignoring the urge to defecate. A study in which young men deliberately suppressed defecation resulted in prolonged transit through the rectosigmoid with a marked reduction in frequency of bowel movements. Epidemiological studies show a significant association between cognitive impairment and nurse-documented constipation in nursing home residents. Patients with non-Alzheimer dementias (Parkinson disease, Lewy body, vascular dementia) compared to those with Alzheimer dementia are more likely to suffer from autonomic symptoms, including constipation.

### Mood-Related Disorders

Depression, psychological distress, and anxiety are all associated with increased self-reporting of constipation in older persons. In certain cases, the symptom of constipation is a somatic manifestation of psychiatric illness. A careful assessment is required to differentiate subjective complaints from clinical constipation in depressed or anxious patients.

### Stroke

Constipation affects 60% of those recovering from stroke on rehabilitation wards, and a high number of these have combined rectal outlet delay and slow transit constipation. For stroke survivors living in the community, problems relating to bowel evacuation are greatly worsened by difficulties accessing the toilet owing to functional impairment. Fecal incontinence in stroke survivors has been shown to relate more to modifiable disability-related factors such as toilet access and anticholinergic medication use than to stroke-related factors (such as severity and lesion location). Weakness of abdominal and pelvic muscles following stroke also contribute to problems with evacuation.

### Spinal Cord Injury/Disease

Constipation affects the majority of people with spinal cord disease or injury. Age and duration of injury interact to promote complications of chronic constipation such as acquired megacolon, which affects more than half of patients with spinal cord injury. Lumbar stenosis in older people caused by degenerative joint disease may lead

to cauda equina problems with severe rectal outlet delay. One study in younger people showed that an average of 27% (range 0–44%) of rectosigmoid emptying was achieved with each defecation in patients with cauda equina syndromes, versus 81% (range 53–100%) in healthy controls.

### Metabolic Disorders

*Hypokalemia* produces neuronal dysfunction that minimizes acetylcholine stimulation of gut smooth muscle and so prolongs transit through the gut. It should be excluded in cases of colonic pseudo-obstruction and sigmoid volvulus. *Hypercalcemia* causes conduction delay within the extrinsic and intrinsic innervation of the gut. Surgical treatment of hyperparathyroidism reverses the neuromuscular bowel dysfunction seen with this condition. Patients with *myxedema* have been observed to have edema of the gut wall with mucopolysaccharide deposition, although whether this contributes to the colonic hypomotility seen commonly in *clinical hypothyroidism* is uncertain. Patients on *long-term renal dialysis* have prolonged age-adjusted transit time, more so in hemo- than peritoneal dialysis. In a questionnaire study from Japan, 63% of hemodialysis patients complained of constipation. Important contributors to this problem were thought to be high (49%) use of resin to avoid hyperkalemia, suppression of the defecation urge while undergoing dialysis, and low fiber intake. Resin administration also places elderly inpatients at risk of fecal impaction.

### Colorectal Cancer

Colorectal cancer has been linked with both constipation and use of laxatives, although this risk association is likely to be confounded by the influence of underlying habits. One study, adjusted for age and potential confounders, found that having fewer than three reported bowel movements a week was associated with a greater than twofold risk of colon cancer, with the association being most strong in black women. As the prevalence of colorectal cancer increases with age, index of suspicion should be higher in older adults. Constipation alone, however, is not an indication for proceeding to colonoscopy (see below).

### Rectocele

Posterior vaginal wall prolapse and rectocele is not uncommonly seen in older multiparous women. These individuals have an increased risk of rectal outlet delay, particularly incomplete emptying and need for digital evacuation. This is presumably caused by mechanical obstruction, as this association is not seen in women with anterior pelvic prolapse.

## PRESENTATION

Table 93-7 lists the important aspects of the bowel history that should be elicited from an elderly person who complains of constipation. It is essential to identify rectal evacuation difficulties where present in order to manage the patient effectively. Table 93-2 lists reasons why constipation may be underestimated in frail elderly patients. Conversely, studies have shown that adults complaining of constipation frequently underestimate the number of bowel movements per week,

**TABLE 93-7****Diagnosis of Constipation in Older People***Bowel History*

Number of bowel movements per week
Stool consistency
Straining/symptoms of rectal outlet delay
Duration of constipation
Fecal incontinence/soiling
Irritable bowel syndrome symptoms (abdominal pain, bloating, passage of mucus)
Rectal pain or bleeding
Laxative use, prior and current
Psychological and quality of life impact of bowel problem
Urinary incontinence/lower urinary tract symptoms

*General History*

Mood/cognition
Symptoms of systemic illness (weight loss, anemia)
Relevant comorbidities (e.g., diabetes, neurological disease)
Mobility
Diet
Medications
Toilet access (location of bathroom, manual dexterity, vision)

*Specific Physical Examination*

Digital rectal examination including external and internal sphincter tone
Perianal sensation/cutaneous anal reflex
Rectal prolapse/hemorrhoids
Pelvic floor descent/rectocele
Abdominal palpation, auscultation
Neurological, cognitive, and functional examination

*Tests*

Indications for plain abdominal radiograph
Empty rectum with clinical suspicion of constipation
Evaluation for fecal impaction
Persistent fecal incontinence despite clearing of any rectal impaction
Evaluation of abdominal distension, pain, or acute discomfort
Persisting complaints of constipation with increasing laxative usage
Indications for colonoscopy
Systemic illness (weight loss, anemia etc.)
Bleeding per rectum
Recent change in bowel habit without obvious risk factors
Indications for anorectal function tests
Severe or persistent symptoms of rectal outlet delay
Persistent fecal incontinence with clinical evidence of anal sphincter weakness

so it is helpful to have them keep a stool chart for 1 week to document frequency and characteristics of their bowel movements and associated symptoms. A recent history of altered bowel habit should prompt an exploration of precipitants (e.g., medications, stroke), and where unexplained, an evaluation for colorectal cancer. Abdominal pain, rectal bleeding, and certainly any systemic features such as weight loss and anemia should prompt further investigations for underlying neoplasm.

Perianal fecal soiling should be asked about and looked for; it is a common and embarrassing symptom that patients are reluctant to volunteer. In one large nursing home study, 38% of elderly individuals who complained of constipation reported fecal soiling of undergarments. Overflow fecal incontinence typically presents as frequent passive leakage of watery stool, sometimes confusing patients and carers (and occasionally health care providers) into thinking they

have “diarrhea” rather than constipation. Impaction must be ruled out in the presence of fecal soiling or incontinence. The other important diagnoses to consider in older people are loose stools caused by inappropriate laxative use, other drug side effects, or undiagnosed bowel disease. Bowel diseases that are especially prevalent in older people include *Clostridium difficile* colitis, lactose intolerance (more common in people aged 60–79 than in those aged 40–59 years), late-onset Crohn, and tumor.

IBS should be a diagnosis of exclusion in older people, and only made in those with a many year history of intermittent IBS symptoms such as abdominal distension or pain relieved by defecation, passage of mucus, and feeling of incomplete emptying (Rome criteria). Rectal pain associated with defecation should alert the physician to rectal ischemia as well as to other more common anorectal conditions. Rectal bleeding should prompt further evaluation for underlying tumor disease, unless examination clearly reveals bright red blood from anal fissure or hemorrhoids. Lower urinary tract symptoms may be exacerbated by constipation and should be documented.

A person’s attitude to their bowel problem (positive, acceptance, denial, distress, apathy) and the impact on their quality of life (changes in usual family, social, physical, and work-related activities) should be included when taking a history. Some health care providers share the generally held belief that constipation is an inevitable consequence of aging, and qualitative work has shown that patients can feel that their problem is not being taken seriously. A thorough clinical history and assessment is an important first step in developing a sound patient–physician partnership, which enhances successful outcomes in managing what is usually a chronic condition.

## CLINICAL EVALUATION

### Digital Rectal Examination

Digital rectal examination is required in all patients who report constipation to reveal rectal impaction, rectal dilatation, hemorrhoids, anorectal disease, and perianal fecal soiling. Retained stool in rectal impaction does not have to be hard; loading with soft stool is commonly seen in older people taking laxatives who have problems with rectal outlet delay. Absence of stool on rectal examination does not exclude the diagnosis of constipation. A dilated rectum with diminished sensation and retained stool suggests rectal dysmotility. External sphincter tone is assessed by asking the patient to “squeeze and pull up” around the examining finger. Indicators of reduced internal anal tone are easy insertion of the finger into the anal canal and gaping of the anus on applying gentle traction to the anal margin. Anal sphincter weakness should prompt (1) careful prescribing to avoid causing fecal leakage though excessive laxative-induced softness of stool, and (2) instruction in anal sphincter strengthening exercises (Table 93-8). Absent cutaneous-anal reflex (gentle scratching of the anal margin should normally induce a visible contraction of the external sphincter) and, in particular, perianal anesthesia points to significant sacral cord dysfunction with associated rectal dysmotility. Proctoscopy is a simple, quick, and useful test for diagnosing internal hemorrhoids, and abnormalities of the rectal wall. Where rectal impaction or outlet delay is identified, a postvoid residual volume should be measured as urinary retention may coexist.

**TABLE 93-8****Patient Education***Toilet Habits and Positioning*

Do not delay having a bowel movement when you feel the urge.

Put aside a particular time each day (we would advise after breakfast) when you can sit on the toilet without being in a hurry.

A relaxed attitude to bowel evacuation will especially help if you have problems with straining or a feeling of anal blockage.

If straining is a problem, it is helpful to have a footstool under your feet while sitting on the toilet as this increases the ability of your abdominal muscles to help evacuation of stool.

*Abdominal Massage*

Lie on the bed with pillows under your head and shoulders.

Your knees should be bent up with a pillow underneath them for support.

Cover your abdomen with a light sheet.

Massage your abdomen with firm but gentle circular movements starting at the right side and working across to the left side.

Continue the massage for approximately 10 minutes.

This massage should be a pleasant experience—if you feel any discomfort then stop.

*Diet*

To help prevent constipation you should eat more of the foods from List A and less of the foods from List B. Foods in list A tend to make the stool softer and easier to pass, because they are high in fiber. Foods in List B tend to make the stool harder, because they bind together the contents of the bowel.

List A: Fresh fruit, prunes and other dried fruit, whole meal bread, bran cereals and porridge, salad, cooked vegetables (with skin where possible), beans, lentils.

List B: Milk, hard cheese, yogurt, white bread or crackers, refined cereals, cakes, pancakes, noodles, white rice, chocolate, creamed soups.

You should increase your fiber intake gradually because sudden change in fiber content may cause temporary bloating and irregularity. It is important to eat the foods that contain fiber all through the day and not just at one meal such as breakfast.

Increase the amount of fluid that you drink gradually up to 8 to 10 glasses a day. Try to drink more water, fruit juices, and fizzy drinks.

*Sphincter Strengthening*

Learning to do your exercises

Sit in a comfortable position with your knees slightly apart. Now imagine that you are trying to stop yourself passing wind from the bowel. To do this you must squeeze the muscle around the back passage. Try squeezing and lifting that muscle as tightly as you can. You should be able to feel the muscle move.

Your buttocks, abdomen, and legs should not move at all. You should be aware of the skin around the back passage tightening and being pulled up and away from your chair. Really try to feel this. You are now exercising your anal sphincter muscles. (You do not need to hold your breath when you tighten the muscles!)

Practicing your exercises

Tighten and pull up the anal sphincter muscles as tightly as you can. Hold tightened for at least 5 seconds, then relax for at least 10 seconds.

Repeat this exercise at least 5 times. This will work on the strength of your muscles.

Next, pull the muscles to approximately half of their maximum squeeze. See how long you can hold this for. Then relax for at least 10 seconds.

Repeat at least 5 times. This will work on the endurance or staying power of your muscles.

Pull up the muscles as quickly and tightly as you can and then relax and then pull up again, and see how many times you can do this before you get tired. Try for at least 5 quick pull-ups. Try this quick pull-up exercise at least 10 times each day.

Do all these exercises as hard as you can and at least 5 times a day. As the muscles get stronger, you will find that you can do more pull-ups each time without the muscle getting tired.

It takes time for exercises to make muscle stronger. You may need to exercise regularly for several months before the muscles gain their full strength.

*Instructions for Using Suppositories*

These may be inserted into your rectum (back passage) by your nurse or carer or yourself if you are physically able to do it.

If necessary go to the toilet and empty your bowels if you can.

Wash your hands.

Remove any foil or wrapping from the suppository.

Either lie on your side with your lower leg straight and your upper leg bent towards your waist or squat.

Gently but firmly insert the suppository, narrow end first, into the rectum using a finger. Push far enough (approximately one inch) so that it does not come out again.

You may find your body wanting to push out the suppository. Close your legs and keep still for a few minutes.

Try not to empty your bowels for at least 10 to 20 minutes.

## Pelvic Floor/Rectal Prolapse

Excessive perineal descent is observed by asking the patient to “bear down” while lying in the lateral position. Normal perineal descent is less than 4 cms (can be eye-balled by drawing an imaginary line between that ischeal prominences). Rectal prolapse may also be observed in this manner, though lesser degrees of prolapse may only be identified by having the patient strain while sitting on a toilet or commode. An examination for posterior vaginal prolapse (bearing down in the gynecological position) is appropriate in all women with

constipation, especially those reporting incomplete rectal emptying and the need to manually evacuate.

## General Assessment

A broad assessment should be undertaken in older patients with constipation, focusing on predisposing causes. History should include over-the-counter medications, diet, and fluid intake. Examination should include cognition, mood, and function. Appropriate

laboratory tests include complete blood count; plasma electrolytes; glucose; and bone, liver, and thyroid profiles.

### Plain Abdominal X-Ray

Clinical diagnosis can usually be made on the basis of a thorough history and examination. However, a plain abdominal radiograph is useful in patients without rectal impaction in whom colonic loading is suspected because of a high-risk profile, constipation-related symptoms, or fecal incontinence. In those patients who continue to report troublesome constipation-related symptoms despite regular laxative use it can guide management by showing the following:

- No stool—patient may require education about what constitutes a normal bowel habit and no increase and possibly a reduction in laxative usage.
- Colonic fecal loading—patient requires education on lifestyle measures and a change in type or increased dose of laxative.
- Rectal loading with a clear colon—patient requires suppositories or enemas, and no increase and possibly a reduction in laxatives.

Marked fecal loading in the descending and sigmoid colon correlates well with prolonged transit time, as does the presence of feces rather than air in the cecum (Figure 93-1). Dilatation of the colon (>6.5 cm maximum diameter) in the absence of acute obstruction points to a neurogenic component to bowel dysfunction, and thus identifies patients at risk of recurrent colonic impaction. Rectal dilatation (>4 cm) implies dysmotility and evacuation problems. Finally, in patients with abdominal distension and/or pain, an abdominal radiograph has to be done to rule out acute problems such as sigmoid volvulus and small bowel obstruction secondary to severe impaction.

### Colonoscopy/Bowel Preparation

Chronic constipation alone is not an appropriate indication for colonoscopy; the range of neoplasia found is similar to that in asymptomatic patients undergoing primary colorectal cancer screening. Further investigation is of course warranted in the context of systemic illness or laboratory abnormalities. Barium enema has now largely

**FIGURE 93-1.** Abdominal radiograph of an 83-yr-old man with Parkinson disease and long-standing symptoms of continuous fecal leakage. As his caregiver at home, his wife was changing his clothing up to six times a day. The rectosigmoid colon is completely impacted, and the dilated bowel loop implies obstruction. He was briefly hospitalized for disimpaction with enemas and laxatives, resulting in complete resolution of incontinence. He and his wife were educated in regular use of laxatives and suppositories, as well as in lifestyle measures.

**TABLE 93-9**

#### Bowel Preparation in Older People

Give regular laxatives (e.g., Movicol 2 sachets daily) and enemas or suppositories for at least 1 week before the procedure, with a longer run up period in patients known to have constipation, or with comorbidities such as diabetes
Individualize the cathartic regimen (e.g., 1–2 L of GoLYTELY daily over 2 to 3 days in those unable to drink 4 L, or use of alternative preparations such as sodium picosulfate)
Identify potential nonadherence (“Can the patient drink 4 L of GoLYTELY in 24 h?”)
Preempt unpleasant side effects (“Will the patient be able to reach the toilet in time to avoid fecal leakage?”)
Use oral phosphosoda with caution as administration in older people increases in serum phosphate, even in patients with normal creatinine clearance
Consider preprocedure plain abdominal x-ray for evaluation of persisting fecal loading
Where possible, give clear fluid diet prior to administration of bowel preparation

been superseded by colonoscopy in older patients—colonoscopy causes significantly less discomfort than barium enema as well as is diagnostically more sensitive. A review of 400 colonoscopies in octogenarians and upwards showed a good safety profile but low cancer detection rate for symptoms (e.g., constipation, abdominal pain) other than bleeding (2% vs. 12%).

Inadequate colonoscopies are common in older people because of poor bowel preparation. Older age, constipation, reported laxative use, tricyclic antidepressants, stroke, and dementia have been associated with inadequate preparation and thus taking longer to instrument the cecum. A study of 101 inpatients showed that even in those who took 75% to 100% of their prescribed treatment, bowel preparation was satisfactory in only 50%. Table 93-9 lists issues relevant to bowel preparation in older people.

### Anorectal Function Tests

Anorectal function tests are rarely required in assessment of constipation in older people. They may be indicated in patients with severe and persistent rectal outlet delay, in order to diagnose pelvic dyssynergia, which is more effectively treated by biofeedback than laxatives. Another indication is fecal incontinence of formed stool that persists despite clearing of fecal impaction. Anorectal tests (including endoanal ultrasound) can measure the integrity of the anal sphincters and thus guide management of incontinence toward conservative treatment (sphincter strengthening exercises and biofeedback therapy), or surgical intervention (sphincter reconstruction).

## COMPLICATIONS OF CONSTIPATION IN THE ELDERLY

### Fecal Incontinence

Constipation is a common, treatable, preventable, and often overlooked cause of fecal incontinence in older people (Table 93-4). Few medical symptoms are as distressing and social isolating for older

people as fecal incontinence, a condition that places them at greater risk of morbidity, mortality, dependency, and nursing home placement. All too often, untreated overflow leads to hospitalization of vulnerable older patients. Many older individuals in the community with fecal incontinence will not volunteer the problem to their general practitioner and, regrettably, physicians and nurses do not routinely inquire about the symptom. This “hidden problem” therefore leads to social isolation and a downward spiral of psychological distress, dependency, and poor health. Even when older people are noted by health care professionals to have fecal incontinence, the condition is often poorly assessed and passively managed, especially in the long-term care setting where it is most prevalent.

Overflow (continuous fecal soiling and fecal impaction on rectal examination) was identified as the underlying problem in 52% of frail nursing home residents with long-standing fecal incontinence in one study. A therapeutic intervention consisting of enemas until no further response followed by lactulose achieved complete resolution of incontinence in 94% of those in whom full treatment compliance could be obtained. Notably, this study showed that only 4% of nursing home residents with long-standing fecal incontinence had been referred to their primary care physician for further assessment, reflecting a tendency toward unnecessarily conservative nursing management (e.g., use of pads and pants only). Another nursing home study found that daily lactulose and suppositories plus weekly enemas only effectively resolved overflow incontinence when complete rectal emptying was consistently achieved over a period of 2 months. An effective therapeutic program for overflow incontinence depends on the following:

- Regular toileting (ideally 2 hourly, which also promotes mobility)
- Monitoring of treatment effect by rectal examination and bowel chart
- Responsive stepwise drug and dosage changes
- Prolonged treatment (at least 2 weeks)
- Subsequent maintenance regimen to prevent recurrences

### Fecal Impaction

Fecal impaction is an important cause of comorbidity in older patients, increasing the risk of hospitalization and of potentially fatal complications. A survey of patients admitted to acute geriatric units in the United Kingdom over 1 year reported that fecal impaction was a primary reason for hospitalization in 27%. In frail patients, fecal impaction may present as a nonspecific clinical deterioration; more specific symptoms are anorexia, vomiting, and abdominal pain. Findings on physical examination may include fever, delirium, abdominal distension, reduced bowel sounds, arrhythmias, and tachypnea secondary to splinting of the diaphragm. The mechanism for the fever and leucocytosis response is thought to be microscopic stercoral ulcerations of the colon. A plain abdominal radiograph will show colonic or rectal fecal retention associated with lower bowel dilatation (Figure 93-2). Presence of fluid levels in the large or small bowel suggests advanced obstruction; the closer the fecal impaction is to the ileocecal valve, the greater the number of fluid levels seen in the small bowel.

### Urinary Retention/Lower Urinary Tract Symptoms

Rectosigmoid fecal loading may impinge on the bladder neck causing some degree of urinary retention. At a population level, two

**FIGURE 93-2.** Abdominal radiograph of a 73-yr-old man with chronic schizophrenia who has taken anticholinergic neuroleptics for many years. This was his third hospital admission for colonic impaction. The arrow points to the cecum, which is full of stool, indicative of slow transit. Fecaloliths are visible in the pelvic region.

recent Finnish studies of older women and men showed an independent association between constipation and lower urinary tract symptoms (LUTS) in both genders. A case-control study from Singapore looked at risk factors for urinary retention (defined as postvoid residual volume [PVRV] > 100 mL by portable bladder scan) in hospitalized women aged 65+ and found that after adjustment for relevant confounders, constipation was the primary predictor, increasing the risk of retention fourfold (other predictors were urinary tract infection and previous urinary retention). Urinary symptoms of difficult voiding were unreliable in diagnosing retention in this study, suggesting that it is good practice to do screening PVRVs in hospitalized older women with constipation, particularly in the context of coexisting urinary tract infection. A prospective cohort study from Israel examined the impact of treating chronic constipation on coexistent LUTS in older people (mean age 72). After 4 months, there was a significant improvement in constipation symptoms, LUTS (including urgency, frequency, and voiding), mean PVRV (reduced from 85–30 mL), and fewer urinary tract infections. There are case reports in frail older people, of bilateral hydronephrosis associated with renal failure that resolved following fecal disimpaction.

### Stercoral Perforation/Colon Ischemia

Fecal impaction increases the risk of stercoral perforation of the wall of the colon (usually sigmoid) secondary to ischemic necrosis. Stercoral perforation can also occur in chronically constipated persons where pressure from a hard fecaloma produces an ulcer with characteristically necrotic and inflammatory edges; these individuals tend to present with sudden onset of acute abdominal pain. Prompt surgical intervention and rigorous treatment of peritonitis are needed to prevent the high mortality rate associated with this condition. A case-control study found that the most prevalent risk factor for colon ischemia in 700 cases was the use of drugs that cause constipation (one in three cases compared to only one in nine controls).

### Sigmoid Volvulus

Chronic constipation in frail older people is the leading cause of sigmoid volvulus in the developed world. Volvulus is

- the third commonest cause of large bowel obstruction in the United States;

- more likely in constipated patients with Parkinson disease and neuropathic colon (e.g., from spinal cord disease or long-term neuroleptic treatment);
- associated with hypokalemia;
- treated in the first instance by sigmoidoscopic detorsion (high recurrence rate);
- managed surgically, usually by partial colectomy, when sigmoidoscopic deflation fails (in approximately two-thirds of cases).

### Colonic Pseudo-obstruction

Acute colonic pseudo-obstruction (Ogilvie syndrome) is most likely to occur in hospitalized frail older people with a history of chronic constipation who are acutely medically ill, or in postoperative phase. It presents with abdominal distension and colonic dilatation on x-ray, with a cecal diameter of 10 cm or more. Nil by mouth, flatus tube, and correction of electrolyte imbalances (particularly potassium and magnesium) are initial treatments, progressing to neostigmine (if no cardiac contraindications), and then endoscopic decompression if dilatation persists. Administration of polyethylene glycol (PEG) after initial resolution of colonic dilatation has been shown to reduce the likelihood of recurrence requiring escalation of therapy.

### Rectal Prolapse

Prolonged straining at stool in constipated patients can result in rectal prolapse of varying degrees, and older people are more at risk from developing fecal soiling as a result. Surgery should be considered for full thickness prolapses, and laparoscopic versus transabdominal repair is now an effective treatment (including improving bowel-related symptoms) with a low recurrence rate.

### Diverticular Disease

Left-sided diverticulosis coli affects 30% to 60% of people older than 60 in developed countries. Etiology has been attributed to high intraluminal pressures while straining at stool in people who have a low fiber diet. A case-control study of patients (mean age 68) with acute uncomplicated diverticulitis showed 74% to have prolonged transit (longest in those with constipation symptoms), and 59% small intestinal bacterial overgrowth. New approaches to preventing recurrence of symptomatic flare-ups of diverticular disease are use of mesalazine and *Lactobacillus casei*, separately or in combination.

### Psychological Impact/Quality of Life

Quality of life and daily living are affected by functional bowel symptoms in older people, even following adjustment for other chronic illnesses. Patients with constipation generally have an impaired quality of life compared with the general population, though few studies have looked at this specifically in older people. A Hong Kong study of community-living people aged 70+ showed an independent association between constipation and low morale as measured by the *Philadelphia Geriatric Morale Scale*. One large Canadian study of the general population found an association between constipation and a low *SF-36* score, with the rate of physician visits for constipation being strongly predicted by the physical component of the *SF-36*.

The *Patient Assessment of Constipation Quality of Life* questionnaire is a validated tool for assessing quality of life over time that has been used in older adults in long-term care; scores correlate with abdominal pain and constipation severity. Patients whose constipation is associated with abdominal pain or IBS symptoms score even lower on quality of life measures, plus have poor general health perception. For patients with spinal cord injury, a *neurogenic bowel dysfunction score* has been constructed and validated that correlates to quality of life score. Fecal incontinence has a demonstrable negative impact on quality of life in community surveys, correlating with self-reported symptom severity.

Constipation in long-term care residents unable to communicate because of dementia has been linked to physically aggressive behavior by independent association. A U.S. study of almost 9000 care home residents looked at independent characteristics associated with the development of wandering behavior over a 1-year period and found that constipation increased the risk almost twofold. The authors postulate that residents with dementia may wander to alleviate constipation-related discomfort, and care home providers should be alert to this.

## NONPHARMACOLOGICAL TREATMENT

More often than not, the consultation between a general practitioner and an older person reporting constipation will result in a laxative being prescribed. Among frailer older people, nursing home studies show high rates of self-reported constipation, despite very substantial levels of laxative prescribing. These observations have led to speculation that nonpharmacological treatments for constipation are underused as first-line treatment in nonsevere constipation, and as adjunctive treatment even when laxatives are deemed necessary. Symptoms of difficult evacuation may be particularly amenable to nonpharmacological approaches such as stool softening and bulking through increasing fiber and fluid intake, pelvic muscle strengthening exercises, and footstool elevation of the legs during evacuation (see below). A systematic review examining nonpharmacological treatment of chronic constipation in older people in 1997 found no studies evaluating the effect of exercise therapy and only a few nonrandomized trials examining fiber and fluid supplementation, and there has been little further research in this area since then. Available data, expert opinion, and practical recommendations are summarized below.

### Education

Educating patients as to what constitutes normal bowel habit should be one of the first steps in managing self-reported constipation. Patients with no or mild symptoms of constipation should be encouraged to discontinue chronic laxative therapy. Withdrawal may be easier to achieve in the more controlled environment of a nursing home, than in the community where over-the-counter medications are so readily available. Patients who require laxative treatment for constipation should be told to aim for regular, comfortable evacuation rather than daily evacuation, which is often their preconceived norm.

Educational interventions promoting lifestyle changes for patients with chronic constipation should focus on exercise and diet, and ideally be based on the cognitive Theory of Planned Behavior.

In order to persuade older people with constipation to change their lifestyle, they need to be convinced that

- their current behaviors are “bad for their bowels”;
- bowel-related and general health improvements associated with recommended measures are worth the trouble and expense of changing;
- it is they who are responsible for what they eat, how much exercise they take, and so on (internal locus of control);
- they have the skills and knowledge to modify their own lifestyle to improve their constipation, if they choose to do so (self-efficacy).

It is important to provide people with clearly written educational materials. An RCT in stroke survivors with constipation evaluated the impact of a one-off nurse-led assessment (with feedback to primary care physician) and educational session including provision of booklet. At 6 months, postintervention subjects reported improved bowel function in terms of number and normality of bowel movements; at 1 year, they were more likely to still be altering their diet and fluid intake to control their bowel problem. [Table 93-8](#) illustrates some of the patient-centered instructions from this study booklet, which are relevant to all older people with constipation.

Other RCTs have sought to influence fiber intake at a population level. Nutrition newsletters sent to older Americans in their homes significantly improved their dietary fiber intake. Another community intervention used media and social marketing in educational targeting of small retirement communities under the theme “Bread: It’s a Great Way to Go,” and reported a result of a 49% decrease in laxative sales and 58% increase in sales of whole meal and whole grain bread.

Educating home carers on maintaining fecal continence in patients with dementia (with focus on constipation and other contributing factors) increased knowledge levels significantly. Home carer involvement in bowel care plans is also crucial in patients with chronic neurological diseases other than dementia such as Parkinson disease, stroke, and neuropathic bowel.

## Diet

A meta-analysis of 20 nonrandomized studies in younger adults with constipation associated additional wheat bran with increased stool weight and decreased transit time. Evidence for the effectiveness of fiber in treatment of constipation in elderly people is more equivocal. In one community study, higher fiber intake was associated with lower laxative use among older women, but in another study, higher intake of bran was associated with no reduction in constipation symptoms and greater fecal loading in the colon on abdominal radiography. In older hospitalized patients, daily bran supplementation increased weekly bowel movement frequency and improved overall symptoms as compared with placebo. There have been several “before and after” studies in nursing home residents reporting that addition of dietary fiber (ranging from bran to processed pea hull) or fruit mixtures (apple puree to fruit porridge) to the daily diet improved bowel movement frequency and consistency, and reduced laxative intake and the need for nursing intervention. Bias cannot be excluded from these nursing home studies, including that of concomitant increased fluid intake contributing to these positive results. But despite these reservations, these observational studies emphasize the usefulness of increasing dietary fiber, fluid, and fruit in older

people at high risk of constipation. Additional benefits should not be discounted; for instance, adding oat bran to the diet in one study reduced cholesterol levels more markedly in older versus younger women.

In practical terms, at least 10 g of fiber with additional fluids should be recommended to patients. While coarse bran rather than more refined fiber is more effective in increasing stool fluid weight, it is far less palatable, and is more likely to cause initial symptoms of increased bloating, flatulence, and irregular bowel movements. Fiber should therefore be recommended to older individuals in the form of foods such as whole meal or whole grain bread, porridge, fresh fruit (preferably unpeeled), seeded berries, raw or cooked vegetables, beans, and lentils. A crossover trial in subjects aged 60+ that entailed taking a daily kiwi fruit resulted in bulkier and softer stools and increased bowel movement frequency. Fiber supplementation should also be culturally appropriate. Chinese food is typically low-fiber, and dietary additives such as konjac glucomannan can serve as “natural laxatives.” Other examples of natural laxatives are aloe vera and rhubarb, both of which contain stimulant anthraquinone derivatives like senna.

## Fluids

An Italian RCT in adults aged 18 to 50 with chronic constipation showed that the beneficial effect of increased dietary fiber was significantly enhanced by increasing fluid intake to 1.5 to 2 L daily. Upping fluid intake by two 8-ounce beverages a day for 5 weeks in dependent nursing home residents significantly increased bowel movement frequency and reduced laxative use. This “hydration program” used a colorful beverage cart and four beverage choices to stimulate residents’ interest in drinking. Regarding type of fluids, a RCT comparing the effect of drinking carbonated versus tap water found that the former significantly improved constipation scores, as well as functional dyspepsia and gallbladder emptying. Caffeine is known to increase both bowel and bladder smooth muscle activity, though its impact on constipation in older people is not documented. Subjects randomized to receive juice containing probiotics (*Lactobacillus rhamnosus* and *Propionibacterium freudenreichii*) for 4 weeks had a 24% increase in defecation frequency compared to those receiving unsupplemented juice.

## Physical Activity

An RCT in middle-aged inactive patients with chronic constipation showed that regular physical activity (30-min brisk walk and 11-min home exercises a day) decreased colonic and rectosigmoid transit time and improved defecation pattern according to Rome II criteria. A review of physical activity interventions in older adults concluded that incorporating exercise naturally into a person’s day tends to provide the most effective means for increasing activity levels. Studies conducted in older nursing home patients showed the following outcome:

- Six months of moderate intensity exercise training had no impact on constipation symptoms or habitual physical activity (RCT).
- Six months of 2 hourly prompted toileting improved measures of daily physical activity and functional performance, but did not alter bowel movement frequency (RCT).

- Daily exercise in bed and the use of abdominal massage reduced laxative and enema use in chair-fast patients, although transit time was unaffected (non-RCT).

Existing evidence would tend to support exercise programs to influence constipation in nursing home residents within the context of addressing other risk factors also. Daily exercise for immobile elderly patients, including positioning out of bed into a chair for up to 60-minute periods with chair-lifts at 15-minute intervals, may also have benefits.

## Abdominal Massage

Abdominal massage added to the standard bowel regimen in spinal cord patients has been shown to shorten colonic transit time and increase weekly bowel movement frequency. A vibrating device that applied kneading force to the abdomen once a day for 20 minutes was evaluated in elderly constipated nursing home residents in Greece, and after 12 weeks resulted in softening of stool, increased bowel movement frequency, and a 47% reduction in transit time. Case reports show that physiotherapists can incorporate daily 10 minute abdominal massage into home activity programs for community-dwelling people suffering from constipation with good effect.

## Pelvic Floor and Sphincter Strengthening Exercises

Where rectal outlet delay and/or persistent straining is associated with excessive pelvic floor descent, pelvic strengthening exercises should be taught. In women, it is helpful to do the teaching while undertaking a pelvic examination (with the examining hand resting on the posterior vaginal wall), so that positive verbal feedback can be given when the patient correctly contracts the pelvic floor. Pelvic floor retraining can help rectal outlet symptoms, but a greater degree of perineal descent is predictive of poorer treatment responses. Sphincter strengthening exercises (Table 93-8) should be taught to patients with fecal soiling and/or weak external sphincter.

## Toileting Habits

Small nonrandomized studies show that regular toileting habits (scheduled evacuation) restores comfortable evacuation in stroke survivors (with the assistance of digital stimulation) and in older postoperative inpatients. The preservation of the gastrocolic reflex with aging supports the rationale for postprandial toilet visits. Care should be given to treating hemorrhoids and any other anorectal condition in these patients. Expert opinion supports the use of footstools during evacuation in individuals with weakened abdominal and pelvic muscles to optimize the Valsalva maneuver.

## Toileting Access—Privacy and Dignity

Toilet access should be assessed and facilitated particularly in patients with mobility, visual, or dexterity impairments. Bathroom comfort and privacy must be considered, particularly for individuals in institutional settings. Reluctance to use the toilet in institutional settings has been linked to residents developing fecal impaction in case reports. Table 93-10 summarizes basic but important recommendations relating to toileting and maintaining privacy and dignity.

**TABLE 93-10**

### Toilets and Toileting—Maintaining Privacy and Dignity

A multidisciplinary assessment should be made of older person's ability to access and use the toilet [3]

Commodes/sani-chairs/shower chairs

- should be available to residents in institutional settings [3];
- should provide a safe seated position for prolonged use by older people with skin vulnerability and trunk support problems (e.g., padded seat, footstool if feet are unsupported, back and arm support, grab rails etc.) [3].

Older people should be given the opportunity to use the toilet (either directly or by using a sani-chair or shower chair) rather than a bedside commode [3]

Bedpans should be avoided for defecation purposes

Transportation to the toilet and use of the toilet or commode should be carried out with due regard to privacy and dignity

A direct method of calling for assistance should be provided when an older person is left on the toilet/commode

When using a commode

- methods to reduce noise and odor should be offered;
- methods to facilitate bottom wiping should be available;
- in living area and cannot be emptied immediately, a chemical toilet should be offered instead [3].

Level [1] indicates good evidence, i.e., consistent results from well-designed, well-conducted studies.

Level [2] indicates fair evidence, i.e., results show benefit, but strength limited by number, quality, or consistency of studies.

Level [3] indicates poor evidence, i.e., insufficient because of limited number, power, or quality of studies.

*Adapted from Potter et al. Bowel Care in Older People.*

## Medication Review

A careful review of the medication regimen is necessary to eliminate, reduce the dosage, or substitute other medications for those that predispose to constipation. As an example, a selective serotonin reuptake inhibitor may provide an effective alternative to tricyclic therapy for elderly patients with depression and persistent constipation. Newer antipsychotic agents (e.g., quetiapine) are less likely to cause severe constipation in older people than older agents.

## PHARMACOLOGICAL TREATMENT

### Laxative and Enema Use and Abuse in Older People

A Food and Drug Administration (FDA) Advisory Panel has registered concern over the widespread overuse of over-the-counter (OTC) laxatives; laxatives are second only to analgesics as the most commonly used OTC medications by older people. OTC laxative use is common in the United States and Europe, and is encouraged by advertising and popular ignorance of adverse effects. Only 38% of OTC laxative users in Italy were guided in their choice of laxative by a physician; the remainder were influenced by pharmacists (21%), relatives or friends (16%), and advertisements (12%). Six percent of users reported adverse effects.

Several researchers have documented an enormous increase in the use of laxatives in older people in the community with little relation

to either frequency of bowel movements or the need to strain. One-fifth to one-third of regular laxative users do not consider themselves to be constipated, and many people take them through a misguided belief in the benefits of regular purgation. One study showed that 78% of elderly persons who used laxatives regularly had never gone for more than 3 days without a bowel movement. Habitual rather than surreptitious abuse is more likely in older individuals; repeated purging empties the colon of stool that would normally descend into and distend the rectal ampulla, thereby removing the urge to defecate, and prompting the patient to take further laxatives. This habitual profile of overuse means that older people are less likely to have the electrolyte imbalances that have been documented in younger people who abuse laxatives. However, chronic laxative use in patients aged 80+ has been associated with increased plasma homocysteine, independently of other relevant factors such as institutionalization and dementia. This may be caused by impaired absorption of folate; low folate levels have also been associated with long-term laxative use in older people.

Although patients in hospitals and nursing homes are at higher risk for clinical constipation, this does not entirely justify the very high levels of cathartic prescribing in these settings. Seventy-six percent of hospitalized elderly are prescribed at least one type of laxative. A prospective study of 2355 nursing home residents in the Netherlands showed that over the course of 2 years, 47% were started on laxatives, with 79% of these continuing with the treatment long-term. Prescribing rates in U.S. nursing homes are high at 54% to 74%, with almost half of these users being prescribed more than one agent. Most commonly prescribed agents are stool softeners (26%), magnesium salts (18%), and stimulants (16%). Two contributing factors may lead to over-prescribing of laxatives to older patients:

- Lack of objective confirmation of the diagnosis by the prescribing physician or nurse
- Prescribing patterns of laxatives that are clinically ineffective

For instance, in U.S. nursing homes, docusate (a fecal softener with little or no laxative effect) is the predominantly prescribed agent.

### Evidence-Based Summary of Laxative, Suppository, and Enema Treatment in Older Persons

Many reported trials of laxative and enema treatment in older people are low quality, limited by unclear definitions for constipation, inconsistent outcome measurement, and underreporting of potential confounding factors during the trial period (e.g., fiber intake). The absence of good level evidence may in part underlie the somewhat empirical way in which laxatives are prescribed to older people. A 1997 systematic review of effective laxative treatment in elderly persons found that the few published randomized controlled trials were potentially flawed owing to small numbers and other methodologic concerns. In the 10 years since that review, there has been little rigorous research specific to the older population. The following conclusions are drawn from meta-analytical reviews (1997, 2001, 2002, 2004) of efficacy of laxatives in treating chronic constipation in adults:

- Availability of published evidence is poor for many commonly used agents including senna, magnesium hydroxide, Bisacodyl, and stool softeners.

- In trials conducted in older people, significant improvements in bowel movement frequency were observed with a stimulant laxative (cascara) [3] and with lactulose [2], while psyllium [2] and lactulose [2] were individually reported to improve stool consistency and related symptoms in placebo-controlled trials.
- Level [1] evidence supports the use of PEG in adults.
- Level [2] evidence supports the use of lactulose and psyllium in adults.
- None of the currently available trials include quality of life outcomes.
- In trials conducted in older adults (>55 years), there is little evidence of differences in effectiveness between categories of laxatives.
- A stepped approach to laxative treatment in older people is justified, starting with cheaper laxatives before proceeding to more expensive alternatives.

Table 93-11 summarizes the onset of action, mechanisms of action, potential side effects, and benefits of selected laxatives in current usage, and the following discussion describes efficacy and safety.

### Stimulant Laxatives

*Senna* is a cheap and safe agent for use in elderly people with functional constipation. A trial of cascara (a similar plant-derived stimulant laxative) in older hospitalized patients increased bowel movement frequency by an average of 2.6 bowel movements per week as compared to placebo. Administration of 20 mg of senna daily for 6 months to patients older than 80 did not cause any significant losses of intestinal protein or electrolytes, and repeated studies in mice show no evidence of myenteric nerve damage resulting from its use. Senna generally induces evacuation 8 to 12 hours following administration, and should therefore be taken at bedtime. Frail elderly patients may have even slower response times, and may also require several weeks of daily use before achieving regular bowel habit. Maintenance therapy with senna is appropriate in patients with chronic constipation, and it can be used in higher doses for short-term treatment of fecal impaction. In patients with weak anal sphincters, the senna alone may be sufficient to treat constipation without causing or exacerbating fecal incontinence through excess stool softening.

*Bisacodyl* is a useful alternative stimulant laxative to senna. A recent treatment (Bisacodyl 10 mg daily) versus placebo RCT in primary care patients (mean age 62) with chronic constipation showed improved stool frequency and consistency without side effects.

*Phenolphthalein and castor oil* should not be used in older people because of a high risk of side effects including malabsorption, dehydration, lipoid pneumonia, and, with heavy prolonged use, cathartic colon.

### Bulk Laxatives

Bulk laxatives are generally underprescribed to older people, despite evidence that they increase bowel movement frequency (by a mean of 1.4 bowel movements per week as compared to placebo), and improve consistency and ease of evacuation. This may partly be because of intolerance in the form of bloating and unpredictable bowel habit in the first weeks of taking them, and also of caution

TABLE 93-11

## Laxative and Enemas Used in Older People with Constipation

AGENT AND TYPE	ONSET	MECHANISMS OF ACTION, SIDE EFFECTS, AND BENEFITS
Senna/cascara/Bisacodyl <i>Stimulant</i>	8–12 h	Direct stimulation of myenteric plexus, alteration of salt and water transportation, prostaglandin E-like effect. May cause dose-dependent cramps and diarrhea, so titrate dosage. Long-term use associated with melanosis coli, but does not cause ‘cathartic colon’. May cause false-positive urine test for urobilinogen. Improves propulsive action, softens stool, shortens transit time. Suitable for long-term use.
Psyllium Methyl cellulose Calcium polycarbophil <i>Bulk</i>	12–72 h	Hydrophilic fibers, resistant to bacterial degradation, leads to bulkier and softer stool and peristaltic stimulation. May cause transient bloating, flatulence. Good fluid intake needed. Avoid use in bedridden or dehydrated patients. Causes more frequent passage of well-formed stools, reduces evacuation discomfort caused by hard stools. Suitable for long-term use.
Magnesium hydroxide (milk of magnesia) <i>Magnesium salt</i>	0.5–3 h	Stimulates release of cholecystokinin, increases secretion of electrolytes and water into gut lumen. Rapid action may cause watery stool, dehydration, fecal incontinence. Hypermagnesemia in renal insufficiency. Avoid magnesium citrate. Unsuitable for long-term use.
Lactulose/sorbitol <i>Hyperosmolar</i>	24–48 h	Nonabsorbable disaccharides degraded into low-molecular-weight acids, which osmotically draw water into the colon causing reflex prolonged tonic gut contractions. May cause abdominal cramps and flatulence, especially if taken with large amount of fruit. Increases transit, softens stool. Safe for use in diabetic patients and renal failure. Suitable for long-term use.
Polyethylene glycol <i>Hyperosmolar</i>	30–60 mins	Potent hyperosmotic action, shortens transit time. May cause nausea, abdominal cramps, incontinence, and loose stool, dose should be titrated against effect. Useful in treatment of fecal impaction, bowel preparation. Long-term use in patients with hypotonic colon or resistant constipation.
Docusate sodium <i>Softener</i>	24–72 h	Stimulates cyclic-AMP increasing fluid secretions, reduces surface tension, and promotes penetration of water into stool. Ineffective in treatment of constipation. Risk of fecal soiling in older women. Long-term use alters morphology of gut mucosa. Unsuitable for long-term use.
Phosphate (Fleets) Sodium citrate Arachis oil Tap water <i>Enemas</i>	2–15 min	Contractile response to gut dilatation, lavage effect. Phosphate: hyperphosphatemia, tetany, fluid retention, avoid use in renal failure. Mineral oil: useful for acute disimpaction. Tap water: useful for disimpaction. Can be used long-term in patients with recurrent impactions.
Bisacodyl/glycerine <i>Suppositories</i>	10–45 min	Rectal contractile response to increased volume. Daily Bisacodyl use may cause rectal burning and cramps. Suppositories helpful for rectal outlet delay, persistent straining, prevention of recurrent rectal impactions. Suitable for long-term use.

on the part of prescribers because of the documented risk of impaction with these agents in frailer patients with poor fluid intake. Psyllium has been associated with increased stool frequency in people with Parkinson disease, but was not shown to alter transit time. Bulking agents are generally useful in older individuals with mild to moderate constipation who are able to tolerate them and who drink sufficient fluids. They have the additional benefit of reducing abdominal pain in patients with irritable bowel syndrome, limiting flare-ups of diverticulitis, and facilitating painful defecation associated with hemorrhoids. Furthermore, psyllium significantly lowers serum cholesterol by binding bile acids in the intestine. Available preparations are natural nonwheat fibers such as psyllium and ispaghula husk, and synthetic compounds such as calcium polycarbophil and methylcellulose. The synthetic compounds tend to be cheaper and are available in more easily administered tablet forms, as compared to reconstituted powder, which can be hard for older patients to swallow. The synthetic bulking agents and the natural fibers are equally effective in increasing stool frequency and volume. It should be noted that bran in tablet form is considerably cheaper than bulk laxatives, but the former may cause even more bloating

and unpredictability of bowel habit, and may also, unlike bulking agents, predispose to malabsorption of iron or calcium in elderly people.

### Magnesium Salts

Magnesium salts are the most commonly prescribed type to elderly in hospital, and magnesium hydroxide is popular in OTC laxative sales. There is only one published study evaluating magnesium hydroxide in elderly people, a small trial in nursing home residents, which suggested that this laxative was more effective than a bulking agent in increasing bowel movement frequency and softening stool. Magnesium salts may be favored by physician and patient alike because of their rapid action, but in general, a gradual catharsis is preferable to restore regular bowel habit in older persons. Their potent catharsis increases the risk of fluid and electrolyte losses, and of fecal incontinence in less-mobile people, or in those with weak sphincters. Furthermore, magnesium levels should be monitored in all elderly people who are using magnesium hydroxide on a regular basis, as hypermagnesemia can occur even with normal serum creatinine levels.

Long-term use of magnesium hydroxide is contraindicated in chronic kidney disease. The more potent salt magnesium citrate carries an even greater risk of side effects, including promoting colonic pseudo-obstruction in frailer patients, and is therefore not recommended for use in the elderly population. Based on evidence and known side effects, there is no clear role for using magnesium salts in treatment of chronic constipation in older people.

### Hyperosmolar Laxatives

Hyperosmolar laxatives are the most rigorously studied laxative group in the current literature. The following summarizes findings from nursing home studies:

- Lactulose (or the related agent lactitol) versus placebo shortened transit time, increased bowel movement frequency (by an average of 1.9 bowel movements per week), and improved stool consistency.
- In a comparison study with a bulking/stimulant combination agent, lactulose was a little less effective in influencing bowel pattern and consistency.
- Lactulose and sorbitol were equally effective in mostly eliminating the use of other laxatives and enemas in residents with dementia and chronic constipation, with sorbitol being considerably cheaper.

In the community, a well-designed trial of ambulatory older veterans with severe constipation also showed lactulose and sorbitol to be equally efficacious. Lactulose and sorbitol are effective agents in treating chronic constipation in older people in all health care settings, with sorbitol being the cheaper option.

Polyethylene glycol (PEG, GoLYTELY, Movicol) is a more potent hyperosmolar laxative than lactulose as demonstrated by its impact on transit time in normal subjects. In an RCT of hospitalized patients (mean age 55 years), in comparison to lactulose, PEG produced a greater increase in bowel movement frequency and a greater reduction in straining, but at the expense of a higher mean number of liquid stools. A similar efficacy and side-effect profile plus a reduction in laxative expenditure were shown with use in long-stay residents of a mental health institute with constipation. Its use in treatment of fecal impaction (in combination with daily enemas) in elderly nursing home residents showed greater efficacy than lactulose, without the dehydration or hemodynamic side effects. Another RCT of adults (aged 17–88) with fecal loading on x-ray or rectal examination, and bowels not open for 3 to 5 days showed that 1L (or 8 sachets) a day of PEG plus electrolytes for 3 days resolved impaction in 89% of patients, with few adverse effects. The current evidence base suggests that the role of PEG in older people is for acute disimpaction (ensuring that easy toilet access is guaranteed) and for regular use as a laxative only in high-risk people whose constipation has proved resistant to milder and cheaper alternatives.

### Fecal Softeners

Docusate sodium has been shown experimentally to have no effect on colonic motility, and little or no laxative action, even at doses of 300 mg/day. In an RCT of adults with severe constipation comparing docusate with psyllium, docusate proved significantly inferior for both softening stools and increasing bowel movement frequency. A systematic review of prospective controlled trials evaluating oral

docusate in chronically ill people (though hampered by poor data) showed only a small trend toward increased stool frequency, and concluded that there was insufficient evidence to support its use in this population. Nevertheless, docusate is frequently recommended and used in older people as a laxative as well as fecal softener. This is of particular concern in the nursing home and hospital settings, where constipation may as a result be undertreated with an increased risk of fecal impaction. Furthermore, docusate (in combination with the stimulant danthron) increases the risk of fecal incontinence in nursing home residents. Current evidence suggests that docusate is unhelpful in the treatment of constipation or rectal outlet delay in frail older people.

### Enemas

Enemas have a role in both acute disimpaction and in preventing recurrent impactions in susceptible patients. They induce evacuation as a response to colonic distension, as well as by plain lavage; the commonest reason for a poor result from an enema is inadequate administration. In one study of nursing home residents with overflow incontinence associated with fecal impaction on rectal examination, daily phosphate enemas continued until no further results was effective in completely resolving incontinence in 94% of patients. Some frail elderly patients with poor mobility and some individuals with neurogenic bowel dysfunction may have recurrent stool impactions despite regular laxative and suppository use, and they will benefit from weekly enemas.

Regular use of phosphate enemas should be avoided in patients with renal impairment as dangerous hyperphosphatemia has been reported. Tap water enemas are the safest type for regular use, although they take more nursing administration time than phosphate enemas, and are not available in certain countries. Soapsuds enemas should never be administered to older patients. Arachis oil retention enemas are particularly useful in loosening colonic impactions. In patients who have a firm and large rectal impaction, manual evacuation should be performed before inserting enemas or suppositories, using local anesthetic gel if needed to reduce discomfort.

### Suppositories

The predominance of rectal outlet delay (including manual evacuation) in older people, many of whom take regular laxatives, is likely to be linked to underuse of suppositories in these patients. Although research data are lacking, clinically suppositories are very useful in treatment of rectal outlet delay, or where symptoms of prolonged straining predominate. Regular suppository administration (usually three times a week, and ideally after breakfast) can effectively control symptoms in these patients. A study of frail nursing home patients with overflow incontinence found that a regimen of daily lactulose and suppositories plus weekly enemas was only effective in restoring continence when long-lasting and complete rectal emptying was achieved. Regular use of suppositories is indicated in older patients with rectal motility and/or recurrent rectal impactions. With appropriate education, many older people can themselves use suppositories; they are easier to insert and more effective if used blunt end first (Table 93-8), and people with impaired dexterity can be helped with suppository inserters designed for spinal cord injured patients. First-line suppository use is with glycerin, a hyperosmolar laxative used solely in suppository form. If ineffective, Bisacodyl suppositories (in

**TABLE 93-12****Pharmacological Treatment of Constipation in Older People—Stepwise Approach***Chronic Constipation*

In ambulant older people

Bulk laxative (psyllium) 1–3 times daily with fluids as required

If symptoms persist add senna 1–3 tablets at bedtime

In individuals with questionable fluid intake or those intolerant of bulk laxatives, start with senna 1–2 tablets at bedtime

If symptoms persist, add sorbitol or lactulose 15 mL daily as needed, titrating the dose to achieve regular ( $\geq 3$  times a week) and comfortable evacuation

In high-risk patients (bedridden individuals, patients with neurological disease, and patients with history of fecal impaction)

Senna 2–3 tablets at bedtime and sorbitol or lactulose 30 mL daily, titrating upwards as needed

If symptoms persist, give PEG (half to two sachets of Movicol daily)

*Colonic Fecal Impaction*

Clinical or radiological obstruction

Daily retention enemas (e.g., arachis oil) until obstruction resolves, before starting oral laxatives

Colonic disimpaction

Daily enemas (preferably tap water) until no further washout result

PEG (0.5–2 L daily or 2–3 sachets of Movicol) with fluids

Ensure that patient has easy access to toilet to avoid fecal incontinence

When impaction resolves, give laxative regimen for chronic constipation in high-risk patients for long-term to avoid recurrence

*Rectal Outlet Delay*

Rectal disimpaction

Manual disimpaction where necessary, followed by phosphate enema(s) for initial complete clearance of rectal impaction

Regular treatment

Glycerine suppositories at least once a week and as required to relieve symptoms

For persistent symptoms, use Bisacodyl suppositories instead of glycerine suppositories

In patients at high risk of rectal impaction (rectal dysmotility, neurological disease) give regular enemas (usually once weekly) and daily suppositories

If stool is hard or infrequent, add daily laxative as for chronic constipation

PEG base) should be used, although daily use can sometimes causes symptoms of rectal discomfort or burning. Bisacodyl suppositories have been shown to be effective in treating severe constipation in patients with spinal cord injuries. The onset of action of suppositories varies by individual from 5 to 45 minutes (most likely influenced by the neurogenicity of the rectum), and so patients should be advised to set a quiet time aside for effective evacuation.

**Enterokinetic Agents**

Altered serotonin (5-HT) signaling may predispose to chronic constipation, and 5-HT<sub>4</sub> agonists (e.g., tegaserod) have been shown to stimulate gastrointestinal motility and increase stool water content. The efficacy and safety of tegaserod in treating chronic constipation were evaluated in an RCT where 13% of participants were aged 65 years and above, but no subgroup analysis was undertaken to look at the specific effects in these older subjects. Tegaserod improves

How can standardized “constipation protocols” for case-finding and risk assessment be implemented across community and institutional health care setting where frail older patients are cared for? [Action Research, Quality Improvement Study]

Why is the prevalence of constipation in nursing homes so high despite heavy laxative use? Is it ineffective laxative prescribing? substandard assessment of patients? underuse of nonpharmacological treatments? [Observational]

What is the impact of nonpharmacological interventions targeting constipation risk factors on bowel and health-related outcomes in frail older people? [RCT]

What are the barriers to older people adopting bowel-related lifestyle measures? [Qualitative Research]

What are the psychosocial and quality of life effects of chronic constipation on older individuals and carers? [Questionnaire Population Studies, Qualitative Research]

What is the effectiveness of enemas and suppositories in treating constipation and rectal outlet delay in older people? [RCT]

Is biofeedback an effective treatment for pelvic dyssynergia in older people with rectal outlet delay? [RCT]

How common is manual self-evacuation in older people, and does prolonged use affect anal sphincter function? [Questionnaire Survey, Anorectal Function Study]

What is the cost-effectiveness of a stepwise approach to laxative treatment in older people with constipation in different health care settings (community, hospital, long-term care)? [RCT]

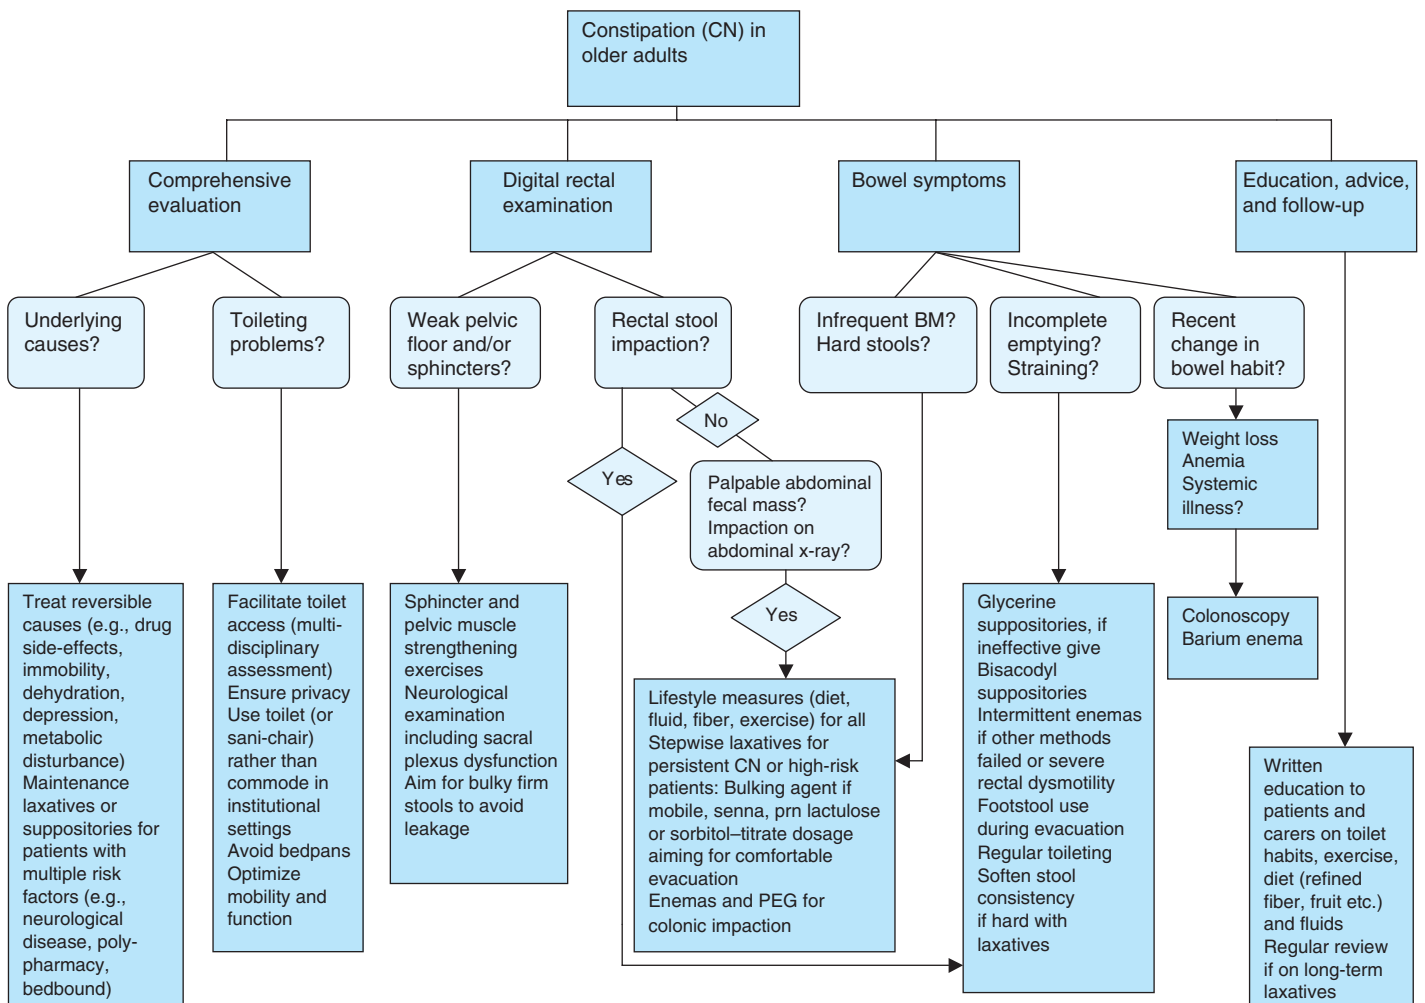

How effective and safe are new enterokinetic agents (serotonin agonists) in treatment of chronic constipation in older people, including frail individuals? [RCT]

*Data from Potter et al. Bowel Care in Older People.*

symptoms of constipation in younger people, particularly women with irritable bowel syndrome, but its side-effect profile includes headaches and diarrhea, and there have been postmarketing reports of ischemic colitis. Serotonin-receptor modulators are also emerging as useful agents in treatment of nonulcer dyspepsia, a motility disorder linked to constipation. The enterokinetic drug prucalopride proved disappointing in treating constipation in people with Parkinson disease. Presently, these agents are not recommended for routine use in older people.

**TREATMENT GUIDANCE**

The 1997 systemic review from the United Kingdom concluded that based on the somewhat limited current evidence, older patients should first be prescribed the cheapest laxative, with alternatives given if this treatment fails. [Table 93-12](#) represents a combination of

**FIGURE 93-3.** A practical approach to assessment and treatment of constipation in older people.

evidence-based and expert opinion in providing treatment guidance, which can be summarized as follows:

- In ambulant elderly with functional constipation, a daily bulk laxative is appropriate for both rectal outlet delay and slow-transit constipation.
- If the bulking agent is not tolerated, or proves ineffective, then senna may be substituted (1–3 tablets at night) with prn sorbitol (or lactulose) if needed to achieve patient-centered goals of comfortable regular evacuations.
- In frailer, less-mobile elderly people at higher risk of impaction, a combination of regular senna and sorbitol (or lactulose) should be used with dosage titration.
- In patients with colonic impaction, oil retention enemas should be administered daily until there are no clinical or radiologic signs of obstruction, and then tap water enemas continued regularly until they produce no further result.
- Where the patient has easy access to a toilet, PEG 0.5 to 2 L daily (or 1–2 sachets of Movicol) should be given as long as is needed to clear the impaction, followed by a regular maintenance laxative regimen of senna and lactulose to avoid recurrence of fecal impaction.
- In cases where toilet access is not so easy (e.g., at home with stairs), a more gradual clear-out using higher-dose senna and lactulose is appropriate to limit problems with incontinence.
- For rectal outlet delay or a predominant complaint of straining, the first-line approach should be regular use of suppositories, and laxatives should only be given for coexisting symptoms of hard or infrequent bowel movements.

## FURTHER RESEARCH

Table 93-13 lists what we do not know about constipation in older people, and ideas for further research. The overall aim in both clinical practice and research should be to develop common evidence-based policies, procedures, guidelines, and targets to promote integrated bowel care for older people within all health care settings.

## CONCLUSIONS

Figure 93-3 illustrates a practical algorithmic approach to assessment and treatment of constipation in older people. Health care

providers should routinely inquire about constipation symptoms in older people, and be alert to the presence of clinical constipation in individuals unable to communicate. In many older people with constipation symptoms, lifestyle advice (diet, fluids, exercise, toileting habits) will preempt the need for laxative therapy. In higher-risk patients, a stepwise approach to prescribing laxatives, suppositories, or enemas should be used, with the goal of achieving comfortable and regular evacuation. Rectal evacuation difficulties should be specifically addressed in order to identify conditions that may require additional interventions.

# Oncology and Aging: General Principles

*Arati V. Rao* ■ *Harvey Jay Cohen*

This chapter discusses many of the general relationships of oncology and aging. It focuses on the epidemiological, basic etiological, and biological relationships between the processes of aging and neoplasia, and on the generalizable aspects of management of malignant disease in the elderly patient. This chapter discusses clinical management of individual malignancies only as an example of general principles. The approach to specific malignancies is covered in subsequent chapters related to the appropriate organ system.

It is now well recognized that cancer is a major problem for elderly individuals. It is the second leading cause of death after heart disease in the United States, and age is the single most important risk factor for developing cancer. Approximately 60% of all newly diagnosed malignant tumors and 70% of all cancer deaths occur in persons 65 years or older according to the NCI Surveillance. As illustrated in [Figure 94-1](#), the total cancer incidence rises progressively through the middle years and then falls off in the later years. However, the age-specific cancer incidence rises progressively throughout the age range. Thus, while the rate of increase diminishes somewhat in the oldest age groups, and the rate actually falls slightly in the very oldest (perhaps a survivor effect), the overall risk for developing cancer is certainly greatest in the later years. Because the number of people in this country older than age 65 years is rising rapidly and the oldest of the old, that is, those older than age 85 years, are increasing at the greatest rate, geriatricians, generalists, and internists will be encountering increasing numbers of elderly individuals with cancer in their practices.

The median age range for diagnosis for most major tumors, common to both men and women, is 68 to 74 years; the median age range at death is 70 to 79 years. The overall pattern for the incidence of age-specific cancer shows a rise with age; overall, 60% of cancers occur in those age 65 years or older ([Table 94-1](#)). This is not uniform for individual cancers and in some malignancies, there is an apparent decrease in incidence in people older than age 80 years. This may be a result of a number of factors, including underreporting or natural selection, which would allow the less-cancer-prone

population to survive. However, cohort effects may have the most significant impact. For example, age-specific annual cancer incidence rates from the SEER Program indicate a fall in incidence in the oldest age groups for both prostate and lung cancer. This changes when the data are corrected for certain known risk factors. For prostate cancer, when only men are considered in the base population at risk, the incidence continues to rise into the oldest age groups. For lung cancer, an apparent decrease in lung cancer incidence in the older age groups might be explained by a smaller high-risk population because of decreased prevalence of smoking in the older age groups. When data derived from the Lung Cancer Early Detection Project for annual cancer incidence in male smokers older than the age of 45 are used, one notes a continuing increase into advanced age. There is little change in the case of colorectal cancer, because the entire population appears to be at risk. For women with breast cancer, data indicate an incidence that continues to rise slowly into advanced age. It has been suggested that data from the most recent survey showing a decrease in breast cancer risk at older ages (>75 years) may be an artifact of recent increases in breast cancer screening in the United States. For other gynecologic malignancies, there does appear to be a decrease, perhaps because of different interactions of hormonal status and neoplasia in hormonally responsive target organs.

Other types of patterns in age-specific incidence may also be seen. For example, Hodgkin's disease has a distinct bimodal distribution in incidence with a peak in the early years and another peak after late middle age. This has led to the suggestion that there actually may be two different diseases involved, one in the young individual and one in the older one, but that they assume similar morphologic features, and so with current technologies we are unable to tell them apart. This impression is further substantiated by the markedly different response to treatment in younger and older groups of individuals with this disease. On the other hand, the most common leukemias and lymphomas in elderly patients are those derived from the B-lymphocyte arm of the immune system. These, including chronic lymphocytic leukemia and multiple myeloma,

**FIGURE 94-1.** Comparison of the percentage of total cancer incidence and mortality by age with age-specific incidence and mortality. (Data from SEER Cancer Statistics Review: 1973–1994. Bethesda, MD: National Cancer Institute, 1997.)

rise dramatically in incidence throughout life, with the real majority of these disorders found in elderly individuals. Whether this dramatic relationship is caused by an enhanced susceptibility of the B-lymphocyte to neoplastic transformation in older individuals is a question relevant to the entire issue of the relationship between the

aging process and the neoplastic process, a subject that is considered next.

Not only does cancer occur at an increased rate in older individuals, but it makes a significant impact on such people's lives, from the standpoint of both increasing morbidity and mortality. As Figure 94-1 also demonstrates, the age-specific cancer mortality continues to rise as a function of age, as does incidence. In support of this observation is the report from the SEER Program that 5-year survivals for most types of cancer decrease with advancing age.

**TABLE 94-1**

**Cancer Incidence in U.S. Patients Age 65+ Years of All Races and Both Sexes**

CANCER	% 65+
Prostate	63.8
Colon	70.2
Pancreas	69.2
Urinary bladder	72.2
Stomach	65.5
Rectum	57.0
Lung and bronchus	67.8
Leukemias	54.3
Corpus uteri	45.3
Non-Hodgkin's lymphoma	54.3
Breast	42.3
Ovary	47.0
<b>All Cancers Combined</b>	<b>55.8</b>

Note: For breast cancer, cancer of the ovary, and corpus uteri only female patients included, and for prostate cancer only male patients included.

Data from SEER Cancer Statistics Review: 1975–2004. Bethesda, MD: National Cancer Institute; 2004.

## RELATIONSHIP OF AGING AND NEOPLASIA

It is difficult to discuss a relationship between two processes—aging (senescence) and neoplastic transformation—both of which are still incompletely understood at this time. To explore the relationship, however, we must first briefly describe the current understanding of the multistep process of carcinogenesis. The first stage of cancer development is known as initiation. In this process, chemical or physical carcinogens, or certain viruses, cause a change in the cell that predisposes it to a subsequent malignant transformation. This change appears to be an irreversible lesion in the genomic deoxyribonucleic acid (DNA) of a stem cell; the lesion may remain stable for a long period. It is not clear whether such an initiated cell can be recognized clinically, but certain disorders such as myelodysplasia or carcinoma in situ, may be a manifestation of this phenomenon.

The next stage of carcinogenesis is called promotion and involves a proliferative phase. Promoters are agents that can induce mitogenesis, or cell division, in an initiated cell. This phenomenon includes the activation of a number of growth factors and transcription

factors, which promote cell proliferation, and which may arise through the events related to changes in oncogenes or tumor suppressor genes noted later. While it appears that a single initiating event is sufficient to begin the process, promotion appears to be most successful when it is repetitive. This may occur shortly after initiation or after a delay and appears to be dose-dependent as well as reversible. For this reason, researchers believe that cessation of cigarette smoking (containing both initiators and promoters) reduces the cancer incidence of former smokers when compared with those who continue to smoke.

The final stage of cancer development in this model is progression. This is actually multiphasic itself and involves the transformation of a cell from a premalignant to a malignant state, the potential clonal evolution of a subset of such cells, and the potential development of metastasis. The latter two phenomena are quite important and have led to the concept of tumor cell heterogeneity. Although we believe that tumors arise from a single “clone of cells,” tumor cells are genetically more unstable than normal cells, yielding progeny with variable proliferative and metastatic potential. Thus, not all cells within a given tumor are the same. Clinically, this may explain such diversity as variable chemosensitivity of tumor cells, the selection of resistant cells, the differential behavior of different metastatic lesions compared with the original tumor and with other metastatic lesions, and sometimes the unpredictable behavior of a particular cancer. Other factors relating to the tumor’s impact on host tissue may also play an important role at this stage. These include the ability to disrupt stromal elements such as the basement membrane and the ability to promote angiogenesis, which supports further tumor growth.

It is clear that alterations in growth regulatory gene function play a critical role in the development of neoplasia. There are two major classes of such genes—oncogenes and tumor-suppressor genes. Oncogenes, or cancer genes, were initially described as viral genes capable of transforming normal cells to malignant ones. Of the various genes, approximately 100 to 200 have been shown to be targets for oncogenic disruption of their DNA structure. Oncogene activation can result in one of two pathways: First, the decision of a cell to divide or undergo senescence and apoptosis (programmed cell death) is altered such that the balance is shifted away from cell death and toward cell survival and proliferation. Second, the oncogene mutations might affect DNA repair, thus predisposing cells to additional DNA damage and activation of additional oncogenes. Oncogenes can be either dominant or recessive. Dominant oncogenes are those for which a functional alteration in one allele contributes to the malignant phenotype despite the persistence of the normal contralateral allele. Recessive oncogenes are called tumor suppressor genes, which normally limit cell growth, enhance apoptosis, and control differentiation and require both alleles to be disrupted to contribute to the cancer process.

A large number of oncogenes have been described. They appear to have the potential for growth-enhancing activity at a series of steps along the mitogenic pathway, including activating signal transduction at the cell surface, producing endogenous growth factors at the cytoplasmic level (e.g., *ras*-like), and increasing the sensitivity of the cell to exogenous (or endogenous) growth factors at the nuclear level (e.g., *myc*-like). Another oncogene, *bcl-2*, codes for an inner mitochondrial protein that blocks apoptosis, or programmed cell death. This mechanism may be of particular interest in the context of senescence, as it may operate by increasing cell longevity rather

than proliferation. Increased cellular oncogenic expression has been noted in many tumors and can be mimicked experimentally by altering the DNA encoding for the oncogene, usually at or near the promoter. Thus, it is possible that the chromosomal damage noted in neoplasia during the initiation and promotion phases, if it occurred near the region of an oncogene, could result in transformation and clonal evolution of the cancer. The evolutions noted in Burkitt lymphoma and chronic granulocytic leukemia may be examples of this process. The expression of more than one oncogene is necessary to cause transformation.

A number of tumor-suppressor genes have been described, and mutations in such genes as *Rb* and *p53* have been described in many human tumors. The normal function of such genes appears to prevent uncontrolled growth as a result of the action of various growth-promoting factors. It has even been suggested that senescence may act as a form of tumor suppression. In fact, the two tumor-suppressor genes just noted, *p53* and *Rb*, are essential for maintaining the senescent phenotype of cells in culture. Inactivation of either gene extends the replicative life span of such cells, and mutations of *Rb* have been linked to both cancer incidence and longevity in mice. This phenomenon would appear to enhance the likelihood of acquiring further mutations, leading to the ultimate development of malignancy. Indeed deletions of *p53*, *Rb*, or both, are frequently found in common solid tumors, such as lung, breast, and colon. Although the inactivation of tumor suppressor genes is important in the development of neoplasia, it is likely that alterations in both oncogenes and tumor-suppressor genes are necessary in many cases to achieve full malignant potential.

It is also important to understand the theory of the “two-hit hypothesis.” As described above, certain tumor suppressor genes are responsible for suppressing the malignant phenotype. In normal individuals, both alleles of such genes would need to be eliminated by random or environmentally induced errors thus requiring “two-hits.” In contrast, families with certain genetic mutations that make them susceptible to cancer already have one abnormal allele of the tumor suppressor gene. Thus, the “first-hit” preexists making them substantially more susceptible to carcinogenic action of the “second random hit.”

How then might the aging process influence the process of neoplastic transformation to result in the markedly increased rates of cancer in older people? General aspects of the aging process were discussed in Chapter 1, and only certain specific aspects relevant to the process under discussion will be reiterated here. [Table 94-2](#) lists the types of theories that appear relevant to an explanation of the striking epidemiologic relationship.

**TABLE 94-2**

**Theories for Cancer Increase with Age**

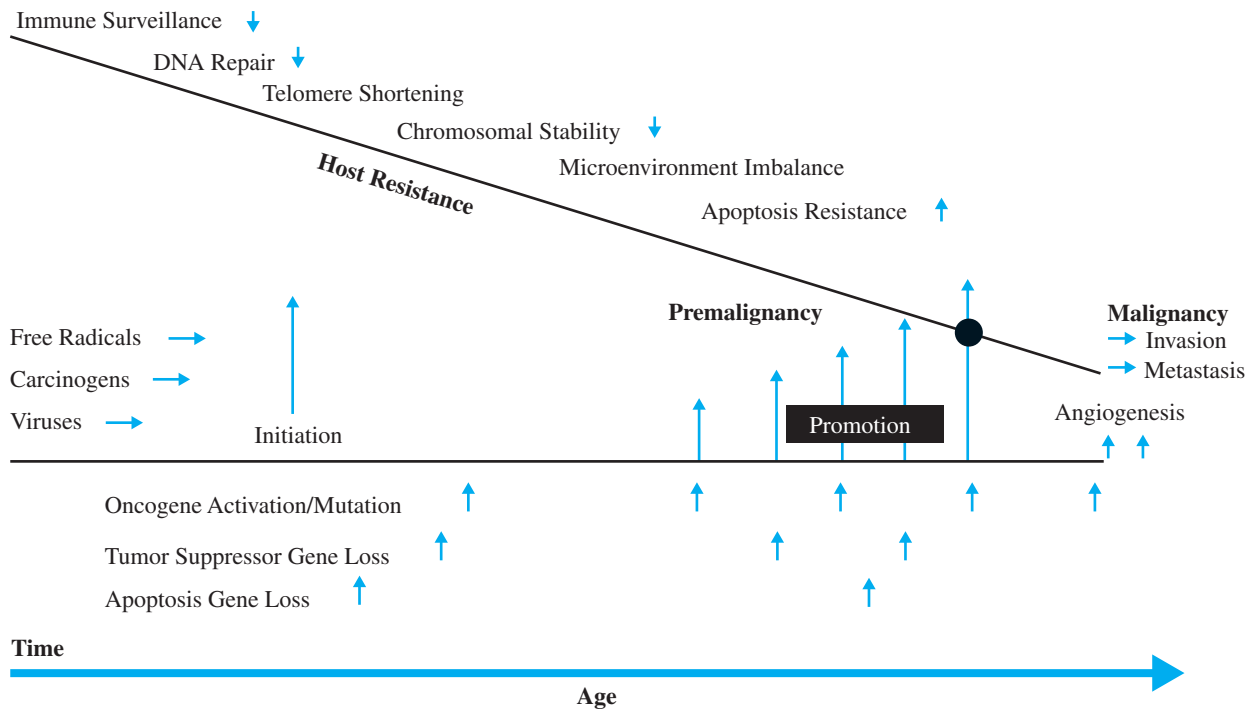

Longer duration of carcinogenic exposure
Increased susceptibility of cells to carcinogens
Decreased ability to repair DNA
Oncogene activation or amplification
Decrease in tumor suppression gene activity
Telomere shortening and genetic instability
Microenvironment alterations
Decreased immune surveillance

1. Longer duration of carcinogenic exposure: It is possible that aging simply allows the time necessary for the accumulation of cellular events to develop into a clinical neoplasm. There is evidence for age-related accumulation and expression of genetic damage. Somatic mutations are believed to occur at the rate of approximately 1 in 10 cell divisions, with approximately 10 cell divisions occurring in a lifetime of a human being. Certainly, the complex set of events required in the multistep process of carcinogenesis, for example, as described for colon cancer in humans, does occur over time. The passage of time alone, however, is not likely to explain the phenomenon, as the time for a mutated cell to become a malignant cell and then subsequently to become a detectable tumor has been estimated to be approximately 10% to 30% of the maximum life span for a given animal species, which may vary from just a few years to more than 100 years.
2. Altered susceptibility of aging cells to carcinogens: Data in this area are somewhat contradictory. In some cases, the incidence of skin tumors in mice produced with benzopyrene has been more related to dose than to age, whereas in other models, accelerated carcinogenesis as a function of age has been demonstrated, as, for example, when dimethyl benzanthracene (DMA) was applied to skin grafts of young and old mice. In addition, an age-related increase in the sensitivity of lymphocytes to cell-cycle arrest and chromosome damage after radiation has been demonstrated. It is also possible that there are alterations in carcinogen metabolism with age, but the findings from such studies have also been contradictory.
3. Decreased ability to repair DNA: It is possible that damage, once initiated, is more difficult to repair in older cells. A number of studies demonstrate decreased DNA repair as a function of age following damage by carcinogens as well as radiation. Such repair failures may also be reflected in increased karyotype abnormalities in aged normal cells as well as in older patients with neoplastic disease.
4. Oncogene activation or amplification or decrease in tumor suppressor gene activity: These processes might be increased in the older host, resulting either in increased action or promotion or in differential clonal evolution. Although evidence is currently limited, there have been observations of increased amplification of proto-oncogenes and their products in aging fibroblasts in vitro as well as evidence for increased c-myc transcript levels in the livers of aging mice. Alternatively, such factors as genetic alterations or DNA damage could lead to inactivation of cancer-suppressor genes. Given that age-related mutations frequently appear to result in the loss of function, alterations in tumor-suppressor genes may prove to be an important mechanism.
5. Telomere shortening and genetic instability: The function of telomeres and the enzyme telomerase appears to be intimately involved in both the senescence and neoplasia processes. Telomeres, the terminal end of all chromosomes, shorten progressively as cells age. This functional decline begins at age 30 and continues at a loss of approximately 1% per year. This shortening appears to be causally related to controlled cell proliferation and limitation of population doubling. It is thought that each time a cell divides, 30 to 200 base pairs are lost from the end of that cell's telomeres. Because the major function of telomeres is to protect the stability of the more internal coding sequences (i.e., allow cells to divide without losing genes), the loss of this function may lead to genetic instability, which may promote mutations in oncogenic or tumor-suppressor gene sequences. Without telomeres, chromosome ends could fuse together and degrade the cell's genetic blueprint, making the cell malfunction, become cancerous, or even die. Telomere length is a predictor of mortality in people aged 60 or older.
 

The enzyme telomerase is responsible for adding back telomeric repeats to the ends of chromosomes, that is, regenerate the telomeres. This enzyme is generally not expressed in normal cells, but it is activated in malignant cells. While telomerase can reverse replicative cell senescence, the indiscriminate expression of this enzyme might increase the likelihood of tumor formation. It is also possible that p53 or Rb inactivation that occurs in senescent cells, or the inactivation of other tumor-suppressor genes, may allow the activation of the telomerase gene and promote cell immortalization and ultimately malignancy.
6. Microenvironment alterations: Older people accumulate senescent cells as shown by  $\beta$ -galactosidase staining. They also have higher levels of IL-6, which is one of the causes of frailty. A number of factors in the tumor microenvironment are critical for the development of the malignant phenotype, especially invasion and metastasis. Senescent cells can compromise tissue renewal capacity, and secrete multiple factors that alter tissue homeostasis. These factors include inflammatory cytokines like IL-1 and epithelial growth factors (e.g., heregulin, and matrix metalloproteinases like MMP-3) and can disrupt the architecture and function of the surrounding tissue and stimulate or inhibit the proliferation of neighboring cells.
 

Senescent fibroblasts disrupt epithelial alveolar morphogenesis, functional differentiation, and branching morphogenesis. Senescent human and mouse fibroblasts also increase vascular endothelial growth factor expression, and hypoxia further induces endothelial growth factor in senescent cells. Thus, senescent cells can create a tissue environment that synergizes with mutation accumulation to facilitate the progression of malignancies.
7. Decreased immune surveillance: A decrease in immune surveillance, or immunosenescence, could contribute to the increased incidence of malignancies. With respect to tumor-related immunity, however, there is a considerable amount of evidence in animal models for a loss of tumor-specific immunity with progressive age. This includes the altered capacity of old mice to reject transplanted tumors, the close relationship between susceptibility to malignant melanomas and the rate of age-related T-cell-dependent immune function decline, and the ability by immunopharmacologic manipulation to increase age-depressed tumoricidal immune function and to decrease the incidence of spontaneous tumors. The evidence linking such data to age-associated immune deficiency and the rise of cancer incidence in humans, however, is mainly circumstantial and not likely to be fully explanatory, as the types of tumors seen in the most striking examples of immune deficiency are very different from those seen in the usual aging human.
 

Figure 94-2 summarizes in a schematic fashion the potential interaction of these many factors that may be of importance in the increase of cancer with age. It indicates the interface of time and age-related events, such as free radical and other carcinogenic exposure, resulting in initiation, then cumulative promoting events, including mutations and other alterations in critical genes, which

**FIGURE 94-2.** Age and cancer susceptibility. This figure presents a model incorporating the various factors that may play a role in the increased incidence of cancer with age.

alternately exceed a threshold of host resistance factors, which have been progressively reduced during the aging process.

Cellular senescence suppresses cancer by arresting cells at risk of malignant transformation. However, senescent cells also secrete molecules that can stimulate premalignant cells to proliferate and form tumors, suggesting that the senescence response is antagonistically pleiotropic. Thus, cellular senescence-induced suppression of malignant transformation, a function important for the organism in early life (through the reproductive period), may be selected for, despite the fact that cellular senescence may be quite injurious in later life. In this case, senescence could be viewed as the price we pay in later life for the rigorous attempt to control proliferation to avoid neoplasia early on. The progressive, and no doubt multifactorial, loss of the controls with aging ultimately results in an increase in neoplasia in advanced age despite the early control. From the standpoint of natural selection, both of these outcomes would be acceptable, as they tend to occur long after the reproductive life span. It is likely that through research at the basic level concerning the interactions of aging and neoplasia, we will learn a great deal about the fundamental basis of each. It is hoped that such information will enhance our ability to engage in prevention at the primary and secondary levels.

A large proportion of cancers are potentially preventable. The most obviously available modalities in this regard are avoidance of known and suspected carcinogenic exposures such as tobacco smoke, occupational and environmental chemicals, excessive sunlight, and dietary factors such as excessive fat and smoked, salted, and pickled foods. Although older individuals have potentially acquired a lifetime exposure to such carcinogens, they should still accrue benefits from modifying these behaviors as well as from engaging in positive ones such as the suggested intake of fiber,

vitamins, and fresh vegetables. In recent years, there has been increased interest in cancer prevention through chemopreventive intervention approaches. However, results are inconsistent and some have shown adverse effects. The evidence for tamoxifen as a preventive agent for breast cancer is the strongest, but the agent appears to be less effective in elderly women.

In 2006 the Food and Drug Administration (FDA) approved the use of a human papillomavirus-16 (HPV-16) live particle vaccine to prevent cervical cancer, precancerous genital lesions, and genital warts caused by HPV types 6, 11, 16, and 18. The vaccine is approved for use in females 9 to 26 years of age and has not been studied in elderly patients. The Selenium and Vitamin E Cancer Prevention Trial (SELECT) is an ongoing randomized, prospective, double-blind study designed to determine whether selenium and vitamin E alone and in combination can reduce the risk of prostate cancer among healthy men. The final results from this study are anticipated in the year 2013. Thus, currently there is no compelling evidence for the efficacy of the use of chemopreventive agents among the elderly population, and it still must be considered experimental.

## CLINICAL PRESENTATIONS AND DISEASE BEHAVIOR

### Screening in Asymptomatic Individuals

Elderly patients continue to be underscreened and thus underdiagnosed with cancer. Screening examination for oral and skin cancers is reasonable for high-risk older people as part of an office examination. It is well known that mammography and Papanicolaou (Pap) tests are underutilized in certain older racial and ethnic minority

TABLE 94-3

## Recommendations for Cancer Screening in Elderly People

CANCER	TEST(S)	ACS GUIDELINES	USPSTF GUIDELINES	MEDICARE GUIDELINES	REIMBURSEMENT/MEDICARE COVERAGE
Breast	Mammography (with or without clinical breast examination)	Annually starting at age 40 yr for as long as patient is in good health	Annually or biennially between ages 50 and 69 yr; consider continuing if patient has reasonable life expectancy	Start biennial screening at age 50 yr, continue to offer between 70 and 80 yr if life expectancy greater than 5–7 yr; explain risks, explore barriers	Annual mammography will be reimbursed for women older than age 40
Cervical	Papanicolaou (Pap) test	Annually for 3 yr. If three or more consecutive satisfactory normal annual examinations, the Pap test may be performed less frequently at the discretion of her physician then less frequently, no upper age limit	Biennially or triennially, may stop at age 65 yr if has had regular, normal smears	Biennially or triennially, stop at age 65 yr if patient has had regular, normal smears; obtain history of prior Pap smears and risk factors; perform speculum examination before excluding from screening for hysterectomy	Pap and pelvic every 3 yr. Yearly screening for women who are at high risk for cervical or vaginal cancer or who have had an abnormal Pap smear in the preceding 3 yr
Colorectal	FOBT; flexible sigmoidoscopy; colonoscopy; ACBE	At age 50 yr, offer: annual FOBT, flexible sigmoidoscopy every 5 yr, annual FOBT and flexible sigmoidoscopy every 5 yr, colonoscopy every 10 yr, or ACBE every 5–10 yr	At age 50 yr, offer annual FOBT; flexible sigmoidoscopy every 5 yr; or annual FOBT and flexible sigmoidoscopy every 5 yr	At age 50 yr, offer annual FOBT with or without flexible sigmoidoscopy every 5 yr; consider one-time colonoscopy or combined flexible sigmoidoscopy and ACBE	For individuals older than 50 yr, screening FOBT reimbursed once a year, flexible sigmoidoscopy once every 4 yr or once every 2 yr if patient is high risk. Colonoscopy reimbursed every 2 yr for high-risk patients
Prostate	Digital rectal examination; PSA assay	Both tests annually, starting at age 50 yr	Neither test recommended for the general population	Neither test recommended except in high-risk patients (e.g., family history of disease, African-American)	Annual digital rectal examination and PSA will be reimbursed in men older than age 50
Lung	Chest x-ray; sputum cytology; spiral CT scan; fluorescence bronchoscopy	None of these tests are yet recommended	None of these tests recommended for the general population	None of these tests recommended	No reimbursement
Ovary	Pelvic examination; CA-125 assay; transvaginal ultrasound	None of these tests are recommended	None of these tests recommended	None of these tests recommended	No reimbursement

ACBE, air-contrast barium enema; ACS, American Cancer Society; CT, computed tomography; FOBT, fecal occult blood test; PSA, prostate-specific antigen; USPSTF, United States Preventive Services Task Force.

groups and in those who have less than high school education or live below the poverty level. Only 17% of American Indian/Alaska Native women who are 60 years or older have ever had a mammogram, compared to 38% among all U.S. women of that age. The situations in which periodic routine screening is recommended for all individuals regardless of age are relatively few. A number of organizations have made recommendations, and there is some variation among them. It should be recognized that when applied to elderly persons, especially those older than age 75 years, such information is largely empirically derived. These recommendations are directed at mass screening of populations. When applied to individuals within a physician's office or other practice, they serve only as general guide-

lines for decisions that may be, and often should be, modified by many other factors. Table 94-3 shows the current guidelines of the American Cancer Society relevant to the older adult, those of the U.S. Preventive Health Task Force, a synthesized recommendation by the authors, and Medicare reimbursement. Most of these recommendations do not directly address alterations in strategy for people at more advanced ages. Moreover, there is obvious variability in the recommendations. In general, for malignancies for which screening modalities are potentially useful, in the absence of upper age limits, the expectation of 5 to 10 years of life would appear reasonable as a cut-point. The problem is that assessment of remaining life expectancy for an individual patient may be difficult.

### Breast Cancer

Arriving at a specific recommendation for breast cancer screening in older women has been complicated by several factors. In addition to the lack of specific outcome data for women older than 75 years of age, factors such as increased mammographic detectability of cancers in older women because of the increase in fatty tissue of the breast with age, contrasted with the increased prevalence of comorbid disease, make decision making difficult. The United States Preventive Services Task Force (USPSTF) does not recommend continued screening in elderly women, because most studies of breast cancer efficacy included inadequate numbers of these women. Few, if any, studies have yielded evidence that screening is ineffective in women 70 and older. Given the higher breast cancer incidence and mortality seen in elderly women, as well as the increased life expectancy with little or no activity limitation seen among today's elderly, consideration should be given to including elderly women in the recommendation to receive timely breast cancer screening. Since surgical and adjuvant therapy for breast cancer in older women can often be accomplished without major complications, the cost-benefit ratio for breast cancer screening in this age group may prove to be promising. Thus, breast cancer screening should be a lifelong activity, although cessation has been suggested if remaining life expectancy is less than 5 years. While there are no specific outcome data to support breast self-examination in older women, if it is practiced, it should be made clear that it is not a substitute for mammography and clinical examination.

### Cervical Cancer

In the past, recommendations concerning cervical cancer and the Pap test have been controversial. The effectiveness of this screening modality is widely accepted. Controversy has been centered more around the frequency of testing required and whether testing could be suspended either at a certain age or after a certain number of negative tests. The current American Cancer Society guideline for detection of cervical cancer in asymptomatic women appears to be a consensus position that should adequately address the issue. The guideline states, "All women who are, or who have been, sexually active, or have reached age 18 years, [should] have an annual Pap test and pelvic examination. After a woman has three or more consecutive satisfactory normal annual examinations, the Pap test may be performed less frequently at the discretion of her physician." This recommendation has no specific upper-age limitation, and the discussion of these recommendations contains a reminder that "mature women, those older than 65, also require testing." This is considered to be critical if such women have not had a history of regular Pap testing in their younger years. Thus, we recommend that for the older patient whose history of previous screening is not clear, Pap testing be done until the recommendations have been fulfilled. In addition, in 2003, the FDA approved the HPV DNA test to be used simultaneously with the Pap test to screen for cervical cancer in women age 30 and older. If both the Pap and the HPV DNA test results are negative, a woman's physician may advise her to wait for 3 years before being retested, according to guidelines from the American College of Obstetricians and Gynecologists (ACOG). But more frequent testing is recommended if other high-risk factors are present, such as a weakened immune system or a history of cervical cancer. If only one of the tests is negative, the physician may advise

the woman to return for retesting in 6 to 12 months. For ovarian cancer, acceptable screening methods have not yet been shown to have an impact on tumor-related outcomes.

### Colon Cancer

Recommendations for colon cancer screening center on general agreement over the use of fecal occult blood testing and sigmoidoscopy, with the use of colonoscopy and double-contrast barium enema being more questionable. Prostate cancer screening remains controversial. While some agencies recommend prostate-specific antigen (PSA) screening, this has been done on the basis only of a demonstration of increased ascertainment. There are yet no data on impact on mortality or even quality of life over long periods. Given the large number of false-positives requiring considerable work-up and the high incidence of very indolent disease in older men, the USPSTF decision not to recommend such screening appears reasonable. In any event, if screening is to be considered, a thorough discussion of the risks as well as benefits should first ensue. In such consideration, it would appear that at least a 10-year life expectancy would be required before there is any chance of seeing a positive benefit overall.

### Lung Cancer

For lung cancer, one of the most common malignancies in both genders, specific mass screening is not yet recommended. This is based on a lack of demonstrated cost-benefit efficacy, even in high-risk smoking groups. However, the International Early Lung Cancer Action Project (I-ELCAP) used low-dose spiral CT screening to diagnose lung cancer in 484 of approximately 30 000 participants. Of these 484 patients, 412 (85%) had clinical stage I lung cancer, and the estimated 10-year survival rate was 88% in this subgroup. Thus, spiral CT screening may detect lung cancer that is curable. Of note, ~55% of patients in this study were 60 years or older (predominantly previous or current smokers). Formal recommendations regarding the use of spiral CT scans to screen for lung cancer have not been made.

Despite these widely disseminated recommendations, many individuals do not follow them. This appears to relate to both physician- and patient-derived factors. Despite the increased risk of cancer in the older age group, such individuals appear to avail themselves of routine screening even less frequently than their younger counterparts. The physician and other health care professionals should ensure that the older individual is aware of the importance of screening, that the opportunity for such examinations is provided, and that fears and anxieties about these tests are allayed to as great an extent as possible. Screening education materials, made user friendly for the older person, have been developed and should be used.

### Initial Presentation

As an extension of the screening concept, the goal for initial cancer detection is to make the diagnosis as early as possible, with the hope that treatment at the earliest stages of disease would yield the best survival rates. It is, therefore, of great importance that both patient and physician pay attention to symptoms that may herald the onset of the neoplastic process. Although information on "warning signs of cancer" has been widely disseminated by the American Cancer

**TABLE 94-4****Cancer Symptom Confusion**

<b>SYMPTOM OR SIGN</b>	<b>POSSIBLE MALIGNANCY</b>	<b>AGING "EXPLANATION"</b>
Increase in skin pigment	Melanoma, squamous cell	"Age spots"
Rectal bleeding	Colon or rectum	Hemorrhoids
Constipation	Rectal	"Old age"
Dyspnea	Lung	Getting old, out of shape
Decrease in urinary stream	Prostate	"Dribbling"—benign prostatic hypertrophy (BPH)
Breast contour change	Breast	"Normal" atrophy, fibrosis
Fatigue	Metastatic or other	Loss of energy owing to "aging"
Bone pain	Metastatic or other	Arthritis: "aches and pains of aging"

Society and others, it is often ignored. This is due in part to a lack of knowledge of the implications of such warning signs. Indeed, some have indicated that elderly persons know less about potential cancer symptoms and their significance than do young individuals, which might lead to a delay in presentation. Another factor that might interfere with early diagnosis is what might be called "cancer symptom confusion," that is, a tendency to write off the symptom as simply another change caused by the aging process. Table 94-4 lists examples of such possibilities. Physicians and patients alike may be prone to such assumptions and should be alerted to the fact that a new symptom or a change in symptoms should be appropriately pursued in the elderly individual.

Once having noticed a symptom that appears to be related to cancer, most older individuals do not delay appreciably in seeking medical help. However, in one study from New Mexico of 800 patients older than 65 years, 19.2% of the subjects delayed seeking care for at least 12 weeks and 7.4% delayed at least 1 year. In another study from Finland, women older than 80 years had a longer interval between first symptom and first medical examination for the diagnosis of colorectal cancer when compared to their younger counterparts. Older women, who are at greater risk of developing breast cancer, are also more likely to delay their presentation. Factors associated with delayed presentation include having a nonlump symptom, reservations about seeing a general practitioner, and fear of the consequences of cancer.

Physicians may also be guilty of delaying further diagnostic pursuits in elderly patients. Part of the problem may lie in a failure to recognize new signs and symptoms in patients with multiple disease processes. It is easy to attribute such symptoms as anorexia, weight loss, or decrease in performance status to chronic diseases and to social or psychological changes. The increasing prevalence of findings such as anemia in elderly patients may lower the index of suspicion for attributing the factor to a new specific neoplastic process. The remarkable age-related increase in cancer incidence described earlier in this chapter should be sufficient to promote the maintenance of vigilance in this regard, although it must be balanced by judgment concerning the risk–benefit ratio for diagnostic evaluations in

individual patients depending on their other medical status. Thus, the initial discovery of a new symptom in a previously totally well, active 80-year-old may be pursued rather differently than a similar discovery in a severely demented, bed-bound individual with severe congestive heart failure, diabetes, and pulmonary failure.

### Biological Behavior of Tumors in the Elderly Host

The effect of the aging process on the clinical course of cancer, or to put it another way, whether cancer behaves differently in the older individual—is not clear. Although the SEER data noted previously suggested that in many cancers the 5-year survival rate is lower for older people, it is possible that this is related more to comorbid disease and other factors rather than simply to aging per se. On the other hand, there is a widespread belief that cancers may behave more indolently in elderly patients. These are important issues because they may, to a considerable degree, affect decisions regarding treatment. Both clinical and experimental evidence support both sides of this issue, and it is likely that there is a spectrum of responses dependent on initial tumor types as well as individual host status. One indicator of the phenomenon is the extent of disease at presentation. For most cancers examined, there has been no consistent difference in the stage of disease or presentation for different age groups. For those that have been determined, the directions are not always the same. For malignant melanoma, older patients have been consistently found to have more advanced-stage local disease with deeper penetrating lesions at presentation. For breast cancer, some studies show a greater proportion of older patients with distant metastatic spread at presentation, whereas for lung cancer the opposite has been found, and older patients have been noted to present with localized disease in a greater proportion of cases. Uterine and cervical cancers have in some cases been noted to be later in the course of disease at presentation in older individuals. Of course, even these differences might be related to such phenomena as delay in the patient's presenting for diagnosis (which does not appear to be the case), delay in pursuing the diagnosis, intensity of diagnostic endeavors, or a combination of these factors, or, on the other hand, a greater chance for a serendipitous finding because of more frequent visits to physicians.

Another biologic factor that may influence neoplastic behavior in differently aged hosts is the histologic subtype of the tumor. Thus, while thyroid cancer overall appears to behave more aggressively in the older host, it is also true that a larger proportion of thyroid neoplasia in elderly patients is made up by anaplastic carcinoma, which at any age has more aggressive behavior. However, there is a poorer overall prognosis for older individuals with thyroid cancer, independent of histologic type when compared to their younger counterparts. Similarly, for malignant melanoma, although there is an increased proportion of older people who have melanomas of poor prognostic histologic type and location at presentation, older individuals have a poorer prognosis for survival than do younger ones independent of this phenomenon even for localized disease. Similarly, for lung cancer, the increased proportion of elderly patients with squamous carcinoma of the lung—which is the histologic subset most likely to present as localized disease—partially, but not completely, explains some of the findings just noted. Such biologic differences may be manifested in other ways, as in the case of breast cancer, in which older women have an increased frequency of estrogen receptor–positive breast cancer, probably related to hormonal influences of the postmenopausal state. An additional factor is the

longer tumor doubling time seen in breast cancer cells from older women. Because estrogen-receptor positivity and longer doubling times are associated with better prognosis, with more slow-growing tumors and with longer disease-free survivals, these phenomena—rather than age per se—might provide the reason why this cancer appears to behave more indolently in an older individual. Despite this, overall cancer-related survival is lower in older women, emphasizing the complex interactions of tumor and host that must be considered.

Acute myelogenous leukemia (AML) has a much poorer prognosis in older patients. The biology underlying the poor prognosis and poor treatment outcome of AML in elderly patients has been extensively studied. Among the findings to date are a high incidence of poor-prognosis karyotypes (5q-, 7q-), high frequency of preceding myelodysplastic syndromes, and an increased expression of proteins involved in intrinsic resistance to chemotherapeutic agents. Compared to younger patients, leukemic blasts from elderly patients with AML have a lower propensity to apoptosis following traditional remission-induction treatment with ara-C and daunorubicin. These findings suggest that leukemia in the elderly patient may arise from an earlier stem cell; thus, such a patient may have an impaired capacity for hematopoietic recovery after chemotherapy.

Experimental data in animal models likewise show this spectrum in rate of tumor growth and progression as a function of age. In these studies, the ability to contain tumor growth depends on the particular host tumor system used, thus mimicking the clinical situation to some extent. A proposed explanation for the situation in which the older host more effectively controls the rate of tumor is a paradoxical effect of decreasing immune function with age, that is, decreased activity of those cells in the old host's immune system, which—under the stimulation of the neoplastic process—produce tumor-enhancing factors such as angiogenesis factor. When this occurs, tumor growth might be expected to be diminished. To what extent these various factors play a role in the biological behavior of neoplasia in the aging human host remains a fascinating puzzle to be unraveled.

## MANAGEMENT

This section examines the utility of the major modalities of cancer treatment in the elderly individual. The use of such modalities is heavily conditioned by the initial decision-making process, that is, whether to screen, whether to pursue diagnostic work-ups, whether to treat at all, and how intensively to treat. In such decisions, the physician is often placed in the position of weighing benefits versus risks of diagnostic and therapeutic interventions. This is as it should be, and the physician should take into account the various biologic, psychological, and social factors involved in the patient's well-being. Of great importance in this regard is the patient's own assessment of the value of both quantity and quality of potential survival during and after the treatment for malignancy. In this process, there is a clear need to individualize such decisions, and a decision made for a well elderly patient may be appropriately different than that for a frail elderly patient.

Unfortunately, age bias in diagnostic and treatment decisions for older patients with cancer does exist, and elderly patients are continually underrepresented in clinical trials. Analysis of data on ~60 000 patients treated in phase II and III trials sponsored by the National Cancer Institute between 1997 and 2000 found that only

32% of the participants were aged 65 years or older, despite the fact that this age group accounted for 61% of patients with cancer. Thus, while differences in decisions may be entirely appropriate in certain situations, these must be based on specific individualized patient information and not on categorical decisions made purely on the basis of chronologic age.

We proposed one framework in which the general aspects of such decision making can be considered for the individual patient. This is shown in [Figure 94-3](#) and is called the Comprehensive Geriatric Model. It graphically presents a number of the concepts critical to the care of the elderly patient, that is, that there is a decreased functional reserve and that, as an extension of Engel's Bio-Psycho-Social Model, all of these various aspects of the individual's background must be taken into account when making decisions about the new process, that is, the cancer. Each of these levels, for example, biologic or psychological, can create interactions that influence both the cancer and the host, and, likewise, any intervention directed at the cancer may influence both the cancer and each of these levels of the host's function. Conversely, each of these levels of function, when compromised by the aging process or other comorbid diseases, may influence the ability to deliver these various interventions. Thus, in a sense, a conceptual checklist is presented in which a four-way interaction of various factors can be systematically considered when making decisions. Examples of ways in which physiologic changes occurring with age can impact on cancer treatment are shown in [Table 94-5](#).

The implementation of this concept is through the application of geriatric assessment (as described in detail in Chapter 11) to the elderly cancer patient so that the domains of physiological status, comorbidity, geriatric syndromes, and functional and cognitive status can be assessed and define levels of frailty. One feasibility study to evaluate cancer-specific geriatric assessment included validated measures of geriatric assessment in the following domains: functional status, comorbidity, cognition, psychological status, social functioning and support, and nutritional status. The assessment was administered to 43 patients with breast, lung, and colorectal cancers or lymphoma who were receiving chemotherapy. The average age of these patients was 74 years, and the majority of patients had stage IV disease. The mean time to complete the assessment was 27 minutes, 78% patients were able to complete the self-administered portion of the assessment without assistance, and 90% of patients were satisfied with the questionnaire length. Another report has suggested that care of elderly cancer patients in geriatric evaluation and management units has a positive and sustained effect on their quality of life, including emotional limitation, mental health, and bodily pain. Thus, oncogeriatricians now feel that this information, rather than age per se, should weigh more heavily on subsequent management decisions for use of diagnostic as well as therapeutic technologies for the elderly patient with cancer. The optimal mechanism for practically implementing this approach (e.g., clinic team, inpatient unit, consultation) remains to be determined.

## MAJOR THERAPEUTIC MODALITIES

### Surgery

Surgery and other invasive procedures are frequently involved in initial diagnostic as well as in therapeutic approaches to the elderly

**FIGURE 94-3.** The Comprehensive Geriatric Model. (Reproduced with permission from Cohen HJ, DeMaria L: In: Lazlo J, ed. *Physician's Guide to Cancer Care Complications*. New York, New York: Dekker; 1986:240.)

patient with cancer. The general aspects of surgery in the elderly patient are discussed thoroughly in Chapter 37. Cancer surgery may be accomplished in elderly patients with mortality and morbidity rates that are often similar to those for younger patients and appear to be conditioned more by the extent of comorbid disease and declines in measurable physiologic functions than by chronologic age. In com-

paring potential alternative modalities, it is well to remember that the acute and time-limited stress of surgery may be preferable to many older patients than the more chronic or protracted courses of therapy frequently involved in radiation therapy and/or chemotherapy.

### Radiation Therapy

Radiation therapy is used in the treatment of malignancies with both curative and palliative intent. In an attempt to cure local or regional disease, given that both radiation therapy and surgery might be considered, one must consider whether the cure rate is equivalent and whether there are differences in morbidity or mortality between the procedures that would favor one over the other. Radiation therapy is generally not contraindicated by associated medical conditions, and it may allow maintenance of function of the organ in which the tumor arises. For example, for an elderly person, radiating laryngeal carcinoma and maintaining speech, rather than requiring the learning of laryngeal speech postoperatively, may be of considerable advantage. On the other hand, radiation treatment frequently involves a protracted course of therapy and can cause significant fatigue.

Radiation therapy is also used as an effective adjunct to surgery or chemotherapy or both. For those surgical procedures with high operative mortality, using adjunct radiation therapy to reduce the degree of surgery required may be especially attractive to an elderly patient. The results for adjunct radiation therapy and approaches such as quadrantectomy in breast cancer or lymph node excision in head or neck cancer have been demonstrated to be equivalent

**TABLE 94-5**

#### Aging Physiology and Cancer

AGING PHYSIOLOGY	CANCER RELEVANCE
Cardiopulmonary ↓ Max CO, VO <sub>2</sub> Max ↓ Elasticity	Surgery C/P toxic drugs
Skin—↓ wound healing	Surgery
CNS—↓ brain weight, cerebral blood flow	Patient interactions CNS toxic drugs
Special senses—↓ taste, smell, salivary flow	Nutrition radiation therapy
Hematopoiesis—↓ response under stress	Chemotherapy and radiation therapy
Immune system—↓ response	Infection
Body composition—↓ lean, ↓ fat	Drug distribution
Liver—↓ mass and flow	Hepatic drug metabolism
Kidney—↓ GFR	Renal drug excretion

CNS, central nervous system; C/P, cardiopulmonary; GFR, glomerular filtration rate.

to more extensive surgical procedures. Radiation is also used in a “neoadjuvant” setting, that is, prior to surgery in an attempt to reduce tumor mass and allow greater operability. Palliative, radiation therapy can be extremely effective in providing relief from pain from bone metastases, the effects of brain metastases, control of local obstructive symptoms, and spinal cord compromise. Such treatments can frequently be delivered in courses of 1 to 2 weeks’ duration rather than the longer courses of therapy that may be more difficult to tolerate. However, short courses of high-dose radiation may be associated with a higher incidence of acute side effects. The results of treatment, as well as the incidence of complications, greatly depend on the technology available and its correct application.

The side effects of therapy may create problems for the older patient. The radiation effect on normal tissue is said to be enhanced approximately 10% to 15% in the elderly patient. Logically, those organs with more marked physiological decline would be at greatest risk. Radiation to the oral pharynx and oral cavity can produce a loss of taste, dryness of mucous membranes, and involution of salivary glands, which when combined with a precarious nutritional intake in a frail and elderly individual might be lethal, or certainly contribute a considerable amount of morbidity, if not recognized. Moreover, if daily treatment is tolerated poorly owing to nausea or weakness, treatment may be compromised because of the decreased daily doses, the patient’s unscheduled absences, or decrease in the total planned dose. Because radiation therapy is frequently used in the treatment of lung cancer, pulmonary complications may be of particular importance. In one study, severe radiation pneumonitis was noted more frequently in elderly individuals than in younger ones, regardless of field size and other therapies. Alterations in schedule can be made and still deliver potentially curative radiation therapy to older individuals. This must be done with care, however; although decreasing the daily fraction has not been shown to be detrimental to local control of neck and head cancer, split-dose schedules are associated with significantly lower control rates for some tumor sites.

### Chemotherapy and Hormonal Therapy

Thorough discussions of the principles of pharmacology and of medication use in elderly persons can be found in Chapters 8 and 24. Although still understudied, there are a growing number of direct studies of the effect of age on the pharmacokinetics of orally or parenterally administered chemotherapeutic agents. The declining ability of senescent cells to repair DNA damage may prolong toxicity. Increased destruction of and lower numbers of rapidly renewing mucosal stem cells increase susceptibility to mucositis. Also, reduced hematopoietic stem cell reserve may slow recovery of cytopenias after chemotherapy in older persons. In general, absorption of drugs appears to be affected relatively little as a consequence of age, but may become more relevant as newer oral agents (e.g., fluorinated pyrimidines) become more widely used. Decreased gastric motility and gastric secretions can also add to increased toxicity from these agents. Higher proportions of body fat may increase the volume of distribution of lipid-soluble drugs, such as nitrosoureas. In people with reduced albumin, volume of distribution for drugs bound to albumin, such as etoposide, is increased. Also, drugs like taxanes and anthracyclines that are highly bound to red blood cells are affected when anemia is present. Drug metabolism is also affected by lower hepatic mass and decreased activity of cytochrome P-450 enzymes
